Figure 2 Covariation analysis (also called % same or choice probability). (a) Shared internal direction noise for pursuit and perception. In a simultaneous study of perceptual and pursuit direction signals, the binary psychometric and oculometric decisions were highly correlated across the entire range of signal strengths tested. The correlation expected by chance for two independent mechanisms is 50 % in the no-signal condition and increases monotonically to 100 % in the high-signal condition in which both decisions are always correct and therefore trivially the same. This figure plots the % same (the percentage of trials for which the pursuit and perceptual binary direction decisions were the same) for a single observer as a function of signal strength (direction difference in degrees from a cardinal axis). Note that the observed correlation was significantly higher than expected by chance (error bars show 95% confidence intervals). (b) Shared response to external noise for saccades and perception. In sequential studies of perceptual and saccadic localization with an identical set of noisy search images, the 10-alternative forced choice (10AFC) psychometric and oculometric decisions were correlated across the entire range of signal strengths tested (signal-to-noise levels in d′ units). The correlation expected by chance from two independent mechanisms is 10 % in the zero SNR condition and increases monotonically to 100 % for an extrapolated high SNR condition in which both decisions are always correct and therefore trivially the same. This figure plots the % same (the percentage of image samples for which the perceptual and saccadic 10AFC decisions were the same) for a single observer as a function of signal strength (ratio of peak luminance of the target to the amplitude of the pixel luminance noise). Note that the observed correlation was significantly higher than expected by chance (error bars show standard errors). (a) Adapted from Stone LS and Krauzlis RJ (2003) shared motion signals for human perceptual decisions and oculomotor actions. *Journal of Vision* 3: 725–736. (b) Figure based on data from Beutter BR, Eckstein MP, and Stone LS (2003) Saccadic and perceptual performance in visual search tasks: I. Contrast detection and discrimination. *Journal of the Optical Society of America A* 20: 1341–1355.

Figure 3 Correlated pursued and perceived direction reversals for completely ambiguous motion. For a stimulus that can be perceived as moving rightward or leftward at will, the data show that the perceptual reversal (plotted as percentage rightward or leftward judgments) preceded the oculomotor direction reversal (plotted as mean eye velocity) by slightly less than 100 ms, consistent with perceived motion driving pursuit. The retinal image motion is constant throughout but pursuit changes from rightward to leftward (or vice versa) synergistically with the reversals in perceived motion, which is inconsistent with all retinal image motion models of pursuit. Adapted from Madelain L and Krauzlis RJ (2003) Pursuit of the ineffable: Perceptual and motor reversals during the tracking of apparent motion. *Journal of Vision* 3: 642–653.

pursued. However, the motion of a similarly occluded cross (defined by the exact same segment image motion but merely spatially rearranged) is perceived as nonrigid; the coherent two-dimensional (2-D) object motion interpretation is presumably interfered with by the distracting vertical motion of the segments. Pursuit of a diamond moving along an isotropic trajectory shows an isotropic response (i.e., vertical and horizontal pursuit gains are equal), consistent with the motion of a rigid object. However, pursuit of the cross shows lower overall gain and a clear vertical bias, consistent with the nonrigid object motion percept and the vertical segment motion inference. This finding suggests that object shape information, presumably from the ventral pathway, is influencing perception and pursuit in parallel. Moreover, even an extended version of the retinal image motion model that attempts to minimize the sum (or vector average) of all the retinal segment motions would predict that pursuit of the cross and pursuit of the diamond would be identical.

The emerging picture is that pursuit is driven by a signal related to perceived object motion and not directly by retinal image motion. An object motion model of pursuit (Figure 1(b)) can not only explain

Figure 4 Different pursuit for identical retinal motion related to differences in object shape. Moving occluded line figures with identical object motion trajectories and identical segment motions (but with the segments in different relative retinal locations) can nonetheless be perceived and pursued differently. The data show the horizontal and vertical pursuit amplitudes of four observers in response to a diamond (solid) or a cross (open) configuration representing the same object motion along an isotropic 2-D Lissajous figure. The diamond is perceived to move rigidly and is pursued with an isotropic high-gain response. The cross, however, appears to move nonrigidly and is pursued with a low-gain trajectory biased in the vertical direction of the segment motion. The fact that both of these stimuli generate 2-D trajectories at all is inconsistent with retinal image motion models, which would generate nearly exclusively vertical pursuit in response to the vertical retinal segment motion. More important, the fact that identical physical object motion is pursued differently when different non-motion information generates different object motion percepts is strong evidence that pursuit is driven by an object motion signal shared with perception. Adapted from Stone LS, Beutter BR, and Lorenceau J (2000) Visual motion: Integration for perception and pursuit. *Perception* 29: 771–787.

the wider range of new phenomena described previously but also takes into consideration the wealth of physiological findings demonstrating an extensive role for both parietal (MST) and frontal (frontal eye field (FEF) pursuit area) cortex in trajectory estimation (including prediction). It also acknowledges that these areas, not just MT, provide a major component of the descending pathway to brain stem and cerebellar structures involved in the generation of the motor output signal driving pursuit. The role of cortex in this new view is not to calculate derivatives of retinal motion but, rather, to compute a best estimate of object motion from the available visual information (both dynamic and static) within a cognitive and attentional context. If an object motion signal is sent down to the brain stem (instead of a retinal error signal), then the role of the cerebellar feedback loop must also be reassessed. If object motion is the descending cortical output signal, then the only processing needed to optimize the oculomotor command to the plant is to high-pass prefilter the eye velocity command to compensate for the low-pass filtering of the oculomotor plant. Indeed, the output signals from the cerebellum supporting pursuit have been shown to be a prefiltered version of the subsequent eye velocity signal. Such prefiltering could be achieved via a positive feedback loop that mimics the plant. Another important virtue of this model, in addition to its ability to reconcile a wide range of behavioral and physiological pursuit observations, is that it is easily generalized to other motor systems, whereby the cerebellum would act as a compensator for other motor plants all driven by the same cortical object motion signal (or another relevant perceptual signal). Thus, the hand and the eye can work synergistically when tracking a moving object.

Saccades and Visual Target Selection

The linear systems theory view of the saccadic system has been dominated by variants of a retinal offset model (Figure 5(a)). In this view, the saccadic system is essentially a simple, quasi-linear, bang-bang control system that rapidly corrects retinal position offset by driving this offset to zero through negative feedback. A retinal position error signal from primary visual cortex (V1), modulated by inputs from other cortical areas, is sent down to the superior colliculus (SC) of the midbrain as the retinal target position signal. When a particular locus in the SC map reaches a threshold, that location relays a command for desired eye position to brain stem structures that generate the neural pulse and step signals needed to accelerate the eye and then hold it in its new position, respectively. Although this model includes a detailed description of brain stem structures, as with the retinal image motion pursuit model, the entire visual and decision-making process is the trivial calculation of an unambiguous retinal error signal – in this case, position instead of velocity. Again, such a retinal signal is only unambiguous in the degenerate case of a small spot on a dark background. Furthermore, it is has long been known that nonretinal signals can drive voluntary saccades, such as auditory or visual memory signals.

During approximately the past decade, a number of laboratories have turned their attention to understanding the visual processes underlying saccadic target selection in search and search-like tasks using more realistic visual stimuli with targets of variable signal strength, embedded in external image noise, among similarly salient nontarget 'distractors,' and/or with differing *a priori* location probabilities. These studies have revealed a rich complexity of signal processing, requiring broadly distributed interactions between parietal and frontal cortex and the midbrain.

Numerous studies have illustrated clear links between saccades and perception, further distancing saccadic behavior from raw retinal offset signals. First, it

Figure 5 Saccade models. (a) Retinal offset error models. In this framework, a retinal offset signal is computed in primary visual cortex (V1) (with input from parietal and frontal cortical areas) and then send to the superior colliculus (SC) of the midbrain. When that signal reaches threshold, the SC sends a desired eye position signal to brain stem saccadic structures, which generate the command for eye displacement. (b) Target selection models. In this framework, the totality of the retinal image is processed in parallel to identify candidate target locations. A network that includes the lateral–intraparietal area (LIP), the frontal eye fields (FEF), and the SC works to select a single target using the available bottom-up sensory data modulated by top-down cognitive and attentional factors. The resulting perceived target position signal is then sent to brain stem saccadic structures, which generate the command for eye displacement.

has been shown that saccades and perception appear similarly affected by spatial illusions. For example, saccades (and hand pointing as well) show systematic spatial deviations in the same direction as the spatial misperceptions for stimuli that evoke the Muller–Lyer illusion. Although early reports of this effect on saccades were conflicting, when the saccadic task relies on a visual feature that is distorted by the illusion, the motor response reflects the perceptual illusion. Second, contrast detection and discrimination thresholds are equal for perception and saccades. More important, using noisy search stimuli, the correlation between the external image noise-driven responses of saccades and perception is higher than expected by chance from two independent mechanisms (Figure 2(b)). Thus, saccades and perception appear equally vulnerable to those random spatial features of a particular noise sample that appear target-like. Third, using classification image analysis (a form of reverse correlation), by combining the hundreds of noise samples (sans target) that generated erroneous responses, one can construct an image of the virtual target that saccades and perception were looking for (i.e., an estimate of the template or overall receptive field used in the decision-making process). Not only are the shapes of the classification images from saccadic and perceptual decisions indistinguishable but also their common shape differs significantly from that of the target (Figure 6). Indeed, both images are a high-passed version of the target, which may indeed be optimal if one is searching for the target embedded in the low-pass filtered noise commonly associated with visual neural signals.

The emerging view is that a complicated network between the parietal and frontal cortex, as well as the SC, converges to select a single target using both bottom-up sensory data and top-down cognitive knowledge, expectation, and/or anticipation of reward. Furthermore, ascending feedback from the SC to visual cortical areas appears to play an important role in this process by driving attention-like modulations of visual processing, thereby influencing

Figure 6 Classification image (CI) analysis reveals the saccadic and perceptual 'receptive field' used to search for the brightest 'O' among dimmer Os. The top row shows the raw CI for saccades and perception, respectively. The bottom row shows the normalized and polar averaged cross-section of the receptive fields. Note that the perceptual and saccades receptive fields are both high-pass filtered versions of the Gaussian stimulus cross-section and are well described by difference of Gaussian functions (solid black lines under the red data traces). Thus, not only is the receptive field shape the same for saccades and perception but also the perceptual and saccades receptive fields are more similar to each other than they are to the actual target, providing strong evidence of a shared target template used by perception and saccades during search.

perception, although the exact nature of these modulations is not well understood. The target selection model of saccades (Figure 5(b)) acknowledges the simple fact that the saccadic system is not finding a single target presented in a vacuum but, rather, is selecting the most behaviorally relevant target from among many candidate possibilities. Thus, rather than thinking of visual target localization as a trivial thresholding of a single highly salient spot, studies have reframed saccadic targeting within the context of signal detection theory, addressing the nontrivial question of how to decide where to look next when the target is inconspicuous or is similar to surrounding distractors. Saccadic and perceptual search can be described as a template-matching task in the presence of noise and spatial uncertainty; the template captures essential contrast and shape information about the searched-for target albeit not necessary perfectly matched to the target (Figure 6). Indeed, the similarity of the classification images for perception and saccades (and their shared difference with the actual target shape) strongly suggests that the saccadic system has access to the same shape information as perception, presumably from shared ventral pathways supporting both perception and action.

Although the new framework for saccadic targeting embraces a novel view of visual processing, unlike pursuit, the proposed new visual front end for saccades does not require a fundamental reinterpretation of the role of brain stem saccade-generating structures. However, it is becoming increasingly clear that the SC is not merely a feed-forward output relay to brain stem structures but, rather, plays a key role in the target selection process, along with the lateral intraparietal (LIP) area and the FEF. Consistent with this distributed responsibility for target selection, Schiller and colleagues showed that bilateral removal of either the SC or the FEF leaves the ability to make saccades intact, whereas bilateral removal of both areas destroys that ability. Furthermore, studies in both the Wurtz and Newsome laboratories have demonstrated that stimulation of the SC can modulate perceptual performance, justifying the elevation of the SC into the target-selection network, which was formerly considered to be exclusively cortical.

A New Framework for the Visuomotor Control of Pursuit and Saccades

The major paradigm shift that has occurred in the study of pursuit and saccades is the realization that the visual processing part of the sensorimotor problem is more complicated than originally thought.

When humans 'see' by taking the neural signals coming from the approximately 1 million ganglion cells in each eye to create a full-color 3-D model of the world around them, quite a complicated process has occurred. The sensory information available represents two 2-D projections of the world, one from each retina, and is therefore necessarily incomplete. The human visual system must use the available sensory data (bottom-up information) as well as *a priori* knowledge about the world (top-down information) to infer a best guess of what is actually out there. As such, all visual perception is illusion; what we call illusions are merely those rare instances when the brain's best guess is obviously wrong.

Complex interactions between frontal, parietal, inferotemporal, and occipital cortex, along with the midbrain, are used to combine bottom-up and top-down information into a time-varying best estimate of the oculomotor target. For pursuit, the reconstruction of the target object's motion in the world takes time. An early quick estimate of object motion using the vector average of local edge motions appears to drive early perceptual and pursuit responses, with a more accurate estimate emerging with a time constant on the order of 100 ms. The standard linear system control theory approach of considering only the initial 100-ms 'open-loop' pursuit response to characterize the internal visuomotor transfer function therefore misses much of this elegant, yet sluggish, computational process. Object motion estimation of realistic targets takes time because, after the initial sensory transduction, the visual system must first segregate from the background those pieces of the retinal image that represent individual local motion features. The system must then selectively integrate those pieces that properly belong together into a whole object whose global motion can then be computed. This process is inherently ambiguous because the data set is incomplete (although over time the ambiguity of the object trajectory can resolve itself). Thus, the perceptual and pursuit systems must make visual choices. The preponderance of evidence gathered during approximately the past decade argues that perception and pursuit make the same choice using shared visual motion processing mechanisms broadly distributed across parietal and frontal cortex, with likely input from inferotemporal cortex as well.

For saccades, localizing the target object is also a complex, time-consuming visual process involving both parallel and serial components: parallel because all portions of the visual field are being processed simultaneously and serial because, at low target salience, a sequence of discrete fixation steps is traced as one searches for the target. Presumably, during each fixation, a target-like template is being compared with incoming noisy sensory data in order to determine the 'best' next location to foveate, with multiple locations constantly competing for attention. The preponderance of evidence indicates that perception and saccades make the same choices using shared spatial visual processing mechanisms broadly distributed between parietal and frontal cortex, with inputs from the superior colliculus and inferotemporal cortex as well.

Another difference between the traditional oculomotor models (**Figures 1(a)** and **5(a)**) and the new frameworks (**Figures 1(b)** and **5(b)**) is the coordinate system of the visual signals driving motor actions. The traditional view of saccades and pursuit assumes that the controlled visual signals are in raw retinal coordinates: retinal position, velocity, or even acceleration error signals to be minimized by negative feedback. Not only do the aforementioned MST studies rule this out for pursuit but also a behavioral study of the direction signals driving perception during fixation and pursuit by Krukowski and colleagues in 2003 showed that the limiting direction noise and even the oblique effect are not in retinal coordinates but, rather, in head- or world-centered coordinates. This finding shows that performance in an apparently simple direction discrimination task is limited by neural signals beyond area MT (the highest area mapped in retinal coordinates) and thus in area MST (an area in which retinal motion signals are combined with eye and head motion signals) or another motion area further along in the dorsal pathway. Indeed, there is even direct physiological evidence that some MST neurons encode object motion in world coordinates.

The cortical signals driving saccades are also not simply in retinal coordinates. LIP and FEF both encode target location in 'oculocentric' coordinates, which comprise a coordinate system in which target location is constantly being updated with respect to the current eye position using anticipatory signals about future eye movements (even in the absence of visual feedback). This updating process, first described by Colby, Duhamel, and Goldberg, effectively keeps the target location stably encoded in head-centered space – yet bouncing around in the retinal map with every saccade – presumably as part of the mechanism keeping the world perceptually stable during saccades. Sommer and Wurtz characterized an oculomotor feedback pathway from SC to FEF, via the mediodorsal thalamus, and have further shown that interruption of the corollary discharge signal from the SC disrupts the proper updating of target location, thereby demonstrating that the SC plays a key role in the coordinate system transformation for target localization performed within the cortex.

Clearly, the frameworks in Figures 1(b) and 5(b) are mere cartoons that require much fleshing out. Nonetheless, they succinctly represent the concatenation of a number of conceptual advances that are guiding the next generation of oculomotor researchers and cortical physiologists. Regrettably, this short article can mention only a small number of the many important recent findings. Many researchers are actively working to understand the visual processing for saccade target selection and pursuit object motion estimation and the associated neurophysiological underpinnings. Although much progress has been made, the picture of how an extended network of cortical (and even subcortical) areas interact to shape synergistic perception and sensorimotor control remains incomplete.

Conclusion

Because the sensory 'image' of the world is inherently ambiguous, humans must generate a best-estimate solution to this complex puzzle, using noisy incomplete data and cognitive strategies to construct an internal 3-D model of visual space, in order to interact with their environment and ultimately to survive in the real world. Perhaps, our coherent multisensory perception of the world evolved from the need for the brain to provide a single, decisive interpretation of an ambiguous and incomplete set of visual (and other) signals in order to coordinate the actions of multiple motor systems. Indeed, above and beyond the parsimony argument about limited cortical processing resources, it is difficult to imagine an evolutionary advantage of each neural system developing a set of independent, potentially conflicting, private solutions to the visual problems of detection, discrimination, and target selection.

Introduction

The fundamental problem in understanding perception in any sensory modality is the indirect relationship between our perceptions and the physical world. The challenge this fact presents is especially evident in vision and has been recognized since the beginning of the eighteenth century. The problem is that the images on the retina cannot, by their nature, uniquely specify the physical objects in a scene. For example, physical objects are three-dimensional and what we see also appears to be three-dimensional. Nevertheless, the retinal image is only two-dimensional. As a result, the actual size and arrangement of objects in space are not indicated by the retinal projection as such, and this information cannot be deduced by any logical operation on the retinal image (Figure 1(a)). The physical properties associated with the perceptual qualities of brightness and color are, for the same reasons, unspecified by the information in the retinal image (Figure 1(b)). This quandary in vision is referred to as the inverse optics problem, and the key question in visual perception is how the visual brain solves it.

Beginning with the work of Hermann von Helmholtz in the latter part of the nineteenth century, many vision scientists have supposed that the strategy for solving the inverse problem in perception is to make sensory systems depend in some degree on empirical information (i.e., information about the meaning of ambiguous stimuli based on past experience with what the same or similar stimuli meant). In this way, Helmholtz proposed that the visual system might 'disambiguate' images by an empirical boost that would help out their 'interpretation.' Only recently, however, have vision scientists considered the possibility that percepts might be generated entirely on the basis of the empirical success or failure of visual experience in the past of both the species and the individual. If that were the case, then the purpose of visual processing would essentially be to determine relative probabilities of the possible sources of inherently uncertain stimuli rather than representing the 'features' in the retinal projection.

As a result of these very different concepts of vision – seeing the 'real world' by directly detecting its features versus seeing probable stimulus sources based on statistical evidence – there is considerable debate about what visual processing is actually doing and how best to interpret the wealth of information about the anatomy and physiology of visual neurons that modern neuroscience has provided during the past 50 years (work that extends far beyond the scope of this article). One camp supposes that the way of resolving this debate in vision science is to continue obtaining more information about the receptive field properties of visual neurons, with the expectation that sooner or later it should be apparent how these properties give rise to visual perception. Another camp has tended to focus on visual percepts as such, asking whether what people actually see can tell us about the strategy of visual processing. In fact, both approaches make sense and will eventually need to come together to understand how percepts are generated. The following discussion focuses on perception and the evidence it provides about how this problem is being solved by the visual system.

The Perception of Surface Qualities

Brightness

A good place to begin is the perception of light and dark elicited by different intensities of light, which is called brightness (technically, brightness refers to the appearance of a light source, such as a light bulb, and lightness to the appearance of a surface; for present purposes, brightness is used in its general inclusive sense). Not the least of the reasons for beginning with brightness is that such percepts are arguably the most fundamental visual qualities that humans see. Vision in us or other animals cannot occur without this perceptual quality, whereas other qualities (e.g., color) are expendable (some animals have color vision and some do not). The approximate physical correlate of brightness percepts is luminance, a physical measure of light intensity made by a photometer and expressed in units such candelas per square meter. Like all percepts, brightness is not subject to direct measurement, and it can only be evaluated indirectly by asking observers to report the appearance of one object or surface relative to that of another.

Some Puzzling Discrepancies between Luminance and Brightness

Given that brightness is the subjective experience of the intensity of a light stimulus, logical assumptions would be that (1) luminance and brightness are directly proportional since increasing the luminance of a stimulus increases the number of photons captured by photoreceptors and (2) two objects in a scene that return the same amount of light to the eye should

Figure 1 The inverse optics problem. (a) The inherent ambiguity of retinal stimuli, illustrated here in terms of the perception of objects in space. Note that the same linear projection on the retina can derive from an infinite number of linear objects at different distances, of different sizes, and in different spatial orientations. As a result, a retinal image cannot specify its physical source. (b) The inevitable conflation in a light stimulus of illumination, reflectance, and transmittance, the factors that an observer must parse in order to respond appropriately to the pattern of luminance values and spectral power distributions in any visual stimulus.

appear equally bright. It has long been known, however, that perceptions of brightness fail to meet these seemingly simple expectations. For example, two patches returning equal amounts of light to the eye are perceived as looking differently bright when placed on backgrounds that have different luminances (Figure 2(a)). Thus, a patch on a background of relatively low luminance appears somewhat brighter than the same patch on a background of higher luminance, a phenomenon called simultaneous brightness contrast. This effect can be made much more dramatic when the stimulus includes more information about the possible real-world conditions underlying the stimulus (Figure 2(b)), as the German psychologist Adhemar Gelb showed many years ago in a room contrived such that objects could be illuminated by hidden lights.

Until relatively recently, the explanation of this effect was based on the properties of neurons at the input level of the visual system (usually retinal ganglion cells) and the lateral interactions among them. Presumably as a means of enhancing the detection of luminance contrast boundaries (edges), the central region of the receptive fields of lower order visual neurons has a surround of opposite functional polarity (Figure 3). The number of action potentials generated per unit time by neurons whose receptive fields intersect a contrast boundary will therefore differ from the activity of neurons whose receptive fields fall entirely on one side of the boundary or the other.

Figure 2 Simultaneous brightness contrast. (a) Standard presentation of this effect; the two circular patches have exactly the same luminance, but the one in the dark surround looks somewhat brighter. (b) Enhanced effect arising from mutually supportive contextual information. Simultaneous brightness contrast can be much greater when the scene is more realistic, as it is here; as shown in the key, the patches that look very different in brightness again have the same luminance. These stimuli show that the amount of light returned to the eye is not a good predictor of the brightness seen. (b) Adapted from Purves D and Lotto RB (2003) *Why We See What We Do: An Empirical Theory of Vision*. Sunderland, MA: Sinauer.

For example, the neurons whose receptive field centers lie just within the target on the dark background in Figure 3 will fire at a higher rate than the neurons whose receptive field centers lie just within the target on the light background (because the former are less inhibited by their oppositely disposed receptive field surrounds than the latter). As a result, many early investigators supposed that the patch on the dark background looks brighter than the patch on the light background because of this difference in retinal output.

The percepts elicited by other stimulus patterns, however, undermine the idea that simultaneous brightness contrast effects are an incidental consequence of an anomalous retinal output in response to edges. In the pattern in Figure 4, for example, the target patches on the left are surrounded by a greater area of higher luminance (lighter) territory than lower luminance and yet appear brighter than the targets on the right, which are surrounded by more lower luminance (darker) territory than higher. Although the average luminance values of the surrounds in this stimulus are effectively opposite those in standard simultaneous brightness stimulus in Figure 3, the brightness differences elicited are approximately the same in both direction and magnitude as in the standard presentation.

If the output of retinal neurons cannot account for the relative brightness values seen in response to stimuli such as the simple patterns in Figures 2 and 4, what then is the explanation? The answer seems likely to be based on the inverse problem as it applies to brightness. In natural circumstances, the luminance of any part of a retinal image is determined by three fundamental aspects of the physical world: the illumination of objects, the reflectance of object surfaces, and the transmittance of the space between the objects and the observer. As indicated in Figure 1(b), however, these factors are inevitably conflated in the retinal image. Thus, an infinite number of different combinations of illumination, reflectance, and transmittance can give rise to the same value of luminance; as a result, there is no logical or direct way in which the visual system can determine how these factors are actually combined to generate a particular retinal luminance value and, thus, what behavior in response to the stimulus is appropriate.

Since successful behavior requires responses that accord with the physical source of a stimulus, this uncertainty means that making brightness percepts directly proportional to luminance values in a stimulus would not provide a guide to successful behavior. A more effective approach to generating brightness percepts – and perhaps the only plausible one – would be to determine the percepts empirically according to the past success or failure observers had experienced interacting with the different combinations of illumination, reflectance, and transmittance generated by natural scenes. In this empirical framework, brightness should always correspond to the relative frequency with which different possible sources had been the source of the same or similar stimuli in the enormous number of visual scenes witnessed by the species during the course of evolution, as well as by

Figure 3 Lateral interactions in the retina and their effect on retinal output. Diagram of the different firing rates of retinal ganglion cells as a function of their position with respect to a light–dark contrast boundary.

Figure 4 Stimulus pattern that elicits perceptual effects that cannot be explained in terms of lateral interactions arising from local contrast effects. The pattern and its effect are called 'White's illusion' after the psychologist who first described it. individual observers during their lifetimes. This idea harks back to Helmholtz's suggestion in the nineteenth century that empirical information might be needed to augment what he took to be the more or less veridical (i.e., 'true to life') information supplied by sensory mechanisms. However, because retinal (and other sensory) receptors cannot provide unambiguous information about the state of the world, the more radical idea currently being examined by cognitive neuroscientists is that visual processing is fundamentally statistical. In this conception, the brightness values seen by an observer should accord with the empirical significance of the stimulus rather than with the physical intensities of light falling on the retina. The biological rationale for this way of seeing brightness is that by using the outcome of experience accumulated by trial and error during phylogenetic and ontogenetic experience (i.e., what percept worked in response to a given stimulus), percepts – and, more important, behaviors – evolve to have an increasingly better chance of successfully representing inherently ambiguous retinal images.

Color

A second major quality of human visual percepts is color. Recall that brightness is defined as the perceptual category elicited by the overall amount of light in a visual stimulus. Color is defined as the perceptual category generated by the distribution of that amount across the visible spectrum (i.e., the relative amount of energy at short, middle, and longer wavelengths across the light spectrum). In fact, the experience of color comprises three perceptual qualities: (1) hue, which is the perception of the relative redness, blueness, greenness, or yellowishness of a stimulus; (2) saturation, which is the degree to which the perception approaches a neutral gray (e.g., a highly unsaturated red is a percept that appears largely gray but

nonetheless has an appreciable reddish tinge); and (3) color brightness, which is the same perceptual category described in the previous section but applied to a stimulus that elicits a discernible hue. Together, these qualities describe a perceptual color space (Figure 5). The ability to see colors has presumably evolved in humans and many other mammals (but not all, showing that the ecological value of color is far less than brightness) because percepts that use information derived from spectral differences allow observers to distinguish surfaces in the natural world more effectively than distinctions made solely on the basis of luminance.

Figure 5 Diagram of perceptual 'color space' viewed from the side (a) and looking down on a single plane (b). At any particular level of light intensity (which evokes a sensation of color brightness), movements around the perimeter of the relevant plane correspond to changes in hue (i.e., changes in the apparent contribution of red, green, blue, or yellow to the percept), whereas movements along the radial axis correspond to changes in saturation (i.e., changes in the approximation of the color to the perception of a neutral gray). Each of the four primary color categories (red, green, blue, and yellow) is characterized by a unique hue (indicated by dots) that has no apparent admixture of the other three (i.e., a color experience that cannot be seen or imagined as a mixture of any other colors). These four colors are considered primary because of their perceptual uniqueness, which has nothing to do with the definition of 'primary colors' one may have learned about in an art class.

Color Contrast and Constancy

Like perceptions of brightness, the colors we see are strongly influenced by context. For example, a stimulus patch generating exactly the same distribution of power at various wavelengths can appear quite different in color depending on its surroundings, a phenomenon termed color contrast. Conversely, patches in a scene returning different spectra to the eye can appear to be much the same color, an effect called color constancy (brightness contrast and constancy are equally apparent) (Figure 6). Although these phenomena were well-known to psychologists and vision scientists in the late nineteenth and early twentieth centuries, they were not paid much attention to until Edwin Land's work in the late1950s. Land – a photochemist who among other achievements invented polarizing filters and instant photography and founded the Polaroid Corporation – used three adjustable illuminators generating short-, middle-, and long-wavelength light to illuminate a collage of colored papers. With a telemetric photometer, he showed that two patches that in white light appeared quite different colors (e.g., green and brown) continued to look their respective colors even when the three illuminators were adjusted so that the light being returned from the 'green' surfaces produced exactly the same readings on the three telephotometers that had previously come from the 'brown' surface – a striking demonstration of color constancy. A simpler demonstration of color constancy is shown in Figure 6.

Color contrast and constancy effects present the same problem for understanding color processing as the contextual brightness effects described previously do for understanding how achromatic percepts are generated; together, these phenomena have led to a debate about brightness and color percepts that now spans more than a century. Land tried to explain such effects by a series of postulated algorithms that integrated the spectral returns of different regions over the entire scene (the implication being that color processing in the visual system implemented these algorithms). It was recognized even before Land's death in 1991, however, that this so-called retinex theory did not work in all circumstances and was in any event a description rather than an explanation. Although it far exceeds the limitations of this article, there is growing evidence that, like

Figure 6 Demonstrations of color contrast and constancy. Color contrast: Identical gray patches on the surface of the two cubes (see upper key) can be made to appear either blue or yellow by changing the context in which they occur. Color constancy: Other patches on the surface that have very different spectra and different color appearances in a neutral setting (see lower key) can be made to look more or less the same color (red or reddish in this case), again by manipulation of contextual information. From Purves D and Lotto RB (2003) *Why We See What We Do: An Empirical Theory of Vision*. Sunderland, MA: Sinauer.

achromatic brightness, perceptions of hue, saturation, and color brightness are generated according to the empirical significance of spectral stimuli in past experience.

The Perception of Surface Form

Another basic quality of visual perception is the form of objects. In the simplest case, perceptions of form entail simple geometrical characteristics such as the length of lines, their apparent orientation, and the angles they make with other lines.

The Apparent Length of a Line

A simple starting point in exploring how the visual system generates perceptions of form is how we perceive the distance between two points in a stimulus, as occurs in the apparent length of a line or the dimensions (size) of any simple geometrical shape. It is logical to suppose that the perception of a given line (e.g., a line drawn on a piece of paper or on a computer screen) should correspond more or less directly to its projected length in the retinal image. However, as in the case of brightness and color, this expectation is not met. A well-studied example is the variation in the perceived length of a line as a function of its orientation (Figure 7(a)). As investigators have repeatedly shown during the past 150 years, a line oriented more or less vertically in the retinal image appears to be significantly longer than a horizontal line of the same length, with the maximum length being seen when the stimulus is oriented approximately 30° from vertical (Figure 7(b)). This effect is evidently a particular manifestation of a general tendency to

Figure 7 Variation in apparent line length as a function of orientation. (a) The horizontal line in this figure looks significantly shorter than the vertical or oblique lines, despite the fact that all the lines are identical in length. (b) Quantitative assessment of the apparent length of a line reported by subjects as a function of its orientation in the retinal image (orientation is expressed as the angle between the line and the horizontal axis). The maximum length seen by observers occurs when the line is oriented approximately 30° from vertical, at which point it appears approximately 10–15% longer than the minimum length seen when the stimulus is horizontal.

perceive the extent of any spatial interval differently as a function of its orientation in the retinal image. For instance, as the psychologist Wilhelm Wundt first showed in 1862, the apparent distance between a pair of dots varies systematically with the orientation of an imaginary line between them, and a perfect square or circle appears to be slightly elongated along its vertical axis.

The Perception of More Complex Aspects of Geometry

There is a rich literature on other perceptual distortions elicited by geometrical stimuli, showing in each case that measurements made with instruments such as rulers or protractors are often at odds with the corresponding percepts. Some of the most familiar geometrical illusions – and the ones whose etiology has been most hotly debated – are illustrated in Figure 8. The first example is attributed to Hering, who showed that two parallel lines (indicated in red in Figure 8(a)) appear bowed away from each other when presented on a background of converging lines. In the Poggendorff illusion, the continuation of a line interrupted by a bar appears to be displaced vertically, even though the two line segments are actually collinear (Figure 8(b)). In the inverted-T illusion (Figure 8(c)) the vertical line looks somewhat longer than the horizontal line (see also Figure 7). In the more complex Müller–Lyer illusion, the line terminated by arrow tails looks longer than the same line terminated by arrowheads (Figure 8(d)). In the Ponzo illusion, the upper horizontal line appears longer than the lower one, despite the fact that they are identical (Figure 8(e)). It would be a mistake to conclude that because these stimuli are simple figures that bear little resemblance to real-world objects, they are pertinent to natural scenes. In the tabletop illusion created by Stanford psychologist Roger Shepard, the point is again made that such effects are actually more dramatic when the stimulus is made more realistic (Figure 8(f)).

Studies that have measured the geometry of scenes by laser scanning suggest that these classical geometrical illusions are determined by the statistical distribution of the sources of such geometries in the natural scenes that humans have always been exposed to, consistent with the empirical explanations of brightness and color percepts described previously. The rationale for this interpretation is based on the fact that in the perception of form, as in the perception of brightness and color, the sources of the relevant stimuli are inherently uncertain and that stimulus meanings must therefore be adduced according to past experience.

Conclusions

A basic challenge in understanding vision is explaining how inherently uncertain retinal stimuli give rise to definite perceptions and generally successful visually guided behavior. In each the major visual perceptual domains (e.g., brightness, color, and form), the evidence gleaned over many years increasingly points to a fundamentally empirical solution to the inverse optics problem, which is arguably the central challenge in biological vision. The idea that what we see in response to inherently ambiguous retinal images is a statistical manifestation of accumulated past experience rather than a logical analysis of retinal image features *per se* runs counter to our intuitions about vision. Nevertheless, the phenomenology of what we actually see is difficult to explain in any other way. The biological advantage of generating vision in this manner is that percepts – and the visual circuitry that underlies them – will have progressively evolved to

Figure 8 Examples of some much-studied geometrical illusions: (a) the Hering illusion, (b) the Poggendorff illusion, (c) the inverted-T illusion, (d) the Müller–Lyer illusion, (e) the Ponzo illusion, and (f) the tabletop illusion.

incorporate the vast amount of information derived from the experience of both the species and the individual, much to our advantage. The implication of this framework for understanding visual perception is that the main function of visual processing is instantiating and modulating probabilities that link images to their real-world sources.

Perceptual Learning and Sensory Plasticity: Definitions and Overview

Humans are able to adapt to changing environments through several mechanisms, prominent among them sensory plasticity and learning. Perceptual learning (PL) as a special case of learning is defined as a long-lasting improvement in detecting, discriminating, or categorizing sensory stimuli based on preceding experience and leading to unconscious inference, in the nomenclature of Helmholtz. PL extracts previously unused sensory information and reduces unwanted noise. Thus, it improves the cortical representation of a stimulus, leading to a better detection. It also improves the task of discriminating a stimulus from other stimuli and hence improves stimulus categorization, into categories that also may be learned. As one form of sensory plasticity, it changes both perceptual performance and brain physiology, improving the representation of the outer world in the brains of humans and animals and modifying behavior, usually toward improvement. Sensory plasticity in general coordinates and normalizes the perception of different types of sensory stimuli, for example, by adjusting the neuronal gain to coordinate the reference systems of different sense modalities. The term 'perceptual learning' is more often used in relation to the systemic level – that is, to changes in behavior – while 'sensory plasticity' often denotes changes on the neuronal level. Here, 'sensory plasticity' is used as a more general term including both behavioral and physiological changes in perceptual learning, sensomotor control, and long-term adaptation as a result of experience.

The improvement in PL tends to persist over weeks and months, distinguishing PL from short-term adaptation, sensitization, habituation, attention, and priming, which all produce more transient changes of performance. PL is a form of learning not leading to 'knowing that' and lacking memory traces that can be true or false. Hence, PL is of the procedural type, forming implicit memory traces as opposed to explicit memory, and cannot be communicated to others, while declarative forms of memory can. PL appears to directly modify the neuronal mechanisms underlying the processing of the task required, in contrast to declarative forms of learning. These declarative forms of learning usually lead to memory traces, stored in specialized brain regions such as the hippocampus that are clearly separated from the cortical structures analyzing the stimuli. In contrast to associative forms of learning, PL does not normally bind together contents that were initially separated, as does conditioning, but it improves both the detection and the discrimination of stimuli that could not be detected or discriminated before the training, and coordinates signals from different sense organs.

Through PL, we all learn to extract and discriminate the most relevant features from the multitude of signals supplied by the sense organs, and this sensory plasticity continues throughout life to adapt cortical processing on all levels to new situations. Usually, PL requires attention to the target, thus reserving learning to important sensory tasks, while some learning may also occur without attending to the specific stimulus feature due to general arousal. Hence, on a phenomenological level, PL and attention lead to similar results, both improving performance in perceptual tasks. But the effects of attention are similar to those of habituation and sensitization in that they do not permanently change behavior – as soon as attention is moved to another position or object, performance drops to the initial level. Perceptual learning, on the other hand, improves the processing of stimuli throughout their cortical processing chain in a way that leaves permanent traces. Even after months without training, a perceptual task that has been learned yields better results than another one that was never trained.

Sensory plasticity and PL take place on quite a number of different cortical levels, even on rather early ones. An important distinction between different types of PL is whether the improvement generalizes to stimuli similar to those practiced – a distinction closely related to the question of the cortical mechanisms underlying improved performance. 'Early' stages of processing are more specific for low-level features such as position and orientation of a stimulus. Therefore, a high specificity of PL with little transfer to other orientations or positions indicates a neuronal substrate at early cortical levels, while generalization over stimulus position and orientation is more compatible with a higher level of neuronal changes. The results of psychophysical, electrophysiological, and imaging studies indeed show an involvement of early sensory cortices in PL, with feedback from 'higher' to 'lower' levels of processing. PL involving rather early levels of cortical processing, levels that have been well investigated, thus allows one to probe the mechanisms underlying learning in a relatively well-known part of the brain, and in a brain area that is directly accessible to sensory stimulation.

Stimulus Specificity in 'Early' Perceptual Learning: 'Early Selection'

A perceptual task well suited to test PL is vernier acuity, a type of visual hyperacuity, in which even untrained observers attain discrimination thresholds around 10 arcsec – thresholds which are at least slightly below the spacing of foveal photoreceptors. Through training, thresholds can improve down to 2–3 arcsec. Obviously, performance in these tasks is not limited primarily by the optics of the eye nor by the photoreceptor spacing, but rather by the signal-to-noise ratio of neuronal processing. Hyperacuity, being a very sensitive measure, thus is well suited for studying learning processes in visual perception.

Performance typically improves fast for about 10–20 min of training, slowing down thereafter (see Figures 1). Improvement usually does not generalize to a stimulus rotated by 90° for low-level stimuli (Figures 1(a) and 1(b)), and rotation by as little as 4° is sufficient to decrease performance and increase thresholds (Figure 1(b)) virtually to baseline in vernier discrimination. Improvement is similarly specific for position in the visual field. Training of vernier discrimination at a position in the visual periphery improved performance, on average, by 7% (e.g., increasing from 80% to 87% correct responses). Stimuli subsequently presented at a new visual field position yielded 7% fewer correct responses. Hence improvement did not transfer at all between these visual field positions. Performance improves also monocularly in a number of low-level tasks, similar to binocular training. However, improvement does not fully transfer to the contralateral eye; learning is at least partly specific for the trained eye (Figure 1(c)). In many tasks, training improves performance up to 30% within an hour, but large interindividual differences exist even in quite homogeneous groups of individuals, such as students. The causes for these differences in the ability to improve perception through training are so far poorly understood.

PL is specific for a number of stimulus parameters, such as motion speed and motion direction, improving motion discrimination even with 'paired-dot' stimuli. This finding again indicates that improvement may occur on early levels of processing, since these paired-dot stimuli are supposed not to activate the medial temporal (MT) area, the cortical area most involved in motion detection. Improvement of observers training in a shape discrimination task based on luminance contrast transfers to the detection of a shape defined by temporal structure, but not the other way round, possibly indicating a sequential order in cortical processing. Improvement with a visually masked stimulus is specific for the mask, hence caution is required when judging the specificity of improvement based on masked stimuli.

Even detection of luminance contrasts improves through training, and – unlike vernier discrimination – generalizes across orientations. This finding is surprising, given the fact that humans should be overtrained for contrast detection through everyday life, especially under low illuminances. Obviously, training of some tasks is orientation specific, while generalization occurs in others, indicating different mechanisms underlying PL, with generalization of learning being more pronounced on later (cortical) levels. High stimulus specificity can be considered as a sign for modifications on early levels of processing, selecting the relevant information on these early levels.

Generalization of Improvement in Late Visual Perceptual Learning and 'Late Selection'

PL is not restricted to the simple types of stimuli described in the preceding section, but can also involve learning to discriminate between quite complex classes of stimuli. Examples of more complex tasks include the ability to discriminate, say, between the histology of different tissues, or between different types of wines. Individuals identify stimuli as belonging to a specific class or category, and these categories can even be formed through PL, hence these are not necessarily innate processes (see next section).

Often, the amount of generalization is higher for more complex tasks than for simpler ones (and increases greatly with noisy stimuli), indicating a selection of the relevant information only at a later stage of cortical processing. For example, playing action video games partly generalizes to other tasks, and in visual search two aspects are learned: first, specific stimulus features (not generalizing to other stimuli), and second, a global search strategy that generalizes to other stimuli. This is to say that perceptual learning improves the detection of stimuli as well as their discrimination and categorization, not only by improving their cortical representations and by better defining discriminative features, but also because PL contains a learning of the complex setting for the task at hand, including the type of decision and response strategies required. These learning processes probably take place on a rather cognitive level of processing.

Visual training through reading text seems to modify the way people perceive printed words: reading-related training improves perception of words but not of nonwords. Moreover, the size of the visual span (the range around the center of gaze in which letters

Figure 1 Continued

d

Figure 1 Improvement through perceptual learning in a vernier discrimination task. (a) Mean performance of 12 observers initially improved rapidly in a 1 h training session, but rotation of the stimulus by 90°, indicated by the vertical red line, significantly decreased performance – the improvement achieved through training does not transfer to the new stimulus orientation. (b) Mean thresholds of another 12 observers gradually improved over five 1 h training sessions, but massively deteriorated after stimulus rotation. (c) Performance also improved for monocular vision, for example, with the left eye (LE) patched. However, there was hardly any transfer of improvement when the patch was moved to the right eye (RE). (d) The same specificity was found for thresholds in the condition with 5 h of training for each eye in another six observers. (a) Reproduced Fahle M and Edelman S (1993) Long-term learning in hyperacuity. *Vision Research* 33: 397–412, with permission from Elsevier. (c) Reprinted from Fahle M, Edelman S, and Poggio T (1995) Fast perceptual learning in hyperacuity. *Vision Research* 35: 3003–3013, with permission from Elsevier.

are recognized) expands through training, with an associated increase in maximum reading speed. These findings encourage the use of PL in visual rehabilitation.

Formation of New Visual Categories

Categorical perception denotes the capability of observers to better discriminate between members of different categories, as compared to members of the same category that are equally different. Hence, categorical perception emphasizes both the differences between categories and the similarities within categories, and it is often cited as indicating cognitive influences on perception. Categorical learning improves discrimination in domains such as color perception and shape discrimination, for example, in compound gratings (see Figure 2). In color perception, the discrimination between green tiles and blue tiles is easier than it is between tiles of different shades of green, even if the differences between all of the tiles in physical terms (i.e., in terms of wavelength) are of equal size. In the more artificial discrimination between different gratings, observers discriminate better – after a short training phase – between stimulus pairs from different categories just learned. They detect differences between gratings belonging to different categories more often than before the training, but this is true only for the trained grating orientation, not for the perpendicular orientation. Hence, training of categorical perception improves performance only for pairs of stimuli belonging to different categories and only for the trained stimulus orientation, with a rather sharp decline even for small differences in orientation. The high specificity of categorical learning indicates involvement of 'early' mechanisms unable to generalize across different stimulus orientations. On the other hand, another form of 'category' learning – namely, pop-out in search tasks – can be learned and generalized between different types of stimuli.

Learning in Other Sensory Modalities

PL is by no means restricted to the visual domain. The fast improvement with training auditory tasks is, at least in tone frequency discrimination, mostly due to PL. Discrimination of temporal intervals is relatively specific for interval length, but generalizes to other spectral (tone) frequencies. Similarly, as in the visual system, noise is eliminated at an early level, hence loss of efferent feedback (to the cochlea) degrades auditory perception in noisy stimuli. Reorganization of primary auditory cortex and other brain regions was found after some forms of PL but not in others. A fast

Figure 2 Perceptual learning of new categories. (a) Observers learned to discriminate gratings in the upper half of the figure from those in the lower half of the figure. Discrimination between any two 'neighbors' was equally good initially, but it was better between members of the upper versus the lower half than between members of the same group. This superiority of between-category discrimination disappeared for relatively small rotations of the gratings (b). The graph indicates the orientation bandwidth of the transfer between orientations. (b) Reproduced from Notman LA, Sowden PT, and Ozgen E (2005) The nature of learned categorical perception effects: A psychophysical approach. *Cognition* 95(2): B1–B14, with permission from Elsevier.

reorganization was coupled with high sensory thresholds, while thresholds for the 'reorganized' frequencies were close to normal after several months.

PL induces strong changes in the motor and somatosensory cortices, with significant improvement of two-point tactile resolution and enlargement of the cortical representations of those body parts used during training, possibly due to Hebbian coactivation. Even Hebbian coactivation by means of transcranial magnetic cortical stimulation coupled with tactile stimulation improves tactile discrimination ability, and tactile coactivation induces significant changes in somatosensory cortex. Olfactory learning may rely on changes in the odorant receptive fields of second- and/or third-order olfactory neurons of animals, hence again on modifications on a relatively peripheral level of processing, leading to the synthesis of experience-dependent receptive fields as a result of PL. Finally, PL improves 'taste', for example, by significantly lowering the detection threshold for salt in rats.

Psychophysical Evidence Leading to Models of Perceptual Learning

The steadily increasing amounts of data and insights in PL allow the formulation of ever-improving models of PL, incorporating both specificity and generalization of learning. Important features of these models are the implementation of recurrent (feedback) connections, incorporating internal and external noise, and assessing the change of internal templates. The models show that (1) the reported sharpening of orientation tuning curves can account for the psychophysical data, and that (2) PL seems to improve elimination of external noise, possibly by (3) retuning the internal templates.

At least two different mechanisms seem to achieve PL. According to the reverse hierarchy model, learning starts with high speed at high cortical areas (where it generalizes) and progresses backward toward lower levels if necessary (where it is specific and requires more time). A slightly different view contrasts an early selection theory of PL with a late selection, in analogy to theories on attention, and argues that selection should occur as early as possible to optimize signal-to-noise ratio. The specificity of the slow type of PL for stimulus features such as the exact stimulus orientation, position, and even the eye trained under monocular conditions suggests such an involvement of 'early' stages of cortical information processing, where neurons are specific for visual field position and are activated monocularly, as in the primary visual cortex, V1 (Figure 3). Hence, PL seems to involve changes in functional connectivity between neurons already on the level of the primary visual cortex.

In one respect, such a fine-tuning of information processing on as early a level as possible seems reasonable, removing irrelevant noise as early as possible during cortical processing. In another respect, however, the fine-tuning of peripheral levels of processing is unacceptable for a mature nervous system, since learning of a new task would modify the neuronal front end used to process all stimuli. Hence learning on an early level would interfere with performance in

Figure 3 Hypothetical model for the cortical location of perceptual learning, based on the specificity of perceptual learning on stimulus orientation and the eye trained. Since receptive fields in the retina and thalamus are rotation symmetric, orientation-specific learning would be difficult to realize there. Since single-cell recordings in visual cortices find most neurons beyond the primary visual cortex to be binocularly activated, eye specificity of improvement is not trivial to achieve there. Adapted from Fahle M (2004) Perceptual learning: A case for early selection. *Journal of vision* 4: 879–890, with permission from ARVO.

other tasks. For example, shallow luminance gradients are best detected by large receptive fields, which in turn are unable to detect fine gratings. Training to detect fine gratings would therefore improve their detection by decreasing receptive field size, but would deteriorate detection of shallow gradients. A solution of this apparent paradox would be a task-dependent switching of early cortical signal processing under top-down influence. For example, the balance between (excitatory) receptive field centers and (inhibitory) surrounds could be changed under top-down control, or else the gain of feed-forward connections could be modified, or lateral inhibition on the level of the early sensory cortices may be switched on and off or varied in strength. According to this view, filtering and processing on early cortical stages would be chosen from a repertoire of previously learned alternatives under the influence of top-down control. Of course, some learning may take place exclusively on higher processing levels.

The fast and general mechanism, representing more 'conventional' forms of learning, may be located in more central, or 'late', parts of sensory cortices, such as the parietal and temporal lobes, while the slow and specific mechanism seems to involve early cortical areas, including the primary sensory cortices. Perceptual learning and motor learning are actually similar in several respects and may both rely on changes in neuronal tuning functions.

Generalization is at the heart of useful learning in both systems, and apparently relies on strong top-down influences. It will be an important challenge

Figure 4 Mean thresholds of six amnesic patients who were hardly able to remember the task required throughout one session, but who nevertheless improved significantly over the course of ten blocks of training on a hyperacuity task; performance was much poorer than that in normal controls. Reprinted from Fahle M and Daum I (2002) Perceptual learning in amnesia. *Neuropsychologia* 40: 1167–1172, with permission from Elsevier.

for research in perceptual learning to find conditions of training, allowing for at least some generalization of the improvement attained through training.

A study of six patients suffering from amnesic syndrome supports the hypothesis of a 'low' rather than cognitive level of the underlying mechanisms. Two of the six patients tested clearly improved performance within as few as two sessions with five blocks of 80 presentations each, tested at a 1 week interval (Figure 4). Another two patients improved somewhat, while performance of the remaining two patients stayed constant – similar to the results of about 15% of the healthy student population of around 300 observers we have tested so far. While the patients had no recollection at all after the 1 week gap following the first session that they had participated in such an experiment (and did not remember the experimenter), performance of the six patients as a group improved significantly as a result of training. This finding indicates that PL does not require the neuronal circuits underlying explicit or declarative learning. Finding the reasons why some persons strongly improve through learning remains another challenge for research in perceptual learning. A first hint is that especially those persons improve fast who start from a below-average level of performance, though the correlation between speed of improvement and initial level of performance is weak.

Possible Mechanisms of Sensory Plasticity

Receptive fields of neurons in the primary visual cortex typically consist of an elongated excitatory field center that determines the orientation specificity of the neuron. The neuron is most strongly activated by light falling on the receptive field center without extending on the inhibitory surround. The receptive fields of neurons with different orientation preferences and slightly differing receptive field positions are clearly able to discriminate between a straight vernier and an offset one. The precision of discrimination depends, among other factors, on the width of the receptive field center. So a straightforward and plausible hypothesis regarding the neuronal changes underlying PL with vernier stimuli would be that learning modifies the width of receptive field centers and hence their orientation bandwidth, as indicated previously (see Figure 5). The orientation half-width of neurons in the primary visual cortex seems to vary between around 5° and 40°, while that on later cortical stages is still wider. The orientation half-width of perceptual learning, on the other hand, is around 5°, corresponding better to early than to late levels of cortical processing. So far, there are no clear indications that orientation bandwidth of neurons changes as a result of training.

Physiological Evidence for Sensory Plasticity

What are the neuronal cortical mechanisms underlying the improvement of vernier discrimination through training, leading to PL? It is notoriously difficult to indicate the level of neuronal plasticity on the basis of psychophysical results. Other methods are of help here, and, indeed, both single-cell and sum-potential recordings clearly show plasticity at early levels of sensory processing. While 20 years ago the primary visual cortex appeared as a hard-wired first stage of analysis, more recent electrophysiological evidence points to plasticity even in the adult lateral geniculate nucleus and primary visual cortex, supporting the hypothesis that PL may involve plasticity even of primary visual cortex. However, plasticity on early levels may be less pronounced in the visual system than in other sensory systems.

An early study found changes in early evoked sum potentials of humans as a result of PL, and several others corroborated the basic finding of training-induced changes in evoked potentials. Training an orientation discrimination task, surprisingly, decreases in monkeys the number of neurons in primary visual cortex representing the trained orientation, without any evident changes in receptive field properties there or in inferior temporal cortex. However, neurons in V4, with receptive fields in the trained region of the visual field, narrow their orientation tuning and increase responses as a result of training. Moreover, neurons in V1 change not only their contextual influences but also the classical receptive field properties, depending on the animal's actual task, thereby optimizing the information on the relevant stimulus feature under top-down influence. Similarly, neurons in inferotemporal cortex can show target-selective neuronal responses during visual search. Neurons in V4 respond more strongly to noisy images the monkey has been trained with than to untrained images containing the same amount of noise. Hence, training improves both perception and single-cell responses that are noise specific. In humans, training of visual texture discrimination increases activity in the corresponding quadrant of the visual field representation in V1, as demonstrated by functional magnetic resonance imaging (fMRI), compatible with the hypothesis of modification of 'early' sensory processing.

The neuronal networks modified by PL are influenced by pharmacological agents, as well as by transcranial magnetic stimulation. For example, improvement by coactivation in tactile two-point discrimination is eliminated by lorazepam, a γ-aminobutyric acid receptor

Figure 6 Influences of pharmaceuticals on perceptual learning, pre- and posttraining, using the left or right index finger (IF) for coactivation (rec, recovery). Memantine abolishes perceptual learning by blockade of *N*-methyl-D-aspartate receptor, as does the γ-aminobutyric acid receptor antagonist lorazepam (not shown). Amphetamine increases improvement in perceptual learning; under placebo administration, the learning is less pronounced than under amphetamine. Reprinted from Dinse HR, Ragert P, Pleger B, et al. (2003) Pharmacological modulation of perceptual learning and associated cortical reorganization. *Science* 301: 91–94, with permission from AAAS.

agonist, as well as by memantine, which blocks *N*-methyl-D-aspartate receptors. Amphetamine, on the other hand, increases the improvement (Figure 6).

Top-Down Influences in Perceptual Learning and Sensory Plasticity

Attention is a top-down influence affecting even primary sensory levels, and certainly plays an important role in PL. Several studies have demonstrated that a stimulus feature is better detected if it is attended to – mere presentation of a feature usually does not improve its perception over time through PL. But when a nonattended feature is always presented simultaneously with the attended stimulus, the simultaneous feature improves, too. This indicates that a general 'arousal' lasting less than a second may improve perception not only for attended features, but also for those presented simultaneously. In these rare cases, PL evolves without individuals attending to a specific stimulus feature.

In hyperacuity learning, attention also plays an important role. In one study, two vernier stimuli were presented simultaneously, resembling a cross, but only one of the verniers was attended. Then offset discrimination only for the attended vernier improved over the course of training. As mentioned previously, both PL and attention are able to improve performance, but on rather different time scales: attention immediately but without any permanent change, PL (under the guidance of attention) over the course of an extended training, but leaving long-lasting effects.

Improvement through learning in hyperacuity tasks is possible even in the absence of error feedback, but often is significantly faster in the presence of feedback. If only half of the incorrect responses are followed by an error signal (incomplete feedback), the observer's improvement is about as fast as with complete feedback, whereby each incorrect response leads to an error signal. This finding poses severe problems for all theories of (perceptual) learning based on a teacher signal, which allows the observer to classify each stimulus. With partial feedback, half of the incorrect responses would be classified as belonging to the incorrect class – and this should virtually abolish learning, while it does not. But improvement through training is indeed abolished if observers receive even manipulated, more precisely random, feedback, without any correlation between the correctness of their response and the error feedback (while observers assume that they receive correct error feedback). Improvement through learning is about as fast with block feedback when the percentage of correct responses after each block of 80 presentations is indicated as it is for complete trial-by-trial feedback. Most surprisingly, even manipulating the block feedback in a way similar to the condition of random feedback, by presenting a number uncorrelated with the actual performance of the observer, prevents improvement. Hence, feedback can strongly influence the speed and extent of visual learning, indicating that several top-down influences, not just attention, must play a major role in this type

of learning, even if it occurs partly on early levels of cortical information processing.

Conditions for Consolidation of Learning and Visual Rehabilitation of Patients

New experimental data have broadened the evidence that consolidation of improvement achieved through PL requires sleep or at least rest. Both sleep and restful waking facilitate auditory tone learning, and auditory training with a small number of words improves performance with these words, generalizing to novel words using the same phonemes but with different acoustic patterns. Sleep consolidates improvement in a spoken-language task and the automaticity in an auditory discrimination task. Training identification of vowels both improves performance and enhances amplitude of evoked potentials, decreasing their latency.

Amblyopic patients are clearly benefiting from PL. Training improves contrast sensitivity of amblyopic eyes by about a factor of 2, and increases their acuity significantly. Finally, PL is certainly required when deaf or blind patients learn to use the information supplied by an external microphone or camera via direct electrical stimulation of their cochlea, retina, or cortex. Patients wearing a cochlear implant learn to partially adjust to changes in frequency-to-electrode assignment. Unilateral lesions in macaques, on the other hand, severely disrupt learning and performance in a visual match-to-sample task.

Conclusions and Outlook

Perceptual learning can greatly improve the sensitivity of perception, with thresholds decreasing by a factor of 2 and more within a rather short period of training. This seems to rely on more than one process, with the different processes probably located on different (cortical) levels of signal processing. Improvement through modifications on an early cortical level tends to be more specific for the exact stimulus dimensions than are mechanisms relying on more 'cognitive' processes, and may require longer training. PL usually requires some form of attention (hence, no learning without attending to a stimulus) and is often highly specific for rather low-level features of stimuli, such as their orientation. To achieve optimal performance especially for this type of feature, irrelevant signals and noise have to be eliminated as early as possible during processing. To prevent interference of learning one task with performance in other tasks, the changes achieved on early levels have to be activated, in a task-dependent way, by top-down signals. Easier tasks may not have to involve modifications on the early processing levels, leading to generalization of improvement. Perceptual learning is an important mechanism, enabling humans to improve perception and to cope rapidly with ever-changing demands of sensorimotor requirements when interacting with the external world.

Introduction

Learning and memory is manifested in different forms. The conscious form of memory, such as the recollection of previously seen objects and experienced events, is referred to as declarative memory or explicit memory, which can be acquired with a single exposure. The unconscious form of memory, which includes acquired habits and improved motor and perceptual skills, is called nondeclarative memory or implicit memory, which usually results from repeated experience. Perceptual learning is the unconscious acquisition of improved ability in simple discrimination and detection tasks with practice. It is an important form of implicit memory whereby the brain adapts for better and more efficient processing of recurring stimuli.

Different forms of memory are mediated by different brain structures. Studies on patients with specific damage to the brain memory system, the medial temporal lobe, have shown that despite an inability to form any long-term explicit memory, the patients are able to acquire and retain new perceptual skills, such as making a significant improvement in discriminating small misalignments between two collinear lines, a so-called vernier discrimination task in psychophysical studies (Figure 1(c)). The prevailing view is that all declarative memory shares the medial temporal lobe memory system, and that implicit memory can involve any area of the neocortex or cerebellum. In particular, studies have indicated the sensory cortices, including the primary sensory cortex, as the loci of perceptual learning.

This article focuses on typical perceptual learning that involves simple perceptual tasks and early sensory cortices. For complex visual learning, particularly for that pertaining to the recognition of complex objects and the association between objects, the learning is related to the formation of a more declarative form of memory, which is encoded in higher visual areas such as the inferior temporal cortex (IT) of monkeys and the lateral occipital complex of humans. This form of higher level visual learning is not discussed.

Characteristics of Perceptual Learning

Perceptual learning evolves with practice and time. For an untrained task such as vernier discrimination, a naïve subject's discrimination ability can be significantly improved with a few tens of training trials, indicating an early rapid phase in perceptual learning. Following the initial quick changes, slow and steady improvements are seen across daily training sessions until the subject's performance reaches a plateau. The effects of perceptual learning are virtually permanent. Subjects are able to retain the improved discriminability even if they stop performing the learned task for a couple of years; the longest duration has ever been tested. This enduring improvement suggests long-term plastic changes in the brain.

Although perceptual learning occurs in various perceptual tasks with repetitive exposure to the same stimulus and task conditions, the improved perceptual skill is usually highly specific to the conditions used for training, a phenomenon known as the specificity of perceptual learning. There is usually neither transfer nor interference between learning different tasks. The commonly reported specificity in visual perceptual learning can be divided into four types. First, perceptual learning is restricted to the visual field location where the task stimulus is presented. As the stimulus is moved away from the trained location, the observer's performance gradually regresses to the pretraining level (Figure 1(a)). Second, the learning is specific to the stimulus used for training. A change in simple stimulus attributes such as orientation (Figure 1(b)), or even a change in stimulus context (Figure 1(c)), diminishes or abolishes the learning effect. Third, learning in some visual tasks is specific to the eye being trained. If only one eye is exposed to the task stimuli and the other eye is occluded, the improvement does not transfer to the untrained eye. Finally, the learning is specific to the particular perceptual task being practiced and does not generalize to other tasks. Task dependency of perceptual learning indicates that top-down influences such as selective attention play a critical role in perceptual learning. For the same visual stimulus, a subject's ability to discriminate a subtle change in a stimulus attribute can be improved only if that attribute is attended and used in the perceptual task. The other unattended attributes are unaffected in perception even though the subjects are repeatedly exposed to the same stimulus. For example (Figure 1(d)), orientation and brightness are two attributes of a straight line. When both attributes are slightly altered from trial to trial, the discrimination ability of human subjects is improved only for the attended attribute.

Despite the converging evidence that perceptual learning requires attention to the task-relevant stimulus, studies have shown that an unattended visual stimulus can also be learned. However, in this case of task-irrelevant learning, the unattended stimulus

Figure 1 Illustration of the specificity of perceptual learning. (a) Specificity to the trained visual field location. In a three-line bisection discrimination task, the two outer stimulus lines are fixed as a reference, whereas the central line is slightly displaced from the middle to either side. The subject's task is to determine whether the central line appears closer to the left or to the right reference line. With a few weeks' training, the minimum displacement of the central line for reliable detection of the positional offset (i.e., the threshold for bisection discrimination) greatly decreases. The improved discrimination ability, however, is restricted to the location where the task is practiced (labeled as position '0'). When the same stimulus is moved away from the trained location (from 0 to 4) with the eccentricity kept constant, the training-induced improvement gradually disappears (denoted by a decrease in the darkness of lines). (b) Specificity to stimulus orientation. At the trained location, a 90-degree rotation of the stimulus greatly diminishes the learning effect. (c) Specificity to stimulus context. Even if the task is to discriminate the lateral displacement of the same line at the same location, the learning effect does not transfer to a condition of new stimulus context in which a reference line is fixed at one end of the target line. This discrimination task is also the vernier task mentioned in the text. (d) Specificity to the task-relevant attribute. When both orientation and brightness of a target line are changed from trial to trial relative to a reference line, the discrimination ability of human subjects is improved only for the attended attribute. (a) Adapted from Crist RE, Kapadia MK, Westheimer G, and Gilbert CD (1997) Perceptual learning of spatial localization: Specificity for orientation, position, and context. *Journal of Neurophysiology* 78: 2889–2894.

must coincide with an attended task stimulus for the learning effect to take place. One possible explanation for this subliminal learning is that attentively performing a task activates diffusive reinforcement signals, which interact not only with the task-relevant signals but also with those task-irrelevant signals that are temporally associated with the task stimulus. Therefore, even for the task-irrelevant learning it is still necessary to engage the attentional system of the brain.

Another form of top-down influence on perceptual learning involves feedback that indicates the observer's performance during training. External audio or visual feedback is not a prerequisite to perceptual learning because the learning still occurs without it. However, correct external feedback usually results in faster and more extensive improvement than without any feedback, whereas feedback that is uncorrelated with the subject's responses completely prevents the learning. To reconcile these phenomena, it has been proposed that an evaluation process, which is based either on feedback provided externally or on feedback derived internally from confident trials, is of key importance in perceptual learning.

The characteristics of perceptual learning, when considered along with the functional organization of sensory systems, provide implications for the cortical loci and mechanisms involved in perceptual learning. In the visual system, more than 30 cortical areas are associated with visual processing, and these areas are functionally specialized and hierarchically organized, forming partially segregated modules and pathways for processing different visual information. The primary visual cortex (area V1) is the first stage of visual cortical processing, where neurons are selective for simple stimulus attributes such as orientation. In addition, the receptive fields (RFs) of V1 neurons are, on average, the smallest among all visual areas, and the visual inputs from the two eyes are still partially separate in V1. In higher order visual areas, response properties of neurons get more complex, the RFs get much bigger, and the inputs from the two eyes become indistinguishable. That is, higher visual areas gain selectivity for more complex stimuli such as faces but loose spatial resolution and ocular identity. Therefore, given the specificity of learning to simple stimulus attributes, spatial location, and the trained eye, the involvement of early visual areas in visual perceptual learning can be deduced from the functional organization of the visual system. On the other hand, the dependence of perceptual learning on attention to specific stimulus attributes and tasks, together with the remarkable effects of feedback signals on learning, suggests an involvement of top-down control and an interaction between cortical areas.

Neuronal Mechanisms

In addition to the implication from psychophysical studies, a line of physiological evidence suggesting the involvement of early sensory cortices in perceptual learning comes from the accumulated findings that these cortical areas are highly plastic even in adults. The primary sensory cortices, including the primary somatosensory (area S1), auditory (area A1), and visual (area V1) areas, are well organized into topographic maps to represent the sensory surfaces, forming so-called somatotopic, tonotopic, and retinotopic

maps, respectively. After injury to the peripheral sensory surface in adult animals, the topographic maps will undergo pronounced reorganization processes. A similar plastic change in all these early sensory cortices is that the regions and neurons that used to represent the lesion surface start to represent adjacent intact surface. For instance, a laser-induced retinal scotoma removes visual input to the corresponding retinotopic region in V1 and silences cortical neurons within that region, producing a cortical scotoma (Figure 2). However, over a period of 2 months following the retinal injury, the cortical scotoma substantially shrinks: neurons within the cortical scotoma regain responsiveness by shifting their RFs outside the retinal scotoma. This reorganization has been shown to be cortically mediated rather than being a rearrangement of thalamocortical afferents. The plasticity of early sensory cortices observed during recovery from injury has been suggested to serve as the neural basis of perceptual learning under normal physiological conditions.

In agreement with the speculations from psychophysical and lesion studies, plastic changes associated with perceptual learning have been directly demonstrated in early sensory cortices. These changes can be grouped into several categories, which to some extent depend on the nature of perceptual tasks and could reflect different cortical mechanisms of perceptual learning.

Figure 2 Plasticity in adult V1. A retinal lesion (a) immediately silences the corresponding retinotopic region in V1 (b). The retinal lesion induces plastic changes in V1 in such a way that neurons within the cortical scotoma regain responsiveness to visual input from the area surrounding the retinal scotoma (c). Adapted from Gilbert CD (1992) Horizontal integration and cortical dynamics. *Neuron* 9: 1–13.

Expansion of Cortical Representation

The topographic maps in S1 and A1 have been shown to be able to reorganize with perceptual learning. This process is known as cortical recruitment, whereby the cortical area representing the trained sensory surface expands by recruiting the adjacent cortical areas previously representing the untrained surface. For example, after training monkeys to perform a tactile frequency discrimination task using a small surface of one digit, remarkable reorganization of the somatotopic map in S1 has been observed, characterized by a significant increase in the size and complexity of the territory representing the trained skin area. Similarly, training on an acoustic frequency discrimination task results in an extensive increase in cortical area representing the trained frequencies within A1.

Intuitively, with the participation of a larger area of cortex and a proportionally greater number of neurons, better performance should be achieved in the discrimination task at the trained location due to probability summation: the probability of detecting a stimulus increases with the number of detectors (neurons), assuming that the detectors are at least partially independent and that a subset is enough to signal the presence of the stimulus. Nevertheless, it is a matter of some debate whether the learning-associated cortical recruitment is actually responsible for the improved discrimination ability. Although there has been some supporting evidence that cortical recruitment in S1 and A1 can be correlated with improved performance in discrimination tasks, results have also been reported that there is no cortical recruitment in A1 associated with training on an auditory frequency discrimination task. Moreover, an expansion of cortical representation of the trained sensory surface occurs at the expense of the representation of adjacent surface. If an increase in representation is responsible for the enhanced discrimination ability on the trained sensory surface, a decrease in representation would presumably result in impaired discrimination ability on the adjacent untrained surface. Compelling evidence for such a phenomenon is still lacking. In the visual system, the absence of transfer between very similar tasks also argues against cortical recruitment. For example, in the bisection (Figure 1(a)) and vernier (Figure 1(c)) discrimination tasks mentioned previously, the spatial offset of the same target line is discriminated in the same visual field location but within different stimulus contexts. If the improvement in one task is mediated by cortical recruitment, one would expect to see an improvement in the other task. In fact, studies have shown that no change occurs in the retinotopic map in V1 after extensive training on bisection discrimination. However,

changes do occur in V1 neuronal response properties that can account more for the context and task specificity of the learning.

Changes in Stimulus Selectivity of Neurons

Instead of getting more neurons involved, another potential mechanism of perceptual learning is to increase neuronal selectivity for the stimulus attributes that are relevant to the trained task, as supported by electrophysiological studies in monkey V1. One of the remarkable properties of V1 neurons is their sensitivity to stimulus context, a phenomenon called contextual modulation whereby neuronal responses to a stimulus in the RF are modified by other stimuli located outside the RF. Contextual influences seen in V1 indicate that V1 neurons are selective for more complex features in visual scenes in addition to basic stimulus attributes. Studies have revealed that the neuronal mechanism of contextual modulation can be retuned by perceptual learning so as to fit the requirements of the discrimination task.

In the bisection discrimination task (Figure 1(a)), the positional offset of the target line is determined relative to the flanking lines. Earlier studies on contextual modulation in V1 showed that neuronal responses to a line positioned in the RF and orientated at the cell's preferred orientation are usually slightly inhibited by a second parallel line placed on either side of the RF. However, as shown by a study in which monkeys were trained on a three-line bisection

Figure 3 Perceptual learning modifies response properties of V1 neurons in a task-specific manner. (a1) After training monkeys on a bisection discrimination task using three horizontal lines, responses of single V1 neurons to another test stimulus were recorded when the animal either did the trained bisection task or simply maintained its fixation at the fixation point (FP). The test stimuli consisted of two lines, an optimally oriented line fixed in the center of the RF (denoted by the small gray square) and a second parallel line (indicated by 's') placed at different locations on either side of the RF (bottom of (a2); at position 0 degrees the two lines were superimposed). (a2) The normalized responses of a V1 cell to the test stimuli as a function of the position of line 's.' When the animal was performing the simple fixation task, placing 's' on either side of the RF slightly suppressed neuronal responses relative to the responses at position 0 degrees, where a single line was located in the RF. In contrast, when the animal was performing the bisection task, the weak contextual inhibition was changed into strong facilitation. The difference in contextual modulation between the fixation and bisection task conditions was seen only in the trained area. (b1) To further isolate the effect of perceptual task *per se*, monkeys were trained to do two different discrimination tasks with identical stimulus patterns at the same visual field location. The stimuli consisted of five simultaneously presented lines: an optimally oriented line fixed in the RF center and flanked by four additional lines surrounding the RF. In different trials, the arrangement of the two side flankers (s1 and s2) was randomly assigned from a set of five different configurations (illustrated at the bottom of (b2) and (b3); labeled from −2 to +2). Each configuration differs from the others in the separation between the three side-by-side lines (in condition '0' the three lines were equidistant; in the other conditions either s1 or s2 was closer to the central line). In the same trials, the two end flankers (e1 and e2) were also independently assigned a random configuration from a set of predefined arrangements, such that the end flankers were collinear with each other but misaligned with the central line to either side. The animal was cued to perform either a bisection task based on the three side-by-side lines or a vernier task based on the three end-to-end lines. (b2, b3) Two examples of V1 cells in response to the five-line stimuli under the two task conditions. Neuronal responses were examined as a function of the position of the two side flankers s1 and s2 when the animal either performed the bisection task, in which s1 and s2 were task relevant, or performed the vernier task, in which the same s1 and s2 were task irrelevant. (a1, a2) Adapted from Crist RE, Li W, and Gilbert CD (2001) Learning to see: Experience and attention in primary visual cortex. *Nature Neuroscience* 4: 519–525. (b1–b3) Adapted from Li W, Piech V, and Gilbert CD (2004) Perceptual learning and top-down influences in primary visual cortex. *Nature Neuroscience* 7: 651–657.

discrimination task, this contextual effect in V1 can be greatly modified (Figures 3(a1) and 3(a2)). For a large proportion of cells, the modulatory effect caused by the second line is profoundly increased during the performance of the bisection task. In a subset of these cells, weak contextual inhibition is even reversed to strong facilitation (Figure 3(a2)). The changes in magnitude and, in some cases, polarity of contextual modulation are present only in the trained area while the animal performs the learned task, suggesting a task-specific modification of neuronal response properties. A more rigorous examination of task-specific contextual modulation was provided by a subsequent study. Monkeys were presented with an identical set of stimulus patterns on which they were trained to perform either a bisection or a vernier discrimination task (Figure 3(b1)). This study showed that V1 neuronal responses are strongly modulated by the stimulus attribute relevant to the immediate task, but that they are little affected by the other task-irrelevant attribute (Figures 3(b2) and 3(b3)). Information theoretic analyses revealed that, compared with the task-irrelevant condition, neuronal responses carry significantly more information about the same stimulus attribute when the attribute is used by the animal to solve the discrimination task. Taken together, these findings suggest that V1 neurons in the trained animals take on novel response properties related to the discrimination task, and that the exercise of these acquired response properties requires the same stimulus and behavioral context as that during training. This neuronal mechanism coincides with the specificity of perceptual learning.

Besides the selectivity for stimulus context, basic tuning properties of V1 neurons can also be modified by perceptual learning, leading to an improvement in neuronal selectivity for simple stimulus attributes. For example, in both area V1 and area V4, a steepening in orientation tuning curves around the trained orientation has been reported in a subset of neurons after training monkeys on orientation discrimination. The orientation tuning curves of V4 neurons are also generally narrower in the trained region.

Learning-associated cortical recruitment, as well as changes of neuronal response properties, requires attention to the stimulus attribute relevant to the task. This is consistent with the psychophysical finding that the encoding of the learned information is subject to top-down influences. Moreover, the reorganized cortical maps in A1 and S1 are seen when the trained animals are under anesthesia, suggesting that long-term plastic changes indeed take place in early sensory areas. However, neuronal response properties in V1 that emerge from learning the bisection and vernier discrimination tasks are present only when the animal is executing the learned task. This suggests that top-down influences play a triggering role in recall of these acquired properties for processing the perceptual task at hand. One possible neuronal mechanism is that the information related to a given stimulus attribute is represented at the level of subsets of inputs to a cell, which can be plastically tuned and dynamically gated by top-down signals, probably via interactions between feedback connections from higher cortical areas and intrinsic connections within V1. This flexible mechanism enables multiple learned attributes to be represented by the same neurons without cross-talk, greatly expanding information processing capability in V1. Therefore, the top-down influences are critical in both encoding and retrieving the learned information.

Enhanced Neuronal Responsiveness

An increase in neuronal activity as a result of higher responses from individual neurons or from recruiting additional neurons could account for perceptual learning due to an improvement in the signal-to-noise ratio or to probability summation. On the other hand, a sharpening of tuning can also account for improvement in discrimination, yet this would mean that fewer cells would respond to the stimulus, leading to an overall decrease in neuronal responses.

Some discrimination tasks involve making a fine distinction between a target and a reference along a given stimulus dimension such as frequency, orientation, or shape. It is not surprising, then, that training on such tasks would enhance neuronal selectivity for the task-related stimulus attributes. The changes in tuning properties are, in some cases, accompanied by changes in neuronal responsiveness. Some studies have reported increases in neuronal activity associated with discrimination learning. For example, over the course of learning a tone discrimination task in adult owl monkeys, an increase in sensitivity of A1 neurons to all frequencies is observed during the initial phase of improvement in performance. Subsequently, neuronal responses to the target stimuli are differentially intensified relative to the reference and nontarget stimuli. In monkey visual area V4, after training the animal on orientation discrimination, a narrowing of orientation tuning curves in the trained area is accompanied by an overall increase in neuronal responsiveness. In contrast, an imaging study has shown decreased orientation-specific activity in early visual areas associated with orientation discrimination training. In the case of training on bisection and vernier discrimination, both an increase (Figure 3(b2)) and a decrease (Figure 3(b3)) in neuronal responses are observed in different subsets of V1 neurons, but both changes are associated with

increased selectivity for the task-relevant attribute. The diverse observations suggest that the changes in neuronal responsiveness with discrimination training may be more closely related to the change in tuning properties, which better accounts for the improvement in discrimination ability.

Unlike the discrimination tasks mentioned previously, some perceptual tasks involve detection or identification of the presence or absence of a target, either in isolation near the detection threshold or within a noisy background. In this case, the intensity or signal-to-noise ratio of the target stimulus is more directly related to the task than any other stimulus attribute. Therefore, the responsiveness of neurons to the target is crucial for solving the detection task. Depending on the attributes of the target to be identified, activity in different visual areas is significantly increased with training. It has been reported that an improvement in monkeys' performance on detection of coherent motion of dynamic random dots is correlated with an increase in neuronal activity in areas MT and MST that are involved in motion processing. Visual area V4 is at an intermediate stage along the hierarchical pathway for object recognition. When monkeys are trained to identify natural images degraded by noise, V4 neuronal responses to those familiar and degraded pictures are specifically enhanced. In early visual areas including V1, evidence from electrophysiological and functional magnetic resonance imaging (fMRI) studies shows that training on detection of a target embedded in a background of noise or distracters significantly boosts activity in these early visual areas, and the increased activity is correlated with the improvement in target detection. Training on target detection near the contrast threshold and in the absence of any noise or distracter shows a similar effect. After training human subjects to detect a near-threshold grating patch, the fMRI signal in V1 for the trained orientation is significantly increased relative to the control orientation, and this change is correlated with the improvement in target detection. Based on these accumulated findings, an important neuronal mechanism of learning in target detection near threshold or in noisy environments involves increasing the responsiveness of sensory neurons to the target and thus increasing the signal-to-noise ratio.

Shift of Cortical Representation

A special kind of detection task is visual search, in which a target is camouflaged in a background of similar distracters. Psychophysical evidence indicates that extensive training on searching for a hidden target significantly increases the efficiency of target detection, resulting in a pop-out of the target. Functional imaging studies have shown that, in addition to increased activity in early retinotopic areas, learning to search for a particular shape among distracters results in decreased activity both in higher visual areas involved in shape processing and in prefrontal and parietal areas responsible for attentional control. This suggests that another mechanism of perceptual learning involves a shift of cortical representation of the learned stimulus from higher to lower visual areas for more efficient and less effortful processing of the task stimulus. These findings also indicate that the attentional mechanism is pliable, being modified with training.

Changes in Temporal Response Properties of Neurons

The neural codes for sensory stimuli are included not only in the firing rates of neurons but also in their temporal firing patterns, such as the synchrony of discharges across a population of neurons. It has been shown that temporal response properties of neurons can be modified by perceptual learning. For example, neuronal responses in monkey S1 become more coherent with training on tactile frequency discrimination. This change is highly predictive of the improved performance and thus correlates better with the learning than does cortical recruitment. Similarly, after training rats to use the repetition rate of acoustic noise pulses to find food in a maze, with higher repetition rates indicating shorter distances between the animal and the food, A1 neuronal responses to high-frequency pulses become stronger and more phase-locked to the stimuli. In early visual areas of cat, gamma oscillations – an indication of response synchrony among neurons – are increased for a behaviorally relevant stimulus on which the animals were trained. These findings suggest that the enhanced temporal response properties of a population of neurons can serve as another neuronal mechanism of perceptual learning.

Conclusions

Experience-dependent plasticity in sensory cortex serves as the neural basis of perceptual learning throughout the life. Depending on the attributes of the stimuli to be learned, different neuronal mechanisms are evoked to encode the learned information, which can be stored by modifying the functional properties and architecture of early sensory cortices. These changes usually take place in a task-specific fashion under top-down control. Similar top-down influences are required, at least in some visual perceptual learning, to retrieve the learned information relevant to a specific task. This cortical mechanism provides

an effective way to avoid any interference between learning and performing different perceptual tasks.

Perfusion MRI

T T Liu, E C Wong, and R B Buxton, University of California at San Diego, La Jolla, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

The first demonstration that the signal measured with magnetic resonance imaging (MRI) can be made sensitive to neural activity used an injected intravascular contrast agent that alters the MR signal as it passes through the brain. The investigators compared the dynamics of the agent in visual cortex during a rest condition and, with a second injection, during sustained visual stimulation. Although this contrast agent approach ignited the field of functional neuroimaging with MRI, and has now become a standard technique in clinical practice, it has had only limited applications in basic neuroscience studies of brain function. However, it demonstrated that local perfusion changes associated with neural activity can be detected with MRI and then used to map patterns of activation. Soon after this demonstration, the blood oxygenation level-dependent (BOLD) effect was discovered, and this quickly supplanted the earlier perfusion-based technique. With BOLD imaging, the signal changes associated with neural activity arise from a local increase in blood oxygenation, because the fractional blood flow increase is larger than the fractional change in the oxygen metabolic rate. No injections are needed, because the BOLD effect is an intrinsic change in the MR signal related to magnetic properties of hemoglobin, making experiments easier to perform, and also allowing measurement of dynamic changes.

Although imaging methods based upon BOLD contrast are currently the predominant method for functional magnetic resonance imaging (fMRI) of the brain, the interpretation of changes in the BOLD signal can be complicated by factors such as age, disease, and medication, because the magnitude of the BOLD response depends on the matching of changes in blood flow and oxygen metabolism. In addition, BOLD methods can only detect changes between two states, and so are insensitive to chronic conditions. A different approach to fMRI, based upon arterial spin labeling (ASL) methods, offers a useful complement to BOLD fMRI. Like BOLD, the ASL approach requires no injections, and exploits the ability of MRI techniques to selectively 'tag' water in different regions by inverting the proton magnetization, a noninvasive and easily repeatable method to label inflowing blood. It can provide quantitative measures of both resting-state levels of cerebral blood flow (CBF) and of the functional CBF response associated with evoked neural activity. It is also insensitive to slow signal drifts, which can contaminate the BOLD signal. When combined with measures of the BOLD response, measures of functional CBF responses can be used to estimate functional changes in the cerebral metabolic rate of oxygen.

Cerebral Blood Flow

Cerebral blood flow, or perfusion, is a measure of the rate of delivery of arterial blood to a capillary bed in tissue. The standard unit of measurement for CBF is milliliters of blood per 100 g^{-1} of tissue per minute, and a typical value in the human brain is 60 ml 100 $g^{-1}min^{-1}$. Assuming an average brain tissue density of 1 g ml^{-1}, the average CBF may also be written as 60 ml 100 ml^{-1} $min^{-1} = 0.01\ s^{-1}$. In a typical ASL experiment, about 1 s is allowed for the delivery of blood. This corresponds to 1 ml of blood delivered to 100 ml of tissue. As a result, the overall MR signal change due to the delivered blood is only about 1% of the total signal due to the tissue. This small percentage contributes to the low intrinsic signal-to-noise ratio (SNR) of ASL methods.

Overview of ASL

MRI is based on manipulating the magnetization of protons, primarily in water molecules, to generate a detectable MR signal, and the MR image is then a spatial map of this signal. Initially the magnetic moments of the protons partially align with the main magnetic field of the MRI system to create a local magnetization. When radiofrequency (RF) magnetic fields are applied, this magnetization can be tipped over to create a detectable MR signal, or fully inverted by a 180° RF pulse. After an RF pulse the magnetization relaxes back to alignment with the main magnetic field, typically requiring a few seconds, and the magnetization can then be tipped again by another RF pulse to generate a new MR signal. The effects of the RF pulses can be quite selective, exciting only a thin plane or a broad band. Most ASL methods measure CBF by taking the difference of two sets of images: tag images, in which the magnetization of arterial blood is inverted or saturated, and control images, in which the magnetization of arterial blood is fully relaxed. In this way the arterial blood delivered to an image voxel has

a positive magnetization in one image and a negative magnetization in the other, while the static protons contribute the same signal to both and so subtract out in the difference image. The basic steps are as follows:

1. Arterial blood flowing toward the region of interest (ROI) is tagged by magnetic inversion or saturation (see Figure 1). This tagged blood flows into the imaging slices or volume and also relaxes toward equilibrium with the longitudinal relaxation time constant of blood (see red curves in the bottom half of Figure 1).
2. After a delay TI (known as the inversion time) to allow for inflow of tagged blood, an image is acquired in the slice(s) or volume of interest. This image is referred to as the tag image.
3. As discussed previously, the delivered blood signal is only about 1% of the static tissue signal. In order to remove the contribution of the static tissue to the tag image, a control image of the same slice is acquired in which inflowing blood is not tagged. The magnetization of this control image is shown by the dashed blue lines in the bottom half of Figure 1.
4. Taking the difference of the control and tag images yields an image $\Delta M = M_{\text{control}} - M_{\text{tag}}$ that is proportional to CBF. This is shown as the difference of the blue and red lines in Figure 1.
5. Tag and control images are typically acquired in an interleaved fashion, and the running difference of the control and tag images is used to form a perfusion time series (see later, section titled 'Processing of ASL data').

ASL Methods

There are currently three classes of ASL methods, pulsed, continuous, and velocity selective, as summarized in Figure 1.

Pulsed ASL – Tagging Based on Location

In pulsed ASL (PASL), short (5–20 ms) RF pulses are used to saturate or invert a slab of magnetization that is proximal to the region of interest. These techniques have the advantages that they provide high inversion efficiency and use little RF power. Disadvantages are that they depend on the coverage and uniformity of the transmit RF field to determine the geometry of the applied tag.

Continuous ASL – Tagging Based on Location and Velocity

In continuous ASL (CASL), long (1–3 s) RF pulses are used in conjunction with a static gradient field to irradiate a narrow plane of spins with RF energy. The plane is chosen proximal to the region of interest so that inflowing arterial blood flows through in a direction that is roughly perpendicular to the plane. When the RF amplitude and gradient fields are properly adjusted, flowing blood undergoes adiabatic flow-dependent inversion when traversing the irradiated plane. Because the tag can be applied closer to the region of interest (on average), this can result in a higher overall tagging efficiency than is possible with pulsed techniques. However, this technique requires a large amount of average RF power and

Figure 1 Pulsed, continuous, and velocity-selective arterial spin labeling (ASL) methods use various methods to either invert or saturate the magnetization of arterial blood. The difference, ΔM, between control and tag images is proportional to cerebral blood flow. Adapted from Liu TT and Brown GG (2007) Measurement of cerebral perfusion with arterial spin labeling. Part 1: Methods. *Journal of the International Neuropsychological Society* 13: 526–538, copyright © 2007 INS. Reprinted with permission.

can be limited by specific absorption rate (SAR) considerations at higher fields. A recently introduced form of CASL, dubbed pseudo-CASL, uses repeated RF pulses instead of a continuous RF wave.

Velocity-Selective ASL – Tagging Based on Velocity

In the velocity-selective ASL (VS-ASL) technique, an RF pulse train is applied that selectively saturates flowing spins with no spatial selectivity. Because it tags all blood that is flowing above a selected cutoff velocity, this technique has the advantage that the applied tag is close to all the target tissue. This results in a small and uniform transit delay for the delivery of the tagged blood to the tissues of interest (see below regarding transit delays).

Perfusion Quantification

The ASL difference signal ΔM is proportional to CBF but also has a complex dependence on a number of physiological parameters. Variations in these physiological parameters can cause systematic errors in the CBF measurements, and the goal of quantitative ASL methods is to minimize these errors. The primary sources of errors are (1) the transit delay Δt between the tagging region and the imaging slice, (2) the temporal width τ of the arterial bolus in PASL techniques, (3) the presence of tagged intravascular blood that has not yet perfused its target capillary bed, (4) the dependence of relaxation on the exchange of water between blood and tissue compartments, and (5) the clearance of water by outflow.

Transit delays arise in spatial tagging methods because of the need to place the tagging slab in PASL or the tagging plane in CASL some distance (1–3 cm) from the imaging slice in order to minimize the perturbation of spins in the imaging region. To allow all of the tagged blood to travel from the tagging region to the imaging region, the inversion time TI must satisfy the condition $\mathrm{TI} > \Delta t + \tau$, where Δt is the transit delay and τ is the temporal width of the tagged bolus. Although increasing the inversion time reduces the sensitivity to transit delays, it also reduces the magnitude of the difference signal ΔM, which is decaying exponentially with a relaxation time that is of the same order as the transit delay (the T_1 of blood is approximately 1600 ms at a magnetic field of 3 T). Typical inversion times are 1000 and 1400 ms for CASL and PASL, respectively. In contrast to CASL and PASL, transit delays are typically negligible in VS-ASL because the velocity-selective tagging process saturates arterial blood with velocities down to 1–2 cm s^{-1}, corresponding to vessels (roughly 50–100 μm arterioles) that are close to the capillary bed and within the imaging region. This insensitivity to transit delay makes VS-ASL a particularly attractive method for functional ASL studies of those individuals, such as stroke patients, who may exhibit long transit delays.

In CASL methods the temporal bolus width τ is determined by the temporal duration (typically 1–3 s) of the continuous inversion pulse. However, in PASL methods, the temporal width depends on the velocity of arterial blood in the tagging region, which typically increases with functional activation. To reduce the sensitivity to the temporal width, a spatial saturation pulse can be applied to the tagging region at a time TI_1 after the inversion pulse. If $\mathrm{TI}_1 < \tau$, then the temporal width of the bolus is TI_1, and the measured signal is proportional to the product of CBF and TI_1.

A related source of error is the presence of tagged blood in the arteries and arterioles that has entered the imaging slice but is destined to perfuse to more distal slices. If the image is acquired before this blood has time to leave the imaging slice, the intravascular signal will contribute to the ASL difference signal and lead to an overestimate of CBF. Typically, this is not a problem when using pulse sequence parameters that also control for transit delays. In addition, flow-weighting gradients can be used to attenuate the intravascular signal, at the cost of a reduction in the SNR of the desired difference signal.

Improper modeling of the exchange of water between blood and tissue components can lead to significant errors in CBF quantification, especially in tissues with low CBF, such as white matter. For these cases, a simple two-compartment model of exchange can be used to improve accuracy. Finally, errors due to the clearance of water by venous outflow are usually negligible given the inversion times used in most ASL experiments, but may need to be considered in high-flow conditions or when long inversion times are used.

Processing of ASL Data

In most ASL fMRI experiments, control and tag images are acquired in an interleaved fashion, as shown in Figure 2. A perfusion time series is then formed from the running subtraction of the control and tag images. An example of this process is shown in Figure 2, where the perfusion images are formed from the difference between each control image and the average of the two surrounding tag images or from the difference between the average of two surrounding control images and a tag image. The type of differencing shown in Figure 2 is referred to as

Figure 2 Formation of a perfusion time series from the 'surround subtraction' of control and tag images. An example arterial spin labeling (ASL) time series of control (green) and tag (blue) signals is shown in the upper right-hand plot. The perfusion time series created by surround subtraction is shown in the lower right-hand plot. The red bars indicates the time of stimulus. Adapted from Liu TT and Brown GG (2007) Measurement of cerebral perfusion with arterial spin labeling. Part 1: Methods. *Journal of the International Neuropsychological Society* 13: 526–538, copyright © 2007 INS. Reprinted with permission.

surround subtraction, and represents one specific approach to the filtered subtraction of control and tag images. Other common approaches are pairwise subtraction and sinc subtraction. These approaches all share the property that they can be modeled as the modulation of the control and tag images (e.g., multiply all control images by +1 and all tag images by –1) followed by convolution with a lowpass filter. For fMRI experiments with block designs (e.g., long periods of on/off), surround and sinc subtraction approaches tend to provide the best performance. In contrast, for randomized event-related experimental designs, pairwise subtraction can provide better performance (e.g., less filtering of the hemodynamic response function). However, all filtered subtraction approaches lead to inevitable broadening of the hemodynamic response function. Unfiltered approaches based upon general linear models of the ASL experiment can be used to eliminate this broadening and can also provide improvements in statistical power.

As with BOLD fMRI experiments, cardiac and respiratory fluctuations are a major source of noise in ASL experiments, especially at higher field strengths. Since the inherent SNR of ASL methods is typically much lower than that of BOLD fMRI, the need for methods to reduce physiological noise is especially pronounced. Retrospective image-based methods have been shown to significantly reduce physiological noise in ASL data and should be used whenever possible. An example is shown in Figure 3.

Simultaneous Estimates of CBF and BOLD

ASL data for fMRI are often acquired with single-shot acquisition methods such as echo-planar imaging (EPI) or spiral readouts. In addition to their sensitivity to flow introduced by the tagging process, these images can also exhibit BOLD contrast. For example, with gradient echo readouts, the images exhibit a BOLD weighting. Dual echo acquisitions are particularly useful for simultaneous perfusion and BOLD imaging. Images acquired at a short echo time (e.g., 3 ms) can be used to form a perfusion time series with relatively little BOLD weighting, while images acquired at a later echo time (e.g., 30 ms) can be used to form the BOLD time series.

A BOLD time series can be formed from the control and tag images through a running average approach that is analogous to the filtered subtraction approach used to form the perfusion time series. In general, the

Figure 3 Example of the hippocampal cerebral blood flow (CBF) response to a memory encoding task before (top panel) and after (bottom panel) the application of physiological noise correction. Mean responses from a population of ten older individuals (mean age 74 years) are shown with standard error bars. The horizontal green bars denote the times during which novel images were shown.

BOLD time series is formed by the convolution of the control and tag images with a lowpass filter. For example, the method analogous to surround subtraction would be a surround average consisting of the average of each image with the average of its two nearest neighbors. The BOLD time series are inherently flow-weighted because of the tagging process. In PASL experiments the flow-weighting can be reduced by the application of a presaturation pulse applied in the imaging plane either immediately prior to or immediately after the application of the tagging pulse.

Temporal Resolution

The temporal resolution of perfusion fMRI is inherently poorer than BOLD fMRI because of the necessity to form tag and control images and to allow time for blood to be delivered from the tagging region to the imaging slice. In a typical PASL experiment, a repetition time (TR) of 2 s or more is used, so that one tag and control image pair is acquired every 4 s. By comparison, the temporal resolution of BOLD fMRI is typically 1–2 s and can be as low as 100 ms for specialized applications. Methods for improving temporal resolution include turbo-ASL and single-shot ASL. In turbo-ASL, a control image is acquired after the inversion pulse at a delay (typically 100 ms) that is too small for blood to have flowed into the imaging slice. A tag image is then acquired at an interval of *TR* (typically 1 s) after the control image. In single-shot ASL, background suppression is used to suppress static tissue, thus eliminating the need for a control image. While these methods can improve temporal resolution, the quantification of the resultant ASL signals is more complicated than are the more standard methods.

SNR and Contrast-to-Noise Ratio

As discussed on the first page, the SNR of ASL methods is inherently low because the inflowing blood magnetization is typically only about 1% of the tissue. The low SNR combined with the poor temporal resolution of ASL results in a low contrast-to-noise ratio (CNR) for quantitative ASL fMRI experiments, as compared to BOLD. Due to the low inherent SNR of ASL methods, noise reduction methods (such as the physiological noise reduction method discussed earlier) should be used wherever possible. Background suppression methods that attenuate the static tissue component also have the potential to reduce noise, but their application for simultaneous CBF/BOLD experiments is not straightforward. For functional mapping experiments in which quantification of CBF is not required, nonquantitative versions of ASL, such as turbo-ASL and close-tag CASL, can be used to improve the CNR. For example, the CNR of close-tag CASL at 1.5 T has been shown to approach that of the BOLD signal for a finger-tapping experiment.

In brain regions such as the orbital frontal cortex, the presence of pronounced magnetic susceptibility gradients can lead to severe signal dropouts in gradient-echo BOLD imaging, due to the long echo times employed. Because perfusion fMRI measures do not require BOLD contrast, these signal dropouts can be reduced through the use of either short echo time

readouts or a refocusing pulse sequence. The relative SNR of perfusion fMRI measures can therefore be higher than that of BOLD measures in these brain regions.

Spatial Coverage

At present, most ASL fMRI studies use two-dimensional (2-D) multislice acquisition methods in which the data are acquired on a slice-by-slice basis. For CASL and PASL methods, the slices are typically acquired in an inferior-to-superior manner so that slices that are further from the tagging region are acquired at later times. The number of slices that can be acquired depends on (1) the acquisition time for each slice, (2) the time TR – TI that is available for slice acquisition, and (3) the need to acquire slices before the difference signal ΔM has decayed away due to the longitudinal relaxation of blood. Due to these considerations, ASL studies typically acquire a smaller number of slices (e.g., 3–15) than do whole-brain BOLD studies (e.g., 30–40 slices), with thicker slices (e.g., 5–8 mm) than would be used in a BOLD study (e.g., 3–4 mm). Recently, ASL fMRI studies with single-shot 3-D acquisitions have been demonstrated. The 3-D acquisition methods with refocusing pulse trains can reduce susceptibility artifacts, are well-suited to the use of background suppression methods, and are a natural match for the nonspatial tagging scheme used in VS-ASL. However, 3-D methods are not as well suited for simultaneous measurements of CBF and BOLD.

Applications of ASL in fMRI

Quantitative Assessment of Brain Activity

Because it can provide a quantitative measure of a fundamental physiological quantity (i.e., CBF), ASL has the potential to better reflect neural activity as compared to BOLD, which is a complex function of a number of physiological variables. As compared to BOLD, ASL measures of functional CBF changes have been shown to exhibit decreased interindividual and intersession variability and a more linear relation to neural stimulus, possibly reflecting a more direct link between CBF and neural activity.

Although the majority of studies using perfusion fMRI have focused on the visual and motor cortices, there have been a growing number of studies aimed at measuring the CBF response to more complex cognitive tasks. Perfusion fMRI has been used to successfully detect CBF responses associated with language generation, visual attention, memory encoding, working memory, and sequence learning.

When combined with BOLD measures, ASL measures of CBF can be used to derive estimates of functional changes in the cerebral metabolic rate of oxygen ($CMRO_2$), which has been shown in animal studies to be correlated with functional changes in neuronal spiking frequency. In human fMRI studies, the addition of simultaneous measurements of CBF and BOLD responses to a hypercapnic stimulus (administered carbon dioxide) can provide information that is then used to calibrate the BOLD response and estimate functional changes in $CMRO_2$. This approach has been used to demonstrate a linear coupling in the visual cortex between functional changes in CBF and $CMRO_2$. The use of combined CBF and BOLD measures is especially important for fMRI studies of populations, because factors such as medication, age, and disease can complicate interpretation when only BOLD measures are acquired.

Simultaneous measures of CBF and BOLD with ASL are also useful for understanding the mechanisms underlying the BOLD response. For example, ASL measurements have been used to examine whether poststimulus undershoots in the BOLD signal are due primarily to a slow return to baseline in cerebral blood volume or a prolonged elevation of $CMRO_2$.

Insensitivity to Low-Frequency Noise

Low-frequency drifts are present in most fMRI time series data and tend to reduce the statistical power of BOLD experiments. As discussed in a previous section, perfusion time series are formed from the filtered subtraction of control and tag images. This subtraction process greatly attenuates low-frequency drifts and can make ASL more sensitive than BOLD for experimental paradigms with long periods. For example, the insensitivity of ASL to low-frequency drifts has been used to study increases in CBF that persisted for at least 8 min after the completion of a stressful task. In another experiment demonstrating the stability of ASL measurements, patterns of activation were detectable when comparing resting images on one day with activation images on the next day, a comparison that would not be possible with BOLD imaging.

Spatial Localization

Because CBF directly measures the amount of arterial blood that has been delivered to the capillary beds, it has been hypothesized that the functional CBF signal may be more localized to the sites of neuronal activation than the BOLD signal. With the quantitative ASL methods described above, the measured CBF signal is

primarily from small arterioles, capillaries, and brain tissue. There is relatively little signal in the arteries because the inversion delays are chosen to allow enough time for the blood to flow to the target tissue. In addition, there is relatively little outflow of the tagged blood into the venous circulation, because (1) the inversion delays are on the order of the T_1 of blood, which is typically less than the capillary transit time, and (2) there is rapid exchange of water between the vascular and tissue compartments, which effectively slows the outflow. By contrast, the BOLD signal derives primarily from veins and their surrounding tissues. In work examining the visual orientation columns in the cat brain, it was found that the ASL signal provided a more convincing functional map of these very high-resolution structures than did the BOLD signal.

Summary

Perfusion fMRI using ASL offers a useful complement to standard BOLD techniques. ASL methods provide a quantitative measure of CBF that has the potential to better characterize the magnitude and localize the sites of the underlying neuronal activity. Two important drawbacks of ASL techniques for fMRI are that both the temporal resolution and the sensitivity of ASL are lower than those of the BOLD contrast mechanism, so the choice of these methods should be tailored carefully to the biological questions at hand, or used together to provide additional physiological or metabolic information.

Introduction

In the past few years, the core circadian clock genes that make up the 'transcriptional/translational' feedback loop that generates circadian rhythms at the molecular level have been identified. We now know that although the master pacemaker in the suprachiasmatic nuclei (SCN) regulates the timing, either directly or indirectly, of most circadian rhythms in mammals, many organs/tissues of the body can generate circadian rhythms independently of the SCN *in vitro,* and are thus called 'peripheral circadian oscillators.'

These revolutionary developments have opened up an entirely a new area of biomedical research focused on the importance of internal timing for health and disease. In this article we review the current knowledge regarding peripheral circadian oscillators and the role that these oscillators may play in the regulation of health status of an organism.

The Circadian Clock in the Retina

The alternation of light and dark is the most reliable timing cue on our planet, and therefore it is not surprising that the retina has evolved a precise timing mechanism that allows it to anticipate and then to adapt to the more than 1 million-fold change in light intensity during a 24 h period.

The retina was the first extra-SCN oscillator to be discovered in mammals. Several studies have now demonstrated that many of the physiological, cellular, and molecular rhythms that are present within the retina are under the control of a circadian clock, or more likely a series of circadian clocks that are present within this tissue (Figure 1). For example, the disk shedding that occurs in the rod photoreceptors is under circadian control. Shedding persists in animals with SCN lesions or a transected optic nerve, indicating its independence from the central circadian pacemaker. Additional studies have reported that sensitivity to light-induced photoreceptor damage is modulated by the circadian clock via a cyclic adenosine monophosphate (cAMP)-dependent pathway. Other important retinal functions, such as visual sensitivity, are also under circadian control.

Although results from these studies suggested that retinal physiology was regulated by a circadian clock, they were not sufficient to conclude that an independent circadian pacemaker was located within the retinal tissue. The definitive demonstration of the presence of an autonomous retinal clock in mammals was achieved a few years ago when it was shown that a circadian rhythm of melatonin release persisted in mammalian retinas maintained in culture. In light/dark cycles, melatonin levels were high during the night and low during the day. In constant darkness, the circadian rhythm of melatonin release free-ran, exhibiting a period close to 24 h. The circadian rhythm of melatonin release in the retina can be entrained by light *in vitro* and is temperature compensated. Such results demonstrated that the retina can be considered a *bona fide* circadian pacemaker, since it satisfies the three fundamental properties (i.e., free-running, entrainment, and temperature compensation) that describe a circadian rhythm.

The retina is a heterogeneous tissue with many different types of specialized cells, several of which have been shown to express clock genes. Although we know that the circadian pacemaker driving melatonin synthesis is localized within the neural retina, we still do not know which cell types contain the circadian clock. The most recent experimental evidence indicates that the dopaminergic neurons, but not the photoreceptors, express mRNA for several clock genes and therefore these cells are the most likely candidates for the location of the retinal circadian pacemaker. Additional investigations have indicated that mutations in 'clock genes' influence the retinal clock a manner similar to that observed in the SCN, thus suggesting that the molecular mechanism responsible for the generation of circadian rhythms in these two structures is the same.

Previous work has clearly established that the mammalian circadian system is hierarchically organized and that the SCN is the master circadian oscillator that orchestrates circadian rhythms throughout the body (see later). New evidence suggests the presence of a similar hierarchical network of circadian clocks within the mammalian retina. In contrast, circadian rhythmicity of dopamine and its metabolites is not necessary for the generation of the melatonin circadian rhythm in photoreceptors. Thus, the circadian pacemaker controlling melatonin synthesis is insensitive to destruction of the inner retina, as well as to lesions of the SCN, and therefore should be considered the master circadian clock within the mammalian retina.

Finally, it must be mentioned that the retina plays a vital role in circadian organization of the whole organism, since it is the only source of photic information to the SCN (and hence to the rest of the body).

Figure 1 The circadian clock in the mammalian retina controls several rhythms that are important for the functioning of the retina and for the health of the photoreceptors. cAMP, cyclic adenosine monophosphate; AANAT, arylalkylamine *N*-acetyltransferase.

Removal of the retinas may affect the stability and the period of behavioral rhythms as well as the rhythmicity in some parts of the SCN.

Peripheral Circadian Oscillators

During the past decade our understanding of the functional organization of the mammalian circadian system has undergone significant advances. The cloning of putative clock genes has provided new tools with which to study mammalian circadian organization. It has become apparent that the expression of these genes is not restricted to the SCN and the retina, but instead they are expressed throughout the body. Furthermore, in many organs and tissues the genes are rhythmically expressed with a pattern similar to that seen in the SCN, albeit delayed by several hours. While some studies using population sampling methods have indicated that the rhythmic expression of these genes in peripheral tissues disappears in animals in which the SCN is removed, controversy remains, since these studies would not be able to detect a rhythm among animals no longer synchronized within the group.

The view that the SCN drives the rhythms in peripheral structures has been challenged by two seminal discoveries. First, Schibler's team reported that a serum shock can induce circadian oscillation in immortalized fibroblasts. Later, Menaker's group developed a transgenic rat in which the Period 1 (*PER1*) promoter was fused to the firefly luciferase gene to provide a real-time index of gene transcription in living tissue. This new powerful tool was used to demonstrate that many organs and tissues contain oscillators that are capable of generating circadian rhythms *in vitro*. Altogether, these early studies demonstrated three important points: (1) circadian oscillation in mammals can be produced by nonneuronal cells, (2) circadian oscillators are widespread within the mammalian body, and (3) only the SCN is capable of producing long-lasting circadian oscillations (Figure 2). However, more recent evidence has suggested that this third conclusion may not be true. A study using an engineered mouse that carries the luciferase enzyme fused to the Period 2 clock gene (*PER2*) has suggested that peripheral oscillators remain rhythmic in the absence of the SCN, but are no longer coherently organized.

The control and coordination of peripheral oscillators appears to differ among tissues. For example, a 6 h phase shift (delayed or advanced) of the light/dark cycle immediately resulted in phase shifts in the Period 1–luciferase activity rhythms in the SCN, while skeletal muscles and lung took 6 days to adjust to new light/dark regimens. The results obtained with the liver were even more surprising, since the delay phase shift was not completed even after 16 days in the new light cycle. The mechanisms responsible for such differences in the characteristics of circadian rhythms of the SCN and of the various peripheral tissues are still unknown. These results have been used to explain the malaise that results from rapid transmeridian travel and, more importantly, from shift-work schedules.

Aging has a variety of influences on rhythms in peripheral tissues, such as the advance of peak phase in the pineal gland and kidney or the complete loss of rhythmicity in the lung. Also, microarray studies have revealed that while between 8% and 12% of the genome is oscillating with high amplitude in each peripheral tissue, there is little overlap among these tissues with respect to which transcripts oscillate. This key finding suggests that peripheral rhythms serve local functions specific to the organs in which they are generated.

Figure 2 Representative circadian rhythms of bioluminescence from cultured suprachiasmatic nuclei (SCN) and peripheral organs explanted from a Period 1 and luciferase (*PER1–luc*) transgenic rat. Black and white bars show the animal's previous light/dark conditions. Rhythmicity in the SCN persisted for several cycles (top), but only for a few cycles in the peripheral organs. Characterization of human rhythmicity is of high therapeutic value to the diagnosis and treatment of disease. In particular, humans undergoing chronomodulated chemotherapy could be more effectively treated if clock phase and amplitude could be easily assayed for each patient. Using current approaches, the characterization of human circadian rhythmicity is complicated and expensive, since each experimental participant needs to be housed in a specially designed room within a hospital or research facility. Therefore, it would be of great value to devise new techniques that will allow for easier and more economical monitoring of circadian parameters in humans.

There is compelling evidence that the cellular and molecular mechanisms that generate circadian rhythms are similar between the SCN neurons and nonneuronal cells located in organs and tissues outside the brain. Therefore, circadian characterization of tissue biopsies has potential as a surrogate approach to studying the whole person. Indeed, recent work has demonstrated the feasibility of this approach. Human fibroblast cultures were monitored for circadian rhythmicity *in vitro*. From this initial study it emerged that the period lengths of human fibroblasts showed a greater interindividual variation than what has been observed in studies at the whole organism level. This new technology represents a major step forward in our ability to monitor human circadian rhythms and will allow us to develop new diagnostic tools to screen for genetic mutations as well to assess the effects of shift work, jet lag, and sleep deprivation on the circadian system.

Synchronization of Peripheral Oscillators

A poorly understood aspect of circadian organization in mammals is the means by which the SCN synchronizes circadian rhythms in the rest of the body (Figure 3). Experimental evidence suggests that both humoral and neural factors are involved in this process. Previous studies have shown that several humoral factors may act as synchronization factors. In the central nervous system, transforming growth factor-α (TGF-α) is one, but probably not the only, diffusible factor responsible for the transmission of circadian information from the SCN to the other brain regions. In the periphery it appears that glucocorticoids, angiotensin II, and retinoic acid may each play a role in the entrainment of peripheral oscillators. The results from studies examining glucocorticoids have shown that the analog dexamethasone can induce circadian gene expression in cultured rat-1 fibroblasts, and systemic injection in the mouse affects the phase of circadian gene expression in the liver, kidney, and heart, but not in SCN neurons.

It is worthwhile to mention a new study in which the authors, using a parabiosis approach whereby two animals share a blood supply but have independent nervous systems, have shown that nonneural (behavioral or bloodborne) signals are adequate to maintain circadian rhythms of clock gene expression in liver and kidney, but not in the heart, spleen, or skeletal muscle. Furthermore, although SCN transplants may restore the circadian rhythms in locomotor activity, this procedure fails to restore circadian rhythms in melatonin, serum corticosterone, and cortisol levels as well as gonadal and testicular regression, thus suggesting that the SCN must employ more than just humoral signals to control peripheral rhythmic events. Indeed, new neuroanatomical data using retrograde tracing techniques have demonstrated that the SCN projects to several organs, including the hypothalamic–pituitary–adrenal axis, the hypothalamic–pituitary–gonadal axis, the hypothalamic–pineal axis, and the hypothalamic–pancreatic axis. Taken together, these results indicate that the SCN orchestrates the expression of circadian rhythms in different peripheral organs by diverse pathways, and more importantly that these signals can be very specific in their target action.

Behavioral Rhythmicity Driven by Structures outside the SCN

So far we have described endogenously generated rhythms in retinal melatonin synthesis and period 1 and period 2 gene expression in peripheral tissues. These rhythms likely have local action, organizing physiology within the time domain in a specific manner for each tissue. However, circadian rhythmicity generated outside the SCN also has the capacity to influence global physiology and behavior. Food-anticipatory activity arising in animals fed a single daily meal and chronic methamphetamine-induced rhythmicity are two circadian behaviors that challenge the notion that the SCN plays a unique role at the top of the circadian hierarchy.

Figure 3 Schematic model representing the organization of the mammalian circadian system. The suprachiasmatic nuclei (SCN) receives the photic information from the retina via the retinohypothalamic tract (RHT), then the SCN conveys this information to other circadian oscillators via neural (blue lines) or humoral (red lines) pathways. Some peripheral oscillators can also influence the rhythmicity in the SCN via humoral (pineal) or neural (retina) pathways. Food can also acts as a potent synchronizing signal for the liver and for the SCN.

Food intake patterns are governed by endogenous and exogenous cues, and likely act to reinforce the cyclic nature of behavior and physiology. For example, nocturnal rats eat mostly at night. This food intake acts to control the circadian phase of digestive tissues such as the alimentary tract and the liver. Experimentally altering the timing of food intake has dramatic effects on physiology and circadian behavior. Restricting food access to a 4 h window during the day leads to expression of a circadian behavior termed food-anticipatory activity (FAA). This behavioral pattern is characterized by an increase in locomotor activity in the hours preceding meal access. This can be observed by measuring feeder approaches, wheel-running activity, general cage activity, and core body temperature increases. FAA in rats exhibits some of the hallmarks of a circadian rhythm, including persistence during food deprivation, resetting transients following an abrupt shift of the feeding time, and limits of entrainment in the circadian range such that a meal interval of 22–28 h will produce FAA, but an interval that is larger or smaller will not.

FAA has been observed in a wide variety of mammalian species, including several rodents, rabbits, marsupials, and primates. Among nonmammals, honeybees, birds, and fish have all been observed exhibiting FAA in some form. While the conserved nature of the ability to predict mealtime suggests its adaptive importance to organisms at many levels of the foodchain, its function is unknown. It has been speculated that for rodents at least, FAA is analogous to foraging. FAA may be an arousal signal that is activated several hours prior to the time at which food was successfully and safely found on previous days, thereby allowing lead time for the animal to leave its burrow and travel to that location.

While it is well established that the SCN is necessary for the generation of behavioral circadian rhythms entrained by environmental light, the mammalian SCN is not required for FAA. Lesions placed in the SCN, as well as lesions of many other brain structures, have failed to abolish this behavior. Studies have implicated the paraventricular nucleus, nucleus accumbens core, the parabrachial area, and, most recently, the dorsomedial hypothalamic nucleus in some behavioral measures of FAA. However, none of these regions seems to be completely necessary for the prediction of mealtime when multiple behavioral measures are considered.

While peripheral structures do quickly entrain to meal access when that meal is provided at times that are at odds with the light cycle, studies have suggested that these peripheral rhythms are independent from FAA. For example, one can observe FAA without entrainment of metabolism by providing highly palatable food on a schedule, but allowing *ad libitum* access to regular chow. Also, gastrointestinal tissues exhibit molecular rhythmicity that in some circumstances does not match the pattern of FAA.

The circadian clock responsible for FAA remains somewhat of a mystery. Another circadian behavior for which the underlying mechanism is totally unknown is chronic methamphetamine-induced circadian rhythmicity. First described by Shinichi Honma and his group in Sapporo, Japan, this behavior is typified by a long free-running rhythm in constant darkness or constant light, even in mice or rats with SCN lesions. It is induced by simply placing low-dose methamphetamine in the drinking water. If the animal is rhythmic, the rhythm will lengthen and in some cases split into two components with different periods. Presumably these two rhythms are the outputs of the SCN, and another circadian clock that has not yet been discovered but is currently identified as the methamphetamine-sensitive circadian oscillator (MASCO). If the animal is SCN lesioned or is arrhythmic from long-term exposure to constant light, a rhythm will emerge after a latency that can vary from 1 week to one or several months. The period of this rhythm is dependent on the concentration of methamphetamine in the drinking water.

It has been argued that the rhythms induced with chronic methamphetamine are the product of an hourglass timer, rather than a circadian oscillator. If a rat or mouse ingests water containing methamphetamine, activity will increase, leading to further water intake, lasting until the animal tires. Sleep is then followed by a new bout of water/drug intake and increased activity. If the period of this sleep/wake pattern was similar to 24 h, it would appear as if an endogenous rhythm was driving the behavior, even though it is actually caused by a self-reinforcing cycle of drug intake followed by rest. However, the methamphetamine-driven free-running rhythm exhibits characteristics that strongly suggest that it is driven by MASCO rather than by an hourglass, or interval-timing, mechanism. For example, an 8 h removal of methamphetamine from the water results in either no change in the rhythm or an advance of the phase. An interval mechanism would predict a phase delay. Also, there is evidence of persistence of the rhythm after sustained withdrawal of the methamphetamine, and of transients during entrainment to a methamphetamine delivery schedule. These observations are all consistent with the hypothesis that MASCO, a true circadian oscillator independent from the SCN, drives this behavior.

Since both methamphetamine-induced rhythmicity and FAA are non-SCN-based behavioral rhythms that are typified by hyperactivity, it has been speculated

that they arise as the output of the same, as-of-yet unidentified, circadian clock in the brain. If so, identification of the substrate for one will solve the mystery of the other, thereby greatly advancing our understanding of the mammalian circadian system.

Conclusions

Several studies in the past 10 years have demonstrated that circadian oscillators are widely distributed within the mammalian body and that possibly each cell within the body contains a circadian clock. However, these peripheral oscillators are organized by the central circadian pacemaker located in the SCN, indicating that the mammalian circadian system is hierarchically organized. The mechanisms by which the SCN controls peripheral oscillators, as well as the roles that these peripheral oscillators play in the maintenance of normal physiology and health, are topics of active investigation.

Peripheral Nerve Regeneration: An Overview

P M Richardson, Queen Mary, University of London, London, UK

© 2009 Published by Elsevier Ltd.

Spontaneous Recovery of Function in the Central Nervous System

Following axonal injury in the adult mammalian nervous system, some neurological function is usually regained spontaneously over a period of months, despite the absence of functional axonal regeneration. The importance of alternative pathways in such recovery of neurological function can be demonstrated by a second lesion, after initial recovery of function. For example, after lesion of the deep cerebellar nuclei, monkeys initially develop tremor and lose coordination, and then slowly recover. This recovered function is then irretrievably lost if somatosensory regions of the cerebellar cortex are ablated at a second intervention. The efficacy of compensation by spared neural elements varies among neurological pathways and among functions mediated by given pathways. For example, after division of the corticospinal tract in rats, locomotion is transiently impaired whereas fine reaching movements of the forelimb never recover.

The formation of new synapses in the adult mammalian brain was convincingly proved for the first time in an electron microscopic study in 1969. New synapses from spared afferents are formed on deafferentated postsynaptic sites in the septal nucleus, hippocampus, red nucleus, spinal cord, and many other neuronal nuclei in the central nervous system (CNS) and are electrophysiologically functional. A second pattern of sprouting is seen proximal to the site of axonal transection, analogous to growth after horticultural pruning. In the spinal cord, new connectivity can provide a polysynaptic pathway to replace a monosynaptic pathway. The capacity to form new connections through extensive axonal elongation, over micrometers rather than millimeters, accounts for the recovery of function that is anticipated after partial spinal cord injury but which is exceptional after clinically complete loss of function.

Other forms of synaptic plasticity are demonstrable. With contemporary imaging techniques, is now possible to visualize in real time retraction and extension of dendritic spines in hippocampal slice preparations. Synaptic plasticity may be molecular rather than morphological, a classic example being long-term potentiation in the hippocampus, a brain-derived neurotrophic factor-dependent phenomenon whereby postsynaptic responses are enhanced by previous electrical activity. This type of synaptic plasticity underlies learning, and presumably relearning, after neural injury. Disinhibition of synapses within minutes of injury can unmask previously silent connections. For example, after unilateral cervical spinal cord injury, activity in the ipsilateral phrenic nerve ceases only to reappear immediately after a second injury to the contralateral phrenic nerve. In the 'crossed phrenic reflex,' preexisting connections between contralateral descending fibers and phrenic motorneurons are believed to be activated by a hypoxic stimulus.

Another potential mechanism of spontaneous recovery of function is remyelination of axons demyelinated by inflammation or trauma. Demyelinated axons not only fail to conduct impulses but also are vulnerable to Wallerian degeneration because of loss of trophic support. Endogenous oligodendrocytes are capable of remyelination in toxic, inflammatory, and traumatic animal models of demyelination.

Morphological and molecular synaptic plasticity and, to a lesser extent, remyelination are major mechanisms of recovery of function after neural injury. The potential to enhance such spontaneous recovery by electrical activity is demonstrated by observations that locomotion in cats with spinal cord lesions can be improved by early assisted training on a treadmill.

Peripheral Nerve Regeneration

Cellular events underlying Wallerian degeneration and axonal regeneration have been well characterized for many years. Distal to the site of injury, axons degenerate and myelin disintegrates over several days and the debris is phagocytosed by macrophages within 2 weeks (in the rat). The environment created by Schwann cells, macrophages, fibroblasts, and other endoneurial cells supports axonal regeneration at a rate of several millimeters per day.

During Wallerian degeneration, Schwann cells increase in number and become aligned in bands of Büngner. They stop synthesizing mRNAs for myelin protein, ciliary neurotrophic factor, and other proteins and start to synthesize another group of mRNAs, such as those for p75 nerve growth factor receptor and monocyte chemoattractant protein-1. The Schwann cell phenotype during Wallerian degeneration, distinct from that of immature Schwann cells or myelinating or unmyelinating Schwann cells in an intact nerve, is determined by inflammatory cytokines and the loss of axonal signals to Schwann cells. If Schwann cells are deprived of axons for months,

they eventually atrophy and die and the endoneurium ceases to support axonal regeneration well. The prototypic, but not unique, axon-to-Schwann cell signaling pathway, comprising neuregulin and its erbB2–erbB3 receptor dimer, stimulates Schwann cell survival, mitosis, and myelin formation. Two classes of molecules in the endoneurium promote axonal regeneration. Components of the extracellular matrix, in particular laminin, guide and stimulate axons through interaction with their integrins. Diffusible neurotrophic molecules such as nerve growth factor, brain-derived neurotrophic factor, and leukemia inhibitory factor have local actions on the growth cone and retrogradely influence the nerve cell body: their synthesis is strongly increased during Wallerian degeneration. The ability of Schwann cells to redifferentiate in response to axonal degeneration is one critical component of the capacity for regeneration in the peripheral nervous system.

Macrophages in the endoneurium of injured nerves increase in number through recruitment of macrophages and proliferation of resident cells. Macrophages also accumulate around axotomized neurons in dorsal root ganglia. Leukocyte infiltration into the peripheral nervous system after injury is selective for monocytes/macrophages, with minimal involvement of lymphocytes and polymorphonuclear neutrophils: it is regulated by chemokines and cell adhesion molecules that mediate interactions between leukocytes and the vascular endothelium, in particular, monocyte chemoattractant protein-1. Macrophages phagocytose axonal and myelin debris and contribute to the induction of neurotrophic factors, in particular, nerve growth factor. If macrophage invasion into the distal nerve segment is prevented, then axonal regeneration is impaired.

Another series of morphological changes is observed in the cell bodies of axotomized neurons in dorsal root ganglia or in the spinal cord or brain stem. Neurons may die after division of their major peripheral axons, the likelihood being greater if the injury is close to the cell body or if the animal is young. 'Chromatolysis' of neurons refers to the dispersion of ribosomes and peripheral displacement of the nucleus. That inducible events in the nerve cell bodies contribute to axonal regeneration is demonstrated by a variety of 'conditioning' phenomena whereby axonal regeneration is accelerated by a previous or additional axonal injury. Regeneration of the peripheral axons of primary sensory neurons is accelerated by a more distal nerve injury 1 week before the crush injury and regeneration of the central axons of these bipolar neurons is strongly enhanced by a concomitant injury to the corresponding peripheral axons. The propensity for regeneration induced in neurons by axonal injury persists for months, but not indefinitely. Changes in gene expression in neurons following nerve injury include the appearance of messenger ribonucleic acids (mRNAs) for regeneration-associated genes and alteration in either direction of neuropeptide mRNAs. These changes are triggered by changes in retrograde axonal transport. For example, the retrograde influence of nerve growth factor is decreased at least until axons encounter a compensatory source in the distal nerve segment, and this deprivation accounts for a decrease in neurofilament mRNA and many of the fluctuations of neuropeptide mRNAs. The retrograde axonal signals that induce regeneration-associated genes are less well defined. The products of regeneration-associated genes in axotomized sensory neurons include transcription factors (c-Jun), growth factors (brain-derived neurotrophic factor and interleukin-6), growth cone proteins (growth-associated protein-43), and proteins of less well-known function, such as small proline-rich repeat 1A, and their induction is believed to underlie the propensity for regeneration in these neurons. The ability of neurons to redifferentiate is a second factor in the capacity for regeneration in the peripheral nervous system (PNS).

A major limitation to the results of nerve repair stems from the lack of guidance cues to lead axons to their former destinations. Functional recovery is much better after crush injury with preservation of endoneurial architecture than after repair by nerve suture or nerve graft when this physical guidance is lost. Although some cues specific to motor or sensory axons appear to exist, their ability to restore appropriate connections with the periphery is limited. The most important determinant of recovery following nerve repair in human beings is the nature of the injured nerve. For example, the radial nerve with relatively few sensory fibers and an uncomplicated pattern of muscle innervation recovers much better than does the ulnar nerve, a mixed nerve innervating diverse muscles.

Peripheral nerve injury evokes changes in connectivity in the spinal cord, thalamus, and cerebral cortex. Particularly after partial nerve injury, synaptic rearrangement in the dorsal horn of the spinal cord may lead to painful phenomena, including allodynia and hyperesthesia. After a neurotization procedure providing novel peripheral connections (for example, between the intercostal nerve and the biceps), plasticity in the cerebral cortex may improve functional recovery.

Neural Repair in the CNS

Cellular and molecular strategies to repair the brain or spinal cord have been devised. Cellular therapies aim to replace either neurons or glial cells, and

molecular therapies aim to stimulate the nerve cell body or counteract inhibitory influences in CNS glia.

Replacement of neurons, appropriate to the treatment of neurodegenerative disorders, was pioneered by Bjorklund and Stenevi. Following extensive animal studies, fetal mesencephalic tissue was transplanted into the striatum of patients with Parkinson's disease. The cells survived and yielded modest, long-lasting clinical improvement: possible mechanisms of action include integration of grafted neurons into host circuits, release of dopamine by the grafted cells, and beneficial humoral actions of fetal neural tissue. More limited success has been obtained through the grafting of fetal neural tissue into the brains of patients with Huntington's disease. Because of the considerable practical difficulties in obtaining human fetal nervous tissue for transplantation, attempts have been made to generate neuronal cell lines from embryonic stem cells. Also, efforts are under way to enhance the proliferation and differentiation of stem cells indigenous to the adult mammalian brain. Although proof of the principle has been obtained that neuronal replacement can improve or arrest decline of function in neurodegenerative disease, neuroprotective measures such as local administration of neurotrophic factors perhaps hold more hope for future success.

Glial cell transplantation to promote axonal growth in the CNS is based on the premise that such growth could be supported better by replacing astrocytes and oligodendrocytes with more permissive cell types. Reports a century ago that CNS axons could regenerate into a peripheral nerve graft were confirmed many years later by new axonal tracing techniques. It is now apparent that axons from many but not all classes of CNS neurons can grow into the environment provided by Schwann cells and other endoneurial cells. However, two factors have severely limited the success of this strategy in promoting functional recovery. First, the percentage of axons from any given CNS fiber tract that grow into a peripheral nerve graft is small, particularly if the injury is distant from the nerve cell body. Second, axons that enter such grafts have limited ability to exit from them and form new synapses. Olfactory ensheathing cells hold promise to overcome the second obstacle. They are a mixed population of Schwann cells and other cells which support olfactory system axons with the unique ability to grow from the PNS into the CNS in adult mammals. Whereas axons regenerating in dorsal spinal nerve roots fail to penetrate the PNS–CNS interface at the root entry zone, axons regenerating in the olfactory nerve successfully enter and form synapses in the olfactory bulb. Although the cellular and molecular differences between cells in the endoneurium of peripheral nerves and olfactory ensheathing cells have not been fully defined, the unique ability of the latter cells to shepherd axonal growth into the CNS provides a rationale for using them in repair of the CNS. Indeed, transplantation of olfactory ensheathing cells after partial spinal cord injury in rats has led to remarkable recovery of motor function. The rapidity of behavioral improvement, within 10 days, suggests that the recovery is likely due to short-distance sprouting rather than to long-distance regeneration. Other peripheral ensheathing cells – for example, from immature animals – may also support axonal growth across CNS injury sites better than do adult Schwann cells. A less daunting challenge for glial cell transplantation is to restore conductivity to nerve fibers demyelinated by inflammation or trauma. Schwann cells, olfactory ensheathing cells, and oligodendrocyte precursor cells have all shown some promise in this regard.

Two major classes of molecules that inhibit axonal growth in adult CNS glial tissue are myelin-associated proteins and chondroitin sulfate proteoglycans. Three proteins associated with CNS myelin, myelin-associated glycoprotein, Nogo, and oligodendrocyte myelin protein, each strongly inhibits neurite growth *in vitro*. All three act through a receptor complex comprising the Nogo receptor and p75 neurotrophin receptor, which activates the small GTPase Rho and its downstream target Rho-associated kinase, which, in turn, inhibits growth cone extension. Local administration of antibodies to the Nogo receptor and of Rho-associated kinase inhibitors have been found to promote regeneration and recovery of function after spinal cord injury in rodents. Curiously, mice with null deletion of the Nogo receptor do not show enhancement of regeneration of spinal axons. Likewise, delivery of chondroitinase to the injured spinal cord improves both functional recovery and axonal regeneration. For both types of treatment, the improvement of functional recovery precedes and exceeds the enhancement of axonal regeneration and may be mediated through increased synaptic plasticity.

A second impediment to axonal regeneration in the CNS is the difficulty in raising a strong regenerative response in axotomized neurons. Some success has been achieved in enhancing regenerative responses in CNS neurons through neurotrophic factors and small molecules. For example, infusion of brain-derived neurotrophic factor in the red nucleus induces regeneration-associated genes in the neurons and increases the regeneration of rubrospinal axons into a peripheral nerve graft, and injection into the globe of a viral vector delivering ciliary neurotrophic factor increases axonal regeneration from retinal ganglion cells. In general, neurotrophic factors must be

delivered locally in the vicinity of nerve cell bodies, as their side effects upon systemic administration are prohibitive. Cyclic adenosine monophosphate (cAMP) also increases the propensity of neurons to regenerate *in vitro* and *in vivo*, and the need for local delivery can be obviated by systemic administration of a phosphodiesterase inhibitor. Research in the past generation has revealed unexpected plasticity and capacity for recovery in the adult mammalian CNS and has characterized some of the underlying molecular, cellular, and physiological mechanisms.

Perirhinal Cortex

G W Van Hoesen and A Solodkin, University of Iowa, Iowa City, IA, USA

© 2009 Published by Elsevier Ltd.

This article is reproduced from the previous edition © 2004, Elsevier B.V.

The perirhinal cortex in terms of topography can be localized 'around or in the vicinity of' the rhinal sulcus in all mammals and marsupials. Almost always, it occupies the depths of the sulcus and/or its lateral bank, interposed between the entorhinal cortex medially and the neocortex along the lateral surface of the cerebral hemisphere. In nonprimates it is a narrow strip of cortex seemingly only a few cell diameters in width, but in primates and, especially, humans it is a sizable area of cortex. The location of the perirhinal cortex in the human brain can be somewhat confusing since the rhinal sulcus is shallow and truncated typically, bordering only the anteriormost parts of the entorhinal cortex. This results in the repositioning of the perirhinal cortex posteriorly to the medial bank of the collateral sulcus when the rhinal sulcus ends (Figure 1(a)). Nevertheless, it continues to separate the entorhinal cortex from the neocortex and is 'peri' to these rather than to the rhinal sulcus *per se*. Braak and Braak introduced the term 'transentorhinal cortex' to account for this arrangement in the human brain and to emphasize what they regarded as the transitional nature of this cortex.

The cytoarchitecture of the perirhinal cortex is unique, and Brodmann designated it as area 35, setting it apart from the entorhinal cortex, or Brodmann's area 28, medially and the medial part of the inferior temporal gyrus, or Brodmann's area 36, laterally. It lacks a well-defined internal granular layer or layer IV, and layer II is accentuated, having an admixture of small and slightly larger neurons with darker staining characteristics in cell stains. Layer III resembles that of the isocortex but is often thin in comparison with a notable lack of density. Layers V and VI contain very large neurons and are not well differentiated. These are classic cytoarchitectural features of what Sanides termed the proisocortex, the cortex that forms the bulk of the limbic lobe. Accordingly, this cortex characterizes dorsal parts of the limbic lobe such as the cingulate gyrus and ventral parts such as the perirhinal cortex. While it is tempting to view these as 'transitional' cortical areas interposed between the older allocortex and newer isocortex, this is in all likelihood too great a generality. They are too large in size to be viewed in this fashion, they have their own unique cell types, layers and neurotransmitters, and such a view precludes assigning unique functional attributes to the proisocortices – for which there are many. The term meso or intermediate cortex seems to contain less prejudice.

Little is known about the subcortical axonal connections of the perirhinal cortex, but a substantial amount of information exists regarding its cortical inputs and outputs. For example, the perirhinal cortex is connected to many other parts of the limbic lobe including the cingulate, insular, temporal polar, posterior parahippocampal and orbital frontal cortices. In the monkey, strong neocortical projections course to the perirhinal cortex as well, but these arise primarily from the visual association cortex on the lateral surface of the temporal lobe and the visual association cortex that occupies the junction of the temporal and occipital lobes both laterally and ventrally. These along with posterior parahippocampal projections link the perirhinal cortex powerfully with the visual cortices at least in primates. However, it is equally important to appreciate that some of the stronger connections of the perirhinal cortex are made with the entorhinal cortex that lies medial to it. Since the latter has strong reciprocal connections with the hippocampal formation, it follows that the perirhinal cortex is a critical link in reciprocal cortical neural systems that couple together the visual association and limbic cortices with the hippocampal formation. Although the details are not as well known, it would not be surprising if other cortical areas functionally linked to additional modalities access and receive projections from the hippocampal formation via the perirhinal cortex.

Recent investigations in humans and nonhuman primates add substantially to a growing neuroscience interest in the perirhinal cortex. For example, in the human brain acetylcholinesterase staining for axons partitions the perirhinal cortex into distinct columns spanning the superficial layers (Figure 1(b)). These appear to be axonal plombs with a regular periodicity. Immunostaining for the calcium-binding protein parvalbumin reveals a similar columnarity or modularity (Figure 1(c)). This acquires greater interest in view of the fact that neurofibrillary tangles in Alzheimer's disease begin first in the perirhinal cortex and Alz-50 immunostaining for the abnormally phosphorylated tau protein A68 and fluorochrome staining with Thioflavine-S for neurofibrillary tangles reveals sharp columns of affected neurons with pathology-free interspaces separating the columns (Figures 2(a) and (b)).

Figure 1 (a) Cross-section through the ventral medial part of the temporal lobe in the human brain stained with the Gallyas cell stain showing the location of the perirhinal cortex (pc) along the medial bank of the collateral sulcus (star). The parahippocampal gyrus at this level is dominated by the entorhinal cortex (ec) which also covers the gyrus ambiens (ga). am, amygdala; hp, hippocampus; lv, inferior horn of the lateral ventricle. (b) Distribution of acetylcholinesterase in the perirhinal cortex of the human brain on the medial bank of the collateral sulcus (star). Note its modular appearance in the superficial cortical layers and the distinct columns of staining. (c) Immunostaining for parvalbumin on the medial bank of the collateral sulcus (star) in the human perirhinal cortex. Note the modular bands of immunoreactivity in both the superficial layers (more lightly stained) and deeper layers (more darkly stained).

Thus, there is a growing body of evidence that the perirhinal cortex is distinctly modular in the human brain and that this organization is partially disassembled in Alzheimer's disease.

Last, it is noteworthy that ablations in monkeys confined to the cortex in the depths and lateral bank of the rhinal sulcus produce object recognition memory impairments as great or greater than hippocampal ablations and exacerbate the impairment when combined with entorhinal or hippocampal lesions. These findings, now observed by several groups, suggests that the perirhinal cortex not only plays an important role in memory, but may, in fact, have a unique or even pre-eminent role relative to other ventromedial temporal lobe structures.

Figure 2 (a) Thioflavine-S fluorochrome staining for neurofibrillary tangles in Alzheimer's disease in the perirhinal cortex along the medial bank of the collateral sulcus (star). Note the distinct columns of diseased neurons and the pathology-free interspaces between them. (b) Alz-50 immunostaining for the abnormally phosphorylated tau or A68 protein in Alzheimer's disease in the perirhinal cortex along the medial bank of the collateral sulcus (star). Note the columns of immunopositive neurons that characterize this cortex.

In summary, the perirhinal cortex is a pivotal cortical area in the medial temporal lobe interconnecting the hippocampal formation together with other parts of the limbic lobe and with the lateral temporal and occipitotemporal association cortices. Its cytoarchitecture and cortical input and output have been known for some time in several species, but recent behavior and pathological data suggest that it plays a role in visual memory. These observations are of great interest since the perirhinal cortex is affected early in Alzheimer's disease and appears to be the first cortical area that contains neurofibrillary tangles in this disorder. Finally, in the human brain a distinct modular organization exists suggesting that this cortex is specialized functionally and is not a simple transition area separating the entorhinal and inferior temporal cortices.

Perirhinal Cortex: Neural Representations

M W Brown and M Eldridge, University of Bristol, Bristol, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

This article primarily concerns what is known of the neural representations in the perirhinal cortex that relate to the identification of stimuli and their associations, and to judgments about prior occurrence. After some background anatomical information, a summary is given of the results of ablation experiments that indicate the functions of the perirhinal cortex. These functions include roles in perception, particularly for object-related information, and in memory, notably but not exclusively recognition memory and paired-associate learning. A brief overview of recent attempts to find synaptic plastic substrates for the memory functions of the perirhinal cortex is also included. The article does not include the results of human brain imaging, except when mentioned in passing when of particular pertinence.

Perirhinal Cortex

In the last 20 years, the perirhinal cortex has received increasing scientific attention because of its important roles in perception and learning. The perirhinal cortex is located in the anterior and medial portion of the inferior aspect of the medial temporal lobe of primates (Figure 1). Although in the past there has been considerable variation in the definition of the boundaries of the perirhinal cortex, there is now broad agreement that in the monkey it extends immediately lateral to the full extent of the rhinal sulcus and includes the cortex corresponding to both areas 35 and 36 of Brodmann. In the rat, the perirhinal cortex (areas 35 and 36) is located on either side of the caudal part of the rhinal sulcus. The precise extent of the corresponding region in the human brain remains uncertain.

Overview of Connections

The perirhinal cortex is highly interconnected with many other brain regions. It receives highly processed sensory information of all modalities and provides an important route for transferring information to and from the hippocampus. Its position at the top of the sensory processing hierarchy and at the gateway to the limbic system means that it is ideally placed to play important roles in sensory perception and memory. Once a stimulus may be identified, the perirhinal cortex processes aspects of its past history and associations.

In the monkey, the most prominent input arises from the inferior temporal cortex (unimodal visual areas TE and TEO), although it also receives input from the auditory, olfactory, and somatosensory association areas of cortex (Figure 1(a)). Further substantial inputs arise from polymodal association areas, including the prefrontal and cingulate cortices, entorhinal cortex (and, thereby, indirectly from the hippocampus), parahippocampal cortex (areas TH and TF), and cortex of the dorsal bank of the superior temporal sulcus. Perirhinal outputs largely mirror their inputs with strong connections to the entorhinal cortex (again, therefore indirectly connecting to the hippocampus), parahippocampal gyrus, prefrontal cortex, and unimodal and polymodal sensory association areas. The perirhinal cortex also has reciprocal connections with the amygdala and thalamus (mediodorsal and midline nuclei) and sends outputs to the tail of the caudate nucleus and ventral putamen. In addition, it receives input from brain stem monaminergic cell groups and cholinergic input from the basal forebrain. A parallel, similarly widespread pattern of connectivity is found in the rat (Figure 1(b)).

The perirhinal cortex is juxtallocortex, cortex of a type that is transitional between the neocortex and the archicortex and paleocortex of the hippocampal and entorhinal regions. Unlike the neocortex, area 35 lacks an inner granular layer (layer 4) and this layer is very narrow in area 36. Again, in contrast to the neocortex, the perirhinal cortex does not have an obviously columnar organization.

Overview of Functions

There is a very large body of evidence indicating that the perirhinal cortex plays a central role in certain aspects of recognition memory. The evidence is clearest for familiarity discrimination for single items. There is also much evidence of a role in perceptual functions, although this role is not universally accepted. In addition, the perirhinal cortex is involved in other types of memory linked to learned associations made with items (notably reinforcement learning and paired-associate learning). Details of the neuronal responses related to such functions are given later.

Overall, ablation studies provide strong evidence for a role for the perirhinal cortex in object identification, although some findings have challenged this conclusion. Monkeys with perirhinal lesions have been shown to be impaired in a series of tasks designed to test object identification. Thus, there is

Figure 1 Position and some major connections of the perirhinal and neighboring cortices: (a) in the monkey (ventral view); (b) in the rat (lateral view). Below each brain image, routes are shown by which sensory information may reach the perirhinal cortex and the connections from the perirhinal cortex to the hippocampus. The arrow thickness indicates the relative size of the projections. 35 and 36, perirhinal cortex areas; C, caudal; D, dorsal; DG, dentate gyrus; EC, entorhinal cortex; POR, postrhinal cortex; R, rostal; rs, rhinal sulcus; STG, superior temporal gyrus; STS, superior temporal sulcus; SUBIC, subicular complex; TE, TEO, Te2, Te3, visual association cortex areas; TH and TF, parahippocampal cortex areas; STSV, superior temporal sulcus ventral. From Witter MP, Groenewegen HJ, Lopes da Silva FH, and Lohman AHM (1989) Functional organization of the extrinsic and intrinsic circuitry of the parahippocampal region. *Progress in Neurobiology* 33: 161–253.

impairment in perceptual oddity tasks, in which the odd one of a set of images must be chosen; tasks requiring object identification from different views or partial views of the same object; and tasks in which an object previously experienced only by touch must be selected using vision. In addition, monkeys with perirhinal lesions are particularly impaired on tasks requiring discrimination between visual stimuli with a high level of feature ambiguity. It has been argued that, when perceptual deficits have not been found, the tasks may have been solved using discrimination based on individual features rather than whole objects as entities in themselves. When test has been made, the evidence indicates that it is possible to dissociate the mnemonic and perceptual functions of the perirhinal cortex.

The ability to recognize the novelty or familiarity of individual items is an important aspect of recognition memory. Such recognition memory relies not only on identification (perception) but also on judgment of prior occurrence (memory). The involvement of the perirhinal cortex in the judgment of prior occurrence for individual items is widely agreed on. In one view it forms part of a unified medial temporal lobe memory system; an alternative view is that its role is differentiable from that of the hippocampus (the hippocampus is concerned with recollective, complex associational, and spatial aspects of recognition memory, whereas the perirhinal cortex is concerned with single-item familiarity discrimination and simple associations). The pattern of impairments after perirhinal cortex lesions has been doubly dissociated from neighboring areas such as the middle temporal gyrus, which corresponds to the dorsal part of visual area TE; hippocampus; and amygdala. Thus, whereas lesions of the middle temporal gyrus impair color discrimination but spare recognition memory, lesions of the perirhinal cortex impair object

recognition memory but not color discrimination. Further, in both monkeys and rats, hippocampal or fornix lesions lead to marked impairment in spatial tasks with relatively mild or no effect on recognition memory, whereas perirhinal cortex lesions result in the opposite pattern of deficits. Amygdalar lesions impair food preference learning but not delayed matching to sample with infrequently repeated stimuli, whereas perirhinal lesions result in the opposite pattern of impairment. These double dissociations demonstrate that the perirhinal cortex is necessary for visual recognition memory even when functionally isolated from structures to which it is connected both in the ventral visual processing stream and in the medial temporal lobe. In addition to these results for visual tasks, perirhinal lesions impair tactile recognition memory in monkeys and olfactory recognition memory in rats, although auditory recognition memory seems to be spared.

Ablation studies also indicate that the perirhinal cortex is necessary for making certain (although not all) associations involving objects. Such work has shown that perirhinal lesions impair tasks involving associations of objects with other objects, odors, tastes, and tactile or auditory information. Such associations may also be abstract. Monkeys with perirhinal lesions are impaired in a task in which they must respond to a sequence of discriminations to obtain a reward; the results suggest a role of the perirhinal cortex in forming associations between objects and position in a series or proximity to reward in a sequence. In addition, perirhinal lesions in rats produce impairments in conditioned avoidance tasks, notably contextual fear conditioning; the impairment relates to processing of the conditioned stimulus rather than the spatial context of the task.

Neural Responses Related to Stimulus Identification and Linked Associational Functions

Stimulus Identification

Visual information processing is largely divided between two pathways: a dorsal visual stream primarily associated with spatial perception and sensorimotor output, and a ventral visual stream primarily associated with object identification. The latter pathway runs in the posterior–anterior direction through successive processing areas from the primary visual cortex, via area V4, to the inferior temporal cortex, including area TE, which supplies strong projections to the perirhinal cortex. Electrophysiological evidence indicates that neurons in the anterior regions of the ventral visual stream code more complex visual representations than do neurons in the more caudal regions. The perirhinal cortex can be considered to be at the top of the hierarchy of the processing regions, and it has been suggested that it is necessary for the perception of objects as entities as opposed to the identification of their individual features.

Most studies of neuronal response properties concerning stimulus identification in the anterior temporal lobe have concerned visual stimuli and the inferior temporal cortex. Although it is clear that some such studies have included perirhinal neurons, the sensory response properties of perirhinal neurons have rarely been distinguished from those of other anterior inferior temporal neurons. (Past uncertainties about the boundaries of the perirhinal cortex have not assisted in making such distinctions.) Indeed, only a few distinctions have been described between the responses of neurons in anterior TE and in the perirhinal cortex, and these chiefly relate to associative or mnemonic properties (see the sections titled 'Correlates of long-term memory and learned associations of frequently repeated stimuli,' 'Neuronal responses related to paired-associate learning,' and 'Neural responses related to judgment of prior occurrence').

In conscious monkeys, typically more than half of recorded perirhinal neurons are reported as being visually responsive. When reported, more than half of these visually responsive neurons respond to the majority of complex stimuli tested, although by no means with equal vigor to every stimulus. Nevertheless, some perirhinal neurons respond only to restricted classes of stimuli, such as faces or stimuli of a particular color. Accordingly, the responses of perirhinal neurons signal information about the physical features of visual stimuli. It has been reported that a higher proportion of neurons are stimulus selective in the perirhinal cortex than in area TE. Unfortunately, in spite of the suggestion that the perirhinal cortex is critical to object identification, no recordings examining this issue have included the perirhinal cortex. As in TE, when single stimuli are viewed, perirhinal receptive fields are large and may encompass a region extending into both visual hemifields. There has been little study of perirhinal responses in relation to stimulus constancy, but again evidence indicates that it is similar to that found in TE, with similar responses being found when stimuli are shown across different positions or at different sizes. Although some tendency for clustering of similar perirhinal responses has been reported, there is no strong anatomical or physiological evidence that the perirhinal cortex has a columnar organization.

Anatomical connectivity indicates that the perirhinal cortex is a polymodal area, yet there is still

no published major study of polymodal perirhinal responses (although commonly perirhinal neuronal activity in both monkeys and rats is found to vary with all aspects of the behavioral task during which recordings are made and not merely to the presentation of sensory stimuli). Studies of neuronal responses in rats indicate that the responses of perirhinal neurons encode stimulus-specific visual and olfactory information but do not encode detailed spatial information.

Correlates of Attention and Short-Term Memory

Two types of neuronal activity that occur in many brain regions in relation to attentional and short-term memory tasks are also found in the perirhinal cortex: response suppression and delay activity. When monkeys are trained to select a target stimulus presented among nontarget stimuli, neural responses to the behaviorally irrelevant stimuli are suppressed, whereas the response to the behaviorally relevant target stimulus remains unchanged (see Figure 2). This change in responsiveness reflects a neural mechanism encoding the learned salience of a given stimulus. Delay activity is found during the interval between stimulus presentations in short-term or working memory tasks such as delayed matching to sample. In such tasks, a stimulus is presented in an acquisition phase and, after a possibly variable but relatively brief (<1 min) delay interval, there follows a choice phase in which a decision must be made on the basis of the stimulus presented in the acquisition phase. For many perirhinal neurons, the activity in the delay period carries information concerning the stimulus presented during the acquisition phase (i.e., it is stimulus specific). Such activity maintains a representation of that stimulus online and may be a correlate of the stimulus being held in mind. In certain cases, the response of the neuron to the stimulus may then be enhanced when it is repeated on match trials. Again, the activity change shows that perirhinal activity is modulated by attentive and mnemonic factors.

Figure 2 Differential delay activity and response suppression: (a) experiment design; (b) graph of population response for 22 monkey inferior temporal (including perirhinal) neurons. For each neuron, one stimulus that evoked a strong response and one that evoked a weak response were chosen. As shown in (a), either stimulus was presented as the cue (first bar on time scale in (b)), and after a delay, the cue stimulus had to be selected (by making a saccadic eye movement to it; second bar in (b)) from a display of both stimuli in the choice phase. Thus, whichever stimulus was the cue, the display during the choice phase was of both stimuli. The activity was averaged for each neuron for trials using the good and poor stimuli and then across neurons to produce a population response. Note that the delay activity between the end of the cue stimulus presentation and the appearance of the choice stimuli is greater for the good than for the poor stimuli. Also note that the response to the display of both stimuli during the choice phase is rapidly suppressed when the poor stimulus is the target. Thus, across the population of neurons only those that respond strongly to the target are strongly active during the delay and the choice phases. The responses of other neurons are rapidly (~200 ms) suppressed in the choice phase. * indicates the start of saccadic eye movement (note that this is later than start of suppression). From Desimone R (1996) Neural mechanisms for visual memory and their role in attention. *Proceedings of the National Academy of Sciences of the United States of America* 93: 13494–13499.

Correlates of Long-Term Memory and Learned Associations of Frequently Repeated Stimuli

A number of different types of long-term change have been reported in the responses of perirhinal neurons trained on different tasks in which stimuli are seen many times and associated with reward. The findings emphasize the plasticity of the perirhinal cortex in relation to different processing demands. This plasticity and adaptation to specific learning situations may explain what are, at first, apparent inconsistencies in some reported findings. Let us review information available about perirhinal neuronal responses related to examples of such long-term changes and learned associations that are concerned with frequently presented stimuli.

First, the response change that has been reported most often is found in delayed matching tasks using small stimulus sets in which the stimuli are frequently repeated. In such experiments, the response to a stimulus changes (becoming variously either stronger or weaker for different neurons) according to whether it occurs as the choice stimulus on a match or mismatch trial. Such response changes establish that perirhinal neuronal responses can be determined

by more than the physical characteristics of the presented stimulus; the responses can also reflect the behavioral context in which the stimulus is presented. In one description, such responses therefore contain information about the learned associations of the stimulus and, hence, may be said to convey information concerning the behavioral meaning of the stimulus. In another description, the responses contain information about the recent occurrence or nonoccurrence of the stimulus and, hence, are related to a temporal rather than any more abstract context and therefore to judgment of prior occurrence.

Second, sequence learning provides stronger evidence that perirhinal neurons can respond on the basis of the behavioral meaning of a stimulus (its abstract associations) rather than solely according to the physical characteristics of the stimulus. Consider findings from experiments in which a monkey has been trained in a task in which different length sequences of stimulus presentations occur before the availability of reward. The animal learns that certain stimuli signal the position in the sequence (e.g., first or last). Certain perirhinal neurons respond according to the position in the sequence leading to reward that is signaled by a stimulus rather than according to the physical attributes of the particular stimulus. This type of response to a stimulus' implication rather than its appearance was not observed for neurons in TE. Recent results indicate that the development of such perirhinal responses can be blocked by local infusion of an oligonucleotide that interrupts dopaminergic transmission.

Third, when the same stimuli are used repeatedly for tens or hundreds of trials and the animal must attend to these stimuli to gain reward, the responses to these highly familiar stimuli show a gradual increase in magnitude. This finding (along with others) indicates that perirhinal neuronal representations of stimuli are plastic even in the adult. They adapt to experience, presumably to optimize the processing of behaviorally important information.

Neuronal Responses Related to Paired-Associate Learning

Correlates of the Sequential Pairing of Stimuli

Both recording and lesion experiments in monkeys have established the importance of the perirhinal cortex for visual paired-associate learning. In this task, the animal learns across many trials to associate arbitrarily assigned pairs of complex visual stimuli, so that, after a delay following an initial (cue) stimulus presentation, the animal selects (e.g., by touching) the other stimulus of the pair (its paired associate). Two neural substrates of this form of associative learning have been identified in perirhinal cortex: (1) stimulus-specific delay activity and (2) the occurrence of strong responses to both of the stimuli that have been paired (such paired responsiveness occurs more frequently than expected by chance; see Figure 3). Thus, the learning results in single neurons that can code for both of a pair of stimuli; that is, information from both stimuli has converged on individual perirhinal neurons. Such pairs have not been found in TE; there, neurons are responsive only to individual stimuli.

Although sensory information is fed forward from TE to the perirhinal cortex, memory retrieval is fed

Figure 3 Example stimulus-selective neuronal response for learned paired-associate stimuli: (a) Raster display and peristimulus time histogram for the trials; (b) mean (+ SEM) discharge rates during the cue period (60–320 ms from the cue onset) for each of 12 learned pairs of stimuli. The example monkey perirhinal neuron was strongly activated by both members of a particular pair of associated stimuli. In contrast, its responses were negligible when presented with members of any of the 11 other stimulus pairs. In (a) the response to the preferred stimulus as the cue stimulus is indicated by the thick black line and the response to its paired associate is indicated by the gray line. The thin black line denotes the averaged responses in the trials in which other stimuli were used as the cue. The horizontal gray bar indicates the cue presentation period. Note the continuing (delay) activity for the preferred stimuli after the cue stimulus is turned off. Note in (b) that the responses to both members of pair 4 are much greater than the response to any member of the other 11 paired associates. *PCI*, pair-coding index. Reproduced from Naya Y, Yoshida M, and Miyashita Y (2003) Forward processing of long-term associative memory in monkey inferotemporal cortex. *Journal of Neuroscience* 23: 2861–2871, copyright © 2003, with permission from the Society for Neuroscience.

back from the perirhinal cortex to TE. Figure 4 illustrates the firing rate of a perirhinal neuron and that of a neuron from area TE in response to the stimulus to which they both respond preferentially. Memory-retrieval signals appear first in the perirhinal cortex, after which TE neurons are gradually recruited to represent the sought target. It has been established that the perirhinal changes involve and are dependent on the immediate early gene *Zif268*. Anatomical tracing indicates that paired-associate learning is associated with changes in the pattern of axonal connectivity between TE and the perirhinal cortex. Such alterations in the functional architecture of the perirhinal cortex may facilitate the reactivation of newly formed object representations and, moreover, may form a neural basis for the process of memory retrieval.

Correlates of the Simultaneous Pairing of Stimuli

In contrast to findings for paired stimuli presented sequentially, when pairs of stimuli are shown simultaneously, inferior temporal (including perirhinal) neuronal responses to the stimuli shown individually appear to be unchanged even after many such pairings. However, responses to the stimuli shown as a pair are slowly changed by learning. In such experiments, the animal learns to respond (saccade) to whichever one of the two stimuli has been previously shown as a cue. After training, when both stimuli are displayed simultaneously the neuronal response is enhanced if the animal must saccade to the stimulus to which the neuron responds better, but it is reduced when the neuron must respond to the stimulus to which it responds more weakly. Thus, the cortical representation of the pair appears to have become more differentiated. This differential response develops across trials in which the two stimuli are paired when the pairing is repeated many times. The alteration of the representation of the pair of stimuli in the cortex is presumably a result of the altered effectiveness of interconnections within the cortex. Moreover, measured across a range of stimuli, two neighboring perirhinal neurons tend to respond more similarly if the stimuli are familiar (presented many times on the previous day) than if they are relatively novel (not seen before the day of recording). The finding suggests that as a result of repeated experience perirhinal neurons that respond similarly to particular stimuli tend to become grouped.

Neural Responses Related to Judgment of Prior Occurrence

In addition to the changes detailed in previous sections, the responses of certain neurons in the perirhinal and neighboring cortices signal information concerning the previous occurrence of infrequently encountered stimuli. Most strikingly, responses of such neurons are strong for stimuli that have not been seen previously and weak once these stimuli appear again. We term such responses repetition sensitive. They have characteristics necessary for making judgments of prior occurrence, and they have been related to the recency and familiarity discrimination aspects of recognition memory. These response changes have also been called stimulus-specific adaptation and response suppression; however, these phrases carry implications concerning the underlying mechanisms or functionality of the changes that cannot

Figure 4 Neuronal activity during paired associate memory retrieval in monkey for a neuron: (a) in the perirhinal cortex (A36); (b) in area TE. Shown for each neuron are raster displays and peristimulus time histograms for trials in which the preferred stimulus (upper graphs) or its paired associate (lower graphs) were presented as the cue stimulus. The black lines indicate responses to the preferred cue stimulus (upper graphs) or its paired associate (lower graphs); the gray lines indicate the mean responses to all 24 stimuli. Note that for the paired associate of the preferred stimulus, the delay activity in the perirhinal cortex is high from the time that stimulus presentation ends, whereas there is a delay before such activity appears in TE. The delay activity in TE is dependent on a signal fed back from the perirhinal cortex. From Naya Y, Yoshida M, and Miyashita Y (2001) Backward spreading of memory retrieval signal in primate temporal cortex. *Science* 291: 661–664.

currently be justified. In particular, to date no evidence has been found that the response reductions (decrements) are dependent on an active suppressive or inhibitory mechanism. Moreover, the term response suppression is used in relation to attentional processes; the use of the same term for a different process involved in familiarity discrimination is inappropriate.

Most information about repetition-sensitive responses comes from monkeys and visual stimulation. Next, we present the characteristics of these neuronal responses, with generalizations across modalities and species (discussed later).

Response Characteristics

Up to 25% of perirhinal neurons have a reduced response to familiar (compared to novel) visual stimuli, representing approximately 60% of the visually responsive neurons (Figure 5). Note that such change divides perirhinal neurons into two classes: those that have repetition-sensitive responses signaling information concerning even a single prior occurrence of a stimulus and the remainder that do not. The overall tendency to response reduction on repetition is sufficiently large that it is readily seen in population

Figure 5 Example of repetition-sensitive monkey perirhinal neuronal response: (a) first appearance of ten initially novel pictures; (b) repeat appearance of the ten pictures. Responses are stronger to first than for the repeat appearances. One stimulus was shown (bars above the histograms) on each trial of a serial recognition memory task. To be rewarded, the monkey had to press left (L) for the first appearance and right (R) for a repeat appearance of the stimulus. The first and repeat trials have been grouped in this display, but were intermixed when presented. Controls (not shown) established that the difference in activity was not due to the different behavioral responses. Note also that the neuron does not respond equally strongly to the first presentations of the ten different pictures; that is, its activity carries information about stimulus features as well as prior occurrence. From Brown MW (1990) Why does the cortex have a hippocampus? In: Gabriel M and Moore J (eds.) *Learning and Computational Neuroscience: Foundations of Adaptive Networks*, pp. 233–282. Cambridge, MA: MIT Press.

measures of neuronal activity from this cortex. Except under specific circumstances (see next section), response increases with stimulus repetition occur at a level below that expected by chance. Response reductions with repetition have been described for three-dimensional objects and two-dimensional pictures of objects, faces, patterns, and scenes. Repetition-sensitive responses also encode information concerning the physical features of the stimuli, just as do responses that are not repetition sensitive. Thus, for example, some neurons respond only to novel faces and not novel objects or only to novel stimuli of a certain color. Similar response changes are found in the perirhinal cortex (areas 35 and 36), adjacent visual association cortex (anterior TE), and neighboring lateral entorhinal cortex.

In experiments in which both novel and highly familiar stimuli have been repeated, it has been possible to show that there is more than one pattern of response change on stimulus repetition. Under the conditions of the original experiments, these response types were termed novelty, recency, and familiarity because of the type of information signaled. Novelty responses were strong to first presentations of novel stimuli and weak when these stimuli were repeated or already familiar stimuli were shown; the responses gave out a novelty signal. Recency responses were strong for novel stimuli and for highly familiar stimuli that had not been seen for some time (e.g., 24 h) but weak when either type of stimulus had been seen recently; accordingly, such response changes contained information about the recency of presentation of stimuli. In contrast, familiarity responses were strong for novel stimuli even when they were seen for a second time after a brief interval (e.g., <5 min) but weak for highly familiar stimuli even if they had not been seen for a long time (e.g., 24 h); accordingly, such response changes contained information about the relative familiarity of stimuli. Significantly, these different patterns of response change indicated that information about recency of occurrence could be encoded separably from that about relative familiarity. Collectively, perirhinal neurons signaled information about both familiarity and recency. Further study of the properties of the response changes indicated that the term 'familiarity response' was potentially misleading. A better description is that they are slow-change responses because such responses are reduced when an initially novel stimulus is shown for a second time if the interval between its presentations is sufficiently long (e.g., >10 min). They are not reduced if the interval is brief. In contrast, the novelty and recency responses are reduced even when an initially novel stimulus is repeated after an interval of <1 s; correspondingly, such responses are fast change (Figure 6). This new designation does not alter the fact that more than one type of information is being signaled and that there must be more than one type of underlying synaptic change (see the section titled 'Synaptic plasticity and modeling of perirhinal neuronal response changes').

Evidence of Relationship to Recognition Memory

The findings of a large number of ablation studies in both rats and monkeys are in agreement that lesions involving the perirhinal cortex cause major impairment of recognition memory tasks that can be solved using familiarity discrimination for single items. The perirhinal cortex is thus necessary for the solution of such tasks. Repetition-sensitive perirhinal responses provide sufficient information to solve such tasks. First, they signal information concerning stimulus novelty or familiarity and recency of occurrence. Second, the responses are changed by a single occurrence of a new stimulus; they therefore evidence single-exposure learning, as does animal and human recognition memory. Third, the system appears to have a very large capacity; even after a monkey has been shown many hundreds of stimuli, the neurons still respond on the basis of whether an individual stimulus has been seen before. The responses are in this way highly stimulus selective. This property also has an important corollary, namely, that the neurons do not respond weakly to a repeated stimulus because of response fatigue; they continue to respond strongly to a subsequent new stimulus. Fourth, the response changes show access to information held in long-term memory. In particular, the response to the second appearance of a stimulus is reduced even when many other stimuli have been seen and a long time has elapsed since the stimulus was first seen. For many such perirhinal neurons ($\sim$70%, compared to $\sim$45% in anterior TE), responses are reduced even when a stimulus has not been seen for 24 h (Figure 6). Neuronal memory spans (the length of time during which reduced responses are still found) of a few days have also been reported, but longer delays have not been tested. These properties establish that the underlying mechanism differs from that of simple habituation produced by a monotonously repeated stimulus. Moreover, the change is not a simple analog of adaptation to prolonged sensory stimulation. Although the fast-change responses might be related to priming mechanisms, evidence from human lesion and psychological studies makes this unlikely. Slow-change responses do not have the characteristics necessary to explain priming. It should be noted that, for many neurons, response reductions fade with the passage of time and that this provides information within the network concerning how recently a stimulus was presented. In addition, response

Figure 6 Mean population memory spans for neurons in the monkey anterior inferior temporal cortex: (a) recency neurons; (b) familiarity neurons; (c) novelty neurons. Mean population responses (averaged within neurons and then across neurons) are shown for first presentations (N) and second presentations after different intervals (numbers of intervening trials in a serial recognition memory task or 24 h). For these intervals, memory across the population increased with time elapsed for familiarity neurons but decreased for novelty and recency neurons. The decrement developed rapidly (<10 s) for recency and novelty neurons but took more than 5 min to become significant for the population of familiarity neurons. * indicates $P < 0.05$ difference in mean response to second presentations compared to first presentations. From Brown MW (2000) Neuronal correlates of recognition memory. In: Bolhuis JJ (ed.) *Brain, Perception and Memory*, pp.185–208. Oxford: Oxford University Press.

reductions with stimulus repetition are found both when stimuli are presented within a recognition memory task (so that the animal must use its relative familiarity to gain reward) and when they are presented without the animal being trained in familiarity discrimination. The response changes are therefore automatic and endogenous; they are not solely induced by training.

Three other types of perirhinal neuronal response change may also be observed during delayed matching to sample tasks in which judgments about the prior occurrence of a target stimulus have to be made in a choice phase following a delay. They signal information of importance to the solution of particular types of delayed matching to sample tasks, but do not have the properties necessary to explain the behavioral features of general familiarity discrimination for infrequently repeated individual visual stimuli. First, when only one stimulus needs be held in mind at a time and a decision related to its prior occurrence made within a short period (seconds rather than many minutes), increased firing (delay activity) is found between the initial stimulus presentation and the subsequent presentation of the choice (match or nonmatch) stimulus. Such delay activity is not observed when more than one stimulus must be held in mind and the interval before the decision is long, so delay activity cannot provide the substrate for general familiarity discrimination. Second, if a monkey is trained to distinguish between a repeated, unrewarded and a repeated rewarded stimulus, some perirhinal neurons show an increase in response to the repeated rewarded stimulus; however, such increases have been found only when there is a single repeated target stimulus and after training on the specific task. Thus, again, the mechanism appears to be specific to a particular type of task. Third, in delayed matching tasks using frequently repeating stimuli, many perirhinal neurons respond differently to the choice stimulus on match and nonmatch trials. However, it has been shown that for many neurons (notably those outside the perirhinal cortex in, for example, the hippocampus) that these match/nonmatch differences are the same for novel as for familiar stimuli; hence, such differences do not signal the novelty or familiarity of a stimulus. Match/nonmatch differences therefore cannot provide a substrate for general familiarity discrimination, although they may provide information important to judging the recency of occurrence of the stimulus.

One other aspect of perirhinal neuronal activity must also play an important role in familiarity discrimination – the correlated firing of action potentials of neurons within local and distal networks. There is still relatively little known about such interactions or the makeup of such networks in the perirhinal cortex. Nevertheless, it has been established that when the activity of synchronously recorded pairs of perirhinal neurons is studied, the firing of one neuron is quite commonly correlated with that of the other. So far, the evidence from such pairs indicates that synchronized firing (when the two neurons fire at approximately the same time) carries less information about the relative familiarity of stimuli than does the firing rate of the neurons.

Evidence for the Local Generation of the Response Changes

Neuronal response changes with the repetition of infrequently repeated stimuli are also found in areas

other than the perirhinal and its neighboring cortices. For example, such changes are found in parts of prefrontal cortex and the striatum, and a small number (~1%) are found in the hippocampus. (Note that neuronal response changes with frequently repeating stimuli are found in even more regions, including the many that demonstrate habituation.) Nevertheless, there is good evidence that response changes with the necessary properties to underlie the familiarity discrimination component of visual recognition memory are initially generated in the perirhinal cortex, although also possibly in the neighboring anterior inferior temporal cortex.

More posteriorly, and earlier in the visual processing pathway, repetition-sensitive response changes have memory spans that last for only a minute or so and are disrupted by one or two intervening stimuli. Such changes cannot explain those found in the perirhinal cortex. Therefore, perirhinal response changes are not merely passive reflections of responses earlier in the visual pathway. There is also evidence that the changes are not passive reflections of those occurring in subsequent processing areas. This evidence comes from the very fast latencies of the response changes found in the monkey perirhinal cortex and neighboring area TE. In the fastest cases, the change between the response to a novel stimulus and that to a familiar stimulus occurs within milliseconds (measurements are accurate to only 10–20 ms) of the response to the visual stimulus itself (70–80 ms). Accordingly, there is no time for feedback from areas further on in the processing hierarchy. Indeed, when such latencies have been measured in the hippocampus, prefrontal cortex, and striatum, they are significantly longer than in the perirhinal cortex. The conclusion is that at least the initial response change must be first generated in the perirhinal cortex (and/or anterior TE). This conclusion receives support from experiments in which drugs have been infused locally into the rat perirhinal cortex. Local infusions of different glutamate receptor antagonists block the acquisition of longer- or shorter-term recognition memory, and no other brain region is able to substitute for the perirhinal cortex for either type of delay period (see the section titled 'Synaptic plasticity and modeling of perirhinal neuronal response changes').

The recording experiments in which repetition-sensitive response changes have been found have employed many controls to establish that the changes are not explicable by behavioral or motivational changes, including changes in alertness, eye movements, and pupil diameter. The speed of the response changes further establishes that they are not artifactually generated because they occur too soon to be explicable as secondary to ocular or attentional changes. It also establishes that these neurons provide a very rapid signal indicating the presence of a novel stimulus. It has been argued that the evolutionary advantage conveyed by the capacity to attend early to novelty provides a reason for the existence of such a network.

Generalization across Modalities and Species

Similar neuronal response changes on stimulus repetition have been described in both the monkey and rat perirhinal cortex. Moreover, recent functional magnetic resonance imaging (fMRI) studies have indicated that signals in the analogous human cortical region are also weaker for familiar than for novel stimuli. Thus, there is a strong indication that the same type of repetition-sensitive response reductions are likely to occur generally across mammalian species.

Such response changes have been largely studied using visual stimuli because of the availability of such stimuli in the very large numbers necessary for such experiments. Because the connections of the perirhinal cortex indicate that it should be a multimodal area, it might be expected that similar results will be found whichever modality is used. Indeed, findings in the rat for olfactory stimuli are consistent with those for visual stimuli. Neuronal activity measurements have not been made with somatosensory stimuli, although perirhinal lesions impair tactile familiarity discrimination. However, lesion experiments suggest that the perirhinal cortex may not be necessary for auditory familiarity discrimination. When neuronal activity is imaged using Fos (which has proved to be a useful marker for imaging activity changes related to visual recognition memory), activity is higher for novel than familiar sounds in the auditory association cortex (as it is for visual stimuli in visual association cortex) adjacent to the perirhinal cortex but not in the perirhinal cortex itself. The implication is that either another region performs the role of the perirhinal cortex for auditory stimuli or that there is a difference in the nature or complexity of the auditory and visual stimuli being employed. The latter suggestion relates to the proposed role of the perirhinal cortex in the perception of objects and the question as to whether the particular auditory stimuli employed are processed as objects. If they are not, this could explain the lack of differential activation of the perirhinal cortex by the novel and familiar sounds.

Synaptic Plasticity and Modeling of Perirhinal Neuronal Response Changes

Descriptions of different types of perirhinal neuronal response changes related to learning have already been presented. It is possible to list these under the

following headings: (1) feature extraction (perceptual categorization), (2) familiarity/recency discrimination (potentially several different mechanisms), (3) paired-associate learning, and (4) reward-association learning. Yet other changes, thought to be related to attentional and/or short-term memory mechanisms, have also been described, such as delay activity and response suppression. It is already clear that there are also developmental changes. The interrelationships and independencies of these different response changes and their underlying synaptic plastic mechanisms are largely unknown, but in the list there are at least eight types of activity change, all of which are observable in the activity of perirhinal neurons under different conditions. The changes observed are dependent on the particular conditions of the experiment and on the particular perirhinal neuron under study. Not all perirhinal neurons show all types of changes, although some may show more than one; again information here is limited.

The perirhinal cortex provides a promising region for the investigation of neural substrates of memory. In recent years, increasing efforts have been made to relate perirhinal neuronal response changes to underlying synaptic plastic changes. This work has variously encompassed paired-associate learning, reward learning, developmental changes, and familiarity discrimination. It has also involved the study of synaptic plasticity mechanisms in slices of the perirhinal cortex.

Perirhinal Plasticity Studied in Brain Slices

In vitro studies have established that both long-term potentiation (LTP) and long-term depression (LTD) can be evoked in the perirhinal cortex by suitable stimulation. The induction of both LTP and LTD are dependent on *N*-methyl-D-aspartate (NMDA) glutamate receptors in the perirhinal cortex, as elsewhere. However, LTD has been shown to have an unusual dependency on activation of metabotropic glutamate receptors. Moreover, in the adult perirhinal cortex LTP is dependent on the activation of NMDA receptors containing NR2A subunits, whereas LTD (and depotentiation) is dependent on NMDA receptors containing NR2B subunits. Again, as in other regions, there are differences between the adult and immature cortices in NMDA glutamate receptor composition and LTD induction mechanisms. Indeed, recently, it has been shown that visual experience triggers such a change between immature and adult perirhinal LTD induction mechanisms.

Signaling Mechanisms Related to Paired-Associate and Reward Sequence Learning

As already mentioned, studies of paired-associate learning in the monkey have established that underlying perirhinal changes involve and are dependent on the immediate early gene *Zif268*. Similarly, reward-sequence learning in the monkey involves dopaminergic mechanisms because perirhinal neuronal response changes are blocked by local infusion of an oligonucleotide that downregulates the expression of D2 dopaminergic receptors. Interestingly, antagonism of the NMDA receptors did not prevent the development of the response changes.

Signaling Mechanisms Related to Recognition Memory

Several studies have been carried out that look at potential substrates of familiarity discrimination in the rat. This work has established that recognition memory is impaired following local infusions into the perirhinal cortex of the muscarinic receptor antagonist scopolamine or of selective antagonists of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), NMDA, kainate, and metabotropic glutamate receptors. When AMPA receptors are blocked, both acquisition and retrieval are impaired. Otherwise, all the studied drug actions involve acquisition and not retrieval. Interestingly, blockade of NMDA and metabotropic glutamate receptors produces recognition memory impairment only when the memory has to be held across a long (24 h) and not shorter (20 min) delay. In contrast and most unusually, kainate receptor antagonism impairs recognition memory after a 20 min but not after a 24 h delay. These results parallel the evidence provided by perirhinal neuronal responses that there must be more than one substrate underlying familiarity discrimination. The indication is that there must be a rapidly induced shorter-term process that is dependent on kainate receptor activation and one or more longer-term processes, more slowly induced and dependent on NMDA and/or metabotropic glutamate receptor activation. In addition, viral transduction of the perirhinal cortex has shown that phosphorylation of cyclic adenosine monophosphate (cAMP) responsive element binding protein (CREB) is necessary for both perirhinal LTP and long-term (24-h) recognition memory, a dependency that parallels findings elsewhere (e.g., in the hippocampus).

Theoretical Models and Plasticity Mechanisms

There are now several theoretical neuronal models both of networks designed to extract features and thereby achieve stimulus categorizations leading to perception and of networks designed to achieve familiarity discrimination. None of these models yet uses specific details of perirhinal circuitry (about which there is still relatively little information). Most of the models have employed synaptic enhancement

(i.e., LTP-like mechanisms) as their primary synaptic plasticity mechanism. One way of achieving the reduced neuronal responses for familiar compared to novel stimuli in such models is by increasing inhibition, but experimental evidence of such increased inhibition is lacking. Recently, it has been argued that models that use separate (but interlinked) networks for feature extraction and familiarity discrimination are more economical. The idea of separate networks is consistent with the observation that perirhinal neurons have responses that are either repetition-sensitive or not, rather than some mixture of the two. Moreover, the calculations indicate that the use of synaptic weakening as the primary mechanism is considerably more efficient than synaptic enhancement. Heuristically, this is because when features repeat across different stimuli, synaptic enhancement leads to certain synapses being successively strengthened so that the neurons with these synapses come to fire selectively strongly for these features (i.e., they signal the presence of such features). In contrast, synaptic weakening has the opposite effect; it emphasizes what is not common rather than what is common across stimuli – but this is what is required for novelty detection. Hence, neuronal modeling has provided an explanation for why perirhinal responses are weaker for familiar than novel stimuli. Under this hypothesis, the synapses that are most strongly activated by a novel stimulus are weakened; when the stimulus occurs again (i.e., when it is familiar), the weakened synapses give rise to a weaker response.

Summary

The position of the perirhinal cortex at the top of the hierarchy of sensory processing areas and at the gateway to the limbic system means that it is ideally placed to play important roles in sensory perception and memory. Ablation evidence indicates that the perirhinal cortex is indeed involved in both perceptual (stimulus categorization) and mnemonic functions. The results of recording studies established that the responses of perirhinal cortical neurons carry information about complex stimuli and relate to stimulus identity, but they have yet to provide evidence for the categorization of objects as entities (as suggested by certain lesion studies). There is much evidence from recording studies that perirhinal neurons are involved in attentive and short-term memory, as well as multiple long-term memory tasks including sequence learning for reward, paired-associate learning, and recognition memory. A variety of different neuronal response changes have been related to these different memory tasks, and studies of their underlying synaptic plastic mechanisms are underway.

Peroxisomal Disorders and Neurological Disease

Introduction

Peroxisomes are ubiquitous, usually spherical, single-membrane-bound organelles, 0.2–1 μm in diameter and numbering several hundred per mammalian cell. First described in 1958 as microbodies in mouse kidney by Johannes Rhodin, their name derives from the peroxide generated in these organelles as a by-product of oxidative reactions. Zellweger syndrome (ZS) was originally classified as a congenital malformation syndrome, the cerebrohepatorenal syndrome, and X-linked adrenoleukodystrophy (X-ALD), a sudanophilic leukodystrophy referred to as Schilder disease. A peroxisome etiology for these disorders was not recognized until the assignment of enzyme defects to the peroxisome, thus defining a new category of human metabolic disease. More than 50 enzymes have since been localized to the peroxisome matrix. The majority are involved in lipid metabolism, including the oxidation of very long chain fatty acids (VLCFAs) and the synthesis of bile acids and ether phospholipids. We now recognize two general classes of peroxisome disorders, the single-enzyme (or protein) deficiencies (SED), including X-ALD, and the peroxisome biogenesis disorders (PBDs). Failure of the peroxisome to assemble correctly leads to multiple enzyme deficiencies in PBDs. Although the underlying gene defects in these disorders have now been identified, the functions of the encoded proteins are still being defined; it remains to relate the clinical features with the disturbances in biochemical pathways. This should lead to improved therapeutic approaches. In this article, we review the clinical phenotypes and molecular genetics of X-ALD and PBDs and discuss current investigations that relate to pathogenesis.

X-Linked Adrenoleukodystrophy

Clinical Phenotypes

X-ALD causes varying degrees of malfunction of the adrenal cortex and nervous system myelin. The estimated overall frequency is 1:17 000. There are several distinct phenotypes. Approximately 35% of patients have the childhood cerebral form. These affected boys develop normally until 4–8 years of age, then suffer dementia and a progressive neurologic deficit that leads to a vegetative state and death. More than 90% of these patients have adrenal insufficiency. In approximately 35–40% of patients, the disorder presents in young adulthood as a slowly progressive paraparesis with sphincter disturbances that primarily involve the long tracts in the spinal cord, referred to as adrenomyeloneuropathy (AMN). Recently, Van Geel et al. demonstrated that 20% of these patients develop progressive inflammatory demyelination, to which they succumb in 1–2 years. This appears to follow the same pattern as the childhood form of cerebral adrenoleukodystrophy, albeit slower in progression. Female heterozygotes of X-ALD are also known to have symptoms related to the underlying metabolic disorder. Approximately 60% have abnormalities resembling adrenomyeloneuropathy. A third of these patients have severe symptoms, another third have slight to moderately severe symptoms, and the remaining third are asymptomatic but have hyperreflexia and diminished vibration sense in the lower extremities.

Genetics

The adrenoleukodystrophy gene, located at Xq28, encodes an integral peroxisome membrane protein with the consensus structure of an ATP-binding cassette (ABC) half-transporter. The gene name has been designated *ABCD1*, for subfamily D, member 1 of a large family of proteins with similar domains, conserved through evolution. The protein is still referred to as the adrenoleukodystrophy protein (ALDP). The functional role of ALDP is currently being investigated. It has been shown to both homodimerize and heterodimerize with related peroxisomal membrane ABC half-transporters, ALDRP, PMP70, and PMP70R, presumably to form a full transporter. The expression pattern of these related proteins varies according to tissue type and time in development, and the substrates transported might depend on the assembled transporter. Since VLCFAs accumulate in X-ALD, and peroxisomal β-oxidation is reduced in spite of the presence of normal enzymatic machinery inside the peroxisome, it has been assumed that ALDP transports either VLCFAs, VLCFA-CoA, or the VLCFA acyl-CoA synthetase. However, the specific substrates for the peroxisome ABC transporters remain to be demonstrated. In the interim, evidence has been presented to suggest that the accumulation of VLCFAs in X-ALD might be secondary to enhanced chain elongation of fatty acids, rather than reduced β-oxidation. This is supported by reports that

ABCD1-deficient mice have elevated VLCFAs, but normal peroxisomal β-oxidation in tissues, and mice with disruption of very long-chain acyl-CoA synthetase do not accumulate VLCFAs, but are deficient in β-oxidation.

To date, more than 450 mutations have been identified in *ABCD1* and are described in the X-ALD database. There are no common alleles, nor a general correlation between genotype and phenotype. Linkage analysis in families has provided support for the hypothesis that at least one autosomal gene, acting in a dominant fashion, can influence phenotype determination. Candidate genes include those encoding proteins involved in the inflammatory response or those involved in the biological pathway of ALDP. However, within a family, the same mutation, whether a missense or deletion allele, can result in any of the ALD phenotypes, and even monozygotic twins with discordant phenotypes have been reported. Thus the disease phenotype that develops might be determined by the independent inheritance of modifier genes, as well as exposure to unknown environmental factors.

VLFCAs and Membrane Stability

VLCFAs may play an important role in the pathogenesis of cerebral demyelination of peroxisomal disorders. Recently it was shown that elevations of C26:0 in lysophosphatidylcholine can be reliably demonstrated in blood spots by tandem mass spectrometry, opening up the possibility of screening for these disorders. It is worth considering the biophysical properties of VLCFAs in this context. Long-chain fatty acids have backbones of 14–18 carbon atoms, designated C14–18, and comprise the majority of dietary fatty acids. VLCFAs have 20 or more carbons. Normally saturated VLCFAs occur in highest concentration in myelin lipids and red blood cell sphingomyelin (C26:0 accounts for 1–5% of total fatty acids in brain cerebrosides and sulfatides). The VLCFAs that accumulate in X-ALD are saturated and unbranched (mainly C24:0 and C26:0). The excess is most striking in the cholesterol ester and ganglioside fractions of affected brain white matter and adrenal cortex, with the phosphatidylcholine fraction containing a 39-fold excess of C26.

In X-ALD, the initial locus of demyelination occurs with reliable regularity in the splenium or genu of the corpus callosum. These regions are most notable for their tight fiber packing. Since VLCFAs diffuse quickly across membranes but are slow to desorb, the tight fiber packing may lead to 'trapping' within the phospholipid bilayer. Further, thickening of the membrane and alteration of membrane topology may be more harmful to regions of higher, rather than lower, fiber density. It is thought that the decreased mobility of VLCFAs makes them 'sitting targets' for activation through acyl-CoA, hence leading to further incorporation into membrane phospholipids.

The greater length of the aliphatic chain causes VLCFAs to be insoluble and alters their physiological properties. The most direct evidence that abnormally high VLCFA levels can alter membrane function is provided by the study of Whitcomb et al., who assessed adrenocorticotropic hormone (ACTH)-stimulated cortisol release in cultured human adrenocortical cells. The addition of C26:0 or C24:0 to the culture medium in concentrations equivalent to those in X-ALD plasma increased the microviscosity of adrenocortical cell membranes and decreased ACTH-stimulated cortisol secretion. These investigators concluded that the VLCFA excess altered membrane structure and suppressed the availability of the ACTH receptor.

Neuroimaging and Pathology

Cerebral involvement in patients with X-ALD is most often first detected in neuroimaging studies (**Figure 1**). Indeed, neuroimaging provides valuable information about prognosis and evaluation of therapies. Magnetic resonance image (MRI) abnormalities most often precede onset of neurologic symptoms, but given the rapid progressive course only precede death by 1–2 years. Eighty percent of ALD patients with cerebral involvement show white-matter lesions that are characteristic with respect to location and attenuation pattern. In these patients, the lesions are symmetric and involve periventricular white matter in the posterior parietal and occipital lobes. These regions are generally hyperintense on fluid-attenuated inversion recovery (FLAIR) sequence or T2-weighted magnetic resonance images. Use of the contrast material gadolinium diethylenetriamine pentaacetic acid (DPTA) demonstrates a garland of accumulated contrast material adjacent and anterior to the posterior hypodense lesions shown on T1-weighted MRIs. Contrast enhancement at the edges of the white-matter lesions is so characteristic as to be almost diagnostic. Proton magnetic resonance spectroscopy (MRS) can anticipate future MRI abnormalities in white matter of ALD patients while it still appears normal on a conventional MRI: MRS spectra demonstrate increased choline and decreased *N*-acetylaspartate (NAA), presumed to reflect biochemical alterations in myelin sheaths and axonal dysfunction, respectively. Even in the normal-appearing white matter of patients with only the Addisonian phenotype, NAA is lower than normal controls.

Figure 1 X-linked adrenoleukodystrophy patient with confluent white-matter lesions on T2-weighted imaging (a) and garland of contrast enhancement following gadolinium injection (b). Major basic protein staining of the occipital lobe shows sparing of the arcuate fibers (c).

Accumulation of contrast material on the MRI correlates well with the histopathological zones described by Schaumburg et al. (Figure 1). Demyelination usually affects the parieto-occipital regions most severely and earliest in the course of the disease. As confirmed by neuroimaging studies, these lesions progress, often asymmetrically, toward the frontal lobes. The edge between the lesion and 'normal' white matter can be distinct or blurred, and subcortical U fibers are usually spared. Atrophy of the corpus callosum and optic nerves is typical, as is the early and prominent involvement of the splenium and posterior limbs of the internal capsule.

The cortical and deep gray matter are unremarkable, as is the brain stem, except for some patients that exhibit foci in the basis pontis or in the pyramidal tracts within the cerebral peduncles, basis pontis, and medulla. Particularly in adulthood the spinal cord may show atrophy of the lateral corticospinal tracts and dorsal columns (adrenomyeloneuropathy). This is not seen in childhood except in the course of extensive downward progression from cerebral lesions. ALD is best known for the intensity and extent of its central nervous system (CNS) white-matter disease, which consists of confluent areas of myelin and oligodendrocytic loss that is replaced by fibrillary astrogliosis. It is important to note that neither the extent nor the intensity of these lesions has been correlated with clinical (hypocortisolism) or pathological defects in the adrenal cortex.

Inflammatory Demyelination in X-ALD

After the initial injury at the site of tightly packed fibers in the corpus callosum, a cascade of inflammatory demyelination ensues. Correlation of clinical and pathologic findings indicates that the progression in cerebral X-ALD is related to the perivascular infiltration of lymphocytes in the brain white matter. This is the most distinctive hallmark of cerebral X-ALD and sets it apart from all other leukodystrophies.

The white-matter lesion shows marked chronic inflammation consisting largely of T lymphocytes, particularly cytotoxic CD8 cells in the early stage, and macrophages. This resembles multiple sclerosis (MS), but differs from it by the paucity of

B cells/plasma cells and the localization of the lymphocytes at the lesion edge in MS and within the demyelinated region in ALD. Areas in which these lesions are present show breakdown of the blood–brain barrier and accumulation of contrast material on gadolinium MRI. Multiple immune cells and effector molecules have been identified in the lesions and on microglial, astrocytic, and endothelial cells, including major histocompatibility complex (MHC) class I and II molecules, CD4 and CD8 cells, tumor necrosis factor-α (TNF-α), interleukin-1, intercellular adhesion molecule (ICAM), nitric oxide, and CD1.

While the exact triggers for the inflammatory response remain unknown, it is speculated that the intracellular accumulation of VLCFAs and the resulting alteration in myelin metabolism poisons cells, leading to cell death and the induction of an inflammatory response. The cascade of inflammatory demyelination appears to be cytokine mediated, perhaps by stimulating TNF-α production in a manner analogous to the well-known effect of lipopolysaccharide. Ganglioside, phosphatidylcholine, proteolipid, and cholesterol ester fractions show the greatest excess of VLCFAs and may be plausible candidates as triggers of demyelination.

Animal Models

ABCD1 null mice have been generated and show tissue accumulation of VLCFAs leading to a detectable clinical phenotype comparable to AMN. Around 15 months of age the ALD-deficient mice exhibit an abnormal neurological and behavioral phenotype. This correlates with slower nerve conduction, and with myelin and axonal anomalies detectable in the spinal cord and sciatic nerve, but not in brain. Thus this model should be useful for investigating the pathogenesis of AMN.

The murine locus for *ABCD2*, encoding ALDRP, was also inactivated, and these mice develop late-onset cerebellar and sensory ataxia. This correlates with a loss of cerebellar Purkinje cells and dorsal root ganglia cell degeneration. Interestingly, none of the mouse models so far has developed the inflammatory demyelination characteristic of human ALD. Research on triggers of inflammation in the setting of elevated VLCFAs is currently lacking. An interesting feature found in both the *ABCD1* and the *ABCD2* knockout mouse models is the presence of ultrastructural alterations of mitochondria in axons and neuronal bodies. The contribution of these mitochondrial alterations to disease pathogenesis remains to be clarified.

Therapy

Table 1 summarizes the therapeutic approaches in peroxisomal disorders. All patients with impaired adrenal function should receive replacement therapy with adrenal steroids. However, this does not impact neurological progression. As neurological disease is thought to be related to lipid accumulation and ensuing inflammation, disease-modifying therapies have focused on both metabolic reversal and immunomodulation.

In asymptomatic boys whose brain MRI is normal, dietary therapy with 'Lorenzo's oil (LO)' helps prevent the onset of cerebral disease. LO is a 4:1 mixture of glyceryl trioleate and glyceryl trierucate. Oral administration of this oil, combined with moderate reduction of fat intake, normalizes or significantly lowers the levels of VLCFAs in the plasma of patients

Table 1 Management of X-linked adrenoleukodystrophy and peroxisome biogenesis disorders

Phenotype	*Follow-up tests*	*Recommended therapy*
Asymptomatic X-ALD	Monitor MRI and adrenal function; neurological and neuropsychological test; family screening	Lorenzo's oil, HSCT if MRI abnormal
Addison-only X-ALD	Monitor MRI; neurological and neuropsychological test	Lorenzo's oil, HSCT if MRI abnormal, adrenal Rx
Cerebral X-ALD	Neurological and neuropsychological test; family screening; adrenal function	HSCT if mild, adrenal Rx
AMN	Brain MRI, adrenal function; SSEP; EEG; psychiatry; family screening	Adrenal Rx, physical therapy, Lorenzo's oil (?), HSCT (?)
X-ALD heterozygotes	Adrenal function; MTS; SSEP; EEG; family screening	Genetic counseling, physical therapy, adrenal Rx, Lorenzo's oil (?), general support
PBD	VEP; BAERs; ophthalmological examination; brain MRI; renal and cardiac ultrasound; hepatic enzymes and clotting factors	Vitamin K supplementation; dietary measures (?) (DHA and bile acid supplementation, phytanic acid restriction)

AMN, adrenomyeloneuropathy; BAER, brain stem auditory evoked response; DHA, docosahexanoic acid; EEG, electroencephalogram; HSCT, hematopoietic stem cell transplantation; MRI, magnetic resonance imaging; MTS, mitochondrial targeting signal; PBD, peroxisome biogenesis disorder; SSEP, somatosensory evoked potential; VEP, visual evoked potential; X-ALD, X-linked adrenoleukodystrophy. Adapted from Moser HW, Raymond GV, Lu S-E, et al. (2005) Follow-up of 89 asymptomatic patients with adrenoleukodystrophy treated with Lorenzo's oil. *Archives of Neurology* 62(7): 1073–1080.

with X-ALD within 4 weeks. This does not significantly alter the rate of disease progression in boys who are already symptomatic when therapy is initiated, particularly those with the cerebral inflammatory phenotypes. However, a preventive effect is seen in asymptomatic boys whose brain MRI is normal. Another candidate for lowering VLCFAs may be lovastatin. Treatment with lovastatin may reduce high plasma levels of hexacosanoic acid (C26:0) by a shift to monounsaturated VLCFAs, but the clinical benefit remains to be demonstrated. Recently it was recognized that omega oxidation may be an alternative pathway for VLCFA degradation. This pathway accounts for 5–10% of total fatty acid oxidation in the liver and is catalyzed by P450 enzymes. Finally, overexpression of ALDRP can correct VLCFA levels in human cells and in the *ABCD1* mouse model. In the future, stimulation of these enzymes may be available for therapeutic intervention in X-ALD.

Cerebral inflammation occurs in less than half of patients with the known gene defect and remains the disease aspect requiring utmost vigilance and monitoring. For patients in the early stage of the cerebral inflammatory phenotype, hematopoietic stem cell transplantation (HSCT) leads to improved neurologic outcome and survival. Although the mechanisms of the benefit of HSCT are unclear, it is thought that donor-derived cells enter the nervous system and gradually replace perivascular microglia, thereby ameliorating the metabolic milieu. Alternatively, or in addition, the favorable effect may be due to the immunosuppression implemented during the HSCT preregimen. Peters et al. have reported the follow-up of 126 patients with X-ALD who had received either bone marrow or umbilical cord HSCT during the period 1981–99. Outcome was favorable in patients with the following characteristics at the time of transplant: early stage of illness, limited neurological deficits, and limited MRI involvement. In this group the 5-year survival was 92% and the neurological and functional status far superior to that in the nontransplanted group. For the group with more advanced deficits, 5-year survival for the transplant group was less than that in the nontransplant group (45% vs. 60%). Reduced-intensity preparative regimens for HSCT may become an important approach in X-ALD patients who have marked progression of neurologic symptoms to reduce regimen-related toxicities and multiorgan system complications. Additionally, cord blood transplantation may be an option. Regardless of procedure, HSCT is strongly recommended only for patients in the early stage of cerebral X-ALD.

Immunosuppressive treatment in cerebral ALD has shown limited success, though has only been tested in small numbers of patients with significant neurologic deficit and advanced disease. Interferon-β and intravenously administered immunoglobulin (IVIg) do not appear to halt the course of progressive cerebral ALD. The use of cyclophosphamide and steroids has been reported in five patients (ages 6–20 years) with rapidly progressing neurologic symptoms and abnormal brain computed tomography (CT) scans 4–7 months after their first neurologic symptom. Rate of progression for four patients was unchanged compared to controls; however, the fifth patient remained stable at 3 years of follow-up. Given the success of immunomodulation in autoimmune diseases such as multiple sclerosis, the testing of available immunotherapies in cerebral ALD remains an area of great interest.

Peroxisome Biogenesis Disorders

Clinical Phenotypes

The PBDs are a heterogeneous group of autosomal recessive diseases with an estimated incidence of 1 in 50 000. Based on clinical, biochemical, and molecular criteria, they are divided into the Zellweger syndrome spectrum (ZSS) and rhizomelic chondrosyplasia punctata (RCDP). ZSS includes ZS, neonatal adrenoleukodystrophy (NALD), and infantile Refsum disease (IRD) and represents a continuum of disease, from severe to mild, rather than distinct disorders. ZS patients are distinguished by facial dysmorphology, profound hypotonia, and minimal psychomotor development. Clinical features include cataracts, glaucoma, and optic atrophy, progressive hepatocellular disease, renal cortical cysts, and epiphyseal stippling (or chondrodysplasia punctata) of the patella. Adrenal function may be deficient on provocative testing or during episodes of stress. The incidence of cardiac and other malformations is increased over the general population. The EEG, auditory, and somatosensory evoked responses are typically abnormal. Most ZS patients die within the first year of life due to secondary infection, aspiration, or progressive liver disease. NALD patients usually survive the first year, but can develop a leukodystrophy with a degenerative course characterized by demyelination and cortical atrophy. The IRD group may survive through adolescence and manifest moderate to severe mental retardation, hypotonia, progressive retinopathy, and sensorineural deafness. Facial dysmorphology is less apparent in NALD and IRD. Around half of PBD ZSS patients have phenotypes consistent with IRD. The full spectrum of phenotypes continues to unfold and has included patients with cerebellar ataxia and cholestasis, Usher-like syndromes, peripheral neuropathy, and late-onset leukodystrophy.

PBD RCDP includes classic RCDP1 and milder variants. The incidence of RCDP is around 1/100 000. Patients rarely survive beyond late childhood and have rhizomelia, extensive chondrodysplasia punctata, cataracts, seizures, and profound growth and mental retardation. Cervical spine stenosis is reported and can be accompanied by spinal cord compression. As in PBD ZSS, there is increased incidence of congenital malformations. Death is often secondary to respiratory complications from chronic aspiration, restricted chest wall movement, and a small pulmonary cage. The recent identification of several patients with features of adult Refsum disease (ARD) and *PEX7* gene defects suggests that RCDP1 might also be viewed as a disease continuum.

Genetics

Around 15 mammalian genes required for peroxisome assembly have now been identified; they are termed PEX genes and the proteins they encode are peroxins. PBD ZSS is associated with defects in 12 PEX genes, whereas RCDP1 is associated only with *PEX7*. The frequency of gene defects and roles for the encoded peroxins in the assembly process are listed in Table 2. Despite the high frequency of a few founder alleles, it is not possible to predict the PEX gene defect of a ZSS patient based on phenotype alone. However, PEX mutations predicted to result in null alleles are associated with ZS, whereas missense mutations are more often associated with NALD or IRD. Indeed, a number of patient surveys have shown that homozygosity for the nonsense alleles, *PEX1*-Ile700TyrfsX42 and *PEX10*-Leu272-ValfsX65, predicted a ZS phenotype, whereas homozygosity for *PEX1*-Gly843Asp predicted IRD. For RCDP1, all patients homozygous for the frequent nonsense allele, *PEX7*-Leu292X, have classical disease.

Biochemical Deficiencies

Mammalian peroxisomes are a hub of vital enzymatic activities that include β-oxidation of VLCFAs, oxidation of D-amino acids and L-lysine, ether phospholipid synthesis, and glyoxylate and polyamine catabolism, as well as oxidoreductase reactions that both generate and degrade oxygen radicals. The peroxisomal β-oxidation pathway degrades straight chain and branched, saturated and unsaturated

Table 2 PEX gene defects associated with peroxisome biogenesis disorders

PEX gene[a]	*Frequency in peroxisome biogenesis disorders in Zellweger syndrome spectrum*	*Role in peroxisome* assembly[b]
PEX16	<1%	Membrane synthesis
PEX19	<1%	
PEX3	<1%	
PEX5	2%	Peroxisome targeting signal 1 (PTS1) receptor
PEX13	<1%	Docking site for matrix protein import
PEX14	<1%	
PEX2	3%	Translocation site for protein import
PEX10	3%	
PEX12	5%	
PEX26	5%	Recycling of targeting receptors
PEX6	10%	
PEX1	70%	
PEX7	100% of RCDP1, a few patients with ARD[c]	Peroxisome targeting signal 2 (PTS2) receptor

[a]The designation for the encoded protein is peroxin (e.g., *PEX16* encodes peroxin 16).

fatty acids with a carbon chain length >C22, as well as long-chain dicarboxylic acids. In addition, peroxisomal β-oxidation is required for the synthesis of bile acids and docosahexanoic acid (DHA), a polyunsaturated fatty acid found in myelin and photoreceptor cells, and the inactivation of certain prostaglandins, leukotrienes, and xenobiotics. The peroxisomal enzymes dihydroxyacetone phosphate acyltransferase and alkyldihydroxyacetone phosphate synthase initiate ether phospholipid synthesis. Subsequent modifications lead to the generation of plasmalogen species. Plasmalogens are important membrane constituents in a variety of tissues, including myelin. There is evidence to support a role for these molecules in membrane fusion events and signaling pathways. In addition, plasmalogens can protect cell membranes from free radical damage through their vinyl–ether linkage.

The PBDs are diagnosed by documenting deficiencies in more than one biochemical pathway of the peroxisome. Tests routinely used are measurements of plasma VLCFAs and phytanic acid (PA), and erythrocyte plasmalogens. In addition, pipecolic acid, produced from lysine, and bile acid intermediates can be measured. Once metabolite levels consistent with peroxisome enzyme deficiencies are obtained, it is recommended that the enzymatic defects be confirmed in fibroblast cultures. In general, the degree of the enzymatic defect and biochemical disturbance correlates with the severity of disease. RCDP1 patients have a subset of biochemical abnormalities restricted to defects in peroxisome targeting signal 2 (PTS2) protein import: they are deficient only in plasmalogen synthesis and phytanic acid oxidation (PAO). Although peroxisomal thiolase is a PTS2 protein, RCDP1 patients have normal β-oxidation of VLCFAs, compensated by a second peroxisomal enzyme with thiolase activity, sterol carrier protein 2 (SCP2).

Around 15–20% of patients with a clinical diagnosis of ZSS will have a SED in β-oxidation, either acyl-CoA oxidase (ACOX1) or multifunctional protein-2 (MFP-2). Similarly, around 5% of RCDP patients will have a SED in the two peroxisomal enzymes required for plasmalogen synthesis. Given the congruity in these SED and PBD clinical phenotypes, it has been suggested that the major pathology of ZSS is determined by defects in β-oxidation and that plasmalogen deficiency determines RCDP. While this seems to be the case for RCDP, it remains to define the normal functions of plasmalogens in tissues and relate this to the disease process. Narrowing the pathway in ZS is more challenging, since peroxisomal β-oxidation affects a broad range of cellular metabolites and processes.

Cellular Phenotypes

In addition to the correlation between clinical phenotype and genotype in the PBDs, there is also a correlation between these parameters and cellular phenotype in ZSS patients. Peroxisome morphology and matrix protein import can be visualized in cells using immunohistochemistry. In ZS patients, peroxisomes are reduced in number, enlarged in size, and have a limited capacity to import matrix proteins; they are aptly called 'ghosts.' Patients with milder disease tend to have more abundant peroxisomes that import more matrix proteins. In fact, residual peroxin function in cell lines from patients with milder disease can be further enhanced, and this is attractive for the design of future drug-based therapies. First, when fibroblasts from NALD and IRD patients are cultured at 30 °C, there is partial recovery of peroxisome number, matrix protein import, and enzymatic activities. The mechanism was shown to be improved protein folding at lower temperature or increased amounts of an otherwise degraded peroxin. Furthermore, when PBD cells are cultured in 4-phenylbutyrate, a compound that stimulates peroxisome proliferation, matrix protein import and enzyme activity improve. Finally, fibroblasts from NALD and IRD patients routinely cultured at 37 °C frequently exhibit a characteristic 'mosaic' pattern in which some cells import matrix proteins, but adjacent cells in the same microscopic field do not, implicating microenvironmental differences that might promote residual peroxin function.

Neuroimaging and Pathology

A number of neuropathological investigations have been reported and delineate three major types of neurological involvement in ZS: neuronal migration abnormalities, hypomyelination, and selective neuronal involvement. Gross inspection frequently shows polymicrogyria and pachygyria, hypoplasia of the corpus collosum, and deficient olfactory lobes. The inferior olive is disorganized, and hypoplasia of the cerebellar vermis can be present. These changes coincide microscopically with heterotopias of cerebral neurons and Purkinje cells, the presence of immature neurons, and reduction in neuron numbers. The pattern of medial pachygyria and lateral polymicrogyria is a distinguishing feature of ZS (Figure 2). Migration defects in the NALD brain are more variable and less severe. Polymicrogyria and neuronal cell loss can be seen, but extensive demyelination is the hallmark of this disorder, apparent in the cerebrum, midbrain, and cerebellum. Most cases have shown a widespread sudanophilic leukodystrophy, often associated with perivascular accumulation

Figure 2 Zellweger patient with perisylvian polymicrogyria on hematoxylin and eosin stain (a, c) and gross brain inspection (b).

of lymphocytes as in X-ALD. The boundaries of the demyelinated areas are usually sharply demarcated and there is reactive gliosis. Studies of IRD brain, although limited, show reduced neuron number and cerebellar atrophy without active demyelination. There can be dysplastic olives and Purkinje cell heterotopia. Thus early defects in brain morphogenesis correspond to the degree of peroxisome dysfunction. Defects in β-oxidation remain a likely suspect in pathogenesis, as brains from patients with D-bifunctional protein deficiency also show a similar spectrum of abnormalities.

MRI of the brain shows abnormal cortical gyral patterns, with regions of microgyria primarily in the frontal and perisylvian cortex, together with thickened pachygyric cortex in the perirolandic and occipital regions. Ventricular dilatation and subependymal germinolytic cysts are seen. In RCDP, cranial MRI shows delayed myelination and both cerebral and cerebellar atrophy. Decreased choline:creatine ratios and increased levels of mobile lipids have been observed on MRS and might reflect plasmalogen deficiency, the major biochemical abnormality in RCDP. The milder patients have less severe skeletal involvement and psychomotor defects, and may have normal MRI studies.

VLCFAs accumulate in membrane phospholipids in ZS brain and in intracellular trilamellar inclusions composed of VLCFA cholesterol esters. The accumulation of VLCFAs might have a toxic effect on cells, inhibit neuron migrations, and disrupt myelin. Plasmalogen levels in ZS brain are also severely deficient and likely contribute to pathology. However, striking neuronal migration abnormalities are not seen in RCDP. In RCDP brain, there is a general decrease in neuron number and white matter, dysplastic olives, and progressive cerebellar degeneration. An additional consequence of plasmalogen deficiency is the accumulation of the fatty alcohol substrates, demonstrated by Rizzo et al. in plasma from RCDP patients. Fatty alcohols may contribute to the neurological features in RCDP, based on features similar to Sjögren–Larsson syndrome.

Animal Models

In order to gain further insight into the pathogenesis of ZS, mouse models with complete deficiency of *PEX2*, *PEX5*, *PEX13*, and *PEX11β* have been engineered. These mice recapitulate many of the aspects of the ZS phenotype, including the metabolic consequences of peroxisome elimination and abnormalities in brain formation, hypotonia, and early demise. Detailed investigations of these models reveal an altered distribution of cortical neurons and defects in neuronal migration, commencing early in the cytogenetic epoch and demonstrated by birthdating experiments using 5-bromodeoxyuridine (5-BrdU). Other abnormalities include a delay in neuronal differentiation and extensive neuronal apoptosis (*PEX5*, *PEX11β*). Cerebellar layer formation is delayed, and there is increased apoptosis in granular neurons. Purkinje cell morphology is abnormal, displaying stunted dendritic trees and abnormal arborization (*PEX2*). In *PEX11β* null mice, peroxisome abundance is decreased, but there are no defects in matrix protein import and only mild deficiencies of β-oxidation and ether lipid biosynthesis, challenging the idea that the

clinical features are directly related to the severity of the metabolic abnormalities. An alternative model of pathogenesis has been proposed in which the disease phenotype correlates with the abundance and distribution of peroxisomes, in addition to their metabolic activity. Further, mice with targeted disruptions of *PEX5* in neuron and glial cells, or in hepatocytes, have been engineered. Although complete peroxisome elimination is not achieved until birth, the accumulation of VLCFAs at midgestation is as severe as that seen in the generalized *PEX5* null model. Targeted elimination of peroxisomes in the brain results in moderate cortical migration defects that correct postnatally and might reflect migration delay. Local elimination of peroxisomes from the liver results in postnatal arrest of neuron migration, particularly in the cerebellum, which still develops in the postnatal period. Thus, peroxisome metabolism in extraneuronal tissues influences the development of the murine brain.

Variable abnormalities of mitochondria have been noted in liver, brain, and muscle from ZS patients, specifically pleomorphic mitochondria with distorted cristae and reduction in activity of respiratory chain complexes. This might result from increased oxidative stress secondary to peroxisome deficiency and might equally be a factor in the pathogenesis of ZS. Similar mitochondrial abnormalities are observed in tissues from PEX null mice. The mouse models have also been used to test potential therapeutic interventions. Supplementation with DHA, beginning *in utero*, normalizes DHA levels in brain but does not improve the migration disorder. Bile acid supplementation improves cerebellar abnormalities, implicating the accumulation of C27 bile acid intermediates in the cerebellar toxicity observed postnatally in these mice.

Management

There is no specific therapy for these disorders and any therapy should address the fact that features begin prenatally and therefore should be tailored to disease severity. Systematic evaluation of patients with ZSS should include visual and auditory evoked response testing, ophthalmological examination, brain MRI, renal and cardiac ultrasound, and evaluation of hepatic enzymes and clotting factors (see Table 1). ACTH and cortisol levels should be measured to determine the extent of adrenal dysfunction. Infants may require a gastrostomy tube to ensure appropriate nourishment. Water-miscible preparations of fat-soluble vitamins, including vitamin K, should be provided. Dietary interventions have included restriction of metabolites that accumulate and replacement of those that are deficient. Reports of these approaches in patients are mostly anecdotal and have not been systematically studied. For example, repletion of erythrocyte plasmalogen levels has been achieved by dietary administration of plasmalogen precursors such as batyl alcohol, but this did not improve the clinical status in the few patients in which it was tried. Oral bile acid administration improved hepatobiliary function in an infant with ZS. More recently, patients have received DHA supplementation, but the clinical benefit to this therap–y has not yet been proved. An IRD patient received an orthotopic liver transplant, resulting in improvement in biochemical parameters, but clinical improvement is not yet known. Due to the benefit of dietary phytanic acid restriction in ARD, this is often prescribed for surviving PBD patients.

Conclusion

The underlying gene defects in peroxisomal disorders have only partially revealed insight into the neuropathogenesis of X-ALD and PBDs. Where there is a strong genotype–phenotype correlation in the PBDs, there is none in X-ALD. The elevations in VLCFAs seen in these disorders have been implicated both in the process of inflammatory demyelination and in cortical migration defects. The murine models will be useful tools to sort out both AMN and the cortical migration defects in ZS. The presence of ultrastructural alterations of mitochondria in axons and neuronal bodies in both disorders suggests that the cross-talk between mitochondria and peroxisomes might contribute to the pathogenesis. As the complex functions of the peroxisome are still under investigation, any therapeutic success will depend on a clear understanding of the altered proteins and their exact function. This understanding will be expedited by the combined investigations in patients, cellular, and animal models.

Role of Peroxisomes in Neurons

The potential role of peroxisomes in neurons is not well understood, except for the metabolism of very long-chain fatty acids (VLCFA). In human patients and in mice with peroxisome biogenesis disorders, neuronal migration is clearly affected. It is unclear whether this migration defect requires the function of peroxisomes in neuronal tissue or whether peroxisomes in nonneuronal tissues can provide this function. Experiments in mice show that the tissue-specific restoration of peroxisomes in the liver of mice deficient in peroxisome biogenesis does partially correct the neuronal migration deficits in the brain, but the restoration of peroxisomes in both tissues, rather than in only one, is more effective in restoring neuronal migration. It is also clear that a β-oxidation deficiency alone cannot cause neuronal migration defects, so other metabolic functions of peroxisomes may be involved. Mice lacking Pex11β, which is involved in peroxisome division, have only mild to no metabolic defects with respect to fatty acid β-oxidation and plasmalogen synthesis, but they still exhibit neuronal migration defects. These results emphasize that we still do not understand how or why peroxisomes affect neuronal migration and whether this is a direct or indirect effect.

Peroxisomes are present in neural and astrocytic processes. The presence of peroxisomes in active growth cones with well-developed filopodia, varicosities, and neural terminal-like (presynaptic axon terminal) structures suggests their importance in the development and/or maintenance of neurites. Whereas many peroxisomes are found in long neurites with growth cones, only a small number exist in short neurites, leading to the suggestion that the short neurites are probably at rest since no growth cones have been observed. Therefore, it was postulated that the presence of peroxisomes in neurites helps their extending activity.

Peroxisome Movement in Mammalian Cells

Based on their motility, peroxisomes fall into one of two groups. The first, comprising a majority (90–95%) of the peroxisomes in African green monkey kidney (CV1), Chinese hamster ovary (CHO), HepG2 cells, and neurites, exhibits randomly oriented, low-velocity movements (average velocity of 0.024 $\mu m\,s^{-1}$) without net organelle translocation in a distinct direction. This movement is independent of actin filaments and microtubules.

The second category of peroxisomes, representing 5–10% of these organelles, exhibits fast movement (with average velocities of 0.26 $\mu m\,s^{-1}$, peak velocities of up to 0.75 $\mu m\,s^{-1}$, and sustained directional velocities up to 0.45 $\mu m\,s^{-1}$ over distances of 11.5 μm), which is saltatory (discontinuous and erratic) and bidirectional (toward and away from the cell center) and results in the displacement of the organelle over distances of 10 μm. The bidirectional movement suggests the involvement of motor proteins of the dynein and/or kinesin families. Peroxisomes belonging to these two populations can spontaneously interchange and behave like the other. The fast movement, but not the slow kind, depends on energy in the form of ATP hydrolysis. Apart from these two movements, peroxisomes can also exist in a motionless 'frozen' state upon complete depletion of metabolic energy.

Whereas the slow movement of peroxisomes is not affected by actin-depolymerizing agents, such as cytochalasins or anticytoskeletal drugs, microtubule-destabilizing agents, such as nocodazole, vinblastine, and demecolcine, completely abolish the fast, saltatory movement indicative of the involvement of microtubules in this process. Peroxisomes are often found in close proximity with microtubules when observed by triple confocal imaging of CV1 cells expressing GFP in peroxisomes, propidium iodide staining of the nucleus, and the immunolabeling of microtubules using anti-β-tubulin antibodies (Figure 1). In contrast to the microtubule-based movement of peroxisomes in mammalian cells, the movement of this organelle in fungi and plants depends on actin and myosin.

Peroxisome–Microtubule Binding *in Vitro*

Although the *in vivo* imaging of peroxisomes and microtubules has exhibited a close association between the two, formal evidence of peroxisome binding to microtubules has come from *in vitro* binding studies. A novel *in vitro* assay was developed in which purified rat liver peroxisomes associate with microtubules coated onto a microtiter plate (Figure 2). The binding was visualized using a confocal laser-scanning microscope and quantified by immunoblotting. The binding was time, temperature, and pH dependent.

Figure 1 Association of peroxisomes with microtubules. Triple fluorescence confocal imaging of CV1 cells expressing GFP in peroxisomes (green), propidium iodide staining of the nucleus (pseudo-colored blue), and immunolabeling of microtubules using mouse anti-tubulin followed by goat anti-mouse IgG-CY5 (pseudo-colored red). (a) A single cell showing the overall distribution of peroxisomes relative to microtubules. (b) An enlarged portion of the image of the same cell showing the close association of many individual peroxisomes (arrows) with microtubules. Scale bar = 10 μm. Reprinted from Wiemer EA, Wenzel T, Deerinck TJ, Ellisman MH, and Subramani S (1997) Visualization of the peroxisomal compartment in living mammalian cells: Dynamic behavior and association with microtubules. *Journal of Cell Biology* 136: 71–80.

Further investigation into this association showed that addition of ATP increased binding, whereas ATP depletion reduced binding. Stripping the peroxisome surface of peripheral membrane proteins by treatment with KCl reduced the binding, which was restored by the cytosol. However, treatment of either the peroxisomes or the cytosol with proteases or *N*-ethylmaleimide decreased binding and this was irreversible. These experiments clearly show the involvement of a peroxisomal membrane protein, probably a peroxisomal cytoplasmic linker protein (CLIP) and some cytosolic factor(s) for binding of peroxisomes to microtubules (Figure 3). When a motor-enriched fraction from chick embryo brain was added to the peroxisomes bound to microtubules, movement of the organelle occurred in an ATP-dependent manner, suggesting the involvement of microtubule-dependent motor proteins in peroxisome movement.

Motors Involved in Peroxisome Movement

Microtubule-dependent motor proteins, namely conventional kinesin (kinesin-1) and cytoplasmic dynein, are implicated in organelle trafficking and cell division. The use of RNAi to selectively inhibit several kinesins (kinesin-1, two members of the kinesin-2 family, three members of the kinesin-3 family, and a member of kinesin-14 or the C-terminal kinesin family) and cytoplasmic dynein in *Drosophila* S2 cells showed that only kinesin-1 and dynein heavy-chain motors are responsible for the movement of peroxisomes. The plus (+)-end directed kinesins carry organelles to the cell periphery, whereas the minus (−)-end directed dyneins ferry organelles back toward the center of the cell. The movement of peroxisomes in neurites of a subline of PC12 pheochromocytoma (PC12D) cells and *Drosophila* S2 cells was studied by time-lapse high-resolution fluorescence microscopy and by fluorescence imaging with one nanometer accuracy (FIONA), respectively, and found to occur in both the anterograde (cell center to cell periphery) and retrograde (cell periphery to cell center) directions (Figure 4). Overexpression of the dynamitin subunit of the dynein activator, dynactin, inhibited peroxisome movement in monkey kidney (COS7) cells. The tau protein, a neuronal microtubule-associated protein, inhibits the kinesin-dependent movement of peroxisomes in primary cortical neurons, retinal ganglion cells, and neuroblastoma cells and makes these cells more susceptible to oxidative stress.

Given the bidirectional movement of peroxisomes, the important question regarding whether the kinesin and dynein motors act simultaneously or sequentially on peroxisomes was addressed experimentally in *Drosophila* S2 cells. The conclusion from these studies was that the two kinds of motors did not act against each other simultaneously but, rather, up to 10 or 11 molecules of one or the other type of motor work together to produce up to 10 times the *in vitro* speed of peroxisome movement. These studies explain why the movement of peroxisomes is saltatory, fast, and occurs over distances that are far greater than the average step size of a single motor molecule.

Regulation of Peroxisome Motility

Peroxisomal motility is sensitive to the extracellular environment and probably to receptor-mediated

regulation in CHO and human umbilical vein endothelium cells. For example, the combination of ATPγS and lysophosphatidic acid (LPA) blocks peroxisome movement probably by action via G-protein-coupled ATP and LPA receptors.

Peroxisome motility in CHO cells is regulated by a GTP-binding protein. Upon microinjection of GTPγS, a nonhydrolyzable GTP analog, there is a complete loss of peroxisome motility, although the effect is not immediate. A similar effect is elicited by activators of heterotrimeric G-proteins, such as aluminum fluoride and mastoparan.

Pertussis toxin, which antagonizes the action of the G_i/G_o class of proteins, prevents the action of GTPγS in inhibiting peroxisome motility, suggesting that this class of G-proteins is involved in the regulation of peroxisome movement. Additionally, inhibition of phospholipase C, classical protein kinase C isoforms, mitogen-activated kinase kinase, or phospholipase A2 (PLA2) affects the ability of this signaling pathway to inhibit peroxisome motility, so these could be signaling molecules acting downstream of the G-proteins. The PLA2 signaling cascade is believed to act via arachidonic acid, whose release inhibits peroxisome movement.

Although much of this information on the regulation of peroxisome movement comes from non-neuronal cells, the principles are likely to be conserved because microtubule-based peroxisome movement is common to mammals and the signaling cascades controlling peroxisome movement are widely distributed in mammalian tissues.

Peroxisome Morphology

Although peroxisomes appear spherical in cross-section under the microscope, they are a highly dynamic subcellular compartment. Peroxisomes often exist in the form of an interconnected network or reticulum. They assume morphologically distinct

Figure 4 A model of peroxisome transport from cell body to growth cone. Peroxisomes, which are formed in the cell body, move to the growth cone via the varicosity by anterograde transport. Peroxisomes play an important role at the growth cone and then return to the cell body by retrograde transport. During transportation, peroxisomes exhibit saltatory movement and/or are oscillating repeatedly. Reprinted from Ishikawa T, Kawai C, Sano M, and Minatogawa Y (2001) Peroxisomes exist in growth cones and move anterogradely and retrogradely in neurites of PC12D cells. *Experimental Cell Research* 266: 260–269.

Figure 5 GFP-PTS1 is targeted to peroxisomal aggregates in COS-7 cells, which contain elongated peroxisomes forming reticular structures. In some COS-7 cells, tubular peroxisomes and/or large peroxisomal aggregates (arrowheads) can be visualized by GFP-PTS1. An elongated peroxisome with a segmented appearance is visible (arrow). Scale bar = 10 μm. Reprinted from Schrader M, King SJ, Stroh TA, and Schroer TA (2000) Real time imaging reveals a peroxisomal reticulum in living cells. *Journal of Cell Science* 113: 3663–3671.

shapes, including tubular structures that fuse to form a reticulum (Figure 5), when cultured cells are treated with defined growth factors (e.g., nerve growth factor) or with polyunsaturated fatty acids, free radicals, or ultraviolet (UV) irradiation. Even tissues engaged in the synthesis of special kinds of lipids exhibit this behavior. Both spherical and tubular peroxisomes move inside cells with similar velocities. Elongated peroxisomes could change shape while moving by shortening in length, collapsing into round structures, or elongating, and they also interacted with other peroxisomes.

Tubular peroxisomes of up to 5 μm can be induced in 40–50% of HepG2 cells by UV irradiation, and this induction occurs via a tyrosine kinase signal transduction pathway because it is sensitive to K 252b, an inhibitor of tyrosine kinase. Hydrogen peroxide also induces tubulation, but hypoxia reduces tubule formation. The overexpression of Pex11β results in tubulation and fission of elongated peroxisomes.

The exact function and the precise mechanism of formation of these morphologically distinct peroxisomal compartments are still under investigation, but tubulation and fission of peroxisomes have been suggested to contribute to peroxisome proliferation and to the response of cells to reactive oxygen species.

Failure of Peroxisome Biogenesis and/or Movement Is Observed in Disease

Whereas peroxisomes are abundant in normal hepatocytes and fibroblasts, their numbers are drastically decreased in peroxisome biogenesis disorders. These include the cerebrohepatorenal or Zellweger syndrome, rhizomelic chondrodysplasia punctata (RCDP), and neonatal adrenoleukodystrophy. Although diseased cells lack detectable peroxisomes when analyzed using antibodies to peroxisomal matrix markers, remnant membranous structures termed 'ghosts' with peroxisomal membrane proteins (PMPs) are present. The presence of these ghosts with PMPs is explained by the fact that the signals and machineries involved in peroxisomal matrix and membrane protein import are different, and most (but not all) of these biogenesis disorders affect only matrix protein import.

Peroxisomes are assumed to play a crucial role in the formation of cortex, cerebellum, and the inferior olivary nucleus because there are severe morphogenic defects in these tissues in peroxisome biogenesis disorders. Analysis of peroxisome-deficient fetuses with focus on neurodevelopment showed defects typical of Zellweger syndrome, such as a defect in the neuronal migration in the neocortex, delay in neuronal maturation, increased apoptosis in the cortical plate, and structural abnormalities in the inferior olivary nucleus.

Human patients lacking the multifunctional protein 2 (MFP2), a D-bifunctional protein with enoyl-CoA hydratase and 3-hydroxy-acyl-CoA dehydrogenase

activities, necessary for peroxisomal β-oxidation of bile acid intermediates and pristanic acid, were found to have neuronal migration defects. MFP2 is involved in the metabolism of VLCFAs. The accumulation of VLCFAs as a result of peroxisomal *β*-oxidation deficiency, depletion of plasmalogens, or reduced content of the polyunsaturated fatty acid docosahexaenoic acid (DHA) play a major role in impairment of neuronal migration. However, in mice lacking MFP2, the neuronal migration defect was not obvious.

In fibroblasts from human patients with PEX1 or D-bifunctional enzyme deficiencies, peroxisome abundance, movement, and association with microtubules are affected. This is also true in mice lacking PEX13. Perhaps these are deficient in the recruitment of a protein that links peroxisomes with microtubules.

Peroxisome Biogenesis Disorders That Affect Neuronal Migration

Peroxisome biogenesis disorders result from defects in *PEX* genes, which code for proteins involved in peroxisome biogenesis and protein import. An important pathological feature of peroxisome biogenesis disorders is defective neuronal migration.

The following are peroxisome biogenesis disorders:

1. Zellweger syndrome or cerebro-hepato-renal syndrome results in abnormal central nervous system neuronal migration due to the lack of functional peroxisomes. Zellweger syndrome phenotype is caused by mutations in any of several *PEX* genes, such as *PEX1*, *PEX2*, *PEX3*, *PEX5*, *PEX6*, *PEX10*, *PEX12*, *PEX13*, *PEX16*, *PEX19*, or *PEX26*. The most striking pathological abnormalities are apparent in the brain. As indicated previously, most of these affect peroxisomal matrix protein import, but a few, such as *PEX3*, *PEX16*, and *PEX19*, affect both PMP and matrix protein import.
2. Neonatal adrenoleukodystrophy is caused by milder mutations in the genes affected in Zellweger syndrome.
3. Infantile Refsum disease (IRD) is the mildest form of impairment among peroxisomal biogenesis disorders. It is also called infantile phytanic acid storage disorder. The biochemical abnormalities are not restricted to phytanic acid but also include accumulation of VLCFAs, di- and trihydroxycholestanoic acid, and pipecolic acid. Mutations in *PEX1*, *PEX2*, or *PEX26* can cause IRD.
4. RCDP: Biochemically, RCDP patients have subnormal levels of red cell plasmalogens and progressive accumulation of phytanic acid. Mutations in the PTS2 receptor, *PEX7*, cause RCDP.
5. Zellweger-like syndrome.

Pharmacology of Fear Extinction

Introduction

The mechanisms of fear inhibition are attracting increasing interest. In the laboratory, fear inhibition most often is studied through a procedure in which a previously fear-conditioned animal is exposed to a fear-eliciting cue in the absence of any aversive event. This procedure results in a decline in conditioned fear responses that is attributed to a process called fear extinction. Extensive empirical work by psychologists has revealed basic behavioral characteristics of extinction, and theoretical accounts have emphasized extinction as a form of inhibitory learning as opposed to an erasure of acquired fear. Guided by this work, neuroscientists have begun to dissect the neural mechanisms involved, including the regions in which extinction-related plasticity occurs and the cellular and molecular processes that are engaged. Several careful reviews on both the behavioral aspects of extinction and the brain areas that are critical for extinction are available, but this article reviews only the pharmacology of extinction. The literature on neurotransmitter involvement in fear extinction is built on the assumption that extinction is a form of inhibitory learning which leaves acquisition-related plasticity relatively intact. Therefore, the same neurotransmitter systems involved in fear conditioning might be expected also to be involved in fear extinction, although certain differences might stem from the excitatory versus inhibitory nature of these two forms of learning.

Before proceeding, it should be noted that the term 'extinction' is commonly used in more than one sense, to refer to (1) the experimental procedure used to produce a decrement in the fear response, (2) the decremental effect of this procedure upon the fear response, which can be measured both at the time of the experimental procedure and at a later time, or (3) the hypothesized associative or cellular process responsible for that effect. For the purposes of this article, we define the experimental procedure as extinction training, the decrement in the fear response measured during extinction training as within-session extinction, and the decrement measured at some interval after extinction training as extinction retention. The term extinction is reserved for the theoretical process underlying the loss of the fear response. Occasionally we refer to short-term extinction and long-term extinction; these terms correspond to stages of extinction memory similar to those defined for other forms of learning.

γ-Aminobutyric Acid

FG-7142, a compound that functionally decreases γ-aminobutyric acid (GABA) transmission, the major inhibitory neurotransmitter in the brain, dose-dependently impaired within-session extinction and, when administered prior to test, blocked extinction retention in the context of extinction training, but had no effect on performance in a novel context. The blockade of extinction could not be explained by state dependency.

Gephryin, a protein that contributes to the regulation of GABAergic neurotransmission by clustering $GABA_A$ receptors at the synapse, is upregulated in the basolateral amygdala (BLA) following extinction training based on mRNA, protein levels, and receptor binding. GABA also has been implicated in the consolidation of extinction. Post-extinction training systemic administration of the GABA antagonist picrotoxin enhanced extinction retention, as assessed with active avoidance. Intra-BLA infusions of the GABA receptor antagonist bicuculline immediately but not 3 h after extinction training facilitated extinction of contextual freezing, and pre-extinction training systemic administration of diazepam, which enhances GABA transmission, impaired extinction retention, although state dependency was not ruled out.

Glutamate

N-Methyl-D-aspartate (NMDA) receptor antagonists, a glutamate receptor subtype, block extinction of freezing and fear-potentiated startle when administered prior to extinction training either systemically or directly into the BLA, or step-down avoidance extinction when administered into CA1 of the hippocampus. In all measures the effects were dose dependent and not due to state dependency. These effects may result from a blockade of extinction consolidation. Thus, pre-extinction training administration of the NMDA receptor antagonist (±)-3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP) blocked extinction retention measured 24 but not 48 h later. However, when CPP was administered prior to extinction training and again 24 h later, without further extinction training, extinction retention tested drug-free 48 h after extinction training was again

impaired. This suggests an NMDA receptor-dependent consolidation process that can be delayed when NMDA receptors are not functional within the normal consolidation time frame. However, using step-down avoidance, it was found that intrahippocampal NMDA antagonist infusion immediately following the first of four daily extinction exposures produced a lasting impairment, which persisted even with additional extinction training without infusions. A similar impairment with pre-extinction training infusions into entorhinal cortex was also seen.

NMDA-dependent extinction consolidation also is seen with the NMDA receptor partial agonist D-cycloserine (DCS). DCS was initially shown to facilitate extinction of fear-potentiated startle when administered systemically or directly into the BLA prior to extinction training. Later it was found that DCS facilitated extinction of freezing when administered prior to or up to 120 min after extinction training, suggesting modulation of consolidation. DCS-facilitated extinction is less susceptible to reinstatement and generalized to a comparably trained but nonextinguished cue, and may only work if some within-session extinction occurs. The effect of DCS appears to be mediated through mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-kinase (PI3K) in the BLA and requires both transcription and protein synthesis.

Dopamine

Although fear conditioning is generally facilitated by dopamine, extinction seems to be disrupted. Systemic administration of cocaine prior to extinction training had no effect on within-session extinction of fear-potentiated startle but impaired extinction retention, an effect not due to state dependency. A similar disruption following administration of cocaine, amphetamine, or the D1 agonist SKF 38393 was also reported. Cocaine and SKF 38393 also disrupted extinction retention when administered prior to test in animals extinguished drug-free. Systemic administration of the D2 receptor agonist quinpirole prior to extinction training impaired extinction retention, although a possible state-dependent effect was not ruled out.

In mice, facilitation of extinction retention by pre-extinction training systemic administration of sulpiride, a D2 receptor antagonist, has been reported. However, using inhibitory avoidance, it was found that D1 receptor knockout mice were impaired in extinction, although ceiling effects in acquisition make the results difficult to interpret. None of this work involved targeted manipulations, so we do not know the locus of these effects.

Acetylcholine

Systemic administration of scopolamine, a muscarinic acetylcholine receptor antagonist, prior to the seventh of eight weekly extinction exposures in a shuttle box impaired extinction retention via a central effect. This effect was dose dependent and observable as long as 9 months after initial training.

Opioids

A critical question regarding extinction is 'how is nonreinforcement detected?' That is, what is the 'error signal' that results from detection of the nonoccurrence of an expected unconditioned stimulus (US)? Most error signal theoretical accounts assume that the magnitude of the associative change produced by a US is inversely related to the degree to which the conditioned stimulus (CS) predicts the US. Hence, the discrepancy between the 'actual' and 'predicted' US drives learning: when the discrepancy is positive (i.e., the US is not fully predicted), excitatory learning occurs; when the discrepancy is negative (i.e., the US is overpredicted), inhibitory learning occurs; and when the discrepancy is zero (i.e., the US is perfectly predicted), no learning occurs. Neural theories propose that as CS learning occurs, it inhibits brain areas normally activated by the US, reducing its effective impact. If the US is withheld, CS-induced inhibition occurs in the absence of any counteractive US-induced excitation, and this somehow initiates extinction-related plasticity.

It has been hypothesized that, over the course of acquisition, the CS induces release of endogenous opioids that reduce the functional intensity of the US by producing conditioned analgesia. Opiate antagonists (e.g., naloxone) given prior to CS–US pairings facilitate fear acquisition by blocking conditioned analgesia. This analgesia-based error correction hypothesis is compelling and accounts for certain difficult-to-explain observations. However, there are indications that opioid involvement in fear conditioning is not limited to the mitigation of functional US intensity. In particular, opioids modulate learning that occurs when there is no shock involved, such as extinction. In fact, earlier work suggested that extinction of active avoidance is impaired by opiate antagonists and facilitated by certain opioids.

Consistent with these older findings, it has been found that systemic administration of naloxone prior to extinction training profoundly retards the development of extinction. This effect is mediated by central, not peripheral, opioid receptors and is not a consolidation or expression effect. Infusions of naloxone or

the μ opioid receptor antagonist D-Phe-Cys-Tyr-D-Trp-Arg-Thr-Pen-Thr-NH_2(CTAP), directly into ventrolateral periaqueductal gray (vlPAG), but not the dorsal PAG, mimic the systemic effect, suggesting that μ opioid receptors are specifically involved in extinction. Extinction also is retarded by intra-vlPAG infusions of the cyclic adenosine monophosphate (cAMP) analog 8-Br-cAMP, suggesting that the effects of naloxone or CTAP on extinction are mediated by cAMP inhibition. Finally, pre-extinction training infusion of RB101(S), an inhibitor of endogenous opioid catabolizing enzymes, facilitates extinction dose dependently and site specifically when infused into vlPAG prior to extinction training.

Cannabinoids

Cannabinoid (CB) receptor (the CB1 receptor) knockout mice showed normal fear conditioning but a profound impairment of both within- and between-session extinction. This effect is mimicked in wild-type mice by giving the CB1 antagonist SR141716A prior to, but not immediately after, extinction training. WIN 55,212-2, a CB1 agonist, had no effect on extinction retention of fear-potentiated startle, whereas AM404, an inhibitor of CB reuptake and enzymatic degradation, dose dependently facilitated extinction retention measured 1 and 24 h after extinction training and impaired reinstatement. These effects were blocked by coadministration of SR141716A.

Neuropeptides

Administration of adrenocorticotropic hormone (ACTH) or vasopressin before extinction training impaired extinction of active avoidance, passive avoidance, and conditioned heart rate. Removal of the posterior pituitary, which decreases ACTH, facilitated extinction with no effect on acquisition. ACTH produced an impairment of extinction retention when administered prior to test, similar to that seen with unsignaled footshock or a shift of context.

This might have occurred by restoring an internal state or 'context' that was present during acquisition because ACTH did not restore extinguished avoidance responses in animals administered dexamethasone, a synthetic glucocorticoid that inhibits the release of endogenous ACTH, prior to acquisition and extinction training. However, ACTH impaired extinction retention even when administered 7 days prior to test, presumably long after any internal state associated with ACTH had dissipated. Although ACTH-induced stress, sensitization, or increased fear may play a role, intracerebroventricular (i.c.v.) and local microinjection of ACTH and vasopressin produced an impairment of extinction retention without concomitant autonomic responses indicative of a stress reaction. Moreover, ACTH attenuates extinction just as effectively in appetitive paradigms as in aversive ones. ACTH and vasopressin may act at the level of the parafascicular nucleus (PFN), believed to be important for processing noxious stimulation such as footshock. Given this localization, ACTH might act to restore the value of a deflated US representation, one explanation of extinction.

Glucocorticoids

In addition to modulating fear memories, glucocorticoids may also modulate the development and consolidation of fear extinction. Systemic pre-extinction training injection of metyrapone, which blocks glucocorticoid synthesis, impaired extinction retention of freezing in mice, although there was no control for state dependency. Dexamethasone, which would mimic the effects of glucocorticoids, dose dependently facilitated extinction when administered systemically pre- or immediately post-extinction training, as did intra-BLA infusions of the glucocorticoid receptor (GR) agonist RU28362. Impaired extinction by metyrapone was blocked by coadministration of a low dose of dexamethasone that was not sufficient to facilitate extinction significantly. The GR antagonist mifepristone likewise impaired extinction dose dependently when infused into the BLA prior to extinction training and blocked the facilitation of extinction by dexamethasone.

Interestingly, posttraumatic stress disorder (PTSD), characterized by a failure to extinguish traumatic memories, has been associated in some studies with abnormally low cortisol levels that may contribute to the persistence of PTSD symptoms by impairing extinction. In fact, daily administration of low doses of hydrocortisone to PTSD patients reduced certain PTSD symptoms including reexperiencing, hyperarousal, and avoidance, perhaps in part through a facilitation of extinction.

Norepinephrine

In mice, systemic administration of yohimbine, which leads to norepinephrine (NE) release, facilitated within-session context and cue extinction and extinction retention. Under conditions that lead to 'incubation' of fear, yohimbine blunted this effect and the B-noradrenergic antagonist propranolol exaggerated it. Using a contextual fear conditioning paradigm in rats, intra-BLA infusions of propranolol immediately after extinction training did not significantly affect

extinction retention but did prevent the facilitation of extinction by intra-BLA bicuculline when the two compounds were coinfused. Intra-BLA infusions of NE after extinction training dose dependently facilitated extinction retention, an effect not blocked by coinfusion of muscimol, suggesting that extinction retention effects of GABA are upstream of noradrenergic signaling.

Brain-Derived Neurotrophic Factor

A time-dependent upregulation of brain-derived neurotrophic factor (BDNF) mRNA within the BLA in extinguished rats relative to nonextinguished controls has been found. Intra-BLA virally mediated infusion of a truncated form of the TrkB receptor, which would block BDNF signaling, prior to extinction training produced a deficit in extinction retention (measured 1 or 24 h after extinction training) but not within-session extinction, suggesting a role for BDNF in the consolidation of extinction memory.

Intracellular Signaling Pathways

Voltage-Gated Calcium Channels

Systemic administration of the L-type voltage-gated calcium channel (L-VGCC) blockers nifedipine and nimodipine prior to extinction training produced a dose-dependent impairment of both within- and between-session extinction in mice. These effects were evident in both context and tone extinction and were not state dependent. Interestingly, nifedipine did not impair extinction when extinction training occurred immediately after acquisition, but was evident when extinction training was delayed by 1 or 3 h, perhaps consistent with behavioral evidence suggesting a difference in the mechanisms of short- and long-interval extinction.

Adenylyl Cyclase/cAMP

Transgenic mice overexpressing type 1 adenylyl cyclase within the forebrain had increased adenylyl cyclase activity, long-term potentiation, and phosphorylated MAPK and cAMP response element binding protein (CREB), a transcription factor, within the hippocampus. In a Pavlovian fear conditioning paradigm, the transgenic mice acquired both tone and context fear normally, but were delayed in context fear extinction relative to wild-type mice. Despite the apparent lack of effect in acquisition, the delay of extinction may have reflected stronger fear memory formation in transgenic animals.

Rolipram, a phosphodiesterase inhibitor that increases cAMP concentrations in the brain, facilitates acquisition of fear and delays extinction. Once again, it is not clear whether rolipram impaired extinction or, alternatively, just increased fear acquisition, which would be expected to delay extinction.

Protein Kinase A

Infusion of the PKA inhibitor Rp-cAMPs into the CA1 region of hippocampus either before or immediately after the first of several extinction trials in a step-down avoidance paradigm produced a persistent impairment of extinction. However, intra-BLA infusions of the PKA activator 6-BNZ-cAMP immediately following each of four daily tone extinction training sessions had no effect on extinction of freezing.

Mitogen-Activated Protein Kinase

Intra-BLA (but not intrahippocampus) infusions prior to extinction training of the MAPK inhibitor PD98059 impaired extinction retention in the fear-potentiated startle paradigm. This was not due to state dependency, although it is not clear whether PD98059 affects the expression of extinction because experiments involving pretest infusions in animals extinguished drug-free were not conducted. A similar disruption of extinction of step-down avoidance following infusion of PD98059 into the CA1 region of hippocampus also has been seen. In the former study, infusions both before and after extinction training were effective, suggesting a role for MAPK in consolidation of extinction memory. Immediate but not delayed (2 or 4 h) post-extinction training infusions of PD98059 into medial prefrontal cortex (mPFC) impaired later extinction retention, using freezing to a tone as a measure of fear.

An upregulation of phosphorylated MAPK (pMAPK) was seen in extinguished wild-type mice relative to nonextinguished controls, and pMAPK actually decreased in CB receptor knockout (CB1−/−) mice that exhibit a profound impairment in extinction. Using a weak extinction training protocol, only a modest increase in pMAPK within the BLA was seen, but this effect was much larger when this same extinction protocol was combined with DCS, an effect blocked by intra-BLA administration of the MAPK inhibitors U0126 or PD98059.

Phosphatidylinositol 3-Kinase

Although direct measurement of changes in PI3K phosphorylation targets such as Akt has been inconsistent, intra-BLA infusions of the PI3K inhibitor wortmannin prior to extinction training blocked extinction of fear-potentiated startle, and intra-CA1 administration of the PI3K inhibitor LY 294002 immediately following daily extinction exposures to

a previously trained context impaired extinction in mice. DCS facilitation of extinction via systemic pre-extinction training administration of DCS was blocked by intra-BLA infusions of wortmannin.

Calcium/Calmodulin-Dependent Protein Kinase II

Intra-CA1 infusions of the CaMKII inhibitor KN-62 prior to, or immediately following, the first of several extinction exposures produced a persistent impairment extinction of step-down avoidance in rats. KN-62 also produced a persistent impairment in extinction when infused into the entorhinal cortex prior to the first extinction exposure. Post-extinction training infusions were not included in this latter study.

Src Family of Tyrosine Kinases

Infusions into the CA1 region of the hippocampus of the Src family inhibitor 4-amino-5-(4-chlorophenyl)-7-(*t*-butyl) pyrazolo [3,4-D] pyrimidine (PP2) immediately but not 180 min after each of four daily extinction exposures blocked extinction, suggesting a role for Src family kinases in consolidation of extinction memory. Subsequent extinction proceeded normally when extinction training was continued in the absence of infusions, indicating the infusions did not produce lasting damage to the hippocampus.

Cytoplasmic Polyadenylation Element Binding Protein

Cytoplasmic polyadenylation element binding protein (CPEB) knockout mice and wild-type controls acquired context fear normally, but the knockouts showed slower rates of between-session extinction. The knockouts also showed deficits in extinction in the Morris water maze, suggesting that CPEB may play a role in the extinction of hippocampus-dependent learning as opposed to fear extinction *per se*.

Calcineurin

The findings reviewed thus far suggest that a significant number and variety of kinases are activated in extinction. In apparent conflict with this, however, are data suggesting that extinction involves upregulation of the protein phosphatase calcineurin (also known as protein phosphatase 2B or PP2B), which would dephosphorylate (inactivate) many of these same kinases. Thus, both amygdalar depotentiation *in vitro* and fear extinction in behaving animals are associated with increased BLA calcineurin protein and enzymatic activity, and both depotentiation and extinction are blocked by pre-administration of calcineurin inhibitors. Like fear extinction, depotentiation also is blocked by NMDA receptor antagonists and L-VGCC inhibitors. Likewise, both extinction and 'quenching' of fear (defined as a loss of recently acquired fear responses following administration of depotentiation-inducing electrical stimulation to behaving animals) are associated with a reversal of fear conditioning-induced increases in BLA phosphokinases (Akt and MAPK), and in both cases the reversal is blocked by pre-administration of calcineurin inhibitors. Based on these similarities, it has been suggested that fear extinction involves a reversal of acquisition-related plasticity through upregulation of calcineurin and induction of depotentiation.

In other words, the argument is that extinction involves 'unlearning,' which, as we have seen, generally is problematic in light of data indicating that extinguished fear responses reappear, but may be an accurate description of the mechanism of extinction under some circumstances. On the other hand, there are some apparent inconsistencies within this body of work that await a satisfactory explanation. For example, if extinction is dependent on calcineurin-dependent depotentiation, why should MAPK and PI3K inhibitors impair extinction when MAPK and Akt are targets of calcineurin and are dephosphorylated following depotentiation-inducing stimulation? It is probable that some of these kinase and phosphatase cascades are modulated differentially within different BLA cell types, such as principal neurons and interneurons, which could explain the apparently conflicting observations. Hence, finer dissection of the cellular processes involved in extinction will require cell type-specific manipulations.

Transcription

Extinction has been associated with an increase in the expression of immediate-early genes in mPFC and BLA and an upregulation of gephyrin and BDNF mRNA in the BLA. A persistent impairment of extinction of step-down avoidance has been found when the transcription inhibitors a-amanitin or 5,6-dichloro-1-b-D-ribofuranosyl benzimidazole (DRB) were infused into the CA1 region of hippocampus 15 min before, but not 1 or 3 h after, the first of several extinction exposures to the apparatus. The lack of effect of post-extinction training administration is somewhat surprising given the likelihood that mRNA transcription is involved in consolidation of extinction memory, although it is possible that the onset of transcription occurs fairly rapidly (<1 h) following extinction training. Facilitation of extinction of fear-potentiated startle by pre-extinction training DCS was blocked by pre-administration of the transcription inhibitor actinomycin D into the BLA, an effect not due to state dependency.

Translation

Most studies employing pre- or post-extinction training administration of protein synthesis inhibitors have reported a profound impairment of extinction, despite differences in the organism being studied, the specifics of the training protocol, the method and timing of drug delivery, and the measure of conditioned fear. However, the issue of whether extinction is dependent on protein synthesis is complicated greatly by the procedural similarities between experiments examining extinction and those examining reconsolidation of conditioned fear.

Clinical Implications

The clinical implications of the work on fear extinction are particularly straightforward. Fear- and anxiety-related disorders such as phobias and PTSD seem to be disorders of fear dysregulation in which inhibition of fear is absent or insufficient in situations that are patently safe. Procedurally, extinction is very similar to several types of exposure-based psychotherapeutic treatments, and thus drugs found to facilitate extinction in rodents are now being tested to see if they will facilitate exposure-based psychotherapy.

DCS Facilitates Exposure Therapy

As we have already seen, DCS facilitates the functioning of the NMDA subtype of glutamate receptor and facilitates extinction of conditioned fear in animals. It has now been shown that DCS facilitates exposure-based psychotherapy in patients with fear of heights, social phobia, and obsessive-compulsive disorder, and similar studies are being conducted by several other groups for PTSD and other disorders. These studies represent outstanding examples of 'translational research' and give hope that the study of extinction in rodents will lead to more and more drugs that may improve exposure-based psychotherapy in several types of psychiatric disorders.

Pharmacology of Sleep: Adenosine

R Basheer, J T McKenna, and R W McCarley, Boston VA Healthcare System and Harvard Medical School, Brockton, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Approximately one-third of the human lifetime is spent in sleep. Undoubtedly, sleep is essential for the physical and mental well-being of the individual. Sleep disorders often lead to impaired daytime performance, with at times dire social and financial consequences. Approximately 40 million Americans suffer from chronic sleep disorders each year, and approximately 20 million experience occasional sleeping difficulties. Sleep pathologies such as insomnia, hypersomnia, or parasomnia occur either as a primary disorder or as a secondary disorder in conjunction with another illness. Research has focused on developing new therapeutic strategies, utilizing an increasing knowledge of the brain regions, neurotransmitters, and related molecular/cellular mechanisms that regulate sleep–wake behavior. In this article, we review the current status of pharmacologic agents and their molecular targets used in sleep therapy, followed by an extensive description of developments concerning adenosinergic mechanisms of sleep regulation. Finally, we discuss the prospects of using adenosine receptors or transporters as therapeutic targets for treating sleep disorders.

General Pharmacology of Sleep

Significant advancements have been made in understanding the brain mechanisms involved in sleep–wake regulation (Figure 1). The three behavioral states, also termed vigilance states, are waking, non-rapid eye movement (NREM) sleep, and rapid eye movement (REM) sleep (also known as paradoxical sleep or dream sleep). The transitions between these states involve different neurotransmitters, their receptor subtypes, and brain regions. Consequently, the pharmacological advances in sleep-promoting and wake or alertness-promoting drugs target a wide range of these neurotransmitter systems.

The first generation of sleep-promoting drugs composed of hypnotics or sedatives are known to enhance the action of the neurotransmitter GABA at the ionotropic $GABA_A$ receptor. Sedatives such as benzodiazepines (diazepam and valium), barbiturates, neurosteroids, and general anesthetics (isoflurane and propofol) target the $GABA_A$ receptor, potentiating the action of endogenous GABA. These drugs specifically bind to $GABA_A$ receptors that contain the γ subunit, in addition to one of the α subunits (1, 2, 3, or 5). These $GABA_A$ receptors are widely distributed in the cortex and other wake-related areas, such as the thalamus, tuberomammillary nucleus, basal forebrain, and hypothalamus. These drugs may act on targets of the sleep-promoting ventrolateral preoptic area (e.g., the tuberomammillary nucleus) by means of enhancing the inhibitory action of GABA to promote sleep.

A second generation of 'non-benzodiazepine' compounds has been developed which targets the $GABA_A$ receptor but is more selective for the α_1 subunit. Such compounds, including zolpidem, zopiclone, and zalplon, are termed the 'z' drugs. A newer class of compounds with similar actions, such as indiplon, is currently being evaluated. Also, a direct-acting $GABA_A$ agonist ($GABA_A$ receptor with α_4–δ subunits), gaboxadol, has been shown to improve sleep induction, maintenance, and sleep architecture. Interestingly, the selective $GABA_A$ receptor types that bind gaboxadol do not respond to benzodiazepines and are present in high density in the cortex, thalamus, and limbic system. At the cellular level, gaboxadol induces c-Fos expression in VLPO neurons, indicating activation of sleep-inducing neurons.

Drugs that act as antagonists of neurotransmitter receptors on wake-active neurons also exert sedative effects. For example, the histamine blockers dipenhydramine, eplivanserin, and pruvanserin are being developed as potential hypnotic agents. Since it is known that activation of the $5HT_{2A}$ receptor induces arousal, the specific receptor antagonist ketanserin has been developed.

Several recently developed compounds have been used to explore new avenues of pharmacological treatment of sleep disorders. GHB (γ-hydroxybutyrate) has been used to treat cataplexy/narcolepsy (sodium oxybate), and this compound is being considered for treatment of insomnia, although its use as a recreational drug has led to strict controls over prescriptions. Melatonin, secreted by the brain's pineal gland, has been considered a possible dietary supplemental treatment for insomnia, and it may help reduce jet lag. The M1 and M2 melatonin receptor agonist ramelteon has received much attention as a novel therapeutic agent for the treatment of insomnia.

Several drugs are targeted toward enhancing the activities of wake-active neuronal circuitry in order to treat conditions of hypersomnia. The most widely accepted drugs for enhancing wake and alertness are dopamine transport blockers, such as methylphenidale and modafinil. The histamine H_3 autoreceptor

Figure 1 (a) Schematic diagram of the major brain circuitry involved in wake and NREM sleep. The arrows show the known connectivity between the brain regions. Solid lines denote excitatory neuronal outputs, and dashed lines denote inhibitory neuronal outputs. The neurotransmitters (red) shown include the following: ACh, acetylcholine; DA, dopamine; GABA, γ-aminobutyric acid; Glu, glutamate; H, histamine; 5HT, serotonin; NA, noradrenaline; Ox, orexin. Forebrain region: BF, basal forebrain. Cortex: LH/PF, lateral hypothalamus, perifornical region; THAL, thalamus; TMN, tuberomammillary nucleus; VLPO, ventrolateral preoptic nucleus; VTA, ventral tegmental area. Brain stem regions: DR/MR, dorsal and median raphe nuclei; LC, locus coeruleus; LDT/PPT, laterodorsal and pedunculopontine tegmental nuclei; PB, parabrachial nucleus; RF, reticular formation. The receptors known to mediate the effects in specific regions (blue) include the following: α_1, excitatory α_1 adrenoceptors; α_2, inhibitory α_2 adrenoceptors; 5HT2A, excitatory serotonin receptors; H1, excitatory histamine receptor. (b) Schematic diagram of proposed inhibitory projections (blue dashed lines) from the ventrolateral preoptic nucleus to proposed wake and NREM sleep-related brain regions. Note that these GABAergic projections are also galaninergic. (c) Schematic diagram of proposed orexinergic excitatory projections (blue solid lines) from the lateral hypothalamus/perifornical region to proposed wake and NREM sleep-related brain regions. (d) Schematic diagram of proposed serotonergic excitatory projections (blue solid lines) from the dorsal and median raphe nuclei to proposed wake and NREM sleep-related brain regions. Adapted from Szabadi E (2006) Drugs for sleep disorders: Mechanisms and therapeutic prospects. *British Journal of Clinical Pharmacology* 61: 761–766; and Saper CB, Scammell TE, and Lu J (2005) Hypothalamic regulation of sleep and circadian rhythms. *Nature* 437: 1257–1263.

antagonists ciproxifan and thioperamide can enhance histamine release and increase waking.

In addition to the previously mentioned neurotransmitters, much research has also focused on endogenous homeostatic factors that integrate sleep regulation with feeding and metabolism, such as the delta sleep factor, cytokines, growth factors, and peptides (orexin, cholecystokine octapeptide, neuropeptide Y, and ghrelin). For example, antagonists of the orexin receptors, such as compound GW649868, are being tested for use as a sedative. Overall, therapeutic strategies that aim to design sleep-promoting and wake-promoting drugs utilize a multitude of approaches developed through knowledge of brain circuitry and manipulation of the different known neurotransmitter systems.

Adenosine as a Potential Target of Hypnotics

The nucleoside adenosine is an endogenous neuromodulator and a homeostatic sleep factor. Developments with regard to adenosine's role in sleep regulation and the delineation of underlying adenosinergic molecular mechanisms have presented several possibilities for treatment of insomnia and hypersomnia. In the following sections, we discuss the brain regions, receptors, and transporters of adenosine that are associated with sleep regulation, and the pharmacological possibilities in designing therapeutic compounds are also discussed.

Adenosine is a ubiquitous molecule, being an integral constituent of several macromolecules such as DNA, RNA, coenzymes, and the high-energy molecule adenosine triphosphate (ATP). The first description of the hypnogenic effects of adenosine was published in 1954 on cats, followed by studies on dogs. Since then, several laboratories have shown that systemic or intracerebroventricular administration of adenosine or agonists of adenosine receptors induces sleep. In 1981, researchers showed that the often-consumed compound caffeine (a theophylline derivative) is behaviorally stimulating due to its structural similarity to adenosine and its ability to block adenosine receptors.

Investigators originally postulated that adenosine levels would increase throughout the brain during wake due to higher neuronal metabolic activity related to ATP breakdown. Thus, in the brain, in which energy metabolism is tightly regulated, adenosine acts as a 'fatigue factor' indicating the need for rest/sleep. In cats, levels of extracellular adenosine, measured by microdialysis, increased 15–20% during wake compared to NREM sleep in brain regions associated with sleep–wake regulation, such as the basal forebrain, cerebral cortex, thalamus, preoptic area of hypothalamus, dorsal raphe nucleus, and pedunculopontine tegmental nucleus. However, prolonged waking achieved by gentle handling revealed a site-specific significant increase in extracellular adenosine in only the magnocellular basal forebrain (140% of the baseline) and, to a lesser extent, in the cingulate cortex. Infusion of adenosine into the rodent or feline magnocellular basal forebrain increased sleep, thus indicating that this region is a major site for the sleep-inducing effects of adenosine. Although adenosine perfusion in other brain regions, such as the pedunculopontine tegmental nucleus and the subarachnoid space ventral to the rostral forebrain, has also been shown to induce sleep, the sleep deprivation-induced increase in extracellular adenosine was rather selective to the magnocellular basal forebrain, suggesting that this region is one of the major sites for the homeostatic regulation of sleep by adenosine.

Four subtypes of adenosine receptors – A1, A2a, A2b, and A3 – have been identified based on their specific order of potency for agonists and antagonists and their particular structure ascertained by gene cloning. Of these, the A1 receptor is widespread throughout the brain, whereas A2a receptors are far more abundant in the basal ganglia and olfactory tubercle, and they are less abundant in the cortex. A2b and A3 receptors are less abundant and their role in sleep is not clear. A1 and A2a receptors are known to regulate adenylate cyclase and cellular activity in opposite ways. The A1 receptor, coupled to the G_i subtype of the G-protein, exerts inhibitory effects, whereas the A2a receptor, coupled to the G_s subtype of the G-protein, exerts excitatory effects on cellular activity. Both A1 and A2a receptors have been implicated in mediating the sleep-inducing effects of adenosine. The effect of adenosine on sleep varies depending on the receptor and the brain region of interest, as described later (**Figure 2**).

Subtype-specific activation of receptors has varying intracellular consequences depending on the receptor-coupling proteins inside the cell membrane (**Figure 3**). The A1 receptor couples to the G_i subtype heterotrimeric G-protein and is recognized for its dual signaling capabilities. It can either inhibit adenylate cyclase activity via the $G_{\alpha i}$ subunit, resulting in reduced cAMP production, or activate phospholipase C (PLC) via the $G_{\beta\gamma}$ subunits, which can lead to inositol trisphosphate (IP_3) production and subsequent release of intracellular calcium by activating IP_3 receptors. In neurons, A1 receptors can activate pertussis toxin-sensitive K^+ channels, as well as K_{ATP} channels, and inhibit Q-, P-, and N-type Ca^{2+} channels. The selectivity of activation and intracellular signaling is also influenced by homo- or heterodimerization. For example, adenosine A1 receptor function can be influenced by the homodimer or heterodimer or by interaction with ectoadenosine deaminase.

A2a receptors are coupled to the G_s-subtype G-protein, and hence increase adenylate cyclase activity. The A2b receptors are positively coupled to adenylate cyclase and PLC. The A3 receptor, like A1, inhibits adenylate cyclase, as well as stimulates PLC and induces intracellular calcium release.

Adenosine has been shown to inhibit neuronal activity by means of A1 adenosine receptors in many of the arousal-related brain regions. In the basal forebrain, where predominantly wake-active neurons have been described, the A1 adenosine receptor has been localized to both cholinergic and non-cholinergic neurons. Perfusion of the A1 receptor

Figure 2 Sagittal representation of the rodent brain showing brain regions with documented adenosine effects on sleep–wake behavior. The brain regions shaded in pink are recognized for A1 adenosine receptor-, blue for A2a receptor-, and green for both A1 and A2a receptor-mediated effects on sleep. BF, basal forebrain; CORT, cortex; LDT/PPT, laterodorsal and pedunculopontine tegmental nuclei; LH, lateral hypothalamus, perifornical region; LPO, lateral preoptic area; NAs, shell of the nucleus accumbens; OT, olfactory tubercle; PRF, pontine reticular formation; SubA, subarachnoid space; VLPO, ventrolateral preoptic area; 3V, third ventricle; 4V, fourth ventricle.

Figure 3 Intracellular signaling pathways of adenosine receptors: A1 and A3 receptors are coupled to pertussis toxin-sensitive G_i-subtype G-protein. Their activation either inhibits adenylate cyclase activity, preventing cAMP production, or activates phospholipase C, releasing diacylglycerol and inositol trisphosphate, which leads to protein kinase C activation. A2a and A2b receptors are coupled to cholera toxin-sensitive G_s-subtype G-protein. Activation of these receptors can increase cAMP production and activation of protein kinase A. The activation kinases can lead to phosphorylation of cellular proteins, including transcription factors such as NF-κB and CREB, leading to changes in gene expression. AC, adenylate cyclase; CREB, cAMP response element-binding protein; DAG, diacylglycerol; IP3, inositol trisphosphate; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C.

antagonist, cyclo-pentyl-1, 3-dimethylxanthine, increased waking and decreased sleep. Reduction of the A1 receptor by infusing antisense for the A1 receptor into the rodent basal forebrain resulted in a significant decrease in slow-wave delta activity during NREM sleep following 6 h of sleep deprivation.

Actions of adenosine at the A1 receptor vary according to its localization, but almost all promote sleep. In cortex, the target of wake-active cholinergic neurons, activation of presynaptic A1 receptors inhibited acetylcholine release, thereby promoting sleep. Presynaptic A1 receptor activation in the ventrolateral preoptic area, known to be sleep active, disinhibited sleep-active GABAergic neurons and led to sleep induction. Also, activation of the somatic A1 receptor on wake-active orexinergic neurons may induce sleep. The wake and REM-active cholinergic neurons of the brain stem laterodorsal and pedunculopontine tegmental nuclei are also directly inhibited by adenosine acting via the A1 receptor. Lastly, in the pontine reticular formation, both A1 and A2a receptors have been implicated in sleep regulation.

A2a receptors are located in select brain nuclei/regions involved in sleep regulation, such as the subarachnoid space, which is located below the rostral basal forebrain and the shell of the nucleus accumbens. Administration of adenosine or the A2a receptor agonist CGS21680 into the subarachnoid space below the rostral basal forebrain or the shell of the nucleus accumbens near the olfactory tubercle has been shown to promote sleep. Data suggest that prostaglandin D2 may induce the release of adenosine and, via A2a receptors, promote sleep. The sleep-inducing effects of both prostaglandin D and the A2a agonist CGS21680 can be blocked by the A2a receptor antagonist KF17937. In the lateral preoptic area, which contains numerous sleep-active neurons, a clear distinction between the behavioral effects of A1 and A2a receptor activation has been reported. A1 receptor activation of the sleep-active neurons in this area resulted in waking, possibly by inhibition, whereas A2a receptor activation induced sleep by stimulating the activity of sleep-active neurons. The olfactory tubercle contains a high density of A2a receptors, but their role in sleep is unknown.

In addition to activation or inhibition of adenosine receptors, changes in the adenosine metabolizing enzymes or adenosine transporters could potentially contribute to extracellular adenosine levels and promote sleep. For example, administration of the adenosine kinase blocker ABT-702 has been shown to increase sleep. Binding of the equilibrative transporter ENT1 was reduced in the basal forebrain following sleep deprivation in rats, suggesting that a decrease in adenosine transport into cells may contribute to the sleep deprivation-induced increase in extracellular adenosine and subsequent sleep.

Thus, research on the effect of adenosine on sleep has revealed a large number of potential targets for the development of pharmacological drugs. The agonists of adenosine receptors may have potential for treating insomnia, and the agents that antagonize adenosine receptors may be useful for treating hypersomnia and increasing alertness.

Adenosine Receptors as Therapeutic Targets

Adenosine receptor modulation has been utilized in the development of useful therapeutics for treating a variety of pathologies, including inflammatory, cardiovascular, and neurodegenerative diseases. A large number of compounds have been generated as agonists or antagonists that are essentially the derivatives of adenosine and methylxanthine molecules, respectively (Figure 4). Advances in molecular modeling have allowed definition of interactions between potential agonists/antagonists and adenosine receptors. Adenosine receptors, like all G-protein-coupled receptors, have a central core consisting of seven transmembrane helices connected with three intracellular and three extracellular loops. The selectivity of these receptors and their respective ligands is often coded by the varying lengths of the N-terminal extracellular domain and the C-terminal intracellular domain, as well as the intracellular loops. In the case of adenosine receptors' consensus sites, N-linked glycosylation has been identified in the extracellular regions, but the location of these sites within the extracellular region and the mode of posttranslational modification vary for each receptor subtype. Site-directed mutagenesis of single amino acids, critical for ligand recognition and responsible for discerning between agonists and antagonists, has been central to the medicinal chemistry of the drug–receptor interaction.

Several potent and selective adenosine receptor agonists have been utilized for treatment, and many are being tested for use in inflammation, analgesia, benign prostatic hypertrophy, and cardiovascular disease, in contrast to the relative paucity of development for use in sleep and wakefulness. Some adenosine antagonists are derivatives of xanthines, but these compounds have limited water solubility and bioavailability. Consequently, nonxanthine compounds with increased water solubility and bioavailability have been synthesized. Examples of A1, A2, and A3 selective agonists/antagonists are presented in Tables 1–3, respectively.

Nucleoside Transporters as Therapeutic Targets

Adenosine is hydrophyllic and its transport across the cell membrane is carried out by two kinds of nucleoside transporters: the equilibrative nucleoside transporters (ENTs) and the concentrative nucleoside transporters (CNTs). The ENTs allow facilitated diffusion of nucleosides, whereas CNTs are cation symporters. ENT1–4 vary in their tissue distribution pattern. In the brain, ENT1 and ENT4 are

Figure 5 Chemical structures of compounds that block nucleoside transporters.

more abundant. There are three subtypes of CNTs (CNT1–3), and CNT2 is most abundant in brain. Although the affinity for adenosine is much greater for CNT2 compared to ENT1 (K_m of 6 μM for CNT2 and 40 μM for ENT1), the adenosine transport rate is much slower with CNT2. In the cortex, CNT2 mRNA levels and, in the magnocellular basal forebrain, ENT1 binding to NBMPR were attenuated after 24 and 6 h of sleep deprivation, respectively. The downregulation of these transporters was suggested to contribute to the observed increase in extracellular adenosine in these two brain regions following sleep deprivation. Consequently, inhibitors of adenosine transporters that increase the levels of extracellular adenosine may be promising compounds for treatment of such sleep disorders as insomnia. Experimental proof of this phenomenon has been obtained in the rat with infusion of the ENT1 inhibitor NBMPR into the basal forebrain, where levels of extracellular adenosine increased and sleep was induced. Several such ENT1 inhibitors, including dilazep, dipyridamole, draflazine, and lidoflazine, all with different molecular structures, have been identified for their ability to enhance the extracellular concentration of adenosine by blocking adenosine reuptake (Figure 5).

Allosteric Modulators as Therapeutic Agents

Adenosinergic receptor activity may also be influenced by compounds that bind to receptor allosteric sites that are topologically distinct from the orthosteric sites to which endogenous ligands, as well as

exogenous agonists and antagonists, bind. Allosteric ligand binding does not overlap with the orthosteric site, thus allowing simultaneous binding of compounds at both sites. These compounds can thus selectively enhance the response to adenosine in only those organs or a localized area of a given organ in which the production of adenosine is increased. At the functional level, molecules that bind to allosteric sites modulate receptor activity by causing conformational changes, leading to either decreased (positive regulators or allosteric enhancers) or increased (negative regulators) dissociation kinetics of the orthosteric ligand. Therefore, the use of allosteric modulators as therapeutic agents has become very attractive. Allosteric modulators exhibit greater subtype selectivity and fewer side effects. Moreover, the neurotransmitter receptors are less sensitive to desensitization or downregulation by allosteric enhancers compared to exogenous agonists. Typical examples are the benzodiazepines, such as diazepam, acting as allosteric enhancers of $GABA_A$ receptors with limited side effects, whereas direct agonists of $GABA_A$ receptors have widespread side effects and are therefore unsuitable for treatment. Similarly, an allosteric modulator of the nicotinic receptor, the alkaloid galanthamine, potentiates nicotinic cholinergic neurotransmission without major side effects and is used for treatment of Alzheimer's disease.

Allosteric Modulators of the A1 Adenosine Receptor Subtype

Allosteric modulators have also been described for adenosine receptors and transporters and are potential therapeutic agents (Figure 6). The benzoylthiophene derivatives, such as PD 81,723 (2-amino-4,5-dimethyl-3-thienyl-[3[(trifluromethyl)phenyl]-methanone) and related analogs, were the first compounds to be identified as A1 receptor-selective allosteric enhancers due to their ability to increase the levels of agonist binding. In the past decade, multiple derivatives of PD 81,723, with variable potency for enhancing the agonist binding to the A1 receptor, have been synthesized. Among them, PD 71,605 (T-62) proved to be a potent enhancer of agonist binding to membranes of Chinese hamster ovary cells expressing the human A1 receptor. 2-Aminothiazlium salts are a new class of allosteric enhancers of the A1 receptor that are suggested to be more stable than benzoylthiophenes. Most of the tests for the potency of this compound have involved *in vitro* systems, however, and clinical use of these compounds has not been reported. On the other hand, tests in animal studies showed that PD 81,723 exhibited some degree of tissue selectivity, modulating neuronal but not adipocyte adenosine receptors. This compound's effects were also species specific, showing greater enhancement of agonist binding in the guinea pig and dog brain compared to the rodent brain. T-62 has been shown to reduce mechanical hypersensitivity in a rat model of neuropathic pain, thus demonstrating its potential use in pain therapy.

Allosteric Modulators of the A2a and A2b Adenosine Receptor Subtypes

The allosteric modulators of the A2a receptor thus far described lack absolute specificity. For example, PD 120918 (4-methyl-7([methylamno]carbonyl)oxy)-2H-1-benzopyran-2-one) has been shown to slow the dissociation of the adenosine agonist from the rat brain A1 receptor, therefore appearing to be not very selective for the A2a receptor. Other compounds, such as amiloride analogs and SCH-202676, increased the antagonist dissociation from the A2a receptor but did not show any effect on the dissociation rate of agonist CGS21680. To our knowledge, no known allosteric compound modulates the A2b adenosine receptor subtype. It is suggested, however, that SCH-20676 can also function as an allosteric modulator of the A2b subtype receptor (Figure 7).

Allosteric Modulators of the A3 Adenosine Receptor Subtype

Two distinct compounds and their derivatives have been identified to act as allosteric modulators of the A3 adenosine receptor subtype. 3-(2-pyridinyl) isoquinoline derivatives were very selective for the

Figure 6 Chemical structures of allosteric modulators of A1 receptors.

Figure 7 Chemical structures of allosteric modulators of A2a receptors.

Figure 8 Chemical structures of allosteric modulators of A3 receptors.

A3 receptor, and they have been shown to enhance binding of the agonist [^{125}I]-N6(4-amino-3-iodobenzyl)-5′-*N*-methyl carboxamidoadenosine (I-AB-MECA, also known as IB-MECA) in a concentration-dependent manner. These derivatives not only enhanced agonist binding to the A3 receptor but also enhanced A3 receptor function (i.e., inhibition of forskolin-induced cAMP production). However, these compounds also demonstrated antagonist-like activity. Further studies have shown that the removal of a 7-methyl group decreased the antagonistic function without any loss in the allosteric enhancing activity, suggesting that a structural requirement for allosteric enhancement might be distinct from those for competitive antagonism (Figure 8).

Another set of compounds, 1H-imidazo-[4,5-c] quinoline and its derivatives, exhibited A3 receptor-selective allosteric enhancement of agonist binding, specific to the human A3 receptors. A few derivatives of this compound decreased the dissociation of the agonist IB-MECA without any effect on A3 receptor antagonist binding or A1/A2a receptor agonist binding. A few of these derivatives, however, tested positive for antagonistic binding to the receptor at the orthosteric site. These compounds demonstrated enhanced inhibition of forskolin-stimulated cAMP production in cells that expressed human A3 receptors.

In addition, another subset of the previously mentioned compounds for the A2a receptor, the amiloride analogs, may be more selective for the A3 receptor. Studies have shown that the former was more effective as an allosteric enhancer for the A3 receptor and acted as allosteric inhibitors of the antagonist binding to A1, A2a, and A3 receptors. Specifically, it was shown that the dissociation rates for IB-MECA binding of the human A3 receptor, as well as forskolin-stimulated cAMP production, were significantly reduced without any effect on the binding of A1 and A2a agonists to their respective receptors, suggesting a higher selectivity of amiloride compounds for the A3 receptor.

Adenosine as a Therapeutic Agent for Other Diseases

In the drug discovery arena, the development of compounds with receptor subtype-specific pharmacodynamics without undesired side effects has been a constant challenge. Several adenosinergic drugs have been described for the treatment of both central nervous system (CNS) and non-CNS-related illnesses. Some of these compounds are already in use, others are in later stages of clinical trials, and many more are being tested in animals. In patients with paroxymal supraventricular tachycardia, a condition defined as an abnormally fast heart rate due to the rapid firing of electrical impulses from the atrioventricular node, intravenous infusion of adenosine has been found to activate A1 receptors and restore a normal heart rhythm. Another A1 receptor-selective agonist, called selodenoson, tecadenoson, or CVT 2759, in clinical trials, has been developed for its capacity to slow heart rate without lowering blood pressure. However, it has been found to have the detrimental side effect of producing renal toxicity.

Activation of A1 receptors has also been recognized to provide cytoprotection during ischemia. The A1 receptor antagonist BG9719 is undergoing phase II clinical trials for improvement of renal function and treatment of congestive heart failure. Adenosine is being used in imaging for the evaluation of coronary artery disease. Another A2a receptor agonist, regadenoson, is also being used for myocardial perfusion imaging. The A2a receptor agonist GW328267 is undergoing phase II clinical trials for the treatment of asthma, a chronic obstructive pulmonary disease.

Other adenosinergic compounds have been developed to treat other pathologies. Some CNS drugs, such as cabamazepine, exhibit pain-relieving effects which are mostly mediated through A1 and, partially, through A2 receptors. Another A1 receptor-selective

agonist, GW-493838, is in clinical trials for the treatment of pain and migraine headaches. An allosteric enhancer of the A1 receptor, T-62, is in clinical trials for treating neuropathic pain. An A1 receptor antagonist, FR194921, is being investigated for use as a potential treatment of dementia and anxiety disorders. NNC-21–0136, another A1 receptor selective agonist, has been shown to be selectively neuroprotective during global ischemia, with significantly few cardiovascular effects. Lastly, the A2a receptor antagonist istradefylline (KW-6002) is in phase III clinical trials for the treatment of Parkinson's disease.

Conclusion

Research has strongly supported the role of adenosine as a potent somnogenic factor. Although no drugs targeting adenosine receptors or transporters have been utilized as compounds for treating insomnia or hypersomnia, there appears to be potential for such therapeutic strategies in the future. With improved understanding of the brain regions and the receptor subtypes mediating the effects of adenosine, it is time to test or design specific modulators of adenosine receptors or transporters for treating sleep disorders. However, it is important to note that one of the basic challenges in using adenosine receptor or transporter modulators as therapeutic agents is the ubiquitous distribution of these molecules and the possibility of undesirable side effects. Strategies that include mediation of effects specific to the brain and, better still, in a localized area of the brain will be important. For example, allosteric modulators may potentiate an adenosine receptor agonist's action in an agonist concentration-dependent manner, which could hold great promise for enhancement of the localized effects of adenosine. The concept of engineering adenosine receptors (neoceptors) in concert with uniquely modified/designed ligands (neoligands) is being explored for use in organ-targeted gene therapy. Early studies have demonstrated successful synthesis of neoceptors for the A2a and A3 adenosine receptors. This approach may hold promise for the future of targeted drug therapy. In summary, the adenosine receptors present a promising target for pharmacological intervention, one heretofore not utilized in the treatment of insomnia and hypersomnia.

Pheromones and other Chemical Communication in Animals

T Wyatt, University of Oxford, Oxford, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Chemical communication is arguably the most widely shared sensory modality, used almost universally across the animal kingdom. From the simplest bacteria to humans, almost all organisms use chemical communication. Within a species, the molecules used for chemical communication are called pheromones. The word pheromone comes from the Greek *pherein*, to carry or transfer, and *horman*, to excite or stimulate. Pheromones are often divided by function, such as sex pheromones and aggregation pheromones.

A broader term for chemicals involved in animal communication is semiochemical (from the Greek *semeion*, sign). Chemical signals broadcast to the world can be detected by individuals from other species. So, for example, pheromones released by bark beetles may attract their predators – which use the pheromones as a kairomone to locate their bark beetle prey. Chemical signals in deceit or propaganda are termed allomones (discussed in the section titled 'Eavesdropping and propaganda').

Evolution of Chemical Communication

Pheromones evolve from chemicals released to the environment that give an advantage to the receiver (and, often, the sender). The clue to such an evolutionary path is often given by the identity of the compounds used as pheromones. For example, the sex pheromones released by female goldfish appear to be very similar to the steroid hormones that are circulating in her blood while her eggs are developing. Male goldfish have evolved great sensitivity to these hormonelike compounds. Presumably, over evolutionary time, males able to detect these compounds, initially inadvertently leaking from females, would gain more fertilizations as they would be better able to find the females about to spawn. There would be selection for greater and greater sensitivity in the 'noses' of the males – to the extent that now male goldfish can detect the waterborne sex pheromones down to nanomolar and picomolar threshold concentrations. Females would gain more-reliable fertilization, so there would be selection for females that, instead of simply leaking these compounds, actually secreted them. Thus, theoretically, something which started as eavesdropping by males could evolve into a pheromone signal produced by females specifically to attract males.

Another example comes from the alarm pheromones in ants, released when threatened by a predator or invading ants from another colony. A bizarre variety of compounds are found as alarm pheromones in different taxonomic groups of ants. The pattern is largely explained when the alarm pheromones are compared with the toxic compounds that are released in fighting or defense in those species – the alarm pheromones appear, in many species, to have evolved from defense compounds.

Thus all kinds of molecules can potentially evolve to become used as pheromones in chemical communication. The size and stability of compounds can often be related to their role in communication. For example, ant alarm pheromones tend to be small, volatile molecules which diffuse quickly. Hyena territorial marking pheromones are high-molecular-weight involatile compounds, which will last a long time. A wide variety of the compounds are used by different species as pheromones, including steroids, fatty acids, and esters. Some aquatic invertebrates and vertebrates, including amphibians, use short peptides as pheromones. For example, the Asian red-bellied newt (*Cynops pyrrhogaster*) uses a decapeptide, sodefrin, as its male sex pheromone. The sea slug mollusk *Aplysia* similarly uses a short peptide.

Small molecules as well as large ones are used by animals large and small. However, terrestrial vertebrates may be different from other animals as their low-molecular-weight pheromones are often delivered loosely in the cleft of a protein, which increases the longevity of the signal. For example, mouse pheromones such as dehydro-*exo*-brevicomin are presented in association with lipocalin mouse urinary proteins (MUPs). Large quantities of MUPs are present in the urine of dominant male mice. The MUPs may also give some individuality to the signal of the male.

As it happens, a closely related compound *exo*-brevicomin is used as a pheromone by some bark beetles as well as male mice. Such a shared use is not unusual. The Asian elephant (*Elephas maximus*) shares its female sex pheromone with some 140 species of moth. The compound is a small, volatile molecule, (*Z*)-7-dodecen-1-yl acetate. This phenomenon comes about because of the common origin of life: basic enzyme pathways are common to all multicellular organisms. In addition, the number of potential different small, and thus volatile, molecules is limited by the number of permutations of combining a small number of atoms. However, moths and elephants are unlikely to be confused by each

other as female elephants produce prodigious amounts of the pheromone (and the amounts produced by a female moth will not be noticed by a male elephant) and male moths are attracted to species-specific combinations of pheromone components, of which the elephant pheromone is just one.

Most chemical communication, such as that of moths, is by mixtures of small molecules which give species specificity to messages. Female moths' pheromones tend to consist of a species-specific combination of fatty acids or alcohols. Males respond to the whole blend as a signal. Unique compounds such as the complex molecule periplanone, used as a sex pheromone by the American cockroach, are unusual, although animals using peptides as their pheromones can have species-specific sequences.

In moths we can see speciation reflected in their chemical communication. Related species may have similar pheromone blends, distinguished by different proportions of the compounds or the addition or loss of certain components. In some moth families, the synthetic pathways for the pheromone blend components are well understood. With this background, the variation in blends produced by different species can be explained by gene frequency changes and mutations, resulting in up- or downregulation of particular enzymes or changes in reaction product or substrate. There may be regional variation in pheromone blends within a moth species, and incipient speciation can sometimes be observed.

Mechanism of Olfaction, Receptor Proteins, and the Evolution of Pheromones

In animals with an olfactory system, pheromones are detected by the olfactory system rather than the gustatory system. The organization of the olfactory system in invertebrates and vertebrates is remarkably similar in functional terms. The great flexibility of the olfactory system means that almost any kind of chemical can potentially evolve into a pheromone if it provides useful information to the receiver. This is because olfaction works by stimulation of a wide range of relatively nonspecific G-protein-coupled receptor proteins (each expressed on different olfactory sensory neurons linked to glomeruli). The system can respond to the widest possible range of odors, even as entirely new compounds are created (in evolving biological systems). Although a given odor may be unlikely to fit any one receptor perfectly, it is likely to stimulate some. If detection of a molecule gives significant selective advantage, then over evolutionary time, the receptors may evolve great specificity to such molecules; so, for example, on the male moth antennae there will be large banks of sensory neurons, each with receptors very finely tuned to one of the key components of that species' female sex pheromone.

Many vertebrates have a second olfactory system, the vomeronasal organ, which projects to the accessory olfactory lobe, as well as the main olfactory system. Depending on species, pheromones are detected by either the main olfactory system or the vomeronasal organ or, as seems increasingly likely, both systems.

Releaser and Primer Pheromones

The first pheromones recognized were sex pheromones which elicited (or 'released') an almost instantaneous behavioral response. For example, in moths, female sex pheromones elicit orientation flights by males toward the female, and when he finds her, in many species, the male fans his wings as part of courtship. This formed the bioassay used to identify the pheromone (see the section titled 'Techniques for studying chemical communication').

Some pheromones produce longer-term physiological changes (primer effects) in the receiver. For example, the female goldfish sex pheromones, besides attracting males, also cause the receiving males to increase their sperm and semen production. Primer pheromones have their effect indirectly via the receiver's endocrine system. The distinctions between primer and releaser pheromones now seem to be less clear-cut than when first defined. There are many interactions between pheromones and the central and the peripheral nervous systems and endocrine systems. Some primer effects can be rapid, and the effects of some behavioral interactions mediated by pheromones can be long lasting.

Another class are modulator pheromones, which are proposed to affect mood in humans though the evidence is not yet strong for these, at least at physiologically relevant concentrations of the putative pheromones.

Odor Signatures versus 'Simple' Chemical Communication (Pheromones)

The pheromones above are defined molecules or mixtures of molecules. There are other situations, such as mate choice based on the odors associated with the immune system, where arguably there is chemical communication, but not of the traditional pheromone type. This is information in the form of an 'odor signature' which differs between individuals or family groups of the same species. This variability in odor

signature makes recognition of individuals or families possible by smell. The odor signature is very complex and is made up from all sources of variation, both genetic and environmental, including recent feeding history or infection. For odor signatures, the differences between individuals or clans are the message. (Some authors have termed these odors 'signaler pheromones.') The odor identity of the stud male mouse in the Bruce effect, in which the odor of a new male causes spontaneous abortion or reabsorption of the embryo in the female, is remembered by neuronal circuits in the accessory olfactory lobe after stimulation via the vomeronasal organ. In contrast, in the female sheep, the odor identity of her lamb is remembered in the main olfactory lobe.

An important feature of odor signatures is that, unlike species-specific pheromones, odor signatures all have to be learned – in mammals, for example, by growing up with litter mates (which are later recognized as kin – and avoided as mates when adult). In ants, the colony identity odor has to be gained from ants in the colony and learned on emergence from the pupa. The importance of learning is demonstrated by cross-fostering experiments, which show a sensitive period of imprinting in the life of many young mammals. Similar results are found with social insects.

The one theoretical exception to the need for learning is the Green Beard scenario, in which three linked genes produce (1) an external marker, (2) a genetic ability to recognize the marker, and (3) a genetically determined appropriate response to look after other individuals with this marker. However, there are only a tiny number of examples, notably in the fire ant and possibly in slime molds.

Production of Pheromones

Pheromones are secreted by a variety of specialized glands in insects and mammals. In the same way that compounds become co-opted as pheromones, glands are found in many different places in animals, usually as adapted skin glands. In mammals these occur in species-specific locations, for example near the eye, around the anus, or on the chin or flanks. Some pheromones are produced by internal organs; for example, the male sex pheromones of the sea lamprey, *Petromyzon marinus*, are bile acids produced by the liver.

In some species, the chemicals used for pheromone communication are collected; for example, male tropical euglossine bees must collect perfume compounds from orchid flowers to use as their sex pheromone. Some butterflies and moths – either as larvae or as adults – sequester plant poisons, and these may be adapted as sex pheromones in courtship (see the section titled 'Sex pheromones').

Bark beetle pheromones may include compounds ingested from the tree sap and then chemically modified by the beetle itself or by symbiotic bacteria in the beetle's gut. Pheromones (or signature odors) are produced by bacterial and fungal fermentation of fatty acids and other compounds secreted in the anal glands of dogs, badgers, and other carnivores.

Range of Roles for Chemical Communication

Pheromones are used for a wide range of functions by animals. As might be expected, they are used especially by nocturnal species. Pheromone signals may be combined with other modalities – for example, on detecting a predator, black-tailed deer signal alarm with both a pheromone and a visual tail-flick signal. Pheromones can be classified by their apparent uses or functions – though a given pheromone can have more than one role in a species, depending on context.

Sex Pheromones

The first pheromones identified were the sex pheromones of moths. It had long been known that male moths could find females at night; pheromones proved to be the means. At first each moth species was thought to have its own single unique compound as its pheromone. As more moth species were investigated, it was discovered that instead, each species had a unique blend of compounds as its pheromone. Different populations of the same species may have subtle variations of the blend, rather like a dialect. Goldfish sex pheromones have already been mentioned.

Pheromones can be the subject of sexual selection. Pheromones may give clues to the status or quality of the pheromone emitter. For example, in many rodents, only high-ranking individuals, with high testosterone titers, will produce the male pheromones.

In some moths which sequester plant poisons for defense, male pheromones are derived from their chemical store in a way which offers an honest signal of the quantity of defensive plant poison he will transfer to the female at mating.

Territorial Pheromones

A key use of chemical communication by terrestrial vertebrates is for the marking of territories. An advantage of pheromones is that they can 'shout' ownership when the owner is not in that part of the territory. Male house mice mark their territories extensively with urine streaks. In the house mouse,

only the dominant male will mark, and he defends this privilege vigorously should a subordinate male be rash enough to mark in the territory of the dominant male. Scrub-living antelopes mark their territories with orbital-gland pheromones, smearing secretions from the gland onto twigs at antelope head height. Some lizards mark their territories with leg gland secretions which have a double signal – a visual one (in the ultraviolet range, which lizards can see) to make it conspicuous from a distance and a volatile chemical signal detectable at close range.

Alarm Pheromones

Alarm pheromones offer a warning or a call for help and marshal attack. Social insects – ants, bees, wasps, and the unrelated termites, all show colony defense coordinated by alarm pheromones. Honeybees release an alarm pheromone when they sting an intruder such as a bear intent on robbing their nest of its honey. The alarm pheromone attracts other bees from the nest to join in the attack. This collective defense can be very effective.

Many freshwater fish species have an alarm pheromone released from skin glands when these are damaged by a predator's closing its jaws on the victim. Other fish detecting the alarm pheromone show escape behavior and greater vigilance.

The evolution of alarm pheromones is relatively straightforward to understand in social insects or other animals living in kin groups. It is harder to explain in fish, which appear to live in groups of unrelated animals. This remains a mystery though one suggestion may be that the alarm pheromones attract other predators, which interfere with the first predator and thus the fish in its mouth escapes.

Aggregation Pheromones

Some animals use pheromones to attract conspecifics. Bark beetles arriving on a tree use aggregation pheromones to attract the critical number of conspecifics needed to overwhelm the tree's defenses. There is an optimum population density for the beetles, below which the beetles do less well – an Allee effect. As beetle density gets greater than the optimum, the pheromone messages released change, and potential settlers are deterred and go to other trees instead.

Many marine animals such as barnacles respond to conspecific chemical cues to select the place to make their once-in-a-lifetime metamorphosis from planktonic larva to sessile adult glued to a rock. The presence of proteins left by adult barnacles indicates that the place is a good one to settle because members of that species have survived to maturity. It also ensures there will be other conspecific barnacles within reach for mating, which is important as these animals fertilize internally.

Externally fertilizing marine animals coordinate density in time as well as space by using pheromones for a chemical duet between males and females which ensures that both sexes release their eggs and sperm into the water at the same time and in the same place. Some of the most spectacular examples come from marine polychaete worms, which spawn in enormous numbers on particular nights, all coordinated by pheromones.

Eavesdropping and Propaganda

Broadcast signals can be 'overheard' or eavesdropped. This happens to pheromone communication in just the same way. Bark beetle pheromones are intended for other conspecifics, but predators have evolved great sensitivity to these compounds and can use them as kairomones to home in on calling bark beetles. Parasitic wasps can use the female moth's pheromones to track down the moths whose eggs they parasitize.

Some species of ant which take over the nests of other ant species use pheromones as allomones ('propaganda'), releasing large quantities of the alarm pheromone of their victim species. This causes the victim species to run about chaotically but leaves the invading species unaffected.

Bolas spiders and some orchids independently show some of the most spectacular uses of allomones to manipulate other species: bolas spiders synthesize the female sex pheromones used by moths and thereby lure male moths to their death. A single spider may produce the pheromones of different moth species over the course of an evening to match the flight times of those species.

Orchids similarly synthesize female bee pheromones to attract male bees – though in this case the deception is for pollination, not to catch prey. Male bees attracted by the apparently authentic pheromone, mistaking it for a female bee, attempt to mate with the orchid flower, pick up pollen, and then fly on to be fooled again, delivering the pollen to another flower of the same orchid species.

Techniques for Studying Chemical Communication

Chemical communication has proved more difficult than other modalities to study. The first reason is conceptual – our own worlds are so visual and auditory that we find it difficult to imagine the central role of chemical communication in the lives of most other organisms. The second has to do with the difficulties

of chemical analysis. Much chemical communication uses vanishingly small quantities of chemical released by the signaler and perceived, at very low concentration, by the receiver of the signal. The quantities can stretch the limits of human instruments for detection (often we can detect the signal only by using the output from the animal's own sense organs – as used in the electroantennogram, an electronic recording made from the antenna of a moth in response to chemical signals). The third challenge is the 'playback' of chemical signals. Organisms are very sensitive to precise molecular shapes of pheromones – even the chirality of molecules has to be correct. This presents real challenges to the skills of synthetic chemists. In contrast to studies of communication by sound, there is no equivalent for pheromones of simple playback of a signal from a tape recorder or a computer-generated artificial signal.

Apart from recordings from the sense organs of animals, a key requirement in the identification of molecules used for chemical communication is a bioassay. This can be behavioral, such as testing whether the candidate molecules elicit the same behavior as the putative pheromone (in testing potential pig sex pheromones, for example, the bioassay could be the lordosis (back arching and presentation behavior of the female pig) given in the presence of odors of the male pig (boar). Or the bioassay could be a physiological one, such as the quantity of semen produced by a male fish after exposure to putative female sex pheromones.

Techniques for visualizing brain activity are gaining ground as tools to investigate the processing of chemical communication. Fluorescing dyes stimulated by free calcium concentrations have been used to investigate brain activity in response to odors in a variety of animals, including honeybees, salamanders, zebra fish, and salamanders. Brain imaging using functional magnetic resonance imaging or positron-emission tomography has been used by researchers investigating chemical communication in vertebrates, including humans.

Exploiting Chemical Communication for Agriculture and Medicine

The importance of chemical communication in the lives of animals offers many opportunities for applied use in agriculture, forestry, and, potentially, medicine. These uses are now well established for insect pest control, but with a few exceptions, their use with vertebrates is only just beginning.

Mating disruption of pest moths in apple orchards by the release of synthetic female sex pheromone provides successful control of codling moth *Cydia pomonella* and other important pests of fruit. The synthetic pheromones seem to prevent males' and females' finding each other, so the females' eggs are not fertilized – and no caterpillars result. Pheromones are particularly useful where pesticide resistance has developed, as has occurred for many pests of cotton. Pheromones provide a way to get off the 'pesticide treadmill,' in which farmers find they have to use additional pesticides to control previously innocuous insects which become pests when their predators are killed by the earlier rounds of pesticides. The specificity of pheromones means that very small quantities can be used and that nontarget species are not affected. Unlike pesticides, pheromones leave predators unharmed, so these methods are compatible with biological control measures.

Pest vertebrates too might be controlled by pheromones. The sea lamprey *Petromyzon marinus* has ravaged the Great Lakes fisheries in North America. Two lamprey pheromones, the male sex pheromone and the larval pheromone, are being explored to see whether they could be used to reduce lamprey populations by selective trapping or diversion. Mice and other pest rodents use pheromones for communication, and these perhaps could be used to control them.

An understanding of priming pheromones could be useful in animal husbandry to, for example, advance puberty and reduce the postpartum period in pigs, and end-seasonal anestrus in sheep. Artificial insemination requires knowledge of when estrus is about to occur – the predictive lordosis response of the female pig is more reliable if they are sprayed with synthetic male pheromone (5α-androstenone, Boar Mate). Fish priming pheromones could be used in aquaculture to replace the individual hormone injections given to male fish to stimulate sperm production before semen collection.

Pheromones can be helpful in modifying the behavior of companion animals, too. A synthetic cat cheek gland pheromone (Feliway) is used to reduce the frequency of spraying by neutered tomcats.

Pheromones may have a role to play in the future control of insect vectors of human diseases, such as the bloodsucking reduviid insects which carry Chagas disease. Nematodes, many of which cause human disease, use pheromones for communication, which might provide a route to control.

Ever since the discovery of the Bruce effect in mice, there has been interest in possible pheromone communication in humans. Humans may have pheromones, but only one effect, on menstrual synchrony, has been well demonstrated. In the distant future, this might lead to discovery of a new kind of birth control.

Conclusions

We are at an early stage in the investigation of chemical communication. Of all the senses, olfaction, because of the chemical communication it enables, is probably going to give us the most surprises in the future.

Pheromones in Humans and Social Chemosignals

M K McClintock, University of Chicago, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Pheromone Definitions

In order to summarize and evaluate the research on human pheromones, it is essential to first clarify the distinction between pheromones and social odors. A pheromone is a chemical signal; it is secreted by one individual of a species and triggers a specific behavioral, neuroendocrine, or developmental response in another individual of that same species. This means that pheromones enable one individual to affect the behavior or physiology of another, and are therefore fundamentally social chemical signals. In addition, pheromones are required only in minute amounts to produce their functional effects, typically several orders of magnitude less than is required to produce the perception of an odor. The relatively minute amount of pheromones necessary to trigger a response is an essential, but often overlooked, characteristic of these chemosignals.

Pheromones were first defined in insect species, in which their behavioral effects are dramatic. For example, the female tobacco budworm moth releases a sex attractant pheromone that is carried downwind, creating a chemical plume. This sex attractant pheromone consists of a mixture of six different kinds of molecules, and only a few molecules are needed to trigger specific neural programs in the male moth, enabling him to fly upwind in a stereotyped search pattern to find the broadcasting female. As pheromones were discovered in other species, ranging from yeast to mammals, it became clear that pheromones serve diverse functions, coordinating behavior and physiology within a social group. Human pheromones are best understood as including different types that are distinguished by the myriad functional effects they produce.

Types of Pheromones

Pheromones are defined by their function, not by their chemical identity or by the receptor or neural systems that mediate their effects. They must be vagile (i.e., capable of being dispersed) either because they are volatile, airborne, or exchanged through physical contact with another individual or a communal surface. Four functional types of pheromones have been identified among all species, of which only three are found in humans.

Releaser pheromones operate quickly on the nervous system to trigger, within seconds to minutes, relatively stereotyped behavior patterns or sets of functionally related behaviors. A mixture of androstenone and androstenol (the common terms for the 16-androstene steroids, 5α-androst-16-en-3-one and 5α-androst-16-en-3-ol) is the releaser pheromone in domestic pigs, *Sus scrofa*. The boar produces androstenone in his saliva, and by shaking his head, flings his saliva onto the sow, triggering her virtually catatonic mating stance, enabling him to mount. Indeed, androstenone is sold in aerosol cans to pig breeders. Even this steroid alone is such a prepotent stimulus that, sprayed on the snout of the sow, the compound elicits the mating stance and allows for artificial insemination.

The suggestion that pheromones could create irresistible sexual attraction may be a good marketing strategy for commercial fragrances, but it is not based on any scientific evidence. On the other hand, several less extreme effects have been demonstrated in humans.

Primer pheromones produce long-term neuroendocrine changes that regulate endocrine systems or development in the recipient. That function must define and classify pheromones, rather than their chemical identities, is clearly illustrated by androstenol and androstenone, which function as both a releaser and a primer pheromone. These androstenes in the boar's saliva accelerate puberty in the immature gilt when she is exposed to the saliva over several days. As a primer pheromone, the androstenes from the boar accelerate her fertility and eventual pregnancy.

Modulator pheromones adjust ongoing behavioral responses to a rich set of social and physical stimuli. They also regulate psychological reactions to a particular context, but without triggering specific behaviors or thoughts. As a consequence, modulator pheromones do not have a prepotent effect on behavior. Rather, they function by changing sensitivity to specific types of stimuli, including their salience, emotional valence, and sensorimotor integration. In essence, they create a context that modulates more prepotent stimuli. In rats (*Rattus norvegicus*), male pheromones increase the intensity of the female's arched-back lordosis reflex elicited when the male mounts her and palpates her flanks. In contrast to the domestic pig, however, the males' modulator pheromone alone is not sufficient to trigger the female rats' mating posture.

Signaler pheromones indicate or 'signal' to other members of the same species attributes of the sender, such as identity, emotional state, reproductive status, or genetic information. The recipient may or may not act on this information and, therefore, in contrast to

releaser and modulator pheromones, signaler pheromones have the least prepotent effect on behavior. Perhaps the best example of an unequivocal modulator pheromonal effect are airborne compounds associated with the major histocompatability complex (MHC), a cell surface protein that uniquely identifies individuals. In mice, this information can be used for mate choice, in selecting another female with which to communally nurse young, and even in determining whether a male is indeed the sire of the pups carried *in utero* by a pregnant female.

Pheromones and Odors

Many pheromones are also odors at high concentrations; they stimulate the olfactory system to create a percept. Percepts have well-characterized functions different from those of a pheromone. For example, androstenol has an odor foul enough to increase depression in people living near pig farms. Nonetheless, at the minute levels at which pheromones operate within a species, none of the four types of pheromone relies on the functional properties characteristic of odors.

Odors have specific functional properties, and the absence of these particular properties can be used to distinguish pheromones from odors. One such property is the capacity to serve as a conditioned stimulus for taste aversion. When mice are made nauseous while an arbitrary odor is paired with their food, the odor becomes a conditioned stimulus for avoiding the taste of the food. In contrast, female pheromones that elicit male mating behavior are only minimally effective as conditioned stimuli for taste aversion. In contrast to odors, pheromones produce little sensory adaptation or stimulus generalization. Behavioral responses to odorants adapt relatively quickly. Pheromonal responses take much longer to adapt, if at all. For example, a sow living next to a boar adapts to his sight and sound, but not to androstenone, his mating pheromone. This behavioral finding is consistent with recent neurophysiological evidence that neurons in the mouse vomeronasal epithelium do not adapt with prolonged exposure to a specific pheromone.

Human Primer Pheromones

Ovarian Function

Women produce ovarian pheromones that regulate the timing of the preovulatory surge of luteinizing hormone (LH) in other women. When presented daily throughout two menstrual cycles, axillary compounds from the follicular phase of the menstrual cycle shorten the follicular phase and advance the preovulatory LH surge of recipient women. In contrast, daily exposure to periovulatory compounds lengthens the follicular phase and delays the preovulatory LH surge. These compounds have no effect on the duration of menstruation, nor on the life span of the corpus luteum, indicating that they affect the neuroendocrine mechanisms of follicular development and the timing of the preovulatory LH surge.

As predicted, axillary compounds from the follicular phase are reported to accelerate the pulses of LH in recipient women, while ovulatory phase compounds slow them. The compounds that serve as ovarian pheromones have yet to be identified. One candidate for the periovulatory pheromone is 3α-androstenol (5α-androst-16-en-3α-ol). It is detectable in female axillary secretions and slows the pulsatile release of LH in women.

The key demonstration of compounds from the axillae of women is the effect on the frequency of LH pulses, the length of the follicular phase, and the timing of the preovulatory surge of LH. A computer simulation of such phase-advance and phase-delay pheromones demonstrates that under specific conditions, ovarian synchrony can develop within groups of females exchanging pheromones. Indeed, menstrual synchrony has been reported among groups of women living together under specific conditions. The conditions under which social synchronization occurs include women: (1) who are living together in small groups, (2) who are close friends, (3) who share activities, (4) who are co-workers, particularly those with high job interdependency but low stress, or (5) who are mothers and daughters.

Other potential forms of the social control of ovulation in women are asynchrony, regularization of the cycle, or changes in the rate of ovulatory cycles. In studies in which menstrual synchrony has not been observed, these other manifestations of pheromonal interactions could be operating. In addition, studies in which menstrual synchrony did not occur include groups of women: (1) who are without the opportunity to synchronize (i.e., have too few concurrent cycles that are both consecutive and ovulatory), (2) who are lesbian couples with prolonged intense contact, (3) who are members of multiple groups, or (4) who are people with particular personality traits.

Although ovarian pheromones were the first human pheromones reported, they may not have been measured in the most significant context in evolutionary terms. From an evolutionary perspective, having many consecutive ovulatory menstrual cycles is a social artifact, not a species trait. Typically, because contraception was inadequate or not practiced, women in their fertile years were less likely to have menstrual cycles than they were to have birth cycles of pregnancy and lactation. Indeed, in agrarian and hunter–gather

populations, an ovulatory menstrual cycle occurs on average no more than three times in 2 years. This is also true for most mammals with spontaneous ovulatory cycles. Therefore, pheromones likely evolved to regulate ovulation in harsher environmental contexts, helping achieve or suppress an ovulation from an infertile state. Such contexts would be the initiation of ovulatory cycles after lactational anovulation, at the end of droughts, at the beginning of reproductive senescence, and at the initiation of puberty. For example, the presence of older sisters, who are undoubtedly ovulating, is associated with delayed puberty in girls.

In other animals, signals from breeding females regulate the fertility of other females in their social group. Indeed, breast-feeding pheromones from lactating women and their infants regulate follicular development in a context-specific manner, increasing the variability of the ovarian cycle in women exposed to the breast-feeding compounds. Only trace amounts of compounds are necessary to exert their effects, and they are effective without being consciously detected as an odor in a way that is associated with ovarian responses.

Primer pheromones from men also affect the timing of ovulation. Women in an all-women college, who are simply in social proximity with men more than three times a week, have shorter and more regular cycles than do women who see men less often. Indeed, exposure to an extract of men's axillary compounds accelerates the pulse frequency of LH, a precursor to the larger surge of LH that triggers ovulation.

Modulator, Not Releaser, Pheromones

Two steroids, α4,16-androstadien-3-one (common name androstadienone) and 1,3,5,(10),16-estratetraen-3-ol (common name estratetraenol), were originally claimed to function as human releaser pheromones that stimulate specific social cognitions. Androstadienone was purported to make women feel specifically more open to social interactions and at ease. Estratetraenol was purported to stimulate self-confidence in men. Subsequent behavioral and psychological data, however, do not support these strong claims for releaser pheromones on specific kinds of social cognition, but indicate instead that these steroids are likely modulator pheromones, which adjust mood responses already being driven by particular social interactions. It should be noted, nonetheless, that continued research may reveal that these steroids are vasanas, compounds with odorlike properties, but that they function below the threshold of conscious detection.

Androstadienone affects diverse aspects of psychological state, depending on the social and psychological context of the recipient. It improves women's mood, particularly in laboratory settings that typically dampen mood (moreover, this improved mood is sustained after returning to everyday life, outside the lab). These effects are obtained with exposure to less than 9 nmol of steroid passively inhaled and verified to be undetectable as an odor, and even when also masked by the strong odor of clove. Simply waving a swab soaked in a 250 μM solution briefly below the nose is sufficient to produce enduring effects. Moreover, similar psychological effects are not produced either by a structurally similar 16-androstene steroid or by muscone, which has a similar odor. Therefore, in minute amounts, androstadienone does not depend on odor properties for its functional effects on the mood of women. But mood is not the only psychological state which androstadienone modulates in women. Women also report feeling more focused and alert when answering computerized questionnaires, and even experience more physical pain in some circumstances. In other contexts, they report feeling more sensual.

The importance of context in determining how the effects of androstadienone are psychologically manifest is particularly salient when men and women interviewers follow the same experimental protocol. When women are in a testing room with a man, which itself modulates mood, androstadienone increases positive mood after the experience; with a woman interviewer, which does not alter mood, androstadienone has no effect. Likewise, when men and women are alone, there are no demonstrable effects of the steroids.

For women, estratetraenol, the 'female' steroid produced by the placenta in pregnant women, has similar, albeit weaker, positive effects on mood, indicating that these steroids do not function simply as sex attractants. In fact, women in the late follicular phase of their menstrual cycles respond more strongly and positively to both steroids than do men. Women feel less anxiety and are less 'down' than during exposure only to the carrier solution. In contrast, men actually feel worse after exposure to the steroids in the same testing environment. This is especially true in response to estratetraenol, directly refuting the hypothesis that estratetraenol might serve as a female sex attractant for men. Indeed, when men have a woman as a tester, which prevents an increase in negative mood during the experiment, estratetraenol exacerbates their negative mood, counteracting the effect of being in the presence of a woman.

When men and women actively sniff androstadienone presented in crystalline form in amounts large enough to have an odor, as well as crystalline estratetraenol, an odorless compound, both still function as modulator pheromones. When men are saddened by a tragic film, androstadienone intensifies their sadness. In women, it has the opposite effect, both ameliorating

the women's sadness and preventing the typical drop in happiness. During an erotic film, however, androstadienone enhances sexual arousal in both men and women. At high, as at low, concentrations, the effects of estratetraenol are similar to those of androstadienone, but weaker. Neither steroid modulates mood when people watch a neutral film. Thus at both low and high concentrations, these compounds consistently modulate emotional state created by other stimuli. Even though they do increase sexual arousal and sensuality in an erotic context, they are clearly not a 'male pheromone' that affects only women and a corresponding 'female pheromone' that affects only men – similar to the sex-specific compounds evolved as releaser pheromones in insects. Note that neuroimaging of hypothalamic activity in response to androstadienone in a neutral context does not follow this pattern, indicating that its effect on sexual arousal likely involves cortical as well as subcortical mechanisms.

Androstadienone and estratetraenol also increase skin conductance, a veridical marker of sympathetic nervous system tone, because the eccrine sweat glands are innervated only by the sympathetic, and not the parasympathetic, system. The increase in sympathetic tone is more pronounced in women, particularly during the fertile phase of their menstrual cycle. In men, the effect is an increase in parasympathetic tone, indicated by warmer hands in men and colder hands in women. The effect of context on these autonomic nervous system effects will help determine whether they play a direct role in modulating psychological reactions to a situation or if they are a consequence of that change in emotional state.

Both men and women produce androstadienone from a variety of sources. The ovary produces androstadienone, as does the testis. Moreover, androstadienone levels are not correlated with testosterone production in men. Both sexes synthesize the steroid in the adrenal. Indeed, it is synthesized in the axillae of some men and women by resident coryneform bacteria, rather than being excreted by apocrine glands. In contrast, estratetraenol is known only to be produced in the third trimester of pregnancy, synthesized from androstadienone in a single step. Although some research reports the effects of 'estratetraene,' this refers to a large class of steroids. Estratetraenol is the more precise common name, indicating the ketone at the third carbon position.

Human Signaler Pheromones

The MHC is a complex, highly polymorphic protein evolved to carry molecules from inside the cell and present them at the cell surface. In the development of the immune system, the MHC and the molecules it carries select out T cell populations that recognize 'self' and would otherwise cause autoimmune disease. When the T cells bind to this complex, recognizing the cell as 'non-self,' they trigger an immunological cascade, removing the foreign cell. It was first discovered in mice that this genetically determined information about individual identity, is associated with airborne compounds that males and females use to discriminate differences of a single allele encoding the structure of the MHC. Behaviorally, this genetic information is used not only for mate choice, but also for guided paternal care, nursing, and other social choices.

Humans also have the capacity to detect and utilize such information. Married couples in an isolated religious community are less likely than random to share more than 5 out of 10 human leukocyte antigen (HLA) alleles (the human MHC), suggesting that humans may choose marriage partners based on signaling pheromones. However, now that humans have been assessed in laboratory tasks, it is clear that perception of this genetic information and choices made are determined by the pleasantness of the body scent. Therefore, the compounds are potentially functioning as odors, and are not signaling pheromones.

When women are asked which odor they would choose if they had to smell it all of the time, without knowing that they were human scents, women choose, and report as more pleasant, the scent of a male with whom they share at least one MHC allele. In a more sexualized context, women report that the scents from a male with more allelic matches are more pleasant. And, ironically, in a neutral context focused only on odor quality, women are indifferent if the scents are from donors' MHC with more matches, and are more likely to find them neither pleasant nor unpleasant. In terms of human pheromones, these data indicate that even in animals, the MHC genetic information may not be a signaling pheromone at all; rather, the genetic information may simply affect the pleasantness of a consciously perceived body scent.

Routes of Action

In principle, therefore, there are several routes by which human pheromones could exert their effects. In vertebrates, pheromones are not defined by a specialized receptor organ, and exert their effects via the main olfactory epithelium, the vomeronasal system, and absorption through skin or mucosa. However, anatomical evidence for a specialized pheromone system in humans is currently ambiguous.

Main Olfactory System

There are genes for several hundred olfactory receptors; these receptors are G-protein-coupled receptors on dendritic cells in the olfactory epithelium and they weakly bind a spectrum of odorants. In larger amounts, in which androstadienone functions as a social odor, repeated sniff-training or exposure over several weeks increases sensitivity fourfold, in contrast to the stable intensity of nonsocial odors such as amyl acetate. The time course of the sensitization and an accompanying shift in the unpleasantness of the odor indicate that there are at least two receptors that are induced by repeated exposure.

Human primer and modulator pheromones may also act via the main olfactory epithelium, as do some other mammalian pheromones. In addition to genes for main olfactory receptors, there are also genes for two other chemoreceptors that are structurally distinct. In rodents, these are also expressed in the main olfactory epithelium and have the high sensitivity and narrow specificity typical of pheromone receptors and function.

The human genes *hV1RL1–hV1RL5* are similar to rodent pheromone *V1R* receptor genes. *hV1RL1* has an intact open reading frame and is expressed in human olfactory epithelium, although the full distribution of receptor cells is not yet established. *V1R* genes have become diversified in primates, suggesting a positive selection pressure for species-specific function, even as the complexity of the primate vomeronasal organ (VNO) has diminished over evolution. In humans, however, the olfactory epithelium does not express the gene for Trp2, a cation channel protein necessary for neural signal transduction in rodent V1R neurons. Thus, if functional, the transduction from chemical to neural information must take place through another mechanism.

The second family of potential pheromone or specialized social odor receptors in the human main olfactory epithelium includes trace amine-associated receptors (TAARs), also G-protein-coupled receptors. In mice, eight classes are expressed in neurons of the main olfactory epithelium. In cell culture, neurons expressing these receptors bind amine-based pheromones and social odors. Genome sequence data indicate that humans have five members in the TAAR family. It now needs to be determined whether message for these genes will be detected in humans, and whether they bind social chemosignals with primer or modulator pheromone functions.

Finally, transepithelial absorption and humoral effects on the brain are also possible. Androstenone (5α-androst-16-en-3-one), the boar primer pheromone, can act humorally, being absorbed through the mucosa and transferred from venous blood to the arterial supply of the brain. Humans, too, can absorb steroids and other molecules through the nasal mucosa and olfactory epithelium, where such molecules enter the blood supply. Additionally, some molecules are carried through retrograde transport along the olfactory nerve to the brain.

Vomeronasal System

Humans also have a VNO along each side of the nasal septum and an associated nasopalatine duct extending from the base of the septum toward the roof of the mouth. In many vertebrates, pheromones are transported through the nasopalatine duct and bind in the VNO at V1R and V2R receptors. Neurons from the VNO then project to an accessory olfactory bulb. In humans, however, there is no evidence that the nasopalatine duct is patent, except in dysmorphologies, neither V1R nor V2R receptors are expressed in the VNO and Trp2 is absent. Likewise, no myelinated neurons have been detected leaving the VNO and adults do not have a distinct VNO accessory olfactory bulb. Finally, occlusion of the vomeronasal duct does not affect the perception of androstadienone in amounts where it is a social odor.

In the human fetus, however, the vomeronasal structures are readily apparent and have cells positive for LH releasing hormone (LHRH) and neuron-specific enolase, indicating they are olfactory receptor cells. Likewise, the human fetus has an accessory olfactory bulb detectable until 26 weeks of age, but no bulb is found at the end of gestation. Thus, many have concluded that this structure only functions to guide neurogenesis of LHRH-containing neurons in the fetus.

A comparative perspective argues that the vomeronasal structures on the nasal septum may have evolved in catarrhine monkeys and apes to serve a function different from that of the VNOs of strepsirhine primates (e.g., lemurs). Although receptors and neural tissue are missing in humans and chimpanzees, in both species the septal tube is lined with ciliated, pseudostratified columnar epithelium, which may serve a glandular secretion and transport function.

Central Nervous System

Androstadienone modulates the state of the brain without being perceived consciously as an odor, changing glucose utilization in distributed systems associated with its affects on mood and attention. When women perform a simple visual–motor task during 20 min of glucose uptake, androstadienone increases glucose utilization in the primary visual

cortices (V1), anterior thalamus, and basal ganglia. Motor systems are modulated, decreasing glucose utilization (superior parietal cortex, premotor cortex, and cerebellum). Finally, even though there is no detectable effect on the primary olfactory system, there are changes in brain regions that receive projections from the olfactory system (inferior temporal lobe, hippocampus, amygdala, hypothalamus, and thalamus).

Even when androstadienone is detectable by women as an odor, and is presented briefly to them as they lie blindfolded in a positron emission tomography (PET) scanner, it does not preferentially activate the olfactory cortical regions affected by other odors. It does, however, alter blood flow in a variety of nonolfactory cortical areas, the most consistent being inferior parts of the prefrontal cortex and the superior temporal cortex. This is the opposite effect seen with the control odors, indicating that androstadienone functions differently even at higher concentrations.

Androstadienone may be processed differently than other odorants by an as yet unidentified secondary subcortical circuit, functionally similar to the secondary visual system that processes an emotionally salient social system. In amounts large enough to be detected as an odor, cortical processing of androstadienone is 20% faster than is processing of odorants that are perceptually similar in intensity and hedonic valence. Whether this is also the case for subthreshold amounts remains an open question.

One possibility is suggested by observations in *Maccaca irus,* an Old World monkey, that there is olfactory input to the lateral hypothalamus, which is more finely tuned to specific odors than is typical of the main olfactory system. This pathway does not pass through the main olfactory areas (prepyriform–entorhinal area or the olfactory tubercle), and instead passes through the septum and nucleus accumbens.

Tantalizing support for this hypothesis comes from PET studies of men and women, both heterosexual and homosexual. Crystalline androstadienone, presented in vials as an odor and without asking individuals to do anything particular other than cooperate with the PET scan, increases oxygen utilization in the medial preoptic area of the anterior hypothalamus of both heterosexual women and homosexual men. In parallel, crystalline estratetrenol affects the paraventricular nucleus of the anterior hypothalamus of heterosexual men and homosexual women. These findings have been presented as evidence for sexual pheromones, specifically linked to sexual orientation – androstadienone linked to attraction to men and estratetrenol linked to attraction to women, putatively serving as sexual pheromones. These data, however, are not consistent with the modulating effects on mood and attention when the component is not consciously perceived as an odor. An alternative hypothesis is that these crystalline steroids function as conditioning odors during sexual interactions, and are consequences, not modulators, of sexual motivation and orientation.

Definition of Pheromone and Its Transition

The term pheromone was coined in 1959 by Peter Karlson and Martin Lüscher, who introduced the term as being

> derived from the Greek *pherin*, to transfer; *hormān*, to excite. Pheromones are defined as substances which are secreted to the outside by an individual and received by a second individual of the same species, in which they release a specific reaction, for example, a definite behavioral or a developmental process.

The introduction of this neologism was not accepted by all. HS Micklem, on reading the 1959 paper in *Nature*, responded with this letter to the editor of the journal, which published the original pheromone paper:

> Karlson and Lüscher[1] have recently proposed the term 'pheromone' for a class of substances which, while resembling hormones in some respects, cannot be included among them because they are not of an endocrine origin. It is claimed that the latter part of the proposed word is derived from the Greek *hormān* (which should properly be *hormōn*), meaning 'to excite'. This is not so. It was apparently the intention of the authors to find a term which, while being derivable from *hormān*, bore little overt resemblance to the word 'hormone'. This they achieved by the improper expedient of dropping the letter 'r', thus mutilating the root of the Greek word. It should be a principle, when a scientific term is derived from classical origins, that the term must by its structure be traceable to those origins. In the case of the word 'pheromone' that principle is not observed: there is no structural clue to its derivation from *hormān*. Indeed, the only Greek verb (apart from *pherein*) which might conceivably be involved in its ancestry means 'to swear'.

In the original definition, a pheromone was a single chemical compound or limited set of compounds that, when released by the sender and detected by the recipient (typically of the same species), would elicit a stereotypical response each and every time. Unfortunately, for most pheromonal responses, each of the components of the definition has fallen by the wayside. In insects, wherein much more is known about pheromones than for mammals, the complexity is enormous. For some responses the chemical stimulus is a bouquet, composed of a delicately balanced mixture of many compounds. In other situations, the pheromone crosses species lines. For example, the pheromone may be released by a predator which is sending out a mimic message – the sex-attractant of the female of the prey species. The male responds to the amorous message only to find itself in the jaws of its predator. In other situations, there may be considerable learning or context specificity, not at all what was in mind when the original definition was presented. Furthermore, there is considerable diversity in the type of message or response that can occur. Its origin aside, some scientists suggest that the term pheromone is redundant or too general, especially as it applies to mammals. Indeed, the word odorant, whether it has a special property, such as influencing physiological response, or providing general information, such as indicating the source of food or the appreciation of a floral fragrance, has been suggested to be fully sufficient. This argument, as usually stated, relies on the following logic: there are no unique terms in vision, audition, or somesthesia, so why use such a unique term in olfaction? Others have proposed that the definition of pheromone be limited to chemical communication wherein both sender and receiver benefit from such communication. Although logically legitimate, this restrictive definition may omit inclusion of pheromonal communication for informational purposes and may include chemical signaling that may not be pheromonal in nature. For example, mother rodents pass to offspring the safety of foods to eat by chemical signals originating in the oral cavity; the mothers eat a food, exhale into the nasal cavity of the offspring, and thereby inform them that the food is safe to eat. To this end, both sender and receiver benefit: the mother secures a safe future for her genetic investment (her genes continue to exist in the form of her offspring and, she might hope, the successors of her offspring), and the offspring learn what is safe to eat. In this context, it would be difficult to mold the odor of food into a pheromonal communication system in which both sender and receiver obtain benefits, although other aspects of this exchange appear to meet the criteria.

Among humans, pheromonal communication may exist as a language that is difficult to understand at the cognitive level. Research suggests that such information may be processed via subcortical pathways and hence may be influencing human responses much more than previously acknowledged.

Types of Pheromones and Typical Responses

The general scheme for mammalian pheromones posits odorants that have specific or selective effects on the physiology or immediate or potential outcome of behavior of recipients. In the present context, pheromone is a legitimate term. Of the four categories of pheromones in mammals, primer, releaser, signaler, and modulator, the last was described from research on humans before research on other mammals, which is an unusual outcome. Typically, research with nonhuman animals initially defines a pheromonal response, and later research extends the category to include humans.

Primer Pheromones

Primer pheromones have many effects that influence endocrine or neuroendocrine mechanisms. These include induced pregnancy failures, shifts in rates of sexual maturation, alterations in levels of circulating testosterone in males, and inhibition of or modifications to estrous and menstrual cycles in females.

Pregnancy At least in rodents (and perhaps in other mammals), primers determine the success of a pregnancy; for example, exposing a recently pregnant female mouse (within the first 5 days of 21-day gestation) to the chemical signals from a strange male mouse (a male that she hasn't yet met or mated with) results in failure of the pregnancy – the fetuses are reabsorbed and, for the female, physiology proceeds as if pregnancy did not occur. In some species of voles, this effect can be observed as late as day 18 of a 22-day gestation. Usually, pheromones from the male with whom she mated do not induce failure of pregnancy. This results from a memory trace of the male's chemical signals that is encoded within the vomeronasal system (in the accessory olfactory bulb; see below); however, the system can be manipulated. After mating, if the original male and his pheromones are removed and replaced by a novel male, the female's vomeronasal system encodes information about this second male. During the subsequent pregnancy, although he is not the impregnating male, the female's pregnancy is unaffected by exposures to this male's pheromones; however, pheromones from the impregnating male will induce pregnancy failure.

Sexual development Chemical cues from adults will influence sexual development in both males and females. In general, in a group of juvenile males in the presence of an adult (usually dominant) male, pheromones from the adult male(s) will inhibit sexual maturation of immature individuals. The inhibited males can and often do escape this inhibition once they migrate from the group to establish a territorial domain elsewhere. An analogous situation is true for females: dominant adult females inhibit the growth of reproductive potential in developing females. This has been found in New World primates – the scent-mark of a mother marmoset monkey, in the absence of her physical presence, can inhibit puberty in her daughters well past the anticipated date of its onset. It is interesting that in situations in which developing young in laboratory conditions are exposed to the chemical signals from adults of the opposite sex, puberty occurs earlier than in siblings not exposed to these chemicals. Whether this pheromonally induced early onset of puberty is a common occurrence in natural populations outside the laboratory is a topic for future research; however, there has been speculation that this phenomenon may occur in humans – young girls enter puberty earlier if they live in a household with a nonbiological father.

Hormone shifts In adulthood, pheromones are known to affect endocrine systems: exposing adult male rodents to the chemical signals from novel adult females results in a surge in luteinizing hormone (LH), as measured by changes in LH-releasing hormone (LHRH). The increase in LHRH subsequently, and quite quickly, increases the levels of circulating testosterone. Presumably, this activates sexual motivation in males and tends to facilitate reproductive behavior. In females a similar situation occurs. Pheromones from novel members of the species (including humans) can influence the pulse cycle of LHRH (as inferred by measures of LH), which may affect the onset of ovulation and/or disrupt normal cycling. Depending on the source of the chemical signals, ovulation may be advanced (by exposing the female to chemical signals from adult males or from females in the preovulatory phase of their cycle) or retarded (by exposing the female to chemical signals from other females in the postovulatory phase of their cycle). In the extreme, when females live among a group in which there is a dense population of females, estrous cycling tends to cease. Exposing a singly housed female rodent to bedding from a cage of group-housed females is sufficient to disrupt cycling. The estrous cycling can be restored by exposing the female(s) to pheromones from adult males. This apparently overrides the endocrine block induced by group housing. In some mammalian species, such as the prairie vole, females do not have an estrous cycle. To become physiologically receptive, the female must first be exposed to a male – that is, to

his pheromones – before she can mate. These chemical cues prime the reproductive axis, for instance by increasing LH, and facilitate successful mating.

Releaser Pheromones

Releaser pheromones trigger specific, often stereotypical, behavioral responses. These include, but are not limited to, selective interest in chemical signals from the opposite sex, sexual attraction, precopulatory communication between male and female (e.g., ultrasonic calling in mice), induced mating postures in females and actual mating behavior, territorial marking and sexual receptivity, intermale aggression, maternal aggression, maternal-like behavior in nulliparous females, and at least in rabbits, nipple attachment and suckling.

Investigation of sexual cues and sexual attraction In many species, pheromones will support active investigation of chemical cues from the opposite sex. For some, the mere investigation of the cues appears to provide positive reward, and a feed-forward loop is established. The reward component, at least in guinea pigs, is supported by inputs through the vomeronasal system. These sexual attractants appear to be the vanguard of myriad sexual signals, many of which may be nonpheromonal, employed to ensure successful mating; however, in some species reliance on pheromones is critical – typically, for males, the absence of pheromonal inputs precludes actual courtship and mating behaviors.

During encounters with other conspecifics, especially the initial meeting of a male and a female, much can be learned, even to the point that synthetic odorants can acquire pheromone-like properties. In one experiment, male mice were exposed to female mice to which Coty Wild Musk cologne had been applied. During this first meeting with an adult female and in all subsequent encounters with females, this group of male mice smelled the cologne in the presence of the female. In subsequent tests with the cologne, in the absence of the females, males treated the Coty Wild Musk as a natural female-associated pheromone and engaged in courtship-related behavior, viz., ultrasonic calling, in its presence. Other groups of males, not having the specific pairing of cologne with females, did not treat the cologne as a pheromone. This rapid and enduring odorant-specific associative learning becomes important when trying to understand apparently conflicting results of experiments in which mechanisms of pheromonal detection were explored.

Sexual attraction, the first pheromonal response to be described in moths, is also the most discussed among humans. A Google search with two terms, viz., 'pheromone human,' revealed over 2 million websites; most offered human pheromones for sale, primarily targeting males. These products typically claimed enhanced success at attracting females; however, caveat emptor is totally relevant (see the section titled 'Releaser pheromones' under 'Evidence for pheromones in humans').

The first mammalian pheromone to be identified chemically was from boars. Found in high concentrations in boar saliva, androstenone (5α-androst-16-en-3-one), and its alcohol derivative, androstenol (5α-androst-16-en-3-ol), when presented to sexually/physiologically receptive sows, elicits a specific postural response, that is, lordosis, from the sow. In lordosis the sow is stationary and the back is arched, allowing mating to progress. Other specific chemical compounds that are active mammalian pheromones have since been identified (see Table 1) albeit none in humans, as discussed in the section titled 'Evidence for pheromones in humans.'

Territorial marking and sexual receptivity Many animals with a home range will actively scent mark their territory, thereby providing a chemical signal of territorial occupation that transcends time. Same-species visitors to the marked territory subsequently can extract information from the chemical signals and may avoid crossing the boundary (to minimize risk of an aggressive encounter), may ignore the territorial mark altogether, or may overmark in an attempt to establish their own territory or dominance. In analogous fashion, both males and females of many species, especially those with limited mating seasons, will advertise sexual receptivity by depositing chemical signals, such as urine or glandular secretions, at discrete locations visited by the opposite sex. For example, moose bulls will dig a shallow pit with their antlers, urinate in the pit, roll in it to become immersed in their odors, and advertise their readiness to mate to receptive females. Cows also engage in such advertisement in a mating arena, urinating profusely at the perimeter of the arena and calling to elicit approach by a bull.

Aggression Both intermale aggression and maternal aggression toward intruders at the nest containing young rely on pheromonal communication. Typically, males, especially dominant males, will attack another male. Attacks often are not directed at females; however, if a female is painted with urine from a male, she often will elicit attack. Females with offspring will defend their young by engaging in maternal aggression directed at intruders. Such behavior relies on the female's recognizing the intruder, usually a male, as such. This is often accomplished through pheromones.

Table 1 Identified pheromones in mammals

Source	*Class*	*Effect*	*Chemical compound(s)*
Male mouse urine	P and R	Attracts female mice; induces estrus; stimulates intermale aggression	2-*sec*-Butyl-4,5-dihydrothiazole 2,3-dehydro-*exo*-brevicomin
Male mouse urine	P and R	Attracts female mice; induces estrus; stimulates intermale aggression	α- and β-Farnesenes
Male mouse urine	P	Accelerates female mouse onset of puberty	Isobutyl amine; isoamyl amine
Male mouse urine	P	Accelerates female mouse onset of puberty	6-Hydroxy-6-methyl-3-heptanone
Female mouse urine	P	Accelerates female mouse onset of puberty	2,5-Dimethylpyrazine
Hamster vaginal secretion	R	Attracts male conspecifics	Dimethyl sulphide
Hamster vaginal secretion	S	Signals estrus	Methyl thiobutyrate
Cat male and female urine	S	Suggested as territorial and sexual status markers	3-Mercapto-3-methyl-1-butanol, 3-mercapto-3-methylbutyl formate, 3-methyl-3-methylthio-1-butanol, and 3-methyl-3-(2 disulfanyl)-1 butanol
Milk from lactating rabbit and her ventrum	R	Seek and seize nipple	2-Methylbut-2-enal
Sebaceous glands around nipples of nursing female cat	M	Suggested as a mixture to tranquillize kittens and adult conspecifics in stress situations	Oleic acid, palmitic acid, linoleic acid, myristic acid, lauric acid, stearic acid
Sebaceous glands around nipples of nursing dog	M	Suggested to have tranquilizing effect on puppies and adult conspecifics in stress situations	Oleic acid, palmitic acid, linoleic acid, myristic acid, lauric acid, pentadenoic acid, stearic acid
Vaginal fluid of estrous female dog	R	Stimulates male sexual arousal and sexual behavior	Methyl *p*-hydroxybenzoate
Boar testis (also found in saliva and other sources)	R	Stimulates lordosis in estrous sows; stimulates oxytocin release in estrous sows; reduces agonistic behavior in piglets; induces feeding behavior in piglets	5α-Androst-16-en-3-one
Boar testis (also found in saliva and other sources)	R	Stimulates lordosis in estrous sows	5α-Androst-16-en-3α-ol; 5α-androst-16-en-3β-ol
Sow, sebaceous glands around milking sow nipples	P	Reduces agonistic behavior in piglets; induces feeding behavior in piglets	Palmitic acid, oleic acid, linoleic acid, lauric acid, myristic acid, capric acid
Ram fleece and anteorbital gland secretions	P	Stimulates secretion of LH in and emission of urine from ewes	1,2-Hexadecanediol, 1,2-octadecanediol, and (unknown) acid compound(s)
Goat, buck fleece	P	Stimulates LH secretion in female conspecifics	4-Ethyl octanoic acid derivative(s)
Asian elephant, facial temporal gland secretions, urine and breath of bulls	R	Stimulates mating-related behavior in follicular-phase female conspecifics	1,5-Dimethyl-6,8-dioxabicyclo [3.2.1] octane (frontalin)
Asian elephant, female urine	R	Stimulates sexual behavior in male conspecifics	(*Z*)-7-dodecen-1-yl-acetate
African elephant, male urine	S and P	Signals reproductive status to female conspecifics	Butanone (elevated level during premusth), acetone and 2-pentanone (elevated levels during musth), and 2-nonanone (elevated level during late-musth)
African elephant, female urine	S and P	Signals reproductive status to male conspecifics	Frontalin, *exo*-brevicomin, α-farnesene and β-farnesene

M, modulator; P, primer; R, releaser; S, signaler.
Adapted from Van den Hurk R (2007) *Intraspecific Chemical Communication in Vertebrates with Special Attention to Its Role in Reproduction*. Zeist, The Netherlands: Pheromone Information Centre.

Without the ability of the female to detect these pheromones, maternal aggression is eliminated, demonstrating the import of these chemical cues.

Other maternal behaviors and nursing At least in rats, chemical cues associated with young pups will elicit maternal-like behavior from nulliparous females. Here, too, without the ability to detect these pheromones, females do not demonstrate this maternal-like behavior.

Young pups use pheromonal cues to locate nipples on the mother. This is readily demonstrated in

rabbits. In this species, it is important for the offspring to find and secure a nipple – there is but a single daily feeding. To facilitate feeding, the ventrum of the doe and her milk contain a nipple-search pheromone. The chemical identity of this pheromone has been described (Table 1).

Signaler Pheromones

This class of pheromones is the broadest and perhaps the most controversial. Some have objected to inclusion of this class because it appears to allow virtually all forms of chemical communication. It is included here because significant information about the sender can be gleaned from chemical cues alone. Information contained in chemical cues includes, but is not limited to, identification of conspecifics; sex; age; status of health; social dominance; pregnancy; level of stress of the sender; family membership; and individual identity, as conferred by genes within the major histocompatibility complex (MHC), which is a set of >50 genes that regulates the immune system. The MHC is perhaps the most variable set of genes in mammals, having many different alleles at myriad loci. Indeed, variation is so extreme that within natural populations, no two individuals (except identical twins) are thought to have identical MHC haplotypes. This indicates that an MHC-related odor profile is unique to each individual, rendering an individual-specific odortype. Recognition of MHC type influences choice of mate; for example, mice typically will choose to mate individuals possessing an MHC type that differs from their own. Experiments have shown that subtle changes within the MHC, such as a single nucleotide polymorphism, can be detected in the respective odortypes of the donors. It is interesting that the odortypes of fetuses 'leak' into and become infused in the odortype of the pregnant female. At least under experimental control, test animals can use this information to indicate paternity of the fetus by matching the fetal signal contained in the mother's odortype to the odortype of the biological father. Perhaps this MHC-related odortype is used by females to identify their biological offspring as early as the day of birth, as illustrated by the ability of a ewe to identify her lamb by smell.

Modulator Pheromones

This class of pheromones was first introduced in 2000 by Martha McClintock on the basis of her studies of responses of humans to chemical signals from other people. It is currently unknown whether analogous pheromones exist in nonhumans; however, based on the existing literature, data suggest that similar communication exists among nonhuman mammals. The most prominent example comes from the results of experiments involving the chemical cues from animals placed in mildly stressful situations. For example, mice temporarily housed in cages whose floors can deliver mild electrical shock can alter their body odor to reflect this stressful situation, as can be measured in responses from mice exposed to the chemical signals from the stressed mice: information about the stressful situation is conveyed in chemical signals to the other animals, which will then avoid the environment associated with stress-inducing stimuli.

In addition to avoiding the location where stressed animals were situated, the recipient animals experience a rise in their cortisol levels, perhaps indicating elevated levels of stress. This perhaps represents a crossover of primer and modulator effects. Similar changes in cortisol levels have been reported in rodents after they are exposed to odors from predators. This is not to suggest that there is cross-species pheromonal communication among mammals, but rather it illustrates how multiple input pathways can affect similar responses.

Evidence for Pheromones in Humans

Primer Pheromones

Often, women who live together tend to synchronize menstrual cycles. Originally studied and described by McClintock, this phenomenon and follow-up studies describing shifts in the onset of ovulation or length of the menstrual cycle on exposure to chemical signals obtained from other women or men, or changes in LH pulsing on exposure to chemical signals from men, offer the best evidence for primer effects in humans. Experiments performed in the 1980s in the laboratory of George Preti suggested that women with irregular menstrual cycles became more regular, for example, closer to a 28-day cycle, after being exposed to chemical cues contained in collections of axillary secretions from men. Axillary secretions from other women tended to shift the menstrual cycle of recipient females in the direction of synchrony. In the McClintock lab, the ovulation-related surge in LH was advanced and the entire cycle shortened in women receiving odorant stimulation from axillary secretions derived from other women who were in the early, follicular phase of their menstrual cycle. Axillary secretions collected from the same women, but at the stage of ovulation, elicited the opposite response in recipient females. In addition to the surge in LH that is related to ovulation, LH release throughout the menstrual cycle exhibits a pulsatile characteristic, albeit at much lower levels. In follow-up work in the Preti lab, the onset of the next LH pulse occurred

more rapidly in women after they were exposed to axillary secretions from men relative to the onset of the LH pulse after exposure to a placebo.

Women who breastfeed their infants, or the infants themselves (or both the women and the infants), appear to generate yet another pheromone that influences recipient, nulliparous women. Relative to women who received placebo treatments, women with a regular sexual partner reported increased sexual desire after exposure to chemical signals collected from the breast area and axillae of lactating women; women without a sexual partner reported many more sexual fantasies.

Releaser Pheromones

As noted above, considerable emphasis has been focused on the sale of sex attractants, usually for men (although some products target women). Many of these products contain androstenone or androstenol, true pheromones, but for pigs. The first pheromone to be identified chemically was determined to be bombykol, the releaser emitted by female silkworm moths to attract males. The identity of the compound was determined by systematically reducing the number of potential candidate chemicals by repeatedly taking apart the complex mix of chemicals emitted by the female moth. By measuring odorant-induced upwind flights by male moths, the investigators were able to determine which subcomponent contained the active ingredient. In an iterative process of taking apart the subcomponents and testing the different parts in a wind tunnel, the investigators were able to identify the critical chemical. It is important to note that there is no publication in the biomedical literature that relies on such a bioassay-driven or response-driven approach to identify a human pheromone, even in its crudest form, such as axillary secretions, which contain hundreds of chemicals.

With one exception, none of the releaser effects discussed above have been implicated in human behavior. The exception is displayed by neonates. Babies will orient in the direction of a breast pad containing chemical cues from the lactating mother. Furthermore, neonates old enough to exhibit controlled movement will crawl in the direction of the breast pad, demonstrating attractant properties. The babies' respective mothers were used as a source of the pheromone, so it is not yet known whether breast odor from another lactating woman would elicit such behavior.

Signaler Pheromones

There are numerous demonstrations of these types of pheromones in humans, and some of the accounts may have overlapping underlying mechanisms. Not all purported situations can be summarized, but the well-documented examples are included.

Mothers can recognize their newborn infant by smell alone shortly after delivery (but fathers cannot). This difference may result from exposure of the mother's olfactory receptor cells to circulating odorants generated by the fetus (olfactory receptors can be activated by odorants contained in blood), which may give the mother many months of exposure during which she potentially could learn the smell of her offspring (but, as noted above, the mother's odor changes too in response to the fetus's cells and immune response).

Individuals can recognize members of their family by smell, which may be based on MHC relatedness or result from years of experience with the odor of family members. In a related discrimination, both men and women can infer underlying MHC type by sniffing clothing worn by individuals; they typically choose the donor who is least similar to the MHC type of the evaluator. It is interesting that the McClintock group members have extended these findings. They have noted that among women, preferences for MHC-related chemical cues are related to the MHC genes they inherited from their father, and they choose chemical cues from donors having some, but not all, alleles inherited from their father. These preferences also are unrelated to the MHC genotypes to which they have been exposed, via MHC-related odorants of the parents, throughout their life, but did not inherit.

Axillary odor from men and women can be discriminated, indicating that information about biological sex is contained within the axillary chemical cues. Recent findings suggest that the ability to discriminate, using the sense of smell, lies in qualitative, rather than quantitative (intensity), differences in axillary odor between men and women. Sexual orientation also influences the production of these axillary cues and how people respond to them. The chemical cues from the four sources, heterosexual men, heterosexual women, gay men, and lesbians, could be discriminated one from the other, at least by members of one or more of the four groups of evaluators. Furthermore, in two-alternative forced-choice tests, in which participants were asked to indicate which sample they preferred, the only participants to consistently choose the gay samples when they were pitted against axillary odors from the other sources were gay men; all other groups chose the alternative sample, that is, that from heterosexual males or lesbians. In the forced-choice comparison between samples from females or heterosexual males, the only group to show a preference was gay males; they uniformly rejected the samples from heterosexual males and chose samples from lesbians.

Modulator Pheromones

More data in this area exist for humans than for any other mammal. For the most part, unfortunately, only half the story has been told. If people are exposed to situations that elicit stress or happiness, body odor changes, presumably to signal the emotive component of the situation. These differences can be discriminated in olfactory-based tests administered to other people. Although few people are able to identify whether the odor originates from a stressed or from a happy person, they can tell that the samples are different. What remains to be determined is whether individuals who are exposed to the chemical signals from a target person who has an altered emotional status also show a shift in their emotional status to mirror that of the target.

In another report, the emotional status of donor males was not manipulated. Rather, chemical cues from the axillae of these donors were presented to females. The hormonal status of the females was monitored, and the participants were asked to rate their mood at selected times during the experiment. Relative to placebo exposures, the chemical cues from males induced a more relaxed and less tense status in heterosexual females, suggesting that there may be a male pheromone that modulates female mood and emotion.

Detection of Mammalian Pheromones

Within the mammalian nose reside six chemical detection subsystems (at least for non-Old World primates and with exceptions for many marine mammals). These include the following:

1. Olfaction *per se*, which receives input from millions of bipolar receptor neurons residing within the main olfactory epithelium (MOE) and projecting axons to the main olfactory bulb (MOB).
2. The vomeronasal system, which expresses bipolar receptor neurons within the tubular vomeronasal organ (VNO), projects axons to the accessory olfactory bulb, and expresses genes for molecular receptor proteins, viz., V1Rs and V2Rs. These genes differ from the large family of olfactory receptor genes (ORG) found in the olfactory epithelium.
3. The septal organ, also with bipolar receptor neurons projecting to the MOB and expressing a subset of ORGs.
4. The Grueneberg ganglion, a small collection of bipolar cells found in the nasal vestibule and projecting axons to the MOB. Many of these neurons express molecular receptors from the vomeronasal family, and some cells express molecular signatures of MOE neurons.
5. Chemesthesis, supported by afferents of the trigeminal nerve.
6. The nervus terminalis, which during fetal development gives rise to most forebrain LHRH-containing neurons that migrate from the nasal cavity to take up residence in their respective destinations.

A final possible type is indicated by the modified glomerular complex and associated necklace glomeruli located at the posterior margin of the MOB surrounding the accessory olfactory bulb. This subsystem is associated with a distinct chemical identity and appears to be activated by suckling behavior in infant rats.

With respect to detection of pheromones, there is no functional evidence to suggest involvement of the septal organ, the Grueneberg ganglion (although it is intriguing that its neurons express receptors from both the vomeronasal and olfactory systems), trigeminal afferents, or elements of the nervus terminalis; however, considerable evidence implicates both olfaction and the VNO in the detection of pheromones. It is important to note that both systems are known to respond to common, nonpheromone odorants.

Two Major Inputs

Most mammals have both olfactory and vomeronasal inputs to the central nervous system; however, the latter appears to be nonfunctional in Old World primates, including humans. This does not mean that Old World primates do not maintain pheromonal communication, as many primary publications and Internet sites suggest. The logic employed in the argument to refute pheromone communication in Old World primates relies on the false premise that pheromones are detected by the VNO and anything that activates receptors in the VNO must be a pheromone. This view held sway for nearly 2 decades, and for good reason; experiment after experiment showed that removal or destruction of the VNO eliminated responses to pheromones. Slowly, however, evidence began to emerge that the VNO was not critical for every pheromonal response. For example, sows can respond to androstenone even though their VNO is rendered nonfunctional; sheep do not need the VNO to detect their lambs; suckling rabbits do not rely on input from the VNO to respond to the doe's cues; and as noted above, sensory cells in the VNO respond to typical odorants not known to be pheromones. It is important to recall that although lacking a functional VNO, humans respond to pheromones. The accumulating evidence strongly suggests that the MOE is involved in the detection of pheromones.

Olfaction has multiple pathways as chemosensory information leaves the MOB. Some pathways may

support cognitive processing of odor whereas others, perhaps subcortical, may support pheromonal responses. Inherently, there is no a priori reason why pheromones should stimulate only neural networks that support unconscious processing of information; pheromones may have primer, releaser, signaler, or modulator effects while at the same time stimulating cognitive appreciation of the smell of the adjacent source of the pheromone. Aah, the chemistry of love.

Fear, Phobia, and Anxiety Disorder

Fears and Phobias

Fear is a normal emotion anchored in mammalian defense systems. It denotes an activated, aversive emotional state that serves to motivate attempts to cope with events that provide threats to the survival or well-being of the organism. The coping attempts are typically centered on defensive behaviors such as immobility (freezing), escape, or attack. Such defense behavior has an evolutionary origin and typically is structured according to the closeness of the threat. For example, distant threats elicit immobility (freezing), which provides camouflage and gives time for scanning the environment to evaluate the threat and potential escape routes. If the threat is closer (e.g., is interpreted as a predator preparing an attack), the likely response is flight and, if necessary, fight. These different behavioral responses are associated with different patterns of metabolically supporting autonomic and somatic activity, which may be used to index fear.

Even though basically adaptive, intense fear may sometimes interfere with normal adaptive functioning. A phobia is an excessive, involuntary, and rationally unfounded fear, which provokes maladaptive avoidance of a specific object or situation. The sufferer typically has insight into the irrationality of the fear given the objective danger involved but nonetheless is unable to voluntarily control the fear and its consequences. However, it is not the intensity or irrationality of the fear in itself that is decisive for a diagnosis of phobia. Rather it is the negative impact on the person's life by the phobic avoidance that qualifies it for the diagnosis. As long as the phobic object or situation can be successfully avoided without interfering with the goals of the individual, the fear does not provide a significant impediment to normal function. For example, an intense fear of flying may be of little consequence for an individual until he or she is offered an attractive job that requires frequent air travel. Then the fear comes in conflict with important goals, and the individual may seek professional help and be diagnosed with flight phobia. Nonetheless, there is a general, albeit not a perfect, correlation between fear intensity and avoidance. Thus, we can meaningfully talk about different thresholds for common fear, intense fear, and phobia, with many more people having strong irrational fears than those showing dysfunctional avoidance qualifying for a diagnosis of phobia.

Types of Phobias

In the fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), phobias are classified among the anxiety disorders, which also include panic disorder, posttraumatic stress disorder, generalized anxiety disorder, and obsessive–compulsive disorder. Phobias are classified into categories depending on the feared object or situation.

Specific phobias concern circumscribed objects or situations in nature (e.g., heights, water, lightening, thunder, darkness, loud noises, or sharp objects), animals, (e.g., snakes or other reptiles, worms, spiders, insects, birds, dogs, cats, or horses), blood-injection-injury (seeing blood or injured people, taking injection, or dental treatment), situations such as enclosed spaces, elevators, bridges, flying, and a miscellaneous category (e.g., fear of vomiting).

Social phobias concern social situations, typically those having an element of social evaluation, such as dating, speaking in front of a group, and meeting unknown (particularly high-ranking) people, and in general, situations involving a risk of social humiliation.

The third category, agoraphobia, is not a separate diagnostic category but is diagnosed in relation to panic disorder, primarily because the fear can be construed as primarily concerning panic attacks (fear of fear). Thus, people diagnosed with agoraphobia avoid a broad set of situations (e.g., public transports, supermarkets, bridges, tunnels, and driving on freeways) in which they lack an escape route to a safe base and, hence, would be left helplessly vulnerable in the event of be a panic attack. Accordingly, they may be able to confront the feared situations if accompanied by a trusted individual.

Phobias are prevalent mental disorders with the estimated lifetime risks in the general US population for each specific and social phobia being approximately 12%. Most cases of agoraphobia are included in the 4.7% lifetime prevalence of panic disorder, but there are also 1.4% of agoraphobia without panic disorder.

Phobic Responses

Typically, phobics are hypervigilant for their phobic stimulus and automatically scan the environment for its actual presence or signs that it may be imminent.

When avoidance fails and the feared situation has to be confronted, people with phobia show a distinct fear response. Subjectively, they report feelings of intense fright and a strong urge to get out of the situation. Behaviorally, they show signs of withdrawal and flight, as well as a facial expression of fear, and this behavioral defense mobilization recruits metabolic support by strong activation of the autonomic nervous system. For example, spider and snake phobics looking at pictures of their feared animals show cardiovascular activation in the form of quick heart rate accelerations (**Figure 1(a)**) and increases in blood pressure (**Figure 1(b)**).

When frightened, we are likely to startle to any unexpected stimulus, such as when a movie audience jumps because of a sudden noise and a dramatic cut after a suspense-building film sequence. Accordingly, people with animal phobia show startle enhancement to brief noise stimuli presented against a background of pictures of their feared animals, whereas nonphobic people tend to show an inhibition of the startle response when viewing potentially fear-relevant animals (**Figure 1(c)**).

Interestingly, phobic responses can be elicited by stimuli that are not consciously perceived. For example, if pictures of snakes or spiders are presented very briefly (15–30 ms) and are immediately followed by a masking stimulus, the perceivers are aware only of the latter. Nevertheless, people with phobia show enhanced psychophysiological responses specifically to the masked presentations of their phobic stimulus. A person with snake phobia, for example, shows an enhanced response to a masked snake but not to a masked spider (**Figure 1(d)**).

Figure 1 Responses of participants highly fearful of snakes or spiders to pictures of phobic and nonphobic content: (a) heart rate responses as changes from prestimulus level in participants selected as being highly fearful of snakes and spiders during repeated 6-s presentations of pictures of their most feared animal and or neutral control pictures; (b) blood pressure data from the same experiment; (c) difference in startle blink magnitude to brief white-noise stimuli presented at different stimulus-onset asynchronies during viewing of animal and neutral stimuli for animal fearful and control participants; (d) Skin conductance responses in participants selected to fear either snakes or spiders to masked pictures of snakes, spiders, flowers, and mushrooms. In (a), note the rapid acceleration of heart rate to the feared animals in animal fearful participants, which stand in stark contrast to the deceleration of the heart to animal stimuli in nonfearful controls; the two groups did not differ in their response to neutral pictures. In (c), note the potentiation of startle blinks to feared stimuli and the inhibition of blinks to neutral stimuli. In (d), note the elevated responses to the masked feared stimlulus. (a–c) Reproduced from Globisch J, Hamm A, Esteves F, and Öhman A (1999) Fear appears fast: Temporal course of startle reflex potentiation in animal fearful subjects. *Psychophysiology* 36: 66–75, with permission from Blackwell Publishing. (d) Reproduced from Öhman A and Soares JJF (1994) "Unconscious anxiety": Phobic responses to masked stimuli. *Journal of Abnormal Psychology* 103: 231–240, with permission from the author.

Neural Mechanisms of Fear

The neural basis of the distinct fear response shown by people with phobias when confronted with their feared object is relatively well understood. It is generated by a neural circuit centered on the amygdala, a collection of nuclei in the anterior medial temporal lobe. The central nucleus of the amygdala has efferent connections to areas in the diencephalon, midbrain, and brain stem that mediate different components of the fear response. The autonomic changes (Figures 1(a), **1(b)** and **1(d)**, for example, are controlled by pathways to the lateral hypothalamus and startle potentiation via connections between the amygdala and brain stem nuclei that control the startle reflex (Figure 1(c)). There are also pathways from the amygdala to the bed nucleus of the stria terminalis, the locus coeruleus, and the basal nucleus of the forebrain that result in the release of corticotropin-releasing hormone from the hypothalamus, activation of noradrenergic pathways, and activation of acethylcholinergic pathways, respectively. In concert, these effects activate large parts of the brain, including the cortex. Instrumental behavior (avoidance and escape), finally, is controlled by pathways to the striatum.

The amygdala receives input primarily through its lateral nucleus, which is connected to all sensory areas of the cortex as well as to the frontal lobes. In addition, there is direct input from the thalamus to the lateral amygdala, via the medial geniculate nucleus for auditory input and via a pathway through the superior colliculus and the pulvinar nucleus of the thalamus for visual input. Presumably through this direct pathway, amygdala may tune visual processing areas of the brain, such as the V1, V2, V4, and inferotemporal cortex. The lateral nucleus projects to other amygdala nuclei such as the basolateral and central nuclei. Because backward masking interrupts visual processing in the primary visual cortex, the subcortical pathway via the superior colliculi and the pulvinar may explain why masked visual stimuli can activate autonomic responses in the absence of awareness of the target stimulus (Figure 1(d)).

Early brain imaging studies of specific phobias showed strong activation of the secondary visual cortices in response to video sequences of phobic stimulation, and both activation (e.g., of the orbitofrontal cortex, anterior insula, and anterior cingulum) and deactivation (e.g., of the dorsolateral prefrontal cortex) of frontal areas but little activation of the amygdala. However, more recent studies using repeated presentations of short-duration (or masked) stimuli have consistently reported amygdala activation to phobic stimuli.

The Genetics of Phobia

The central adaptive function of fear makes it a likely product of evolutionary contingencies operating throughout mammalian evolution (roughly the last 100 My). Accordingly, both the patterns of defense behavior and its underlying neural circuitry have been evolutionarily preserved among mammals. Recent molecular work has isolated a specific gene, stathmin, which is richly expressed in the amygdala and in associated input structures of the fear network in mice and which appears to regulate both innate and learned fear.

Behavioral genetics studies of human twins provide important information about the genetic and environmental bases of the relationships within the phobias, as well as the relationships between phobias and other anxiety disorders. Studies of irrational fears and phobias in large samples of twins show that there is a common genetic factor, reflecting moderate heritability, which accounts for familial resemblance in phobias (animal, situational, blood-injection-injury, social, and agoraphobia). Specific phobias loaded more strongly than agoraphobia and social phobia in this factor. It is likely to reflect something that is common for all phobias, that is, genes coding for avoidance behavior. There are also specific factors reflecting genetic influences for each of the phobias. Although there appears to be little shared environmental influence on phobias, the data suggest that there are substantial unique environmental effects that are both general to phobias and specific to each of them.

There is substantial overlap, revealed as extensive comorbidity, between phobias and between anxiety disorders more generally. Analyses of this comorbidity across different anxiety disorders among twin pairs suggest that specific phobias reflect a unique genetic factor, whereas agoraphobia showed higher loadings in a general anxiety factor (encompassing panic disorder, generalized anxiety disorder, and posttraumatic stress disorder). Social phobia, on the other hand, had an intermediate position by showing loadings in both the specific phobia and the general anxiety factor.

Taken together the genetic findings suggest that specific phobias can be viewed as reflecting a distinct genetic factor, of which one component is shared with the other phobias, whereas another component is unique to each of the specific phobias (animal, situational and blood-injection-injury). These results suggest that specific phobias is the most typical fear disorder and probably reflects excessive activation of the amygdala fear circuit as a response to phobic stimulation.

The Evolution of Fears and Phobias

The functional nature of fear and the evidence suggesting the partly genetic origin of specific phobias imply that fear and phobias are likely to have a joint evolutionary basis. In this perspective, phobias can be viewed as prototypes of fear responses that were favored by natural selection because they provided defenses to important survival threats. These threats are likely to have a major origin in predatory pressure, which is a central force in evolution because of its direct effect on survival and procreation. Indeed, a recent theory on the forces that shaped the evolution of the primate brain gives a central role to the quintessential phobic stimulus – snakes – as an important predator and thus an evolutionary factor shaping the evolving primates. This predatory pressure integrated the expanding system for visual analysis that characterizes the primate brain with the sharpening of the fear circuitry centered on the amygdala that is a common feature of mammalian brains.

According to Lynne Isbell, predatory pressure from snakes affected primate evolution at two critical stages. First, constrictor snakes played an important role in establishing the primate order, and second, venomous snakes provided a critical pressure behind the expansion of the visual system and its integration with the fear system in the anthropoid primates (i.e., monkeys and apes).

Molecular evidence suggests that the ancestors of today's placental mammals appeared in Gondwanaland (the southern supercontinent that incorporated current South America, Africa, Madagascar, India, Australia, and Antarctica) more than 100 Ma. The early molelike mammals had to make their way in a world of reptiles. Indeed, of all the predators of primates that exist today, constrictor snakes were the first to evolve. Raptors and placental carnivores that preyed on the emerging placental mammals appeared considerably later (50–80 Ma). Thus, it is likely that the neural circuitry for defense behavior (the amygdala with associated input and output circuitry) originally was designed to deal with snakes and other reptiles rather than with attacking birds or felines. The to-become primates were, like their mammalian relatives, small and nocturnal with relatively poor vision and were dependent on olfaction for finding their way in the world.

Snakes with a very potent venom delivery system appeared in Asia or Africa about 60 Ma. An effective venom constituted a decisive step favoring snakes in the predator–prey arms race with the small primates, thus putting the burden on the latter to come up with more effective defenses. Venomous snakes are often camouflaged and difficult to detect, concealed in vegetation on the ground or in trees while waiting for prey, and their venom remained a threat even for animals too large to be prey. This put a strong and continuing premium on a visual system that rapidly could detect and activate defense to partly hidden snakes.

Interestingly, Madagascar was already separate from Africa (and Asia of course) when venomous snakes evolved. Consistent with the notion that the threat provided by venomous snakes played a critical role in stimulating primate evolution, all African anthropoids uniformly show fear of snakes, whereas the only the primates of Madagascar, the lemurs, do not. Venomous snakes migrated into South America from the north perhaps as late as 3 Ma with the formation of the Panama-bridge, whereas primates reached South America earlier, presumably directly from Africa. Accordingly, the New World monkeys appear to be more variable in their reaction to snakes than the Old World monkeys.

During the Eocene (roughly 55–35 Ma) the predation pressure from venomous snakes modified the primate visual system that provided input to the fear circuit centered on the amygdala. Because snakes are hard to detect, there was a development of greater orbital convergence, allowing better short-range stereopsis, particularly in the lower visual field. The koniocellular pathway from the retina was further developed to connect the superior colliculus with the dorsal pulvinar nucleus of the thalamus in assisting visual attention and, particularly, the preattentive detection of snakes and other fear-relevant stimuli. Furthermore, it assisted the parvocellular pathways to the lateral geneculate nucleus in allowing trichromacy and superb foveal vision, which may have served to facilitate detection and awareness of snakes on the ground or hidden in foliage. Higher-order visual areas such as parietal cortex and superior temporal sulcus, as well as the dorsolateral prefrontal cortex, also expanded for the same reason.

In addition, the increased reliance on sophisticated vision resulted in olfaction becoming less important and a shift from nocturnality to diurnality. These developments continued into the Oligocene (35–25 Ma) for the Old World anthropoids, but was disrupted for the New World anthropoids who presumably radiated through South America in the absence of venomous snakes. As a consequence, New World monkeys not only show more variable snake fear but they also have more variable visual systems. Thus, in addition to articulating decisive stages in primate evolution, Isbell's theory explains differences in the brains of different primates such as lemurs and Old and New World monkeys in terms of differential exposure to venomous snakes.

The brain that emerged from these evolutionary contingencies had much more cortex than that of nonprimate mammals, most of it devoted to vision.

Furthermore, the refined visual systems were integrated with the amygdala and its associated defense circuitry to the extent that cortical processing of visual input was tuned by the amygdala. Whereas snakes served as the most important evolutionary vehicle, the resulting changes were useful for discovering and defending against more diverse threats. Effective attention deployment and astute perceptual mechanisms, partly relying on rapid subcortical mechanisms, played key roles in the quick identification of threats, which permitted early defense mobilization and provided an adaptive edge in many situations. When anthropoids developed an extended social life, these defense mechanisms could be moved into the social arena, promoting vigilance for subtle social cues when coping with social contingencies and conflicts, a scenario that may help explain the important role of the amygdala in contemporary social neuroscience.

The Role of Learning in the Development of Phobias

The evolutionary scenario gives a perspective on how brain systems behind phobias evolved, and it implies a necessary role for genes in the development of phobias. But whether genes are not only necessary but also sufficient to account for phobias is a contentious issue. Some investigators argue that phobias originate from innate fears, reflecting an unhappy combination of alleles that are sufficient to produce intense fear and avoidance of particular objects or situations. Indeed, many phobias concern evolutionarily relevant dangerous situations, such as snakes, heights, and being confined in closed spaces. Furthermore, there are developmental fears shown by most children at particular ages, such as separation fears, stranger fears, and fears of loud noises and darkness. But it remains difficult to claim that all varieties of phobic objects or situations have their origin in evolutionary contingencies. Phobias are seen to a large and diverse, but still restricted, set of situations focused on potential threat in an evolutionary rather than contemporary perspective. The evidence for the innate view is primarily negative, reflecting the frequent failures of individuals diagnosed with different phobias to recall specific learning episodes as the start of their fear. The recall failures are hardly surprising given that most specific phobias start in early childhood.

Pavlovian Fear Conditioning as a Paradigm for the Acquisition of Phobias

There is a long tradition of understanding phobias as learned through Pavlovian fear conditioning, in which a stimulus that is in itself relatively innocuous (the conditioned stimulus (CS)) comes to signal the occurrence of a threatening stimulus (the unconditioned stimulus (US)). By associating cue to consequence, organisms may prepare themselves for the consequences by recruiting defense behavior in anticipation of the US (e.g., an attacking predator). Thus, Pavlovian fear conditioning favors prey animals in the evolutionary arms race between predator and prey, making this learning process a ubiquitous phenomenon in animal life that emerged early in evolution.

A fear-conditioning perspective on phobias proposes that a phobic stimulus acquires its fear-eliciting potency by association with other dangerous or traumatic events. For example, a dog phobia may have its origin in a childhood dog attack. However, there are several problems with this account. First, it does not explain the relative selectivity of phobias. Furthermore, it implies that phobias should primarily be seen as being to objects and situations that are threatening in a contemporary, rather than an evolutionary, perspective. Second, not all dog phobics recall being attacked by a dog, nor do members of their family. Therefore, direct Pavlovian conditioning may not be the only route to phobia. Other possibilities included observational learning (the dog phobic may have witnessed another person being attacked by a dog, in which case the fear evoked by witnessing this events may become conditioned to dogs) or verbal conditioning (e.g., from admonitions about the dangers of dogs from anxious parents).

The neural basis of fear conditioning is relatively well understood. Basically, the associative link between the CS and the US is formed in the lateral nucleus of the amygdala by *N*-methyl-D-aspartate (NMDA)-mediated potentiation of glutaminergic synaptic connections in a convergence zone of CS and US pathways from the thalamus. In this way, the CS may gain access to some of the US efference to elicit a plethora of fear-related changes mediated by the central nucleus of the amygdala, which is often seen in individuals diagnosed with phobia.

Evolutionary Influences on Pavlovian Fear Conditioning

In the natural environment, it is not any sound or smell that is likely to warn a potential prey of a lurking predator, but sound or smells produced or emitted by the predator itself. Such systematic ecological relationships between the CS and the US could be used by evolution to facilitate fear conditioning to stimuli that have provided recurrent threats in mammalian evolutionary history. Thus, the product of the evolutionary processes already discussed need not necessarily be an innate snake fear; it could be an evolved predisposition to very easily associate fear with snakes and similar threats.

This hypothesis has been confirmed by Susan Mineka and co-workers. Initially they demonstrated that wild-reared rhesus macaques at the Wisconsin Primate Research Center all showed a strong fear of snakes. Lab-reared monkeys, however, did not show snake fear until they were given the opportunity to observe a model wild-reared monkey exhibiting fear to a snake or a snakelike stimulus. For example, different groups of monkeys were exposed to videotapes in which a model monkey exhibited identical (through video splicing) fear responses either to a snake or to a flower. Only animals who had seen the model's fear response ostensibly elicited by snakes showed fear when subsequently exposed to a real snake. In contrast, seeing the same fear response ostensibly elicited by a flower did not produce a fear of flowers. Similar data have been provided from an extensive series of human conditioning studies by Öhman and co-workers. They also demonstrated that fear can be conditioned to masked stimuli, provided that the stimuli are fear-relevant (snakes or angry faces), which may help to explain failures to remember the onset of phobic fear, as well as the more general dissociation between fear and cognition in phobia.

These demonstrations suggest that evolution, rather than programming innate fears to specific stimuli, has generated predispositions to easily associate fear and avoidance to stimuli that are fear-relevant from an evolutionary perspective. Thus, not only are snakes the prototypical phobic stimulus, but phobias result from conditioning to a large but nonrandom set of situations that have in common that they involve some degree of threat (or, in some cases, a lack of escape route), and more from an evolutionary than a contemporary perspective.

Extinction and Exposure Treatment of Phobias

Pavlovian-conditioned fear responses wane if the CS is repeatedly presented in the absence of the US. This phenomenon is referred to as extinction. Conditioning and extinction are separate processes. In fact, the effect of evolutionarily prepared stimuli such as snakes or angry faces in humans typically is more evident in elevated resistance to extinction than in rapid conditioning. Thus, what makes phobia qualify as pathology is the persistence of the conditioned fear. Whereas normal conditioned fear is likely to extinguish though natural encounters with the CS, phobias resist such random exposures, perhaps because scrupulous avoidance of the phobic stimulus protects the fear from extinction.

However, once people with phobias can be persuaded and coached to confront their feared object or situation, the fear most often subsides. It is possible to treat specific phobias with accessible phobic objects (e.g., small animals or injections) in one intense sessions in which the therapist models, goads, and supports the patient to systematically approach the phobic object until it can be touched and handled. Indeed, there is an extensive research literature supporting the efficacy of different forms of exposure therapies for all types of phobias.

Photolysis of Caged Glutamate for Use in the CNS

G C R Ellis-Davies, Drexel University College of Medicine, Philadelphia, PA, USA

Introduction

Caged glutamate is proving an invaluable photochemical tool for neuroscientists. Neurotransmission at central synapses is extremely fast (~10 ms), so rapid solution changes in intact preparations, such as acutely isolated brain slices, are clearly impractical. Thus, the application of a biologically inert, photolabile pro-glutamate (i.e., caged glutamate) to living cells gives neuroscientists the ability to produce a step increase in glutamate concentration that has a similar time course to the release of glutamate by secretion from a single vesicle into the synaptic cleft (as judged by a comparison of spontaneous miniature excitatory postsynaptic current (mEPSC) with evoked EPSCs in cultured hippocampal neurons). In this article, we outline (1) the design criteria for development of these probes, (2) the structures and mechanistic properties of each of the different chromophores that has been used for caging, and (3) the thermal stability and photochemical properties of all caged glutamates.

Design Criteria

There are four important design criteria for the development of any caged neurotransmitter: (1) it must be very stable at neutral pH, (2) it must be efficiently photolyzed on irradiation, (3) it must release glutamate quickly, and (4) it must be inert before photolysis. Thermal stability of the caged glutamate is an important property because it is known that α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) receptors in the central nervous system (CNS) rapidly desensitize. If a 10 mM solution of caged glutamate is applied to a living cell which has as little as 0.5% free glutamate due to spontaneous hydrolysis, then 50 μM free glutamate is present. Caged compounds must be photolyzed with light of wavelength greater than 300 nm because DNA and proteins absorb light in the ultraviolet (UV). Further, if uncaging is effected through the microscope objective, then the caging chromophore should absorb light (the extinction coefficient) efficiently at 340–350 nm because lenses (and other microscope glass) are opaque below this range (some microscope have the rare quartz optics that passes light at 300 nm). If two-photon excitation from a mode-locked Ti:sapphire laser is used for uncaging, then 720-nm light is typically used, leaving longer wavelengths for two-photon fluorescence microscopy (800–950 nm range). The absorbed light must be also used efficiently by the photolytic process (this is the quantum yield for uncaging), otherwise phototoxic doses of light are required to release sufficient glutamate to stimulate receptors. Finally, the caged glutamate must be inert before photolysis. This last criterion is always considered to mean biologically inert, but it ought also to mean fluorescently inert. The prevalent use of fluorescent Ca probes and green fluorescent protein (GFP) technology in neuroscience places an additional design constraint on the caging chromophore; ideally the caged glutamate ought not to be fluorescent in the visible range.

Structures and Mechanistic Properties of Glutamate Caging Chromophores

Sixteen different caged glutamate molecules have been synthesized. The structures and acronyms are shown in Figure 1. Four different classes of chromophores are illustrated: (1) nitroaromatic (CNB-glu, *N*-Nmoc-glu, Noc-glu, DMCNB-glu, DMNPE-glu, DMNB-glu, MNI-glu, NI-glu, MDNI-glu, and antMNI-glu-glu), (2) coumarin (Bhc-glu and DEAC-glu), (3) quinoline (BHQ-glu), and (4) phenacetyl (pHP).

In terms of the photochemical mechanism of uncaging, these chromophores may be grouped into two simple categories: those that use photosolvolysis mechanisms for glutamate release and those that use intramolecular photoredox reactions. All the nitroaromatic-caged glutamates use some type of the latter mechanism for glutamate uncaging, whereas coumarins, quinolines, and phenacetyl caged glutamates used photochemical hydrolysis mechanisms. It must be noted, in the case of Bhc-glu, Noc-glu, and *N*-Nmoc-glu, that photolysis does not directly release glutamate. A second, pro-glutamate carbamate derivative is photoreleased by these three probes, which must undergo thermal aqueous hydrolysis of the carbamate bond (i.e., loss of CO_2) to yield the amino acid. (A detailed discussion of these mechanisms is beyond the scope of this review.)

Aqueous Stability and Purity of Caged Glutamates

Glutamate has been caged at all three of its functionalities (Figure 1). The two carboxylates have been caged as esters (Figure 1, top row). Such esters are inherently unstable to aqueous hydrolysis. CNB-glu

Figure 1 Continued

was the first really useful caged glutamate because it is uncaged quickly and quite efficiently with UV light and it is stable enough at physiological pH to make its use practical on a day-to-day basis. It has been reported that after 2 days at room temperature (RT) only 2% of CNB-glu hydrolyses, and frozen solutions must be quite stable. In contrast, we have found that physiological solutions of DMCNB-glu are so unstable that they are useful only for 20 min before too much free glutamate arises. BHQ-glu is so highly labile (half-life of only 14 h) that the holding current of CA1 neuron in brain slices changed so quickly as to make its use completely impractical. DEAC-glu and pHP-glu are similarly fragile. The amino group of glutamate has been caged in two ways (Figure 1, middle row), either directly as an amine (DMNB-glu and *N*-CNB-glu) or via a carbamate linkage (Noc-glu, Bhc-glu, and *N*-Nmoc-glu). All these cages are completely stable at pH 7.4. Finally, glutamate has been caged via an acylindolinyl bond (Figure 1, bottom row). We have found that solutions of MNI-glu stored at 4 °C for 13 days reveal only 1% hydrolysis, and the dinitro derivative reveal 7%. Frozen solutions of these cages are extremely stable. NI-glu has a half-life of 29 h at 30 °C. The stability of antMNI-glu has not been reported (but it must also be very stable) (see Table 1).

We examined the purity of commercial MNI-glu (from Tocris) and CNB-glu (from Molecular Probes) by high-performance liquid chromatography (HPLC) because most neuroscientists purchase these caged compounds. We found that MNI-glu was 100% pure; there was only one peak in the HPLC trace (254 and 350 nm). In contrast, CNB-glu from Molecular Probes was approximately 98% pure and had one prominent impurity in the chromatogram. Several colleagues have told us that they find batches of MNI-glu from Tocris quite toxic to cells, whereas others have used the commercial compound with considerable success. Our HPLC does not detect free glutamate (the most likely impurity) because there is no useful chromophore in the pure amino acid.

Photochemical Properties of Caged Glutamates

The introduction of CNB-glu in 1994 was a revolution for neuroscience. The cage was not only stable enough for practical use on cultured and acutely isolated neurons, but it had adequate photochemical properties for effective UV photolysis, namely, decent photochemical efficiency (i.e., $\varepsilon.\phi = 75$), accompanied by rapid photolysis (half-time of release of 25 μs). One substantial drawback of CNB-glu is that it is not uncaged by two-photon excitation. An apparent dramatic solution to this deficiency was provided in 1999 by the development of Bhc-glu. This bromocoumarin has a large two-photon cross section (~1000-fold larger than CNB-glu). However, a downside of the complete aqueous stability of the carbamate linkage is the very slow rate of release of glutamate after photolysis of Bhc-glu. This rate ($140\,s^{-1}$, or a half-time of 7 ms) makes highly localized two-photon uncaging impossible because the residence time in the focal volume is a mere 300 μs.

We tested DMCNB-glu, DEAC-glu, and BHQ-glu as possible solutions to this deficiency. As expected, DMCNB-glu did undergo efficient two-photon photolysis (Figure 2); however, as already noted, it is too unstable in aqueous solution for long-term

In (a), rapid, diffraction-limited currents similar to spontaneous mEPSCs are produced when the laser is focused on the synapse (current B). mEPSC, miniature excitatory postsynaptic current.

experiments in brain slices. The BHQ chromophore has a large two-photon cross section; however, to our disappointment, we found that BHQ-glu (0.5 mM) was not only highly unstable in aqueous solution but was also brightly fluorescent at both 720 and 900 nm in artificial cerebrospinal fluid (aCSF) when applied to the slice on the stage of our dual two-photon microscope. In fact, BHQ-glu was sufficiently fluorescent at 900 nm to obscure imaging enhanced GFP (eGFP)-labeled CA1 neurons in the slice culture. Bhc-glu was reported to be quite fluorescent, and DEAC is even more fluorescent than either of these chromophores. These difficulties highlight an important property that is normally overlooked in lists of design specifications of ideal caged compounds, namely that they must be nonfluorescent. Uncaging at single synapses in brain slices *in vitro* has to be at visually identified synapses. IR-DIC optics is used for this purpose, but it is almost always accompanied by fluorescent imaging (of GFP or Ca^{2+} dyes such as fluo-4). Caged glutamate is applied at very high concentrations to brain slices (~2–10 mM), so even moderately fluorescent cages (such as BHQ) can completely swamp any analytical fluorescent signal. Nitroaromatic caged compounds are nonfluorescent and have been widely used in conjunction with all possible fluorescent probes (fura-2, fluo-3, GFP, yellow fluorescent protein (YFP), cyan fluorescent protein (CFP), rhod-2, paGFP, DsRed, etc.) without any interference.

Acylnitroindolinyl-caged glutamates (**Figure 1**, bottom row) represent the best compromise currently in terms of their combination of properties. These molecules are stable enough at neutral pH for long-term experiments. Glutamate is released with excellent photochemical efficiently (i.e., $\varepsilon.\phi$ in the range of 110–4000 at 350 nm). We examined the rate of decay of the aci-nitro intermediate that has been shown to be part of the bond-breaking reaction for nitroinodlinyl-caged acids. Wan and co-workers have made a detailed kinetic study of MNI-acetate as a model compound for MNI-caged acids. They found that acetic acid is released with a rate of $5 \times 10^6\,s^{-1}$. We found that the corresponding rate for MNI-glu was $3 \times 10^5\,s^{-1}$ at pH 7.4. Significantly, NI-glu, MNI-glu, and MDNI-glu are nonfluorescent and so do not interfere with widely used probes such as GFP (the benzophenone moiety of antMNI-glu will not be fluorescent but is probably mildly phosphorescent). Finally, MNI-glu is reasonably sensitive to two-photon excitation and has been widely used to stimulate synaptic transmission at single spine heads in brain slices.

Thus, the acylnitroindolinyl caged glutamates represent the state of the art in caged glutamate probes. These caged compounds are very stable at pH 7.4, and they uncage quickly and efficiently on UV illumination. MNI-glu undergoes useful two-photon excitation that enables neuroscientists to produce three-dimensionally diffraction-limited puncta of glutamate release on the same scale as single spine heads in the CNS.

Photoperiodic Regulation of Reproductive Cycles

E Bittman, University of Massachusetts, Amherst, MA, USA

Introduction

In late February of 1921, Otto Loewi awoke from a dream in which he had imagined a way to test the idea that a chemical signal is released from the vagus nerve. He quickly collected evidence that upon electrical stimulation, a 'vagusstoff' is released that slows the beating of the frog heart. By 20 March, 1921, Loewi had submitted his manuscript to *Pflugers Archiv* and it was soon published. Others were unable to replicate Loewi's finding, however, and the ensuing controversy contributed to a drawn-out debate that delayed acceptance of the principle of chemical neurotransmission for several decades. Only much later did it become apparent that the time of year at which Loewi performed his famous experiment was critical to its success. Seasonal changes in the activity of acetylcholinesterase, and in the concentration of muscarinic receptors, make the effects of vagal stimulation far more difficult to demonstrate after the end of winter.

Many behavioral and physiological functions of animals of the temperate zone exhibit profound seasonal rhythms. Of all phases of the reproductive cycle, it is the care of the young that imposes the greatest energetic demands upon parental species. The young are typically born in the spring, and fertile matings are scheduled accordingly. This is not surprising, given the striking environmental fluctuations that exact a heavy toll on individuals who time their efforts inappropriately. Matching of the timing of reproduction to the annual phase of maximal availability and minimal expenditure of calories (i.e., the abundance of food and warmer temperatures) is thus of great selective advantage. Although fluctuations in temperature and rainfall can acutely influence reproduction, daylength provides a particularly stable and reliable predictor of future energetic demands that enables animals to initiate long-term adjustments. Thus we can readily understand why photoperiod acts as a proximate regulator of neuroendocrine function in seasonal species. In birds, the length of the incubation period dictates that eggs are laid and hatching occurs in the lengthening photoperiods of spring. Similarly, mammals with short gestation periods, such as rodents, are typically stimulated to reproduce by long days. Short days induce reproduction in ungulates, which gestate their young for approximately 6 months. In some species of bats and kangaroos and in some mustelids, mating occurs many months well in advance of implantation. In such cases seasonal cues including photoperiod terminate embryonic diapause at the appropriate time so that young are born in the spring.

Photoperiodic signals also regulate metabolism, growth, and development in a wide variety of plants, invertebrates, and vertebrates. Both annual rhythms in human birth rates and the incidence of seasonal affective disorders indicate the significance of photoperiodism in human health and disease. This article focuses on the mechanisms by which daylength influences reproduction in higher vertebrates, with the predominant emphasis on mammals.

Circadian-Based Photoperiodic Time Measurement

Many physiological events and behaviors exhibit daily periodicity even when animals are maintained in constant conditions. An endogenous circadian oscillator ensures that incompatible processes occur at different times, and that metabolic, thermoregulatory, osmoregulatory, immune, and reproductive functions and arousal are properly scheduled to meet environmental challenges. It was the remarkable insight of Erwin Bünning, one of the pioneers of the study of such rhythms, that a circadian oscillator can be used to measure photoperiod. Bünning imagined that a particular phase of a circadian oscillation might coincide with light only during the long days of summer. Photoperiods of sufficient length would thus trigger seasonally appropriate physiological events. Support for this general model of circadian-based photoperiodic time measurement was first achieved through application of protocols in which long nights were interrupted by brief pulses of light. Although it was found that the effects of long days on reproduction, flowering, diapause, etc. could be mimicked by such regimes, the results are equally consistent with the operation of an hourglass-like timer, with measurement of uninterrupted dark intervals being initiated at dusk. Full validation of the competing hypothesis, that a self-sustaining circadian oscillator underlies photoperiodic responses, awaited the application of 'resonance' experiments. In the most powerful of these designs (**Figure 1(a)**), light is presented to the organism only every second or third circadian cycle. Only a system with the capacity to begin a second or third cycle in constant darkness – that is, to free run – will experience photoinduction when

Figure 1 Experimental evidence for circadian-based photoperiodic time measurement and hypothetical models illustrating coincidence models. (a) Top, light regimens to which white crowned sparrows were exposed in a classic experiment by Follett, Mattocks, and Farner. Birds were maintained in short days (8L:16D), which inhibit reproduction, for many weeks. The last 8 h light phase of this regime is illustrated; different treatment groups are represented by horizontal lines. Groups of birds were transferred to constant darkness (black shading) which was interrupted after various intervals by an 8 h light pulse (white bars). This experiment takes advantage of the fact that reproductive induction in this species, as marked by LH secretion, occurs rapidly upon exposure to the first long day. Blood samples were collected a few hours after presentation of the 8 h light pulse. Bottom, mean serum LH response in groups of sparrows exposed to the corresponding light regimes. Note that both the peaks and nadirs of induction are observed when light pulses fall at circadian (near-24 h) intervals after the last day of the 8L:16D regimen. (b) An external coincidence model can explain the experimental results. A hypothetical rhythm of sensitivity to light is shown by the sinusoidal line. When animals are exposed to short days, the sensitive phase coincides with darkness. After transfer to summer daylengths (16L:8D, middle), part of the sensitive phase is struck by light and partial induction of the seasonal response occurs. In very long days (2L:22D, bottom), nearly the entire photosensitive phase is illuminated, and maximal reproductive induction occurs. (c) An internal coincidence model can explain the same data. It is hypothesized that two circadian oscillations participate, one of which (a) is entrained to dusk and the other of which (b) is entrained to dawn. These might be rhythms of enzyme and substrate controlling a critical process such as gonadotropin secretion. The phase relationship (ϕ) depends upon the length of the night. Only during exposure to summer daylengths does reproductive induction occur.

light is presented at the appropriate phase (during the portion of the endogenous daily cycle which normally takes place 12 or more hours after dawn, i.e., the subjective night).

In Bünning's original model, the coincidence or misalignment of an external event (light) with an internal event (the photosensitive phase of a circadian oscillation) determines whether a long- or short-day response occurs (Figure 1(b)). Light has powerful effects on the entrainment of circadian oscillators, however, and it was soon realized that a multitude of such endogenous clocks reside in multicellular organisms. Others envisioned that the phase of some of these oscillations might be set by dawn, and that of others by dusk. The hypothesis was advanced that as daylength changes through the course of the year, the phase relationship between two or more circadian oscillations might vary. At some times of year, the phase relationship would invoke a summer, and others a winter, physiological state. Such 'internal coincidence' models (Figure 1(c)) are fully consonant with Bünning's hypothesis and the results of resonance experiments.

Encoding the Photoperiodic Message

Understanding of molecular and neuroanatomical bases of circadian pacemakers provides critical insight into seasonal responses. Destruction of the suprachiasmatic nucleus (SCN) of the hypothalamus eliminates not only endogenous daily behavioral rhythms in mammals, but also the estrous cycle and circadian rhythms of pineal, pituitary, and adrenal secretion. Transplantation of fetal SCN to hamsters made arrhythmic by SCN lesions reinstates behavioral rhythms, the period of which matches that of the donor. Furthermore, transplantation of wild-type SCN to arrhythmic knockout mice (i.e., strains that are genetically engineered to be incapable of generating behavioral oscillations) instates locomotor rhythmicity. Thus the SCN must function as a master

oscillator: it is necessary and sufficient for behavioral circadian rhythms.

The SCN is critical to annual rhythms as well. Animals made arrhythmic by ablation of the SCN are unable to use daylength cues to schedule reproduction. Retinal projections to the SCN set the phase of (entrain) circadian rhythms, and photoperiod determines the length of the subjective day. Thus the photoperiod sculpts the discharge pattern of SCN neurons in hamsters (Figure 2(a)) and sets the duration, amplitude, and peak phase of SCN multiunit activity in rats. In addition, daylength sets the duration over which light signals can activate SCN neurons, as indicated by *c-fos* expression.

Just as discovery of the neuroanatomical locus of the circadian pacemaker provided insight into structures that govern photoperiodic responses, research into the molecular biology of circadian oscillations revealed biochemical processes that may underlie physiological responses to daylength. Some of the resulting models resemble internal coincidence schemes suggested by Bünning's hypothesis.

Figure 2 Photoperiod regulates electrophysiological and molecular functions of the SCN, which contains the master circadian pacemaker. (a) Duration of peak multiple unit activity in SCN slices prepared from Syrian hamsters which had been exposed to short (8L:16D), intermediate (12L:12D), or long (14L:10D) daylengths prior to sacrifice. The phase of peak activity in each experimental slice is indicated by small circles and the angle reflects the interval over which spike frequency is elevated. (b) Expression of *Per 2* and *Cry 2* in the SCN of Siberian hamsters exposed to short (open circles) or long (closed circles) daylengths as determined by *in situ* hyridization. Bars below abscissa indicate lighting regime. In short days, *Per 2* mRNA shows a sharper but briefer peak. Expression of *Cry 2* appears little affected by photoperiod. The protein products of *Per 2* and *Cry 2* dimerize to comprise the negative limb of a transcriptional–translational feedback loop that governs circadian oscillations.

Transcriptional–translational feedback loops form the basis of circadian oscillations. The negative arm of the central feedback loop that generates these rhythms is composed of dimers of the protein products of *Period* and *Cryptochrome* genes. *Per1*, *Per2*, *Cry1*, and *Cry2* are expressed in the SCN during the light period when animals are exposed to light:dark (LD) cycles, and during the subjective day when they free-run in constant darkness. The genes *Bmal1* (also known as *Mop3*) and *Clock* are also necessary for the persistence of circadian rhythms, and together their protein products dimerize to comprise the positive limb of the core feedback loop. *Bmal1* also shows a circadian pattern of expression, but its transcription in the SCN occurs during the night. The CLOCK:BMAL1 dimer acts as a positive regulator of *Per* and *Cry* transcription through its binding to E-box enhancers; PER:CRY dimers complete the loop by blocking this drive on *Per* and *Cry* transcription. The model is more complicated in at least two respects. First, PER:CRY inhibits and CLOCK:BMAL1 stimulates the transcription of *Rev-erb* α and RORα, the protein products of which inhibit and stimulate, respectively, *Bmal1* transcription. This constitutes yet an additional feedback loop within the molecular oscillator. Second, the protein products of *Bmal1*, *Cry 1* and *2*, *Per 1* and *2*, and *Clock* all serve as substrates for casein kinase 1ε. The phosphorylation of members of the protein complex determines their stability and nuclear translocation, and thus the period of the circadian oscillator.

In summary, photoperiod regulates the relative amplitudes, durations, and phases of transcription of clock genes, the interactions of which define the operation of the core circadian loops in the SCN.

Efferent projections of the SCN apprise other brain areas of photoperiod and may directly or indirectly trigger seasonal changes in physiological functions. In mammals, photoperiodically driven reproductive cycles cease upon removal of the pineal gland. Synthesis and secretion of melatonin (*N*-acetyl-5-methoxytryptamine; MEL), the principal secretory product of the pineal, is inhibited during the day through a pathway that begins with the circadian pacemaker. Principally through its GABAergic (γ-aminobutyric acid; GABA) projection to the paraventricular nucleus (PVN) of the hypothalamus, but also through glutamatergic, vasopressinergic, and VIPergic (vasoactive intestinal peptide; VIP) input during the night, the SCN controls the pineal's rhythmic secretion of MEL. Descending projections of the PVN regulate the sympathetic preganglionics in the intermediolateral cell column of the spinal cord, which in turn control the superior cervical ganglion. Ganglionic fibers provide noradrenergic input to the pinealocytes which determines the activity of *N*-acetyltransferase (NAT), the rate-limiting enzyme in melatonin synthesis. Co-released peptides and inputs to the pineal from the habenular complex may also modulate melatonin production. The activity of NAT seems principally to rely on transcriptional regulation in rodents, but upon posttranslational mechanisms in sheep and monkeys.

The duration of nightly MEL secretion depends upon daylength, reflecting photoperiodic regulation of transcriptional–translational feedback loops in the SCN pacemaker. This durational MEL signal in turn conveys information about photoperiod to the reproductive neuroendocrine axis: infusions of MEL in patterns typical of photoperiods that prevail during the breeding or nonbreeding season stimulate or inhibit reproduction in pinealectomized animals, respectively (**Figure 3(c)**). The duration of the MEL signal appears more important than its phase, and the ability of the target system to measure the length of the nightly MEL rise appears not to depend upon a circadian timer. Remarkably, the critical daylength for stimulation or inhibition of reproduction may depend upon the animal's photoperiodic history, and may even be communicated from mother to fetus through mechanisms that are not yet understood. Elucidation of this MEL duration measurement system requires description of MEL receptors and their coupling to intracellular signaling pathways.

The situation is different in birds. Although the avian pineal is sympathetically innervated, it is directly photoresponsive. Furthermore, the pineal is unnecessary for photoperiodic control of reproduction. Nevertheless, MEL may regulate seasonal changes in song and perhaps other physiological functions.

Decoding the Photoperiodic Message

The Nature of Melatonin Receptors

Although some MEL receptors may be found in peripheral tissues, it is clear that decoding of the durational MEL signal takes place in the brain and pituitary complex. The use of 2-[^{125}I]iodomelatonin (IMEL) for *in vitro* autoradiography suggests loci of MEL action, and these studies help us to interpret the effects of brain lesions on responses to MEL (**Figure 3**). This ligand clearly demonstrates *bona fide* MEL receptors: IMEL binding sites are specific and of high affinity ($K_d \sim 50$ pM, indicating substantial occupancy at nocturnal physiological serum concentrations), and their occupation elicits intracellular responses. Principal among these is inhibition of adenylate cyclase.

Several MEL receptor genes have been cloned. Three specific MEL receptor subtypes have been identified in

Figure 3 Anatomical and physiological evidence of localized melatonin (MEL) action in photoperiodic mammals. (a) Coronal section of Siberian hamster brain, stained for Nissl substance. Scale bar: 100 μm. (b) Autoradiogram generated by the tissue section in (a) illustrating 2-[^{125}I]-iodomelatonin (IMEL) binding. In all cases shown in this figure, nonspecific IMEL binding is negligible. (c) Combined testis weights of brain intact control (left) or SCN-lesioned pinealectomized experimental (right) Siberian hamsters given 5 weeks of nightly subcutaneous MEL infusions. Infusions with nightly durations of 10 h (mimicking short-day secretory patterns), but not those of 5 h (mimicking long-day patterns), induced reproductive collapse in brain-intact hamsters. 10 h MEL infusions were ineffective in hamsters with SCN lesions. Interruption of the 10 h of nightly MEL infusions (2 × 5 hr) makes them ineffective. (d) Nissl stained coronal section of Syrian hamster brain at the level of the medial basal hypothalamus. (e) Autoradiogram generated by tissue section in (D) showing IMEL binding. (f) Paired testis weight is reduced by nightly infusion of 10 h melatonin in sham-lesioned Syrian hamsters (Sham MEL) compared to controls (Sham Saline). Electrolytic lesions of IMEL-binding region in the dorsomedial hypothalamus(MBHx MEL) relative to lesioned saline infused controls (MBHx Saline). (g) Coronal section of sheep hypothalamus at level of the *pars tuberalis*. (h) Corresponding autoradiogram illustrating IMEL binding. (I). Plasma prolactin (PRL) in Soay rams that were sequentially exposed to winter photoperiods (short days), summer photoperiods (long days), and MEL implants. Top, intact rams; bottom, rams subjected to surgical hypothalamic–pituitary disconnection (HPD). Persistence of control of serum PRL by photoperiod and melatonin in HPD rams indicates regulation by MEL action below the level of the transection (i.e., in the PT). (j) Coronal section through caudal hypothalamus of an Ile-de-France ewe. (k) Corresponding autoradiogram illustrating IMEL binding. (l) Schematic illustration of sheep hypothalamus in the coronal plane illustrating sites in which MEL was surgically implanted. Black circles illustrate sites in which implants induced short-day effect (elevated LH secretion). Open circles illustrate sites at which MEL implants had no effect on serum LH concentrations. Abbreviations: AC, anterior commisure; DMH, dorsomedial hypothalamus; EM, median eminence; FX, fornix; FM, mamillothalamicic tract; MB, Mammillary body; MT, medial thalamus; OCh, optic chiasm; pt, pars tuberalis; PIT, pituitary; POA, preoptic area; IIIV or V, third ventricle.

vertebrates. These are structurally homologous and belong to the same superfamily of seven-membrane-spanning, G_i-protein-coupled receptors. The MT_1 (also known as mel_{1a}) receptor mRNA is of particular interest, because its expression pattern corresponds closely to the maps generated by use of IMEL for *in vitro* receptor autoradiography in mammalian brain. Furthermore, the affinity of this receptor

corresponds closely to that of the physiologically active MEL receptor in the SCN and pars tuberalis. Other members of this MEL receptor family have been identified in various vertebrates, but none can account for the critical function of MEL in reproductive seasonality. The MT_2 (mel_{1b}) sequence contains nonsense mutations in the second exon in both Siberian and Syrian hamsters, and seems not to be expressed in MEL-responsive regions of sheep brain or pituitary. Thus the MT_1 receptor is the likely mediator of photoperiodic responses in seasonal species. Nevertheless, the MT_2 receptor may participate in other putative functions of melatonin, including its capacity to shift circadian phase and to modulate long-term potentiation in hippocampus. A mel_{1c} receptor has been cloned in nonmammalian vertebrates, but is absent in mammals, and a 'MEL-related receptor' has little affinity for IMEL.

Brain Targets of Melatonin: Heterogeneity among Photoperiodic Species

The critical site(s) upon which MEL acts to regulate reproduction seems to be surprisingly variable between photoperiodic species (Figure 3). In rodents, the highest concentration of IMEL binding sites is found in the SCN. In the Siberian hamster, the SCN is critical to photoperiodic responses in two ways: not only does this structure function as a pacemaker to drive the rhythmic secretion of MEL by the pineal gland, but it is also an essential target of MEL. In this species, SCN IMEL binding is largely concentrated rostral to the main retinal input zones, but overlaps with light-induced Fos expression in the ventrolateral region. IMEL binding is regionally co-localized with arginine vasopressin (AVP) mRNA, and dual-label *in situ* hybridization confirms the cellular co-localization of MT_1 receptors with AVP mRNA. Other cell types within the SCN may also be responsive to MEL. Most importantly, destruction of the SCN eliminates the ability of MEL infusions to regulate reproduction in Siberian hamsters (Figure 3(c)). Other brain targets of MEL may also participate, but they are less sensitive than is the SCN and they fail to sustain responses to MEL after the SCN has been destroyed. Nevertheless, somata of the paraventricular and reuniens nuclei of the thalamus contain high concentrations of MEL receptors, and infusion of MEL to these sites can elicit gonadal regression. Interestingly, systemic administration of MEL can induce a second collapse after long-term implants in the SCN have ceased to maintain reproductive inhibition. Presumably, this phenomenon represents independent function of extra-SCN (possibly thalamic) MEL receptor sites.

In contrast to Siberian hamsters, Syrian hamsters remain responsive to MEL after destruction of the SCN. Other forebrain structures, including the dorsomedial hypothalamus (Figure 3(e)) and preoptic regions (including the bed nucleus of the stria terminalis), may be more important in the response to MEL in this species. Only lesion studies and IMEL autoradiography of limited resolution have thus far been used to identify these sites. Thus the phenotype of MEL-responsive cells remains unclear.

In sheep, several lines of evidence suggest that the premammillary hypothalamus functions as a particularly important target of melatonin. First, this perifornical region has a high concentration of IMEL binding sites and expresses MT_1 receptor (Figure 3(k)). In contrast, the ovine SCN contains a lower concentration of IMEL binding sites than do surrounding areas of the hypothalamus and preoptic area. Second, electrolytic lesions that encompass the caudal arcuate and premammillary region of Soay rams affect photoperiodically driven patterns of gonadotropin secretion. Third, implants of MEL in this area stimulate the secretion of luteinizing hormone (LH); (Figure 3(l)). The premammillary hypothalamus is far more sensitive to MEL implants than the anterior hypothalamic region is in this regard.

Reproduction of mustelids (including mink and ferrets) is exquisitely sensitive to photoperiod, and pineal melatonin secretion appears indispensable to this response. Nevertheless, specific MEL binding sites have not been found in the brain. The basis of the difference in the role of the SCN and other brain structures in reproductive responses of these photoperiodic species to MEL is not understood.

The *pars tuberalis* as a target of melatonin Through its control of the MEL secretory pattern, photoperiod regulates seasonal gonadal and thyroidal function. Thus it might logically be expected that lactotrophs, gonadotrophs, or thyrotrophs of the pars distalis might be MEL targets. This seems not to be the case: these cell types lack MEL receptors in adult mammals. In contrast, the *pars tuberalis* (PT) of the pituitary complex clearly plays a major role in MEL-dependent seasonal rhythms of prolactin (PRL) secretion. This structure has consistently been found to contain exceptionally dense concentrations of MT_1 receptor (Figures 3(e) and 3(h)). Importantly, local implantation of MEL into the PT (but not the *pars distalis*) regulates PRL secretion *in vivo*, although LH secretion is unaffected. Most dramatically, Soay rams continue to exhibit photoperiodically driven seasonal rhythms of prolactin (PRL) secretion after hypothalamic-portal disconnection (Figure 3(i)). These cycles persist even though section of the infundibular stalk interrupts gonadal function. Furthermore, systemic administration of MEL continues to regulate PRL secretion

in rams subjected to this operation. When applied *in vitro*, MEL inhibits release from PT of a factor that stimulates PRL secretion from cultured *pars distalis*. It thus appears that MEL acts on the PT to regulate secretion of a peptide that travels in the hypothalamo-hypophyseal portal system to regulate PRL secretion. This 'tuberalin' remains poorly characterized despite its obvious importance to our understanding of seasonal reproduction. It is also likely that MEL regulates secretion of hypothalamic signals (including dopamine, VIP, and thyrotropin-releasing hormone) that may regulate PRL secretion, but the direct action of MEL on the PT must be viewed as the principal means of photoperiodic regulation of the lactotrophs.

Within the PT, the circadian pattern of clock gene expression is regulated by MEL. This contrasts with the SCN, which responds directly to retinohypothalamic input. In rodent PT, MEL acts via the MT_1 receptor to induce rhythmic expression of *Per1*. Short days abolish the rhythm of *Per1* mRNA in the PT of Siberian hamsters. It is expected (but not yet established) that this effect of photoperiod is translated into an absence of PER1 protein in short days. Thus the fundamental operation of the circadian transcriptional–translational feedback loop in the PT is likely altered by photoperiod. The endogenous rhythm depends upon E-box-regulated expression of *Cry* and *Per*, while MEL suppresses adenylate cyclase dependent generation of transcription factors that bind Ca^{2+}/cAMP-dependent response elements (CREs). Alternatively, or in addition, MEL may also act via other signal transduction pathways to alter clock gene expression in rodent PT.

In sheep PT, *Per1/2, Bmal1*, and *Rev-erb* α expression levels continue to oscillate when MEL is suppressed by constant light. Nevertheless, MEL may have a suppressive effect on levels of their mRNAs. In contrast, expression of *Cry1* is induced by MEL. According to a current model (**Figure 4**), the phase relationship between expression of *Per1* and *Cry1* is set by MEL duration. This may provide a mechanism for daylength to act through the pineal to regulate PT function, possibly in order to drive seasonal rhythms of PRL secretion. Validation of this model awaits demonstration that manipulation of clock gene expression (other than through MEL) affects the PT's ability to regulate lactotroph function.

Responding to Photoperiodic Signals

Neural Pathways That Relay Photoperiodic Influences

Once decoded, the MEL signal must engage a neural pathway that ultimately determines the pattern of gonadotropin secretion. Nevertheless, little consistent change occurs in gonadotropin-releasing hormone (GnRH) expression as a result of exposure to inhibitory photoperiods. This has led to the suggestion that it is the secretion, rather than the synthesis, of GnRH that is photoperiodically modulated. Given the progress that has been made in identifying MEL targets, and knowledge about the multiple inputs to GnRH cells, one would think it a simple matter to identify a reasonably complete circuit by which photoperiod controls GnRH secretion. This is not the case: very little is known about the nature and identity of pathways which relay influences of MEL from its neural targets to neuroendocrine effectors. In Siberian hamsters, the SCN is a critical target of MEL and the MT_1 receptor is co-localized with AVP mRNA. Thus vasopressinergic efferents of the SCN represent a principal candidate effector of MEL action in this species. Other SCN outputs may also relay photoperiod information, and it even remains uncertain whether all of the relevant signals are neural. SCN transplants that are encased in polymer capsules which preclude axonal outgrowth are capable of driving behavioral rhythms, indicating the existence of a humoral output of the pacemaker. Although the SCN appears to regulate neuroendocrine rhythms by neuronal projections rather than humoral signals, the relative importance of humoral outputs versus axonal projections of the SCN in relaying the effects of MEL is unknown.

The neural pathways through which MEL action at non-SCN sites drives seasonal reproductive rhythms in other species are also unclear. In sheep, the premammillary region that appears to play an essential role in responses to MEL may regulate dopaminergic cells in the anterior hypothalamus (A14/15), which in turn modulate GnRH release. In sheep and hamsters, photoperiod may regulate the expression of peptides and neurotransmitters that modulate GnRH release, including neuropeptide Y (NPY), dopamine (DA), β-endorphin, and GABA. It is also likely that daylength regulates expression of receptors for these modulators either in GnRH cells or in neurons that control them. Recent identification of a gonadotropin inhibitory hormone (GnIH) in the dorsomedial hypothalamus of Syrian hamsters suggests a possible route by which MEL might regulate LH secretion, particularly in light of evidence that MEL receptors and GnIH are regionally co-localized in this species. It will be important to determine whether GnIH cells are directly responsive to MEL. Kisspeptin-1, a newly discovered modulator of GnRH neurons, is another potential seasonal regulator of reproduction whose modulation by MEL and photoperiod deserves further exploration.

In the spring of 1975, Fred J Karsch performed an experiment designed to test the role of estradiol in the

Figure 4 Experimental data supporting an internal coincidence model for photoperiodic control of prolactin secretion in sheep. Patterns of *Per1* (open circles) and *Cry1* (black squares) expression in *pars tuberalis* of Soay rams exposed to long (left) or short (right) photoperiods. Note that the interval between peak levels of these mRNA species (black bar, asterisk) depends upon daylength. Middle, serum melatonin concentrations in the same animals as a function of zeitgeber time (ZT); the duration of nightly melatonin secretion depends upon photoperiod and determines the levels of serum prolactin. Bottom, hypothetical scheme by which Per-Cry interval (ψ) determines prolactin secretion, as well as other genes (α subunit of gonadotropin, tubulin, neuro-D). The correlational data supporting this model remains to be tested by direct manipulation of *Per* and *Cry* mRNA levels.

regulation of LH secretion in the ewe. When he completed radioimmunoassays about 4 months later, he noted that estradiol had produced a marked suppression of tonic LH secretion which made the ensuing surge more obvious. He quickly repeated the experiment, but to his consternation saw no suppression of serum LH concentrations upon estradiol treatment. Repeating the experiment twice more at intervals of several months, Karsch and colleagues eventually realized that estradiol exerts a potent negative feedback effect only during the anestrous season.

Daylength determines several of the actions of gonadal steroid hormones upon the brain of seasonal breeders. During the nonbreeding season, or upon infusion of MEL in corresponding patterns, the negative feedback potency of gonadal steroid hormones upon gonadotropin secretion increases markedly. This ensures that spermatogenesis and follicular maturation are held in check, as gonadal activation is terminated before levels of gonadotropic support required for completion of these processes is reached. At the same time, the ability of testosterone to activate male sexual behavior, and that of estradiol and progesterone to activate female sexual behavior, is decreased. It is not understood how the same photoperiodic (and MEL) stimulus can simultaneously drive feedback and behavioral responses to the same gonadal hormones in opposite directions. Photoperiod

and MEL treatment can elicit small though statistically significant changes in the expression of receptors for gonadal steroid hormones, and for steroid receptor cofactors, in specific hypothalamic and preoptic regions of seasonal breeders. It seems unlikely, however, that these effects can account for dramatic seasonal swings in the sensitivity and responsiveness of the brain to steroid hormones. Furthermore, exposure of castrated animals to long or short photoperiod can elicit changes in the patterns of gonadotropin secretion (particularly GnRH pulse frequency) even when gonadal steroid hormones are not replaced. These 'steroid-independent effects of daylength suggest an underlying effect of MEL on the pulse generator that may be amplified in the presence of gonadal hormones. The precise mechanisms and circuitry by which photoperiod elicits these dramatic changes in hypothalamo-hypophyseal function remain to be explained.

Photoperiod and Neural Plasticity

The brains of some adult vertebrates are capable of substantial reorganization on a seasonal basis. This is most dramatically illustrated in several species of birds, in which the size and connectivity of nuclei critical to song (including the neostriatal high vocal center (HVc), robust nucleus of the archistriatum, and area X of the parolfactory lobe) undergo substantial volume increases every spring. Although gonadal hormones clearly participate in these changes, these structures also contain MEL receptors and the pineal hormone can suppress growth of the song nuclei even after castration.

Although less dramatic in scale, there is also clear evidence of seasonal changes in brain structure in mammals. Neurogenesis continues throughout adulthood in the subependymal zone of rodents, and newborn cells migrate to the olfactory bulb and dentate gyrus. Photoperiod has a modest but statistically significant effect upon the incorporation of new neurons in the forebrain of Syrian hamsters. Besides a potential role in neurogenesis and/or cell death, daylength may regulate neural connectivity. Production of neuronal cell adhesion molecule (N-CAM) in anterior hypothalamus and preoptic area (POA) also increases upon transfer of Siberian hamsters to long days. Ultrastructural studies reveal seasonal changes in glial ensheathment of GnRH neurons in ewes. During the breeding season, the perikarya of GnRH neurons receive more synaptic contacts from NPY and GABA-immunoreactive axons, while β-endorphin contacts decrease. The human SCN is reported to show an increase in volume and a twofold increase in vasopressin-immunoreactive neurons in autumn over summer levels. It remains uncertain whether any of these changes represent a primary response to daylength or are secondary to seasonal fluctuations of gonadal, thyroid, or other hormones.

Circannual Rhythms: Entrainment by Photoperiod

As already outlined, over the course of the year animals of the temperate zone experience alternate phases of reproductive stimulation and inhibition that are regulated by seasonal fluctuations of photoperiod. In many well-studied species, including Siberian hamsters, Syrian hamsters, deer mice, and mink, a phase of refractoriness to inhibitory photoperiods occurs. Thus gonadal regression is triggered, but reproduction resumes after several months despite continued exposure to daylengths that precipitated gonadal collapse. This recrudescence results from an endogenous mechanism and whose time course ensures that reproduction resumes in time to produce new young in the spring. In such species a second phase of reproductive inhibition cannot ensue unless refractoriness is broken, typically by exposure to daylengths of the breeding season. Interestingly, refractoriness is not accompanied by changes in the pattern of clock gene expression in SCN or PT. This may indicate that refractoriness arises 'downstream' from the mechanism of photoperiodic time measurement, and is consistent with the observation that photorefractory animals can accurately measure daylength in order to break refractoriness.

In some species, however, rhythms of reproduction and other physiological functions including metabolism, pelage, and body weight continue to oscillate with a period of approximately 9–12 months even under experimental circumstances in which daylength is held constant. If refractoriness to photoperiod can be said to exist at any phase of the reproductive cycle, it can be spontaneously broken in the absence of exposure to daylengths other than those that initially triggered reproductive collapse. In some species circannual oscillations persist only within a restricted range of unchanging photoperiods. Nevertheless, it is clear that some species have an endogenous mechanism capable of generating annual rhythmicity.

It is not clear whether a central circannual pacemaker exists in any animal at a single definable locus. Anterior hypothalamic lesions have eliminated circannual rhythms in ground squirrels, but no site has been shown consistently to produce this effect. Furthermore, the results of such lesions on circannual rhythms may depend upon ambient temperature. Evidence that

Figure 5 Circannual rhythms in sheep are entrained by melatonin secretion. Intervals of peak LH secretion, indicating low sensitivity to estradiol negative feedback typical of the breeding season, are illustrated by horizontal black bars over the course of 5 years of an experiment performed in ewes. Each box represents data from one animal. Left column illustrates negative feedback response in three pinealectomized animals maintained in constant photoperiods from 1984 to 1988. Onset and offset of peak LH secretion occurred at circannual intervals. Middle column illustrates response of three pinealectomized ewes to 2 yearly intervals of MEL infusions, one a short nightly duration (LD mel) administered from November through January and the other a long nightly duration (SD mel) administered from May through July. Note that this regimen controlled the phase and period of reproductive induction. Right column illustrates timing of LH secretion in three pineal-intact controls maintained outdoors. Note that LH secretion in the melatonin-infused ewes was out of phase with that of pinealectomized animals and outdoor controls.

the circannual oscillatory mechanism is indicates anatomically and formally distinct from the circadian clock. First, some squirrels sustaining SCN lesions that abolish circadian rhythms continue to sustain circannual rhythms, and some hypothalamic lesions that stop the circannual oscillation permit circadian rhythms of locomotor behavior to continue. Second, birds whose circadian clock was entrained to light:dark cycles whose period (T) was longer or shorter than 24 h experienced neither a lengthening nor a shortening of their circannual period. Thus the circannual rhythm is not a 'counter' of circadian intervals.

Photoperiod entrains circannual rhythms. Without such an entraining input the mismatch between the period of the circannual rhythm and the 12-month environmental cycle would result in inappropriate phasing of reproduction within a few years. This role of daylength as a circannual zeitgeber appears to depend upon MEL (Figure 5). Other endocrine cues can determine whether circannual rhythms persist, or whether animals enter refractory states. Thyroidectomy blocks circannual cycles in sheep, as animals remain in reproductive condition indefinitely. Although thyroid hormones clearly exert their action in the brain, they may nevertheless play a permissive role, in that levels that do not fluctuate seasonally appear adequate to ensure appropriately phased cessation of the breeding season. Access and processing of thyroid hormone to the brain may determine the persistence or termination of photorefractoriness in hamsters and Japanese quail, perhaps though regulation of expression of thyroid hormone-binding proteins (e.g., transthyretin) or monodeiodinase.

The relationships between circannual rhythms and seasonal cycles that require alternation of long and short days remain to be established. Rapid progress in anatomical and molecular definition of photoperiodic responses over recent years inspires hope that even this difficult question can be answered.

Photoreceptor Adaptation

Visual Adaptation

Sensory systems in vertebrates have a remarkable ability to adjust their sensitivity to maintained stimulation, and this is nowhere more impressive than for the eye. The sensitivity of vision is constantly altered over a wide range of ambient illumination. Some part of this process must result from synaptic interactions in the retina and central nervous system, since adaptation in humans and other vertebrates can begin at light intensities that bleach fewer than one rhodopsin molecule per rod outer segment. At such dim intensities, adaptation cannot be mediated by the receptor itself but must take place in some cell that acts as a summation pool, effectively combining the signals of many receptors. How this occurs is still poorly understood. Over much of the range of physiological light levels, however, adaptation is now known to occur principally within the photoreceptors themselves, and the mechanism of this process has been the subject of considerable investigation.

Light Adaptation in a Rod

Figures 1(a)–1(c) show a continuous recording of photoreceptor current made with a suction electrode from the outer segment of a salamander rod. In the absence of background light (Figure 1(a)), there is a resting current in darkness of about 40 pA into the outer segment through the cyclic guanosine monophosphate (cGMP)-gated channels (see Figure 2). A flash of light closes a proportion of the channels, causing a decrease in current. The brighter the intensity of the flash, the greater the decrease in current, until bright flashes close all of the channels, and the response is saturated.

Figures 1(b) and 1(c) show the same rod in the presence of two continuous background illuminations. Presentation of the steady background light produced a maintained response, but with continued illumination the amplitude of the response to the background gradually subsided. If flashes of light were then superimposed on top of the background illumination, the responses can be seen to be smaller, and the photoreceptor less sensitive. This effect can perhaps more clearly be seen in Figure 1(d), where responses have been superimposed to a flash in darkness (largest response) and in the presence of backgrounds of increasing intensity. The backgrounds can be seen both to decrease the sensitivity of the cell and to accelerate the time course of response decay. It might seem that a decrease in sensitivity in the presence of the background would be maladaptive, but this is not the case. The decrease in sensitivity permits the photoreceptor to adjust its operating range to higher intensities in brighter ambient illumination. This makes it possible for the visual system to continue to respond with high sensitivity to differences in illumination, that is, to contrast, at a light level that is appropriate to the brightness of the visual scene.

Mechanism of Light Adaptation

Adaptation in photoreceptors is known to require a second messenger and considerable evidence now indicates that this messenger is the calcium ion. Ca^{2+} flows into the rod outer segment through the cyclic nucleotide-gated channels in darkness and is extruded by an Na^+/Ca^{2+}-K^+ exchange transporter. When the photoreceptor is illuminated (Figure 2), the active form of rhodopsin (called Rh^*) binds to the heterotrimeric G-protein transducin. This causes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on the guanosine nucleotide binding site, and Gα-GTP then binds to an enzyme called cyclic GMP phosphodiesterase (PDE), which hydrolyzes cGMP. The reduction in cGMP concentration causes the cyclic nucleotide-gated channels to close during illumination. This in turn decreases the influx of Ca^{2+} through the channels, and the continued activity of the Na^+/Ca^{2+}-K^+ exchange transporter causes the free-Ca^{2+} concentration in the outer segment to decrease. Over most of the physiological range of the photoreceptor, the outer segment Ca^{2+} concentration is simply proportional to the fraction of channels that are open. This means that the steady decrease in current produced by background light (as in Figures 1(b) and 1(c)) produces a steady decrease in Ca^{2+}, and the amplitude of the decrease is nearly proportional to the decrease in current.

The decrease in Ca^{2+} is known to have a number of effects on the phototransduction machinery (Figure 2). One of the most important of these is the regulation of the guanylyl cyclase, the enzyme that synthesizes cGMP. The activity of the cyclase is regulated by small molecular-weight binding proteins called guanylyl cyclase-activating proteins (or GCAPs). These proteins associate with the guanylyl cyclase at cytoplasmic binding sites near the disk membrane.

Figure 1 (a–c) Responses of same salamander rod to flashes given in darkness and in the presence of two steady background lights. I_F, flash intensity in units of photons μm^{-2}. Background intensities were 1.7 (b) and 37.2 (c) photons $\mu m^{-2}\ s^{-1}$. (d) Responses of salamander rod in darkness (largest response) and in backgrounds of progressively increasing brightness. Responses have been plotted as sensitivities by dividing the current (in pA) by the light intensity (in units of photons μm^{-2}). (a–c) Replotted from Matthews HR (1990) Messengers of transduction and adaptation in vertebrate photoreceptors. In: Herring PJ, Campbell AK, Whitfield M, and Maddock L (eds.) *Light and Life in the Sea*, pp. 185–198. Cambridge, UK: Cambridge University Press. (d) From Fain GL and Cornwall MC (1993) Light and dark adaptation in vertebrate photoreceptors. In: Shapley R and Lam DMK (eds.) *Contrast Sensitivity Proceedings of the Retina Research Foundation Symposia*, vol. 5, pp. 3–32. Cambridge, MA: MIT Press.

When the Ca^{2+} concentration is high in darkness, the GCAPs inhibit the cyclase; when the Ca^{2+} falls, the GCAPs come off the cyclase binding sites, and the rate of the cyclase is accelerated. Activation of the cyclase by low Ca^{2+} causes an increase in cGMP, which allows a fraction of the channels to reopen in spite of the maintained stimulation of the PDE by the background light. It is the cyclase activation that is responsible for the gradual decrease in the amplitude of the response to a maintained background (Figures 1(b) and 1(c)).

Ca^{2+} has also been shown to regulate the cyclic nucleotide-gated channels. This effect seems to make little contribution to adaptation in rods but may be of considerably greater importance in cones. The binding of Ca^{2+} in association with a small molecular-weight binding protein increases the effective affinity of the channels for cGMP, increasing the probability of channel opening, and allowing the current gradually to recover in the presence of maintained illumination. Finally, Ca^{2+} appears to regulate a step early in the transduction cascade, apparently at the level of the rhodopsin molecule itself. Some evidence indicates that this effect is mediated by a low-molecular-weight Ca^{2+} binding protein called recoverin, which may bind to and modulate rhodopsin kinase, the enzyme that phosphorylates rhodopsin. Modulation of kinase activity may regulate the lifetime of Rh^*.

As a result of the effects produced by the altered Ca^{2+} concentration, the steady illumination alters the sensitivity of the rod. This is primarily the result of a change in the steady level of turnover of cGMP, in the following way. The steady illumination produces a maintained increase in the rate of the PDE, which causes the channels to close. The closing of the channels decreases the free Ca^{2+} concentration, as we have seen; this in turn produces an increase in cyclase rate. The consequence is that the photoreceptor reaches a new steady state corresponding to a new level of steady current in the presence of the background (see Figures 1(b) and 1(c)), at which the rate of hydrolysis of cGMP by the PDE is equal to the rate of synthesis by the cyclase, and both are higher than in darkness. This increase in cGMP turnover produces a decrease in the sensitivity of the rod, since more light will be required to alter the PDE rate enough above the background rate to produce a significant and detectable change in the concentration of cGMP. The increase in turnover is also largely responsible for the increase in the rate of response decay in background illumination (Figure 1(d)), since increased turnover allows the change in cGMP concentration to track more faithfully the change in PDE rate produced by the transduction cascade.

Dark Adaptation

When a photoreceptor is exposed to bright light and then returned to darkness, the sensitivity of the cell

Figure 2 Visual transduction cascade in vertebrate photoreceptor showing sites of modulation by Ca^{2+}. Light activates rhodopsin to produce the active intermediate Rh^*, which in turn stimulates a heterotrimeric G-protein called transducin. Activated transducin Gα-GTP binds to the inhibitory (gamma) subunit of the cGMP phophodiesterase (PDE) and activates the enzyme; the PDE then hydrolyzes cGMP. As the cGMP concentration falls, the cyclic nucleotide-gated channels in the plasma membrane close, reducing the inflow of Na^+ as well as Ca^{2+}. Continued extrusion of Ca^{2+} by the Na^+/Ca^{2+}-K^+ exchange protein causes a decrease in free-Ca^{2+} concentration, which appears to have at least three effects on the cascade (arrows): stimulation of the cGMP cyclase to increase the cGMP concentration, alteration of the effective affinity of the channels for cGMP, and acceleration of the rate of rhodopsin kinase, effectively reducing the lifetime of Rh^*. Adapted from Fain GL (1999) *Molecular and Cellular Physiology of Neurons*. Cambridge, MA: Harvard University Press.

remains depressed for a prolonged period. Sensitivity then gradually recovers, by a process known as 'dark adaptation.' Dark adaptation is reasonably rapid if a minimal percentage of the photopigment has been isomerized, since recovery then requires only the return of the PDE and cyclase to their dark-adapted activities, and the return of the photocurrent and membrane potential to their dark-adapted values. If, however, a substantial fraction of the rhodopsin is isomerized, or bleached, recovery requires in addition the regeneration of the bleached photopigment, and 30–35 min (in humans) may be required for the complete return of sensitivity.

To understand why sensitivity recovers so slowly after a strong bleach, we must first consider what happens to rhodopsin after it receives a photon (Figure 3). The activity of Rh^* is quenched by phosphorylation and binding of arrestin, and in vertebrates all-*trans* retinal then falls off the opsin molecule. The all-*trans* retinal is converted into all-*trans* retinol within the outer segment by an enzyme called retinol dehydrogenase. The all-*trans* retinol then leaves the outer segment and travels to an adjacent cell layer, for rods predominantly to the retinal pigment epithelium (or RPE), but for cones apparently also to retinal glial cells. The transit of retinol seems to be assisted in part by interphotoreceptor retinol-binding protein (or IRBP). In the

Figure 3 Pathway for regeneration of bleached photopigment in a vertebrate rod. See text. RPE, retinal pigment epithelium; FA, fatty acid; Rh, rhodopsin; IRBP, interphotoreceptor retinol-binding protein; *hν*, light. Reprinted with permission from Fain GL (2003) *Sensory Transduction*. Sunderland, MA: Sinauer.

RPE or glial cell, the all-*trans* retinol is converted back to 11-*cis* retinal by an isomerase enzyme (also known as RPE65), and the 11-*cis* retinal then diffuses or is transported back to the photoreceptors to recombine with opsin.

When a large fraction of the rhodopsin is bleached, the photoreceptor remains desensitized for a prolonged period because large concentrations of phosphorylated rhodopsin, all-*trans* retinol, and opsin accumulate within the outer segment. All of these intermediates are capable of activating the transduction cascade. The continued activation of the cascade produces an 'equivalent background,' which is in effect very much like a maintained background light, desensitizing the photoreceptor (as in Figure 1) by reducing the Ca^{2+} concentration, and modulating the components of the transduction cascade (as in Figure 2). Phosphorylated rhodopsin produces a small, continued activation of the cascade much like that produced by real light, perhaps as a result of the transient unbinding of arrestin or dephosphorylation of the protein. A much greater effect is generated by all-*trans* retinol, which can bind to opsin and actively stimulate the production of transducin Tα-GTP. For small bleaches, phosphorylated rhodopsin and all-*trans* retinal seem to be the most important contributors to the equivalent background. When a large fraction of the photopigment is bleached, the continued reduction of sensitivity seems to be mostly the result of opsin itself, which in both rods and cones can stimulate the visual cascade. Though the probability of stimulation by a single opsin molecule is low, and much lower than for Rh^*, enough opsin accumulates during large bleaches to produce an equivalent background that desensitizes the rod. Simulation by opsin continues until all of the opsin has recombined covalently with 11-*cis* retinal.

Introduction

Vision begins in the retina, a delicate, multilayered tissue lining the back surface of the inside of the eye. The photoreceptor mosaic is responsible for absorbing the individual photons of light that comprise the retinal image and transforming their energy into neural signals for processing by retinal circuitry and ultimately the brain.

The mosaics of most animals contain two general types of photoreceptors – rods and cones. Although evidence shows that there are other cells in the retina that are light sensitive (e.g., certain types of ganglion cells), the majority of phototransduction occurs in the rod and cone cells. These highly specialized cells have important structural and topographical differences that subserve their unique functional roles in the visual process. In this article, we compare the structural and functional properties of rods and cones and discuss the spatial organization of the photoreceptor mosaic and the relationship between the cone mosaic and color vision.

Photoreceptor Basics

Photoreceptors consist of an outer segment, an inner segment, a cell body, and a synaptic terminal (Figure 1). The outer segments contain the various components of the visual transduction process. All proteins, including photopigments, are synthesized in the inner segment and transported to the outer segment via the connecting cilium. The outer segment of both rods and cones consists of stacks of membranous discs; in cones the discs are continuous with the plasma membrane of the cell, whereas in rods they are free-floating. Embedded throughout the outer segment membrane in each rod and cone cell are approximately 100 million photopigment molecules, which comprise approximately 85–90% of the total protein structures in the outer segments. In both rods and cones, these discs are synthesized and recycled by the retinal pigment epithelium.

Rod and Cone Specializations

Rod and cone photoreceptors have a number of important specializations that give them distinct functional properties. The primary advantage of having two classes of photoreceptors is to allow the visual system to function over a wide range of light intensities, approximately 11 orders of magnitude in the human eye. Rods are extremely sensitive: They are able to detect a single photon and thus work well at very low light intensities. Approximately ten such photon absorptions (whether across ten rods or within a single rod) are required to detect a visual stimulus under these light levels. At a rate of only one photon per rod every 85 min, a person can see well enough to just barely make out the outline of trees against the sky on a moonless night. On the other hand, cones are less sensitive and function best at high light levels. Cones start to respond when they absorb light at a rate of approximately three photons per cone per second, and they can respond well for light intensities up to 1 million photons per cone per second (the photon catch rate on a bright sunny day is approximately 300 000 photons per cone).

An important difference between rods and cones is that rods 'saturate,' whereas cones do not. At moderate light levels, rods reach a maximum response and are unable to respond to continued increases in light intensity. The point at which rods saturate is quite low, and at normal room light levels, rods are saturated. This means that most of the time your vision is based on your cones, which paradoxically comprise only 5% of the total number of photoreceptors in the human retina.

The human retina is directionally selective. That is, light entering through the center of the pupil is more effectively coupled into photoreceptors, and hence perceived as brighter, than light entering through the pupil margins. This is referred to the Stiles–Crawford effect of the first kind and is a consequence of the waveguide nature of photoreceptors. The rods and cones preferentially guide photons incident within a certain range of acceptance angles along the length of the inner and outer segments, and these photons are therefore more likely to be absorbed by photopigment. The waveguiding properties of photoreceptors are due to a larger index of refraction within the photoreceptor than in the interstitial space between them. Cones are more effective waveguides than rods, so they exhibit a greater degree of directional selectivity. This directional selectivity serves an important function in improving

Figure 1 Cross-sectional image of the retina showing the photoreceptors and different cell layers. Reproduced from Boycott BB and Dowling JE (1969) Organization of the primate retina: Light microscopy. *Philosophical Transactions of the Royal Society of London, Series B* 255: 109–194, with permission of the Royal Society of London.

the contrast of the retinal image since obliquely incident, multiply scattered light is not able to effectively couple into cone photoreceptors. This selective rejection of scattered light by cones has a major effect; obliquely incident light is as much as 10 times less effective than light entering through the pupil center. However, this improvement in retinal image contrast comes at the expense of a cone's absolute sensitivity. This loss in cone sensitivity does not affect the sensitivity of the visual system as a whole because of the presence of the more sensitive rod system.

Another important difference between rods and cones regards their spectral response properties, which are determined by the spectral sensitivity of their respective photopigments. Retinal photopigments consist of two parts: a protein (opsin) and a chromophore (11-*cis* retinal in the human retina). Opsins belong to a larger class of proteins called G-protein-coupled receptors. Since all mammalian pigments utilize the same chromophore, it is the opsin portion of the photopigment that determines spectral sensitivity. In the human retina, there are four different photopigment types – rhodopsin (found in rods) and short-, middle-, and long-wavelength sensitive opsin (found in the S, M, and L cones, respectively). Rods have maximum sensitivity at approximately 500 nm, whereas the S, M, and L cones peak near 415, 530, and 560 nm, respectively. A curious feature of the M and L cone pigments is that there is considerable variability within each pigment class. That is, there is not a single stereotyped M (or L) pigment. The variability in spectral sensitivity of these pigments can be directly detected behaviorally or inferred through the use of molecular genetic techniques. The origin of this variation is not well understood, although it almost certainly is related to the genetic mechanisms that give rise to the high incidence of red/green color vision defects.

Topographic Arrangement of Photoreceptors

The previous section outlined the structural characteristics of rods and cones that help differentiate their

functional roles in vision. Each postreceptoral circuit in the retina invariably combines signals from multiple cones in the local patch of retina for which it is responsible. Thus, it is important to understand how rods and cones are organized in the retina in order to construct how the postreceptoral circuitry collects its signals from the mosaic. Next, we review what is known about the topography of the rod and cone mosaics within the human retina. One strategy is to tile the surface of the retina with rods as completely as possible in order to achieve the highest overall sensitivity. Conflicting with this strategy is the need to have a high number of cones in order to achieve high spatial resolution. The manner in which approximately 100 million rods and 5 million cones are interleaved into a single photoreceptor mosaic enables the visual system to function quite well over a large portion of the visual field.

Cone Topography

The cones are distributed unevenly across the retina, with a peak density of approximately 200 000 cones mm^{-2} at the fovea, which is located approximately 15 degrees temporal to the optic disc. Here, cones are packed in a regular triangular array, with the average cone diameter being approximately 2 μm (although this of course depends on the cone density, which is highly variable in central fovea). Cone density decreases precipitously moving away from the fovea in all directions (Figure 2), declining to approximately 30 000 cones mm^{-2} at approximately 400 μm eccentricity. As cone density decreases, the regularity of the mosaic declines and the average cone diameter increases. Cone distribution has a slight radial asymmetry about the fovea, with the nasal and superior retinal quadrants having higher cone density. Beyond approximately 10 degrees, the density of cones reaches a near constant value of 7000 cones mm^{-2} until the extreme edge of the neural retina, where there is an increase to nearly 15 000 cones mm^{-2}. Whether this latter feature of cone topography is an unintended consequence of retinal development or a functional specialization is uncertain.

The foveal specialization has a number of features that serve to optimize spatial vision. First, there are no rods in the central fovea, allowing the cones to be tightly packed in a locally triangular mosaic, with each cone usually surrounded by six neighbors. Second, the inner retinal cells and retinal vasculature are displaced away from the central fovea, providing a clear path for incident photons onto the foveal cone mosaic.

The developmental mechanisms behind the formation of the fovea have been well studied. Although the future location of the fovea can be molecularly identified as early as 24 weeks postgestation, the process of foveal formation is not complete until approximately 4–7 years after birth. The last steps of foveal development include the physical migration of cones toward the fovea – this process results in the characteristic spatial distribution of cones across the retina as discussed previously (Figure 3).

Figure 2 Plot of photoreceptor density as a function of retinal eccentricity. Top panels represent images of the photoreceptor mosaic. The image on the left is of the all-cone foveola, whereas the remaining panels contain both rods and cones (cones are the larger structures). Notice that at greater eccentricities, as the density of cones decreases and density of rods increases, the cones increase in diameter while the rods remain relatively constant in diameter. (Top panels) Reproduced from Curcio CA, Sloan KR, Kalina RE, et al. (1990) Human photoreceptor topography. *Journal of Comparative Neurology* 292: 497–523. with permission from John Wiley and Sons.

Figure 3 Montage showing the distribution of cones in the human retina across the central 5 degrees in one subject. This montage was created by adding many individual 1-degree *in vivo* images acquired with an adaptive optics retinal camera. The dark shadows are due to blood vessels overlying the cone mosaic.

Despite the involvement of the cone photoreceptors in a number of diseases (including age-related macular degeneration, which affects three in ten people older than the age of 75 years), there does not appear to be significant 'normal' loss of cones during aging.

Rod Topography

Rods are absent in the very center of the fovea; the 'rod-free zone' is on average 350 μm in diameter. Moving away from the fovea, rod density increases to a maximum of approximately 180 000 cells mm^{-2} at approximately 12-degree eccentricity. Unlike cones, whose size changes as a function of eccentricity, the size of rods remains nearly constant across the retina at approximately 2 μm in diameter. It has been shown that there is normal loss of rods with aging, although it is unclear why rods (but not cones) show this susceptibility.

Effects of the Receptor Mosaic on Spatial Vision

In addition to the topography of the receptor mosaic, the eye's optics as well as neural factors place limits on spatial vision. The optics of the typical human eye are not capable of focusing a point of light on the retina smaller than approximately 5 μm, and the highest spatial frequency that can be transmitted through the eye's optics to the retina is approximately 60–120 cycles per degree depending on pupil size. The packing of cones also places limits on spatial vision; the highest spatial frequency that the photoreceptor mosaic can accurately sample is one-half the inverse of the cone spacing. This limit, known as the Nyquist limit, is approximately 60 cycles per degree for human foveal vision. Whereas the limits imposed by the eye's optics and the typography of the mosaic are usually well matched in foveal vision, in the peripheral retina the eye's optics are able to form images on the retina with higher spatial frequencies than the peripheral mosaic can accurately sample. It is sometimes assumed that in the absence of optical factors the Nyquist limit determines acuity. However, this is not necessarily the case; for example, rods are as densely packed as foveal cones in much of the retinal mosaic and thus share the same Nyquist limit, yet the acuity of the rod system is an order of magnitude poorer than the cone system due to neural factors, specifically the postreceptoral spatial pooling of rod signals. The receptors also blur the retinal image by averaging all the light that lands within their collection area; however, at the fovea this effect impacts the retinal image minimally because the diameter of a foveal cone (and hence the averaging area) is small compared with the finest detail that can be transmitted through the eye's optics.

Cone Submosaics and Color Vision

Human color and spatial vision is mediated by three spatially distinct classes of cone photoreceptors with different but overlapping spectral sensitivities – the L, M, and S cones. The first stage of color vision is light absorption in one or more of these cone photoreceptors. Once a photon excites a cone photopigment molecule, all information about the wavelength of that photon is lost, and hue can only be recovered by comparing the relative excitations of the three different cone types. Thus, normal color vision is trichromatic since there are only three independent quantities available to the visual system from which the appearance of any stimulus may be inferred. The trichromacy of color vision was established empirically, by noting that humans can match the appearance of any patch of light by a suitable mixture of only three primary lights, long before it was possible to directly confirm that there are indeed three distinct cone types on which color vision depends. There are important differences in the relative numbers and arrangement of the three cone types that have implications for color vision.

S Cones

S cones exhibit a number of morphological and histochemical features that easily distinguish them from L and M cones. They are more cylindrical in shape, serve distinct neural circuitry, and form a spatially independent submosaic from the L and M cones. S cones are relatively sparse in the human retina, with peak density (usually less than 10% of the total cone number) near 1-degree eccentricity and very little intersubject variability. This low S cone density does not significantly impact vision since the shorter

wavelengths the S cones are most sensitive to are those that are most blurred by chromatic aberration, so fewer S cones are needed to sample the relatively coarse short-wavelength image. The density of S cones is lowest in the central fovea, with an S cone-free zone of approximately one-third of a degree existing in most, although not all, human subjects. It is not clear what governs the nonuniform topography of S cones. Whereas S cones tend to be regularly distributed throughout the macaque retina, in humans S cone placement is random near the fovea, with a more regular arrangement as eccentricity increases. This irregularity may reflect disruption during the foveal migration of L and M cones during retinal development. Some have found that S cones, presumably due to their increased size, can disrupt the otherwise normal triangular packing arrangement of the L and M cone array, although this relationship is not always observed.

L and M Cones

Number and arrangement L cones are generally more numerous than M cones in the human retina and tend to occur on average about twice as frequently. Due to the high degree of similarity between L and M cones (it is widely believed that the only difference between an L and an M cone is the particular photopigment it contains), less is known about their retinal topography and neural connectivity than for S cones. Studies that have been performed to date indicate that the L and M cone submosaics are generally randomly interleaved, at least near the fovea, and that the relative numbers of L and M cones are generally constant across the fovea and midperiphery of an individual's retina. However, there do seem to be exceptions to both these rules in at least some individuals. It has been suggested that the L and M cone submosaics may exhibit some degree of clumping in the periphery, based on observations made in macaque retina; however, no direct observations have been made of the relative numbers or arrangement of L and M cones in midperipheral human retina.

Inter- and Intraperson variability Numerous indirect estimates have suggested that there are on average approximately twice as many L cones as M cones in the human retina, with large intersubject variability. Direct information on the numbers and locations of L, M, and S cones obtained with spatially localized retinal densitometry in 10 living human subjects reveals the extent of this variability in L-to-M cone ratio across individuals with normal color vision to be more than a 40-fold range.

We have described the large variability in the ratio of L to M cones across different individuals, but we have not addressed the variability of L-to-M cone ratio within a particular individual's retina. Most studies suggest that the ratio of L to M cones is probably relatively constant across the central retina; however, evidence for this is largely inferential. Direct evidence is available for only two human subjects, one of whom exhibited a significant difference in local L-to-M cone ratio between temporal and nasal retina and the other did not. This indicates that L-to-M cone ratio need not be homogeneous across the central retina and that some individuals may exhibit a nasal–temporal asymmetry in the local L-to-M cone ratio similar to that observed in macaque retina, but how common this asymmetry is remains to be determined. There have been no direct measures of the variability of L-to-M cone ratio with eccentricity in the central and midperipheral retina; however, it is well-known that the ratio of L to M cones increases significantly in the far periphery.

Consequences for color appearance The relative numbers and organization of the three cone classes in the human retina place important constraints on color vision and the neural circuitry responsible for it. Remarkably, color experience is essentially uniform across individuals despite the huge variability in the ratio of L to M cones. For example, unique yellow, which represents the neutral point of the red-green color mechanism and is thought to be driven mainly by differences in L and M cone excitation, varies with a standard deviation of only 2–5 nm. It has been suggested that this uniformity is a consequence of a plastic mechanism that normalizes color experience based on the average spectral content of the environment. In individuals with very extreme L-to-M cone ratios, it is possible to observe some subtle effects of L-to-M cone ratio on vision. For example, there are reports that these individuals have compromised color contrast sensitivity and are more likely to have greater matching ranges on the anomaloscope than those with more balanced ratios. Due to the irregular assignment of L and M cones, these subjects would also tend to have larger patches of effectively color-blind retina (in which only one cone class is present) than those with more balanced numbers of L and M cones, meaning that these individuals would be more prone to misjudging the color appearance of very small objects.

Neural consequences The disordered arrangement of L and M cones seems to strike a balance between the needs of spatial and color vision. As can be seen in Figure 4, random cone arrangement results in patches of retina in which only the L or M cone class is present. Although this patchiness can be

Figure 4 False color images of the trichromatic cone mosaic for three subjects illustrating the large variability in the ratio of L (red) to M (green) cones among individuals with normal color vision. S (blue) cone number is relatively uniform across subjects. The ratio of L to M cones for these subjects is (a) 2.7:1, (b) 1.9:1, and (c) 16.5:1. L, M, and S cones were identified with adaptive optics imaging combined with spatially localized retinal densitometry. Adapted from Hofer H, Carroll J, Neitz J, et al. (2005) Organization of the human trichromatic cone mosaic. *Journal of Neuroscience* 25(42): 9669–9679.

disadvantageous for foveal color vision, it is likely beneficial for high-acuity spatial vision because the neurons responsible for fine spatial vision are more likely to draw their input from cones of the same spectral type, thus avoiding the confounding of spectral and spatial information. This patchiness also creates retinal locations where the resolution of the M or L cone submosaic should be as high as that for the full mosaic, as is observed experimentally.

In the peripheral retina, there are additional advantages conferred by a disordered arrangement of L and M cones. There is a great degree of neural convergence in the periphery so that several neighboring cones drive the center of midget ganglion cells, which are believed to carry the red-green color signal. If more than one cone type contributes to the ganglion cell center response, the chromatic opponency of that cell will be weakened. Thus, red-green color vision would be expected to deteriorate in the periphery. The patchiness in the mosaic that results from random L and M cone arrangement lessens the negative effects of this convergence because it makes it more likely that some peripheral midget cone centers will be driven by cones of the same spectral type. This may explain why color discrimination in the periphery is as good as in the fovea if large enough stimuli are used, although peripheral color vision is significantly disadvantaged for smaller fields.

Despite this apparent advantage for peripheral color discrimination, patches of a single cone type can also be detrimental for color vision, especially in the fovea, because the retina is effectively color blind within them. The irregularity of L and M cone arrangement exacerbates the confounding of spatial and chromatic information on small scales, leading to errors in color appearance for small stimuli or fine spatial patterns. Chromatic aliasing is the general term that refers to perceptual errors of this type; examples are variability and misjudgment of the appearance of small points of light and the Brewster's color phenomenon in which splotches of pastel colors are erroneously seen superimposed on fine black-and-white gratings.

Cone Mosaic in Color-Blind Individuals

Color blindness – general definitions We have described the photoreceptor mosaic and its implications for vision for the normal human retina; we now discuss the photoreceptor mosaic of the color-blind retina. Color blindness refers to a variety of conditions that result in an individual requiring fewer than three primaries to match the appearance of a test light. Although color blindness can be caused by acquired dysfunction in the chromatic pathways, we restrict our discussion to the more common case in which color blindness is an inherited condition caused by the absence or malfunction of one or more of the three types of cones. Dichromacy refers to the absence of one of the cone classes, whereas monochromacy refers to the functional absence of two or even all three cone types. Dichromats can still discriminate a limited range of colors and they require two primaries to match the appearance of any test flash. Monochromats, who are extremely rare, completely lack color vision and can match the appearance of any colored test flash by adjusting the intensity of a single primary.

There are also a group of conditions known as color anomalies in which a person is still trichromatic – that is, the person still requires three primaries to match the appearance of a test light, but the matches that person makes tend to be abnormal and often the matches are made with less precision. A color anomalous individual has three different types of cones but they contain unusual or very similar pigments. Although technically referred to as color blind, these individuals often have quite good color discrimination.

Examples There are three types of dichromacy, representing the loss of L, M, or S cone function.

Loss of either L or M cone function (termed deuteranopia or protanopia, respectively) is referred to as 'red-green' color blindness and is the most common form of color blindness. This is because the pigment genes for L and M cones are found on the X chromosome. It affects approximately 2% of males and 0.03% of females, with approximately 4.5% of females with normal color vision carrying genes for red-green dichromacy. Tritanopia, the form of dichromacy resulting from the complete loss of S cone function, is much more rare and shows equal incidence across gender since the S pigment gene is located on an autosome (chromosome 7).

Historically, there has been some debate about whether the cone mosaic of red-green color-blind individuals contained a full complement of either only L or only M cones (replacement hypothesis) or whether the mosaic contained empty spaces representing the lost class of cones (loss hypothesis). We now know that both of these situations can occur depending on the specific genetic mutation underlying an individual's color blindness. For example, a protanope who does not have L cones because he lacks genes for L cones and instead has multiple genes for M cones will display a full complement of cones in his retina. On the other hand, a deuteranope, who lacks functional M cones because the M pigment gene he has does not encode a functional M pigment, displays gaps in his retinal mosaic that seem to represent the missing M cones (Figure 5). Moreover, there may be important phenotypic differences among individuals with nonfunctioning cone pigments that depend on the severity of the particular mutation.

Also in the family of red-green color vision defects is anomalous trichromacy, which is associated with the loss of L or M cone function and is referred to as deuteranomaly or protanomaly, respectively. There is no good evidence that tritanomaly exists. Deuteranomaly is characterized by the presence of two different types of functional L cones (and S cones), whereas protanomaly is characterized by the presence of two different types of M cones (and S cones). Both are a result of a rearrangement of the X-linked L/M gene array and as such are quite common. It affects approximately 5.5% of males and 0.39% of females, with approximately 11% of females with normal color vision carrying genes for red-green anomalous trichromacy. The severity of the defect has been linked to the spectral separation of the two L or two M cone pigments. Recall that there is not a single stereotyped L or M cone. Thus, for example, a deuteranomalous trichromat could have two L cone pigments that differ in maximum sensitivity by as much as 10 nm or as little as 1 or 2 nm. Likewise, protanomals can have two M pigments that differ by as much as 5 nm or as little as 1 or 2 nm. In general, the farther apart an individual's pigments, the better their residual color discrimination.

There are also three classes of monochromacy: blue cone monochromats, rod monochromats, and cone monochromats. Blue cone monochromats have rods and one functional class of cones (S cones), whereas rod monochromats have only rod function. In addition to being color blind, these individuals have low resolution, tend to be photophobic, and usually have nystagmus. Both of these conditions are very rare; rates have been estimated at 1 in 50 000 for rod monochromacy and 1 in 100 000 for blue cone monochromacy. The few histological studies that have been performed on the retinas of rod monochromats have

Figure 5 Images of the cone mosaic in two individuals with red-green color blindness. Each subject's mosaic contains only S cones and either L or M cones. The first subject (a) has multiple genes for M cone pigments and no genes for L cone pigment; he exhibits a full complement of cones in his mosaic. The second subject (b) has a normal gene for L cone pigment, but his M pigment gene encodes a faulty pigment; his mosaic contains numerous gaps that appear to represent the missing class of M cones. Interestingly, this loss of approximately one-third of the cone photoreceptors does not show up on any clinical test of visual function and this subject enjoys normal visual acuity. Images were acquired with a high-resolution adaptive optics ophthalmoscope. Adapted from Carroll J, Neitz M, Hofer H, et al. (2004) Functional photoreceptor loss revealed with adaptive optics: An alternate cause for color blindness. *Proceedings of the National Academy of Sciences of the United States of America* 101(22): 8461–8466.

given discrepant results for the organization of the retinal mosaic. In some cases, cones were scarce and malformed, whereas in other cases cones seemed present in normal numbers. Rod monochromacy has been shown to be caused by defects in one of two components of the visual transduction cascade in cones – the cone cyclic nucleotide-gated channel (either the α or β subunit) or the cone transducin. Numerous mutations in these proteins have been reported to cause rod monochromacy, and one idea is that the different genetic causes of the disease would lead to subtle phenotypic differences and thus might be responsible for the observed variability in retinal organization among rod monochromats. No direct information is available on the organization of the photoreceptor mosaic in blue cone monochromats. Because of the associated low visual acuity and nystagmus, and since there is no known mechanism that would allow missing L and M cone pigment to be replaced by S cone or rod pigment, the mosaics of these individuals are expected to contain rods and a sparse array of S cones with no other cones present. Cone monochromats have either only L or only M cones and rods; only a few cases have been described and none have had their authenticity completely accepted. These people have been reported to have normal visual acuity and no nystagmus, and they presumably have photoreceptor mosaics similar to regular red-green dichromats except for the lack of S cones. This disease would occur due to an individual inheriting both tritanopia and one form of red-green color blindness. The incidence of cone monochromacy is believed to be approximately 1 in 10 million, but this is based solely on the likelihood of inheriting both tritanopia and red-green dichromacy.

Photoreceptors and Circadian Clocks

S N Peirson and R G Foster, University of Oxford, Oxford, UK

Introduction

Almost all living creatures, including some prokaryotic forms of life (cyanobacteria or blue-green algae), have been shown to possess an endogenous 24 h biological clock, called a 'circadian clock' or 'circadian pacemaker.' The term 'circadian' was originally coined by Frans Halberg in 1959 and is derived from the Latin *circa*, 'about,' and *diem*, 'day.' A circadian rhythm describes an approximately 24 h oscillation that persists under conditions of light and darkness for several cycles. The circadian system provides an endogenous representation of a day and sets the times or phases at which physiological and behavioral events occur with respect to the 24 h environmental cycle. In this way, physiology is 'fine-tuned' to the varying demands of night and day. This facility will only have survival value if biological time remains synchronized or entrained to environmental time. The systematic daily change in the gross amount of light (irradiance) at dawn or dusk provides the primary indicator of the time of day. As a result, most organisms have evolved to use the twilight transition as the main zeitgeber (time giver) to adjust circadian time to local time – a process that has been termed photoentrainment.

The site of the primary circadian clock in mammals is the suprachiasmatic nuclei (SCN) of the hypothalamus; this site receives input from the retina via the retinohypothalamic tract (RHT). The clock within the SCN is a product of intracellular transcriptional–translational feedback loops, involving a number of core clock genes. Despite the fact that the SCN are essential for overt rhythmicity, with ablation of these nuclei resulting in behavioral arrhythmicity, clock genes have also been found to be rhythmically expressed in numerous other tissues, including the heart, liver, lung, and kidney. These peripheral clocks are dependent upon the SCN to maintain appropriate phasing, and in the absence of this central coordinator the individual clock cells become uncoupled or desynchronized, which results in arrhythmic non-24 h physiology (Figure 1).

Circadian Photoreception

The photoreceptors providing the light input to the mammalian circadian system are ocular. In this respect mammals are quite unlike other vertebrate classes, which possess multiple photoreceptors located in structures such as the pineal complex and deep brain. From time to time, extraretinal photoreceptors have been reported to exist in mammals. The most recent report suggested that photoreception could occur in the skin behind the knee in humans. Although widely reported as fact and even incorporated into some textbooks, this finding could never be replicated; most notably, Czeisler's group at Harvard duplicated the methodology precisely and could not achieve the reported finding.

Demonstration that the eyes provide the exclusive light input to the circadian system has been shown repeatedly by enucleation. Eye loss always completely blocks photoentrainment in those mammals examined. Although the photoentrainment process is clearly located within the eye, establishing which ocular cells bring about photoentrainment has been surprisingly difficult. Historically, the only components of the mammalian central nervous system thought to be directly light sensitive were the rods and cones (Figure 2). As a result, all light responses have been attributed to one or both of these photoreceptor classes. Rods mediate scotopic (dim light) vision, providing low resolution but high sensitivity, whereas cones are involved in photopic (bright light) vision and are found at high density in the human fovea, enabling high-resolution color vision. Photoreception by rods and cones is rapid, responding to bright, short-duration stimuli and providing a topographically mapped output via the optic nerve. In addition, signals from the outer retina are processed by the inner retinal neurons, providing the initial stages of image construction, before being relayed via the axons of the retinal ganglion cells (RGCs) to the visual centers of the brain (Figure 2).

By contrast, the RHT projection to the SCN is composed of a small number of morphologically distinct RGCs. These cells (~1% of the total) are evenly distributed across the entire retina and are not topographically organized. Unlike the visual system, the circadian system needs relatively bright, longduration stimuli to achieve photoentrainment and is capable of temporally integrating signals over extended periods of time. Rather than detecting patterns of incoming light from a specific source (radiance), the circadian system detects only gross changes in environmental light (irradiance). A summary of the key differences between circadian and visual photoreception is provided in Table 1. These marked differences between image-forming vision and circadian

Figure 1 Schematic of the mammalian circadian system. (a) Environmental light information is detected by the eye and is transmitted to the suprachiasmatic nucleus (SCN) via the retinohypothalamic tract (RHT). The SCN is the site of the central circadian oscillator, based upon a molecular clock formed by the transcriptional–translational feedback loop of core clock genes and their proteins. Numerous additional tissues contain similar molecular clocks, and the SCN acts to coordinate these peripheral clocks to ensure internal synchronization. (b) Actograms illustrating mouse activity records. Under light–dark conditions, activity is entrained and occurs only during the dark phase. In constant darkness or following eye loss, an animal will free-run with an endogenous period of slightly less than 24 h. Following loss of the SCN, circadian rhythms are abolished, and the animal is behaviorally arrhythmic.

light detection have not been easy to explain, thus leading circadian biologists to investigate how rods and cones might be capable of mediating these two markedly different forms of light detection. The results from these studies are somewhat surprising.

A Novel Photoreceptor System

Initial studies to determine which retinal photoreceptors mediate circadian responses to light took advantage of a naturally occurring mutation in mice, termed retinal degeneration (*rd/rd*). These animals lack rods and show a greatly reduced number of cones. As might be expected, *rd/rd* mice fail to show any classical visual responses to light. Studies were thus undertaken to determine if the circadian system of *rd/rd* mice was similarly impaired. When a mouse is housed under a light–dark (LD) cycle, its circadian wheel-running behavior is entrained. As would be expected of a nocturnal species, mice are largely active during the dark and inactive in the light. Under conditions of constant darkness, entrainment is lost and circadian behavior drifts or free-runs with a period around 23.5 h. If the mouse is then exposed to a pulse of light shortly after activity onset (when the clock 'thinks' it is evening), it will delay the onset of activity the following day (Figure 3). The magnitude of this phase delay ($\Delta\phi$) is intensity dependent and can be used to determine the sensitivity of circadian responses to light. Both the wavelength and intensity of the light pulse can be systematically varied and the effect of these treatments on delaying wheel-running behavior can be assessed in a dose-dependent manner to produce a series of irradiance response curves (Figure 3).

Remarkably, the massive loss of classical photoreceptors in *rd/rd* mice had little or no effect on the ability of mice to phase-shift circadian rhythms in wheel-running behavior. Their irradiance response curves were indistinguishable from those of congenic wild-type controls. Eye loss completely blocked all effects of light on the clock. These initial studies demonstrated that the processing of light for circadian and visual responses must be different, and hinted at the fact that there may be another class of ocular photoreceptor. Such suggestions were met with considerable scepticism and the favored explanation was that, as ~5% of the cones survive in the peripheral retina of *rd/rd* mice, it is likely that only a small number of photoreceptors are necessary for photoentrainment. The development of a mouse model lacking all rods and cones, the *rd/rd cl*, resolved these issues (Figure 4) and demonstrated that both phaseshifting responses and pineal melatonin suppression in response to light were apparently normal. These data provided the conclusive evidence that an

Figure 2 The mammalian eye and retina. Light entering the eye is detected by photoreceptors in the outer retina, the rods and cones. These classical photoreceptors project to bipolar cells, which in turn synapse with retinal ganglion cells. Horizontal cells and amacrine cells are involved in retinal processing. The axons of retinal ganglion cells form the optic nerve projecting to the visual centers of the brain.

Table 1 Response characteristics of image-forming vision and circadian photoreception

Image-forming vision	*Circadian photoreception*
Detects radiance (directional)	Detects irradiance (nondirectional)
Rapid response (milliseconds) to brief stimuli	Insensitive to brief stimuli
Sensitive to dim light (rods)	Relatively insensitive to dim light
Short integration time (seconds)	Long integration time (minutes)
Primary projection via optic tract to LGN and SC, then on to visual cortex	Projects via retinohypothalamic tract to suprachiasmatic nucleus
Output is topographically mapped	Output is unmapped

additional photoreceptor exists within the mammalian eye, and further studies showed that these novel receptors do more than regulate the clock.

In mammals, light-induced pupil constriction is regulated by both rods and cones, but still occurs in animals showing profound damage to these photoreceptors. Not unreasonably, it was assumed that the residual pupil light response was due to the survival of a few rod and/or cone photoreceptors. Pupil measurements were undertaken in *rd/rd cl* mice and showed that these animals maintained a pupillary light response (PLR). Although less sensitive than congenic wild-type animals, *rd/rd cl* mice retained the ability to fully constrict their pupils. Nocturnal rodents will inhibit their general activity when exposed to light during the night. This response, called masking, is thought to complement circadian entrainment by ensuring that activity is restricted to the hours of darkness or near darkness. Masking may be particularly important in environments in which day length changes rapidly and circadian behavior may have difficulty keeping up with the expanding photoperiod. Masking experiments were undertaken in *rd/rd cl* mice and demonstrated that there is marked inhibition of activity upon exposure to light presented 2 h after normal 'lights off.' Thus, phase shifting, melatonin suppression, pupil constriction, masking, and probably a number of other systems are either intact or retained at some level in mice lacking all of their rods and cones. The persistence of such diverse responses to light suggests that the novel photoreceptors might contribute to many more aspects of mammalian physiology and behavior than previously suspected. For example, the irradiance of light has been shown to modulate sleep,

Figure 3 Schematic actogram illustrating mouse locomotor activity. (a) Under a light–dark cycle activity is confined to the dark phase of the 24-h cycle. However, in constant darkness (DD) mice free-run with a period of slightly less than 24 h. If exposed to a brief light pulse in the early evening, the animal will delay its activity onset the following day. The phase shift produced in this manner can be used to assess the sensitivity of the circadian system to light of different wavelengths and intensities. (b) The magnitude of the phase shift is proportional to the intensity of the irradiance provided by the light pulse, and can be plotted as an irradiance response curve.

Figure 4 The *rd/rd cl* mouse provided the conclusive evidence of an additional photoreceptive system in the mammalian eye, despite lacking much of the outer retina. In the absence of rods and cones, these animals are still capable of a range on irradiance detection tasks, including phase shifting, pineal melatonin suppression, and pupillary constriction in response to light. OS, outer segment; IS, inner segment; ONL, outer nuclear layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer; RPE, retinal pigment epithelium.

elevate cortisol, increase heart rate, and increase alertness, performance, and even mood. Whether these irradiance responses are also influenced by non-rod, non-cone ocular photoreceptors remains to be determined. Work currently underway in several laboratories around the world would suggest that this is very likely.

A Novel Photopigment

The first real insight into the nature of these novel receptors came from action spectrum studies. This powerful approach, developed by photobiologists such as the Nobel Laureate George Wald, rests upon the fact that a photopigment (light-detecting

pigment) has a characteristic absorbance spectrum or profile, which describes the likelihood of photons being absorbed at different wavelengths. As a result, a description of the spectral sensitivity profile (action spectrum) of any light-dependent response will describe the absorbance spectrum of the photopigment upon which the response is based. All known animal photopigments consist of an opsin protein, which binds a specific type of vitamin A (e.g., 11-*cis*-retinaldehyde) to form a photosensitive complex (**Figure 5**). The absorption of a photon of light by 11-*cis*-retinaldehyde converts it to an all-*trans* form. This change in shape of vitamin A alters the opsin, which in turn triggers the phototransduction cascade (**Figure 6**). This ultimately causes a change in the electrical activity of the photoreceptor cell that is transmitted by a neural pathway and ends with the perception of light. All vitamin A-based photopigments have a characteristic absorption spectrum. This means that although the peak sensitivity of the pigment may vary widely across the visible spectrum (ultraviolet at 360 nm to deep red at 750 nm), all of these pigments have the same basic shape, rather like a bell-shaped curve (**Figure 5**) – that is, they have a 'spectral fingerprint.'

The first action spectrum to be published on *rd/rd cl* mice was for pupil constriction, and the results described an opsin/vitamin A-based photopigment with peak sensitivity (λ_{max}) in the blue part of the spectrum near 480 nm (opsin photopigment; OP^{480}). The visual pigments of the mouse have λ_{max} values of 360, 508, and 498 nm for the ultraviolet-sensitive (UVS) cone, long-wavelength-sensitive (LWS) cone, and rod pigments, respectively. None of these classical photoreceptors could account for the pupillary responses to light. These studies were followed by an action spectrum in the *rd/rd cl* mouse for phase shifting. Once again, the results described an opsin/vitamin A-based photopigment with a λ_{max} very close to 480 nm. These data demonstrated that not only were rods and cone opsins not required for these irradiance detection tasks, but also that an entirely novel opsin/vitamin A-based photopigment must be present in the mouse eye.

Figure 5 Vertebrate photopigments are all based upon a common plan, consisting of an opsin protein with a vitamin A-based retinal chromophore. (a) Absorption of a photon of light by the retinal chomophore results in isomerization from the 11-*cis* to the all-*trans* configuration. (b) Retinal is constitutively bound to the seven-transmembrane domain receptor opsin, via a Schiff base linkage to lysine in the seventh transmembrane domain. Following photoisomerization the opsin protein undergoes a conformational change, resulting in activation of the G-protein transducin, and initiating the phototransduction cascade. (c) All opsin/vitamin A-based photopigments have a common absorption spectrum, enabling responses mediated by this type of photopigment to be identified. Opsin schematic based upon the model of Palczewski K, Kumasaka T, Hori T, et al. (2000) Crystal structure of rhodopsin: A G protein coupled receptor. *Science* 289: 739–745.

Figure 6 The process by which activation of a photopigment leads to intracellular signaling events and changes in membrane potential is termed phototransduction. (a) Hyperpolarization: Phototransduction by rods and cones has been extensively studied, and the key elements of this signaling pathway are well characterized. Following photoisomerization of retinal, the opsin protein activates the G-protein transducin (PTX, pertussis toxin). Transducin activates phosphodiesterase (PDE), which hydrolyzes cyclic guanosine monophosphate (cGMP), leading to closure of cyclic nucleotide-gated (CNG) channels and hyperpolarization of the photoreceptor cell membrane. (b) Depolarization: The phototransduction cascade used by photosensitive retinal ganglion cells (pRGCs) is poorly understood, but appears to involve a G_q-type G-protein, phospholipase C (PLC), and transient receptor potential (TRP) channels, resulting in depolarization of the pRGC.

Additional evidence for the presence of a novel blue-light-sensitive photopigment in mammals comes from three studies in humans. Two of these studies looked at the light regulation of the hormone melatonin and suggested the involvement of an opsin-based photopigment with a λ_{max} between 450 and 480 nm. The third study looked at light-driven changes in cone function in the eye and defined a pigment with a λ_{max} 483 nm. The similarity of all three human studies to each other, and correlation to mouse OP^{480}, suggest that humans possess an ortholog of mouse OP^{480}.

Photosensitive Retinal Ganglion Cells

The identification of the cells mediating the responses to light was provided by two sets of experiments. Studies on the rat used retrograde tracers injected into the SCN coupled with single-cell recordings on isolated retina in which rod and cone responses were pharmacologically blocked. Parallel studies were undertaken using calcium imaging on the *rd/rd cl* retina. Both approaches identified a population of RGCs which responded directly to light. Significantly, these photosensitive retinal ganglion cells (pRGCs) expressed an opsin called melanopsin.

The melanopsin gene family, also known as *Opn4*, was first identified in *Xenopus*, and orthologs were subsequently isolated from other vertebrate classes, including mammals. Melanopsin generated excitement almost immediately because it was shown to be expressed within RGCs, and the anatomical distribution of these RGCs was remarkably similar to that of cells projecting to the SCN and forming the RHT. More recently melanopsin-expressing RGCs have been shown to project to other nuclei in the brain associated with processing irradiance information. These include the intergeniculate leaflet (IGL), olivary pretectal nuclei (OPN), and the ventrolateral preoptic nuclei (VLPO). The essential data that melanopsin plays a critical role in the transduction of light information in pRGCs came from gene ablation studies. Melanopsin knockout mice ($Opn4^{-/-}$) exhibit attenuated phase-shifting and pupillary responses to light, as well as reduced period lengthening in constant light (LL). However, the critical involvement of melanopsin in photoreception came from triple-knockout studies of mice lacking rods, cones, and melanopsin. These animals were totally unresponsive to light, demonstrating that melanopsin is in some way essential for pRGC photosensitivity.

The possibility that melanopsin acted as a photoisomerase in these cells was eventually excluded by a series of studies in which melanopsin was functionally expressed.

The first investigation of the biochemistry of melanopsin involved expression of melanopsin in COS cells and reconstitution with 11-*cis*-retinal. The resultant pigment showed a λ_{max} between 420 and 440 nm, an absorption maximum considerably shifted away from OP^{480}. The discrepancy in λ_{max} between spectroscopy and action spectra, coupled with the low signal/noise from the absorbance spectroscopy, prompted the use of other approaches to address whether melanopsin can act as a photopigment. Quite independently, three groups combined the expression of melanopsin protein with physiological assays of cellular photosensitivity. All three studies showed that melanopsin transfection can confer photosensitivity to nonphotosensitive cell types (Neuro-2a cells, HEK293-TRPC3 cells, and *Xenopus* oocytes). In addition, these groups were able to show that specific forms of retinal (especially 11-*cis*-retinal) are needed for these responses to light, that light will ultimately trigger the release of intracellular calcium, and that this will involve some form of G-protein interaction with melanopsin. Expression studies on human melanopsin suggest that the λ_{max} of light responses is close to 420–430 nm, and in this regard the findings were similar to those obtained by Newman and colleagues. The studies on murine melanopsin, however, showed an action spectrum for light responses that exhibited a λ_{max} very close to 480 nm. The current consensus from the various groups is that something about the local environment in which melanopsin is reconstituted is important in determining its λ_{max}.

While the phototransduction cascade used by rods and cones has been characterized extensively, the mechanisms used by pRGCs remain poorly understood (**Figure 6**). Unlike rods and cones, pRGCs depolarize in response to light, and in this manner more closely resemble invertebrate photoreceptors. Pharmacological studies on pRGCs have suggested the involvement of a transient receptor potential (TRP)-like channel in these responses. Additionally, pharmacological studies on cells transfected with melanopsin suggest that their light responses are insensitive to pertussis toxin, a blocker of G_i/G_o-type G-proteins, including transducin (the G-protein of the rods and cones). However, agents which inhibit G_q/G_{11}-type G-proteins do prevent these responses. Further downstream, drugs which block phospholipase C (PLC) have been shown to block these responses. These findings suggest a phototransduction cascade more akin to that found in invertebrates. However, these findings are based upon signal transduction pathways which are activated in nonnative cell types, and whether similar processes occur in pRGCs remains to be determined.

pRGC/Rod/Cone Interactions

The pRGCs provide measures of environmental irradiance in mammals. But this does not mean that the rods and cones play no role in these light-detecting tasks. Indeed, several lines of evidence suggest that both classical and novel photoreceptors interact in the detection of brightness. This is clear in the case of the PLR, where the loss of the rods and cones leads to a marked decrease in the sensitivity of the response. In this case, we have suggested that the rods and cones allow a rapid assessment of light transitions and cause an immediate pupillary constriction or dilation. By contrast, the pRGCs are likely to provide sustained responses to prolonged periods of environmental brightness. In the case of the circadian system, the role of the rods and cones is less clear. The loss of these receptors causes only subtle effects on circadian entrainment. By contrast, loss of the melanopsin gene alone merely attenuates circadian responses to light. It is only when all the rods, cones, and melanopsin are genetically ablated that circadian responses to light are completely abolished. As a result, there seems to be a complex and semiredundant interaction between the classical and novel photoreceptor systems of the murine eye in the regulation of the biological clock. Very recent studies in primates has shown that some form of spectral opponency appears to occur in pRGC output, with excitation produced by cones sensitive to medium and long wavelengths, and inhibition from short-wavelength-sensitive cones.

Perhaps this overlap in function should be of no great surprise. There are many good examples wherein multiple photopigments have been shown to regulate circadian physiology in nonmammalian vertebrates, invertebrates, and plants. Why this should be and how these photopigments might interact remain a mystery, but must surely relate to the difficult task of extracting time-of-day information from dawn and dusk. During twilight, the quality of light changes in three important respects: (1) the amount of light (irradiance), (2) the spectral composition of light, and (3) the source of light (i.e., the position of the sun). These parameters of the light environment all change systematically and, in theory, could be used by the circadian system to detect the phase of twilight. However, each of these features is subject to subtle variations or 'noise,' the type and extent of which will depend upon both the species (e.g., sedentary or mobile) and the environment. A general feature of sensory systems is the need to extract an appropriate

signal from background noise, and much of the complexity observed in sensory systems in general is associated with noise reduction. One way to do this is to have different receptors, with slightly different response ranges, sampling the same scene. Perhaps the circadian system utilizes the pRGCs to provide measures of brightness, while it utilizes the rods and cones to detect the direction and color of environmental light. This information would be integrated to provide an assessment of the time of dawn and dusk based upon several features of the changing quantity and quality of light at twilight.

Future Perspectives

Our understanding of the photoreceptors involved in the regulation of circadian physiology has undergone a remarkable transformation in the past decade. The discovery of a previously unrecognized photoreceptor system in the mammalian eye has provided a greater understanding of how light modulates not only the circadian system, but also a whole range of non-image-forming responses to light. As with any new discovery, numerous additional questions remain unanswered. Future studies are required to address the relative contribution of rods, cones, and pRGCs to different irradiance detection tasks; the phototransduction mechanisms used by the pRGCs; whether these cells contribute to our visual perception of the environment; how the signals from the retina are integrated by the SCN to bring about photoentrainment of the biological clock; and the role of classical photoreceptors and pRGCs in the modulation of sleep. Answering these questions will provide a greater understanding of how numerous aspects of our physiology are regulated by the light environment, and may provide future therapeutic strategies for dealing with circadian disturbances associated with jet lag, shift work, sleep disorders, and a range of mental health problems.

Introduction

Photoreceptors are cells that can detect light by virtue of a light-absorbing pigment. In the nervous system, photoreceptors serve to detect light for either image-forming or non-image-forming visual functions. Image-forming vision underlies the detection and recognition of objects and their motion. Non-image-forming vision, on the other hand, simply informs the organism about the intensity and spectral composition of the light in the ambience, often for tracking the time of day or seasonal changes.

Types of Photoreceptors

In the animal kingdom, the great majority of neural photoreceptors are readily identifiable as being either ciliary or microvillous; that is, their photosensitive structure is derived from either modified cilia or modified microvilli. In either case, the photoreceptors are often clustered in special organs (eyes), although they can also be present in small numbers in less well-defined regions of the nervous system. Occasionally, the photoreceptors may not bear any obvious morphological signs of being ciliary or microvillous.

In vertebrates, the most prominent photoreceptors are the rods and cones in the retina of the eyes (also called lateral eyes). Indeed, it was long thought (for well over 100 years) that rods and cones are the only light-sensitive neurons in the retina. However, work in the past several years has now shown that some other retinal neurons are also intrinsically photosensitive. In mammals, these consist of a small subset (about 1%) of the retinal ganglion cells (the axons of which form the optic nerve and project to the brain). Besides the two lateral eyes, the pineal gland of some vertebrates, notably birds and fish, is also light sensitive. In mammals, the pineal gland is not light sensitive, but at least in rodents it has been reported that this organ is light sensitive in neonates. Certain lizards have a structure called the parietal ('third') eye located on the forehead between the two lateral eyes (see the section titled 'Parietal-eye photoreceptors in lizard'). Some amphibians have a comparable structure called the frontal organ. Rods, cones, light-sensitive pinealocytes, and parietal-eye photoreceptors are all of the ciliary type. On the other hand, the classification of the intrinsically photosensitive retinal ganglion cells, which show no detectable ciliary or microvillous morphology, is less clear. Deep-brain photoreceptors also exist in birds, amphibians, and fishes, but not much is known about them.

In invertebrates, the great majority of photoreceptors so far studied are of the microvillous type. These include the photoreceptors in the insect compound eyes and the eyes of squid, octopus, and various mollusks. These microvillous photoreceptors are often called rhabdomeric photoreceptors because their photosensitive microvilli form a 'rhabdom.' Ciliary photoreceptors do exist in invertebrates, with one well-known example being the hyperpolarizing photoreceptor in scallop. There are also single, isolated photoreceptors in the molluskan neural ganglia that do not show any obvious ciliary or microvillous morphology, but at least some of these resemble ciliary photoreceptors in terms of the molecular components they use for phototransduction.

Retinal Rods and Cones

The rod photoreceptors across all vertebrate species are essentially the same structurally and functionally; similar is the case with cones. Rods are very sensitive to light, being able to detect and signal the absorption of a single photon. They are responsible for vision in dim light (scotopic conditions). Cones are much less sensitive to light than are rods (by about 25–100 times, or more in certain vertebrate species), and they are capable of adapting to background light much more effectively. Cones are responsible for vision in brighter light (photopic conditions). The eyes of most vertebrates are rod dominant (i.e., having a lot more rods than cones in the retina), but a few are cone dominant (e.g., those of ground squirrel and chicken). In human, although the retina has mostly rods (95% or more of the photoreceptors are rods), the center of the fovea, which is the part of the retina that mediates acute vision, has exclusively cones. Accordingly, we rely on cones for our daily vision under practically all light conditions, except for the lowest two log units of detectable light intensities.

Humans have three types of cones: red or long-wavelength-sensitive cones, green or medium-wavelength-sensitive cones, and blue or short-wavelength-sensitive cones, each with a different visual pigment. The presence of more than one type of cone with distinct spectral sensitivities is what allows us to discriminate between

monochromatic light at different wavelengths, which are perceived by us as having different colors. Each of these colors is essentially a distinct sensation evoked by a unique ratio of activation of the three cone types due to a given monochromatic light. For example, red light activates mostly red-sensitive cones, less so the green-sensitive cones, and still less so the blue-sensitive cones. Green light activates best green-sensitive cones, less so the red-sensitive cones, and still less so the blue-sensitive cones, etc. If one represents the relative excitations of the three cone types as the three axes of a three-dimensional coordinate system, the direction of a vector in this three-dimensional space then corresponds to a particular color sensation, and the length of the vector represents the brightness. In other words, color and brightness are distinct attributes of the light, with no confusion between them. The same holds when mixtures of two or three monochromatic lights are viewed; namely, each of these mixtures evokes a unique color sensation that cannot be reproduced by any other mixture of two or three monochromatic lights, regardless of their intensities. However, the situation breaks down when four or more monochromatic lights are present in a mixture. There are many mixtures of four or more monochromatic lights (with appropriate relative intensities) that will all appear to us as being identical in color. The reason for this degeneracy is that our retina has only three types of cones. If we had more types of cones, we would then be able to discriminate between light mixtures made up of more than three monochromatic components. In general, it can be shown by simple algebra that, if there are n cone types in the retina, the visual system should be able to discriminate between any two light mixtures having up to n monochromatic components (i.e., perceived by the system as having different colors). Why don't we, then, have more than three types of cones? The answer is that our visual system has to process separately many different attributes of the visual image, including bright/dark contrast, motion, acuity, etc., through complex circuitry, and color is only one of these attributes. Thus, there is inevitable compromise as to how much elaboration the system can devote to any particular visual attribute.

In contrast to cones, we have only one type of rod, all containing the same pigment, rhodopsin, which is most sensitive to blue–green light. Thus, we have no color vision under scotopic conditions, when the cones are inactive. In the vectorial representation described earlier, this situation is equivalent to saying that, with only one type of rod, the 'color perception' is reduced to one dimension, in which all vectors collapse to the same direction (hence no distinct colors), and light intensity (brightness) becomes the only variable, regardless of the complexity of the light mixture. In mesopic conditions (i.e., at light levels where the transition between rod-mediated and cone-mediated vision takes place), rods may also partake in color vision.

The number of types of cones and rods is not uniform across vertebrate species. Some lower species have more than one type of rod (e.g., amphibians) and as many as four types of cones (e.g., fishes). Other species have only two types of cones, including the New World monkeys (with only red-sensitive and blue-sensitive cones). Old World monkeys, like us, have also green cones. The green-pigment gene in us originated from duplication of the red-sensitive pigment gene (the two genes are immediately adjacent to each other). Genetic polymorphisms in the amino acid sequences of the human pigments lead to slight variations in their spectral sensitivity and therefore slight differences in color perception among individuals. The loss of one or more cone pigment genes also leads to various degrees of color blindness (i.e., a lesser ability to discriminate between different light mixtures).

Morphology of Rods and Cones

Morphologically, each rod or cone is made up of the outer segment, the inner segment, the cell body, and the synaptic terminal (**Figure 1**). The outer segment contains the visual pigment, and is where light is absorbed and transduced into an electrical signal. Developmentally, it is a modified cilium that has become highly expanded and folded, giving rise to hundreds of membrane disks tightly and orderly stacked one on top of another throughout the outer segment. In rods, almost all of the disks (except for a small number at the base) have become internalized, that is, their membranes are no longer continuous with the plasma membrane. In cones, the disk membranes remain continuous with the plasma membrane. The membranes of the disks contain the visual pigment, packed to 10^7–10^9 molecules per cell. Associated with the disk membranes are also several phototransduction proteins. The rest of the transduction proteins are either cytosolic or situated in/on the plasma membrane of the outer segment. The inner segment houses the metabolic machinery. The part of inner segment adjacent to the ciliary stalk (called the ellipsoid) is chock-full of mitochondria for handling the heavy energy demand of the outer segment. At the proximal end of the cell are the cell body and the synaptic terminal. Glutamate is the neurotransmitter.

Overlying the outer segments of rods and cones are the pigment epithelial cells, which contain black pigment granules. These cells serve multiple functions.

Figure 1 Morphology of rod photoreceptors. The phototransduction machinery is housed in the outer segment. The figure shows the basic mechanism underlying the light response. In darkness, a circulating current between the outer segment and the rest of the cell (with an inward direction across the outer-segment membrane) keeps the rod depolarized and maintains a high glutamate release at the synaptic terminal. In the light, the circulating current decreases, and the glutamate release is reduced. Reproduced from Yau K-W (1994) Phototransduction mechanism in retinal rods and cones. The Friedenwald Lecture. *Investigative Ophthalmology and Visual Science* 35: 10–32.

One function is to absorb any light not absorbed by the rods and cones at first pass, so as to prevent degradation of the visual image due to backscattering. Another is to mediate the transfer of metabolites, ions, water, etc., between the photoreceptors and the capillaries lying behind the pigment epithelium. A third function is to regenerate the pigment after it is bleached by light (see the section titled 'Phototransduction mechanism in rods and cones'). Finally, the outer segment of both rods and cones continue to elongate on a daily basis through the addition of new disks at the base. The overall length of the outer segment is nonetheless kept constant by the coordinated shedding of distal disks, in conjunction with the phagocytosis of these shedded disks by the pigment epithelial cells. For mouse rods, it takes about 10 days for a disk to travel from the base to the tip of the outer segment. This renewal process may be important for removing any cumulative, deleterious effect of photooxidation in rods and cones. In some nocturnal animals, such as cats and dogs, part of the pigment epithelium is less pigmented, and reflective cells lie behind the epithelium to form the tapetum. This reflective layer serves to back-reflect any light unabsorbed by the rods and cones at first pass, so as to give the light a second chance to be absorbed. The presence of a tapetum explains why the eyes of nocturnal animals glow when illuminated in the dark. The tapetum increases light sensitivity in darkness, but does degrade the visual image somewhat.

Light Response of Rods and Cones

Rods and cones have a membrane potential of about –30 to 35 mV in darkness, and they respond to light with a membrane hyperpolarization, unlike most other sensory receptor cells, which depolarize in response to stimulation. They do not have an action-potential mechanism. Because of their relatively depolarized state in darkness, they continuously release glutamate from their synaptic terminals onto bipolar cells and horizontal cells, the second-order visual neurons in the retina. The light-triggered membrane hyperpolarization reduces the glutamate release. The brighter the light, the larger is the membrane hyperpolarization in rods and cones, and therefore the greater is the reduction in glutamate release. The bipolar cell, which is the second-order throughput neuron, can respond to this decrease in glutamate release with either a hyperpolarization (OFF-bipolar cell) or a depolarization (ON-bipolar cell), depending on the nature of the postsynaptic glutamate receptor it possesses.

The rod and cone responses are relatively slow (with the cone response being the faster of the two), reflecting a second-messenger-mediated transduction mechanism (see the section titled 'Phototransduction mechanism in rods and cones'). For example, the rod response to a dim, brief flash lasts for over a second for cold-blooded animals at room temperature, though faster at the higher body temperature of mammals. The speeds of the rod and cone responses dictate how rapidly the visual system can detect image changes on the retina (temporal resolution), and therefore motion. Because cones have faster responses than do rods, they are better motion detectors. On the other hand, the slower response of rods allows these cells to sum signals slightly spread over time (temporal integration), thus enhancing their sensitivity in dim light, especially useful for static images.

Figure 2 shows the responses of an amphibian rod to a light flash at different intensities, recorded simultaneously with an intracellular voltage electrode and with a suction pipette that records membrane current at the outer segment. The suction pipette shows that an inward current flows in darkness across the outer-segment membrane (which accounts for the not-so-negative resting potential in darkness), and that light decreases this 'dark current' (which accounts for the

Figure 2 Electrical recordings from rod photoreceptors. (a) Diagram illustrating the suction-pipette recording method from a single rod outer segment protruding from a piece of retina. The circuitry follows the same design as patch clamp recording. (b) Response families recorded from a salamander rod simultaneously with a suction pipette (upper panel) and a sharp intracellular electrode (lower panel). Light flashes of increasing intensity (by about factor of 2) were delivered at time zero. The largest responses are saturated, resulting from a complete stoppage of the dark current. The small responses represent averages from multiple flash trials. In the upper panel, negative current means inward current at the outer segment. (a) Reproduced from Yau K-W, Lamb TD, and Baylor DA (1977) Light-induced fluctuations in membrane current of single toad rod outer segments. *Nature* 269: 78–80. (b) Reproduced from Baylor DA, Matthews G, and Nunn BJ (1984) Location and function of voltage-sensitive conductances in retinal rods of the salamander, *Ambystoma tigrinum. Journal of Physiology* 354: 203–223.

membrane hyperpolarization) until its complete suppression by bright light (see also Figure 1). With a bright flash, the voltage response shows a fast re-depolarization from the peak hyperpolarization before settling to a plateau level. This transient 'nose' (especially prominent in rods) is not observed in the response of the membrane current at the outer segment. The nose reflects the effect of a hyperpolarization-activated cation current (I_h) carried by both Na^+ and K^+, with a reversal potential close to 0 mV. This I_h current is situated at the inner segment and cell body, which explains why it is not detected by the suction-pipette recording. The suction-pipette recording method therefore monitors the phototransduction event in the outer segment more faithfully, without much contamination by the signal from other parts of the cell. This recording method has been tremendously useful in examining the details of phototransduction.

With increasing flash intensity, the response increases progressively until saturation is reached. When the transient peak amplitude of the flash response is plotted against the corresponding flash intensity (intensity–response relation), a relation fairly close to the Michaelis relation in enzyme kinetics is found, especially with cold-blooded animals, namely, $R = R_{max}[I_F/(I_F + \sigma)]$, where R is the transient peak amplitude of the response, R_{max} is the saturated response amplitude, I_F is the flash intensity, and σ is the half-saturating flash intensity. While simple, this relation does not really convey the mechanism underlying the generation of the light response. In other words, the relation is purely empirical. For one thing, with increasing flash intensity, the transient peak of the response moves earlier in time (i.e., the time between flash and transient peak of the response, or time-to-peak, gets shorter), due to the decay phase of the response cutting into the rising phase earlier. This is a sign of active adaptation by the cell to progressively brighter illumination. If a long step of light is used for stimulation instead, the response rises to a transient peak and then relaxes to a lower plateau level, with the response relaxation again reflecting adaptation of the cell to steady light. If the flash–response amplitude in Figure 2 is measured instead at a 'fixed' early time in the rising phase of the response, before any light adaptation sets in, the flash intensity–response relation is described instead by the relation $R = R_{max}[1 - \exp(-I_F/\rho)]$, where the half-saturating flash intensity is given by $\rho(\log_e 2)$. This relation bears a simple mechanistic interpretation, namely that each absorbed photon activates a spatially restricted region of the outer segment, within which the transduction effect essentially reaches saturation (i.e., all dark current in this region is suppressed).

The rod and cone photoresponses are detectable as the a-wave in the electroretinogram (ERG), which is a mass recording from the retina with an electrode placed near the cornea of the intact eye. However,

the a-wave does not provide the full time course of the photoreceptor light response because the b-wave (which largely originates from the activity of bipolar cells, especially ON-bipolar cells) of the ERG, which immediately follows the a-wave, obscures the decline phase of the a-wave. The ERG nonetheless provides a very useful clinical tool for assaying rod and cone function in human patients.

Single-Photon Response

It was mentioned earlier that rods are so sensitive to light that they can signal the absorption of a single photon. The response triggered by an absorbed photon is indeed quite large, with an amplitude close to 1 pA, and is directly observable with suction-pipette recording. In amphibian rods, the single-photon response amplitude corresponds to about 3% of the maximum (or saturated) light response. Thus, as few as about 30 absorbed photons will produce a response that is half-maximum. This large signal reflects the high amplification of the signal transduction mechanism underlying phototransduction in rods (see the section titled 'Phototransduction mechanism in rods and cones'). The single-photon response is quite constant in amplitude and highly stereotyped in kinetics: these properties make rods a very faithful photon counter.

In cones, the single-photon response is considerably (25–100 times) smaller, reflecting quantitative (although not qualitative) differences from rods with respect to the underlying phototransduction mechanism. Most of the difference in sensitivity between dark-adapted rods and cones in fact comes from this factor, rather than from the ability to capture light, which is broadly comparable in rods and cones.

Pigment Noise

A visual pigment molecule is composed of a protein moiety (opsin) and a chromophore (the light-absorbing component) covalently linked to the opsin (to be described more in detail in the following sections). Light acts by photoisomerizing the chromophore, thereby activating the pigment. It takes substantial light energy to isomerize the pigment, so the latter is very stable in darkness. Nonetheless, isomerization can, and does, occur spontaneously in darkness due to the thermal energy associated with the molecule, giving rise to false signals about light in darkness. In rods, the rate of spontaneous isomerization is about one event per minute per cell. Considering the large number of pigment molecules present in a cell (see the section titled 'Morphology of rods and cones'), the corresponding rate constant is very low, being about 10^{-10}–10^{-11} s^{-1} at room temperature (and about tenfold higher at 37 °C). This gives a half-life of rhodopsin in the neighborhood of hundreds of years! Thus, rhodopsin can be considered to be very stable, and is ideal for the task of detecting dim light. Cone pigments have a much higher tendency to isomerize thermally, especially the long-wavelength-sensitive (red) pigment. This is not as critical as in rods from the point of view of signal-to-noise ratio, because cones operate in much brighter light. On the other hand, the higher rate of thermal isomerization does mean that there is a higher level of 'dark light' (i.e., equivalent light in darkness). This dark light will trigger light adaptation in cones even in the absence of real light, causing the cones to have a lower sensitivity than they would have if the pigment were stable. In other words, part of the sensitivity difference between rods and cones in darkness may be due to the noisy cone pigment.

Another interesting difference between rod and cone pigments is that rod pigment, once formed from opsin and the chromophore, does not re-dissociate until isomerization followed by bleaching takes place (see the following sections). Cone pigment, on the other hand, has some tendency to re-dissociate into opsin and chromophore without isomerization. Thus, even in darkness, some of the opsin in cones lack chromophore and therefore incapable of signaling light (though this, again, may not matter very much, considering that cones function in bright light). Also, it turns out that opsin itself has a weak constitutive ability to activate the transduction process. This bare-opsin activity can also cause some adaptation by cones in darkness, lowering their sensitivity further. Is there any usefulness in the property of dissociation of cone pigments? Probably not much, in the context of signaling. However, cone pigments need to recycle rapidly (see the section titled 'Phototransduction mechanism in rods and cones') because they operate in bright-light conditions. This rapid recycling requires rapid dissociation of the photoisomerized chromophore from the opsin, then entering the retinal pigment epithelial cell (see the section titled 'Morphology of rods and cones') to be regenerated (reisomerized) to the dark state before returning and recombining with the bare opsin to form nascent holopigment. The rapid dissociation of the photosiomerized chromophore from cone opsin presumably requires a loose (or relatively open) chromophore-binding pocket on cone opsin, which likely impacts the stability of the dark pigment as well, hence the dark dissociation. In other words, the molecular design to achieve rapid regeneration of the bleached pigment may come with a price for the behavior of the dark pigment.

Incidentally, the same weak, constitutive activity of bare opsin underlies the phenomenon of 'bleaching adaptation.' It has been known for a long time that, if bleached pigment is not regenerated, the sensitivity of a rod or cone is suppressed. However, this suppression of sensitivity is far more severe than expected simply from the reduction in photon-capture capability due to the presence of bare opsin (the probability of photon capture varies inversely with the percentage of bare opsin). Indeed, the suppressive effect of bare opsin on sensitivity comes mostly from its constitutive activity to trigger the transduction process (and therefore adaptation) rather than the proportional decrease in holopigment.

The cGMP-Gated Channel

The inward dark current of rods and cones that is suppressed by light goes through a cyclic guanosine monophosphate (cGMP)-gated cation channel on the plasma membrane of the outer segment. This channel is unusual by being directly opened (or 'gated') by a cyclic nucleotide, cGMP in this case. It is a nonselective cation channel, passing not only Na^+ and K^+, but also Ca^{2+}. About 75% of the dark current is carried by Na^+ and the rest is largely carried by Ca^{2+}. In steady state in darkness, the Na^+ influx is balanced by an efflux via the Na^+ pump in the inner segment, and the Ca^+ influx by an equal efflux via a $Na^+/Ca^{2+}/K^+$ exchange mechanism in the outer segment. This $Na^+/Ca^{2+}/K^+$ exchange likewise depends on the maintenance of an inward-directing Na^+ electrochemical gradient by the Na^+ pump. This explains the heavy metabolic load on the rods and cones mentioned at the beginning of this article, and the heavy concentration of mitochondria next to the outer segment. Indeed, the retina has one of the highest, if not the highest, oxygen consumption in the body.

As a ligand-gated channel, the cGMP-gated channel is also unusual in that it shows no desensitization to its ligand, cGMP. While unusual, this feature is functionally important, because it allows the channel to stay open in darkness in the presence of a steady concentration of cGMP in the cytoplasm of the outer segment, and to be closed only by light via a reduction in cGMP (see next section). Rods and cones have molecularly distinct cGMP-gated channels, though these are functionally quite similar. These rod and cone channels are members of a family of cyclic nucleotide-gated (CNG) channels, which also include the channel that mediates olfactory transduction in olfactory receptor neurons in the nose.

One interesting property of the rod and cone cGMP-gated channels (and CNG channels in general) is that, apart from being permeable to divalent cations besides monvalent cations, they are also subject to constant, partial blockage by external divalent cations (Ca^{2+} and Mg^{2+}) under physiological conditions. One consequence of this (kinetically fast) blockage is that the channels have a very small effective single-channel conductance (after low-pass filtering by the membrane time constant). This small single-channel conductance means that the quantization noise associated with the opening and closing of channels is reduced, effectively increasing the signal-to-noise ratio of the light signal.

Phototransduction Mechanism in Rods and Cones

Phototransduction is the process by which the absorbed light triggers an electrical response (the neural signal) in rods and cones. As mentioned in the previous section, this process involves the closure by light of a cGMP-gated, nonselective cation channel. The mechanism by which light closes the channel is now very well understood (**Figure 3**).

As mentioned earlier, visual pigments are made up of opsin, the protein moiety, and a covalently linked chromophore, which is 11-*cis*-retinaldehyde (or simply 11-*cis*-retinal), a derivative of vitamin A. Essentially all land-based animals have the same chromophore, but each rod and cone opsin is a different protein, which tunes the absorption spectrum of the chromophore. Photoisomerization involves a conversion of 11-*cis*-retinal into all-*trans*-retinal. This change unleashes spontaneous conformational changes in the opsin, with the active intermediate, Meta II, being formed within about 1 ms. Meta II then activates transducin, a heterotrimeric G-protein (G_T, composed of α, β, and γ subunits), by prompting the substitution of guanosine triphosphate (GTP) for GDP on the α-subunit, $G_{T\alpha}$; the dissociation of $G_{T\alpha}\cdot$GTP from $G_{T\beta\gamma}\cdot G_{T\alpha}\cdot$GTP in turn stimulates a cGMP-phosphodiesterase (cGMP-PDE) to increase the hydrolysis of cGMP. This enzyme is composed of two catalytic subunits (PDE$\alpha\beta$ in rods or two copies of PDEαs in cones) and two inhibitory subunits (two copies of PDEγs in rods and in cones). $G_{T\alpha}\cdot$GTP acts by binding to an inhibitory subunit and removing its inhibitory influence on a catalytic subunit. The resulting increase in PDE activity lowers the cytoplasmic level of cGMP, and the CNG channels therefore close. This closure of the cation channels produces a membrane hyperpolarization as the light response, and reduces the glutamate release from the synaptic terminal of the cell. The high amplification of phototransduction in rods (described earlier), which allows these cells to signal single absorbed photons, arises in part from the fact that each rhodopsin molecule has a long active

Figure 3 Phototransduction mechanism. (a) Schematic diagram of phototransduction in rods. lifetime in the Meta II state before inactivation sets in (see following paragraph), so that it is able to activate successively a substantial number of transducin molecules.

The termination of phototransduction involves the phosphorylation of Meta II by a specific kinase (pigment kinase, a member of the G-protein-coupled receptor kinase, or GRK, family), followed by the binding of a protein called arrestin to cap the activity of Meta II. At the same time, $G_{T\alpha}$·GTP self-deactivates by its intrinsic GTPase activity, which hydrolyzes the bound GTP to GDP and consequently returns to its inactive $G_{T\alpha}$·GDP state to be ready for activation again after reassociating with $G_{T\beta\gamma}$. The GTPase activity of $G_{T\alpha}$·GTP is enhanced by PDEγ, its substrate, together with a GTPase-activating protein (GAP) complex, which consists of RGS9 (regulator of G-protein-signaling isoform 9) and $G_{\beta 5}$, another G-protein β-subunit or a G-protein β-subunit-like protein. When transducin deactivates, so does PDE by restoration of the inhibitory activity of its PDEγ. The free cGMP concentration then returns to the dark level because of ongoing activity of the cGMP-synthesizing enzyme, guanylate cyclase (GC). In short, there is steady cGMP synthesis and hydrolysis in darkness, and a light flash simply transiently tips the balance toward hydrolysis. Meta II eventually decays to an intrinsically inactive state. The pigment then dissociates into opsin and free all-*trans*-retinal, a process called 'bleaching.' The opsin also loses its bound arrestin and is dephosphorylated by a generic kinase (protein phosphatase 2A). As for the all-*trans*-retinal, it is reduced to all-*trans*-retinol ('-ol' stands for 'alcohol'). All-*trans*-retinol diffuses, perhaps helped by a carrier protein, from the photoreceptor into the pigment epithelial cell, where it is converted into all-*trans*-retinylester, then reisomerized (by the isomerohydrolase enzyme RPE65) to 11-*cis*-retinol and oxidized to 11-*cis*-retinal, before returning to the photoreceptor and combining spontaneously with opsin to re-form the holopigment. Recently, it has become known that Muller cells also possess a self-contained chromophore-regenerating mechanism, apparently specifically for the cones. This additional regeneration mechanism may be important in bright light, when cone pigment has to compete with rhodopsin for 11-*cis*-retinal but may not win out because the nondissociable rhodopsin will out-compete the dissociable cone pigment by acting as a huge sink for 11-*cis*-retinal.

Ca^{2+} has a critical role in active adaptation of the rod or cone to light, as mentioned earlier. Because the CNG channels are permeable to Ca^{2+}, there is a steady Ca^{2+} influx in darkness, balanced by a steady Ca^{2+} efflux via a $Na^+/Ca^{2+}/K^+$ exchanger, an antiporter that uses the standing inward-directed Na^+ electrochemical gradient and outward-directed K^+ electrochemical gradient to extrude Ca^{2+} against its inward-directed gradient. Like the CNG channel, this exchanger is present on the plasma membrane of the outer segment. In the light, the closure of CNG channels stops the Ca^{2+} influx, but the Ca^{2+} efflux through the exchanger continues, resulting in a decrease in the free Ca^{2+} concentration in the outer segment. This Ca^{2+} decrease triggers multiple negative-feedback pathways to regulate phototransduction by opposing the effect of light, thus producing active adaptation by the cell to light. One negative-feedback pathway acts on GC to enhance its activity. The activity of GC is facilitated by guanylate-cyclase-activating proteins (GCAPs), which in turn are controlled by Ca^{2+} in that they act well when not binding Ca^{2+} and poorly when they bind Ca^{2+}. Thus, in darkness, the GC activity is only moderate because the high intracellular free Ca^{2+} keeps the GCAPs in check, whereas in the light, the GC activity is enhanced to oppose light because the GCAPs are more active due to lower free Ca^{2+}. Another pathway apparently acts on the pigment kinase that phosphorylates Meta II to quench the latter's activity, via a Ca^{2+}-binding protein called recoverin. It is thought that recoverin in Ca^{2+}-bound form inhibits the pigment kinase. Thus, in the light, when Ca^{2+} is relatively low and recoverin loses its bound Ca^{2+}, the kinase quenches Meta II quickly to reduce amplification, again opposing light. A third pathway acts on the CNG channel via calmodulin, which in Ca^{2+}-bound form reduces the affinity of the channel for cGMP. Thus, in darkness, the Ca^{2+}-calmodulin binds to the CNG channel and lowers its probability of opening. In the light, calmodulin loses its bound Ca^{2+} and dissociates from the channel, as a result of which the CNG channel is more likely to reopen because of its now higher affinity for cGMP, thus opposing the effect of light. Calmodulin, GCAPs, and recoverin are all EF-hand-type Ca^{2+}-binding proteins. Of the three Ca^{2+}-mediated regulatory pathways, the one on GC is the most important for low and intermediate light levels, above which the one via recoverin begins to kick in, becoming increasingly important with still higher light levels. The regulatory pathway on the channel is weak and of minimal importance.

As mentioned previously, cones have a much lower sensitivity to light, and they also adapt to light much more effectively, compared to rods. The mechanisms underlying these rod–cone differences in the context of a common phototransduction process are still an area of active research. It might be pointed out here that most, though not all, of the proteins involved in transduction have distinct isoforms in rods and cones, so some quantitative differences in the process

between them are not surprising. Also, for rods, because they operate at very low light levels, the decrease in their sensitivity due to substantial bleaching of pigment by light is generally not important in their operating range of light intensities. Cones, on the other hand, operate in bright light. Thus, significant pigment bleaching is common and affects dramatically the sensitivity of cones to light in bright backgrounds. As mentioned earlier, pigment bleaching not only lowers the probability of light absorption, but also substantially reduces the signal generated by an absorbed photon because bare opsin (i.e., bleached pigment) itself has weak transducin-activating activity and triggers the negative-feedback pathways described earlier.

Diseases

Rods and cones can be severely compromised by a variety of disease conditions, genetic or otherwise, that lead to rod and cone dysfunction or irreversible degeneration, causing a partial or complete loss of vision. In the past decade or two, tremendous advances have taken place in the understanding of many of these diseases, thanks to the revelations of the cellular and molecular details of rod and cone phototransduction. These diseases include retinitis pigmentosa, Leber's congenital amaurosis, Oguchi disease, and stationary day blindness, to name just a few. Because of the intimate relationship between the retinal pigment epithelium and the photoreceptors, the degeneration of the latter will also occur when the pigment epithelium malfunctions. An example of such disease is vitelliform macular dystrophy (Best disease), which causes degeneration of the retinal fovea and its vicinity because the pigment epithelium has a defective chloride channel and presumably therefore abnormal transport function. Because the fovea is so critical for everyday vision, any disease affecting this retinal region is particularly incapacitating to the patient.

Parietal-Eye Photoreceptors in Lizard

This section briefly describes the lizard parietal-eye photoreceptor, for the reason that it shows very unusual antagonistic light responses, with underlying mechanisms that reveal the evolutionary path of rod and cone phototransduction.

Many lizards have a parietal eye, situated on the forehead between the two regular (lateral) eyes. The exact function of this eye is still not entirely clear, but the best suggestion so far is that it informs the animal about the passage of time in the course of the day by registering changes in the relative intensities of the spectral components of the ambient light as the day progresses.

The parietal eye resembles the lateral eyes by having a cornea, a lens, and a retina. The retina, however, has only photoreceptors, ganglion cells, and glial cells (i.e., no second-order and associative neurons, including bipolar, horizontal, and amacrine cells, and no retina pigment epithelium). It is also opposite in orientation to the lateral-eye retina in that the photoreceptors face the front of the eye and are therefore the first neurons in the retina to encounter light. The photoreceptors have a well-formed outer segment, with orderly stacked disks. Electron microscopy indicates that the disks, like those in cones, are continuous with the plasma membrane.

One very unusual feature of the parietal-eye photoreceptor is that each cell expresses two pigments: the blue-sensitive pinopsin (first found in the light-sensitive chicken pineal gland) and the green-sensitive parietopsin, an apparently ancient pigment not found in the lateral eyes. The coexistence of two pigments in a single cell fits with the physiology, which involves two antagonistic phototransduction pathways in the same cell. One of these, best activated by blue light, is identical to that in rods and cones, consisting of cGMP-PDE stimulation, decrease in cGMP concentration, closure of CNG channels, and membrane hyperpolarization. The other, best activated by green light, consists of inhibition of the same PDE, increase in cGMP concentration, opening of CNG channels, and membrane depolarization. Thus, it appears that pinopsin activates the hyperpolarizing pathway and parietopsin activates the depolarizing pathway. Interestingly, transducin is not present in these cells. Instead, gustducin appears to take its role, coupling to pinopsin. Although gustducin is not found in any other photoreceptor, it is considered to be a close transducin homolog, with a similar protein sequence and function. G_o, on the other hand, appears to couple to parietopsin. G_o is more different from transducin and gustducin, although still belonging to the same subfamily of G-proteins.

In vertebrates, the involvement of G_o in phototransduction is unique to the parietal-eye photoreceptor. However, in invertebrates, there is precedent for its involvement in vision, notably in the scallop hyperpolarizing photoreceptor, which as mentioned at the beginning of this article, is also of the ciliary type. In this scallop photoreceptor, G_o is coupled to SCOP2, an apparently ancient pigment, to activate a cGMP-signaling pathway analogous, though not identical, to that in rods and cones. Thus, all evidence suggests that a G_o-mediated phototransduction pathway is ancient among ciliary photoreceptors. As such, the parietal-eye photoreceptor appears to retain features

of rod and cone predecessors – a missing link between rods/cones and more primitive ciliary photoreceptors, so to speak. The notion is that a G_o-mediated phototransduction pathway existed in ciliary photoreceptors long ago, before vertebrates evolved. In the course of evolution, however, a chromatically antagonistic, gustducin/transducin-mediated phototransduction pathway was added to the cells having the G_o-mediated pathway for the purpose of analyzing spectral information. This chromatic antagonism is retained by the parietal-eye photoreceptor to the present day. In parallel during evolution, the lateral eyes made their appearance over time but retained only the more recent gustducin/transducin-mediated pathway, delegating the color opponency instead to downstream neurons – a good strategy because complex processing of color information is best provided by elaborate synaptic circuitry. As such, the chromatic opponency within a single parietal-eye photoreceptor represents a very primitive, simple form of color vision compared to, say, what goes on in the lateral-eye retina.

Incidentally, the parietal eye, like the two lateral eyes (and the pineal gland), develops as a protrusion of the diencephalon of the brain during embryogenesis, again pointing its homology to these other structures.

Phototransduction

J B Hurley, University of Washington, Seattle, WA, USA

© 2009 Published by Elsevier Ltd.

Natural scenes produce increments and decrements of illumination on the retina. Phototransduction is the series of biochemical reactions by which rod and cone photoreceptors detect those changes in illumination. Photoreceptor neurons are highly compartmentalized. Phototransduction occurs in the photoreceptor outer segment, a compartment that is highly enriched with membranes and with the enzymes that catalyze the biochemical conversion of light absorption into changes in membrane potential.

Rod photoreceptors initiate scotopic vision – seeing in dim light. Rods are so sensitive that they can respond to individual photons. Cone photoreceptors initiate photopic vision – seeing in bright light. Cones are less sensitive than rods, but they are endowed with the ability to adapt to continuous stimulation even when it is very intense. Vertebrates use the high sensitivity of rods and the adaptability of cones to respond to changes in illumination on backgrounds that range over 11 log units of intensity.

Initiation of Phototransduction

Rods achieve their extraordinary photosensitivity by using a biochemical amplifier. The amplification occurs in a light-activated enzymatic cascade that controls the concentration of 3′,5′ cyclic guanosine monophosphate (cGMP), an intracellular messenger. cGMP regulates the activity of plasma membrane ion channels that allow Na^+ entry. The photoreceptor membrane potential is determined in part by its permeability to Na^+. In darkness, the concentration of cytosolic, unbound cGMP is a few micromolar, enough to partially activate the channels and depolarize the rod. Light stimulates the breakdown of cGMP to close the channels and hyperpolarize the cell.

The detector of light in rods is rhodopsin, a 36 kDa glycoprotein embedded in the disc and plasma membranes of the outer segment. Rhodopsin has seven transmembrane helices, a glycosylated N-terminus, several loops that connect the helices, and a C-terminal tail that extends into the cytoplasm. The 11-*cis* retinal chromophore on rhodopsin can absorb light. Its spectral sensitivity is broad but it is most sensitive to 500 nm photons. Absorption of light drives the chromophore into an excited state. Approximately 70% of the time, the retinal relaxes from this state to an all-trans rather than the original 11-*cis* configuration. The all-*trans*-retinal, newly formed within a hydrophobic pocket of rhodopsin, induces a series of structural changes that propagate through the protein. At one point, the photoactivated rhodopsin takes on a configuration known as Metarhodopsin II (Meta II, also referred to as R*). A representation of the protein–protein interactions that occur during the initial stages of phototransduction is shown in Figure 1. A list of the important steps in the activation of phototransduction is shown in Figure 2. The activated state of rhodopsin (R*) binds to a peripheral membrane protein called transducin ('T'), a heterotrimeric GTP-binding protein (G-protein). The Meta II–transducin interaction stimulates the 39 kDa α subunit of transducin to release guanosine 5′-diphosphate (GDP) that was bound to it and to replace it with guanosine 5′-triphosphate (GTP). Then the GTP-bound α subunit (39 kDa) dissociates from the complex. Activation of transducin in this way is a significant step of amplification. Approximately 100 transducin molecules can be activated by a single Meta II during its lifetime.

Once activated, transducin α diffuses from the site of activation. Hydrolysis of cGMP begins when transducin relieves inhibitory constraints imposed by the small (11 kDa) γ subunits on the larger (90 kDa) catalytic subunits ($\alpha\beta$) of a cGMP-specific phosphodiesterase (Pde). This is the second amplification step of phototransduction. Each Pde can hydrolyze 1000 cGMP per second in a reaction limited only by diffusion of the substrate to the enzyme. The overall amplification of phototransduction in rods is robust. A single photon can stimulate the breakdown of as many as 10^5 molecules of cGMP.

The hydrolysis of cGMP stimulated by light inactivates cGMP-gated cation channels in the plasma membrane of the outer segment (Figure 2). The cellular hyperpolarization caused by closure of these channels is detected by voltage-gated Ca^{2+} channels at the rod terminal. As the activity of these channels is reduced, less Ca^{2+} enters the synaptic terminal and release of glutamate into the synapse slows.

Restoration of the Dark State and Mechanisms of Adaptation

Most biochemical and physiological analyses of phototransduction in the laboratory have made use of brief pulses of light to initiate the photoreceptor response. A flash stimulus can reveal the initial response of a photoreceptor to light and it can also

reveal how the photoreceptor recovers from an impulse. The closure of cGMP-gated channels by a flash of light is transient. The channels reopen, reflecting processes that restore the concentration of cGMP to its dark level. The flash response also provides clues about mechanisms that can contribute to adaptation. Since rhodopsin, transducin, and phosphodiesterase all contribute to cGMP hydrolysis, each must be inactivated to return to the dark state. Resynthesis of cGMP also helps restore the rod to its dark state.

Some of the processes that restore the rod to its dark state occur independently of Ca^{2+}. Others are influenced by changes in the concentration of intracellular free Ca^{2+} that are stimulated by light. The biochemical reactions that inactivate phototransduction are summarized in Figure 3.

Figure 1 A representation of the protein–protein interactions that occur during the initial events of phototransduction. Light converts rhodopsin (R) into an active form, metarhodopsin II (R*), that binds the heterotrimer G-protein, transducin. Formation of that complex stimulates the replacement of GDP with GTP on the transducin α subunit. The activated transducin then activates the phosphodiesterase (Pde) catalytic subunits (α and β) by relieving inhibitory constraints imposed by the inhibitory (γ) subunits.

Ca^{2+}-Independent Mechanisms for Inactivation

Inactivation of photoactivated rhodopsin Meta II is a transient intermediate, but its lifetime is too long to account for the rapid reopening of channels that occurs following brief flashes of light. A reaction that inhibits Meta II activity more rapidly is phosphorylation of the meta II C-terminus. Multiple serines and threonines on the rhodopsin C-terminus can be phosphorylated by rhodopsin kinase (a 68 kDa soluble protein also known as G-protein-coupled receptor kinase 1 (GRK1)). Rhodopsin kinase phosphorylates rhodopsin slowly in darkness, but its activity is stimulated by binding to Meta II. Phosphorylated Meta II is a less effective activator of transducin than unphosphorylated Meta II. Phosphorylated Meta II also has a high affinity for a 48 kDa protein known as arrestin. Arrestin binds to phosphorylated Meta II and blocks further activation of transducin. The roles that rhodopsin kinase and arrestin play in restoration of the dark state were originally inferred from *in vitro* biochemical analyses, but the roles have been confirmed by physiological analyses of genetically modified animals. Rod photoresponses are prolonged in mice in which either the GRK1 or arrestin gene has been inactivated.

Figure 3 Steps in the deactivation of phototransduction. Arr, arrestin; GRK1, rhodopsin kinase; GC, guanylyl cyclase; GCAP, guanylyl cyclase activator proteins; P, a phosphoryl residue; RGS9-Gβ5, a complex of the regulator of G-protein signaling 5 protein with a G-protein β-subunit 5 protein.

Inactivation of transducin Transducin deactivates when it hydrolyzes the GTP bound to it. The reaction is intrinsically slow but a cluster of proteins known as the RGS-9 complex (regulator of G-protein signaling) binds transducin and stimulates it to hydrolyze its bound GTP. The RGS9 complex consists of an RGS9 subunit, a subunit similar in structure to G-protein β subunits ($G_{\beta 5}$), and a membrane-anchoring protein known as R9AP.

Inactivation of phosphodiesterase Once transducin hydrolyzes its bound GTP, the Pde inhibitor (γ) reassociates with the catalytic subunits to inhibit cGMP hydrolysis.

Ca^{2+}-Sensitive Inactivation Mechanisms

In darkness, Ca^{2+} influx and efflux are balanced. Free Ca^{2+} is flushed from the outer segment through a Na^+/Ca^{2+}; K^+ exchanger while influx proceeds through open cGMP-gated channels. The onset of illumination causes a net efflux of Ca^{2+} because the light-induced closure of channels blocks Ca^{2+} entry. Within seconds the concentration of cytosolic free Ca^{2+} decreases from ~500 nM to ~10–50 nM.

cGMP hydrolysis and synthesis also are balanced in darkness. When a flash of light stimulates phosphodiesterase activity, cGMP hydrolysis very quickly exceeds synthesis. However, the balance of hydrolysis and synthesis is restored by a Ca^{2+}-mediated feedback mechanism. cGMP is synthesized in rods by a 110 kDa guanylyl cyclase known as RetGC or ROS-GC. This dimeric membrane protein is not directly regulated by light. Instead, it is regulated by Ca^{2+} and a Ca^{2+}-binding protein known as guanylyl cyclase activator protein (GCAP). In darkness, when [Ca^{2+}] is highest, GCAP binds Ca^{2+} and inhibits guanylyl cyclase activity. When light lowers the intracellular free Ca^{2+} concentration, the apoform of GCAP stimulates the cyclase to restore cGMP and reopen channels.

Biochemical studies performed on photoreceptor homogenates and purified enzymes have revealed that Ca^{2+} can also regulate cGMP-gated channels. Ca^{2+}–calmodulin lowers the affinity of cGMP-gated channels for cGMP. When Ca^{2+} levels decline in light, the channels bind cGMP with greater affinity and reopen. The effect of Ca^{2+} and calmodulin on channel activity appears to be greater in cones than in rods. *In vitro* experiments suggest that Ca^{2+} can also affect rhodopsin phosphorylation. The binding of Ca^{2+} to a protein called 'recoverin' or 'S-modulin' can inhibit rhodopsin kinase activity. Recoverin enhances vision in dim light, but the interpretation of biochemical and physiological studies of recoverin has been controversial. The mechanism by which recoverin influences visual sensitivity is uncertain.

Effects of light on the intracellular distributions of proteins Light influences the distributions of transducin and arrestin among the intracellular compartments of photoreceptors. Transducin concentrates in the outer segments of rods and cones in darkness, but in rods it disperses throughout the cell in light. Arrestin also redistributes, but in the direction opposite to transducin. Arrestin concentrates within the inner segments in darkness, and in light it concentrates in the outer segments. Arrestin redistributes in both rods and cones; transducin redistributes only in rods. The mechanism of redistribution of these proteins is under investigation. Evidence indicates that passive diffusion and trapping by protein–protein and protein–membrane interactions are

important. However, the stoichiometry and light sensitivity of the redistribution process suggest that additional mechanisms may also contribute.

• *Phototransduction in rods versus cones.* Rods respond well only in dim light; cones function best in bright light. Flash responses of rods can last more than a second, whereas cone responses require only a few hundred milliseconds for completion. Rods adapt to light only over a limited range before they saturate, whereas cone saturation is never more than transient. The biochemical activities associated with phototransduction in rods and cones are specialized and may contribute to these differences in physiology. Many of the enzymes associated with phototransduction are expressed from distinct genes in rods versus cones. These include opsins; transducin α, β, and γ subunits; Pde catalytic and inhibitor subunits; and cGMP-gated channel subunits. Other phototransduction enzymes have expression patterns that overlap in rods and cones; the extent of overlap varies across vertebrate species. These include guanylyl cyclases, GCAPs, arrestins, and GRKs. Other proteins (e.g., recoverin and RGS9) are always expressed from the same gene in rods and cones but the levels of expression can differ.

Rods are extraordinarily sensitive to light, so the phototransduction enzymes within them are optimized for signal amplification. The highly sensitive and prolonged responses associated with rods are endowed not by the type of visual pigment expressed but instead by the downstream components of the G-protein cascade. When a cone visual pigment is used to initiate a dim flash response in rods, the response does not differ significantly from a normal response initiated by rhodopsin.

Cones are less sensitive than rods, and they generate faster responses with shorter lifetimes. Transducin is activated less efficiently, and it activates PDE less efficiently in cones than in rods. The level of RGS9 is greater in cones than in rods, so transducin is deactivated faster in cones. In some species, visual pigment kinase activity is also greater in cones than in rods. These types of biochemical differences optimize the performances of rods and cones for nighttime and daytime vision, respectively.

• *Mathematical modeling of phototransduction.* Biochemical and physiological studies suggest that phototransduction is a relatively simple signal transduction pathway. Only one type of stimulus, light, and only one type of receptor, a visual pigment, trigger phototransduction and adaptation. One cannot conclude with certainty that we currently know all of the components in the phototransduction pathway and all of the factors that influence it, but the major components of phototransduction are identified and they have been characterized extensively. Enough information is available about the biochemical activities and the physiological responses of photoreceptors that mathematical models that are consistent with the available biochemical and physiological data can be designed. A puzzling feature of the process of phototransduction in rods has been the unexpectedly small amount of variation in the amplitude and kinetics of rod responses to single photons. Mathematical modeling has been useful for making testable hypotheses that can be used to investigate this unusual phenomenon.

Structures of Phototransduction Proteins

The molecular structures of transducin, RGS9, arrestin, recoverin, and rhodopsin – important proteins that influence phototransduction – have been determined either by nuclear magnetic resonance spectroscopy of native proteins in solution or by x-ray diffraction of crystallized proteins. The structures are consistent with the biochemical activities of the proteins and have provided important insights into the mechanisms of regulation. The molecular architectures of sites that bind key molecules of phototransduction – GTP, cGMP, Ca^{2+}, and 11-*cis*-retinal – are now known and will likely be useful for understanding, and perhaps ultimately treating, the consequences of mutations that cause retinal disease.

Phototransduction and Retinal Disease

Photoreceptors are terminally differentiated neurons specialized to detect light. High metabolic demands, a highly polarized cellular morphology, demands for efficient protein synthesis, and very active vectorial transport systems make the viability of these cells extraordinarily sensitive to mutations that perturb their function.

Mutations in nearly all genes encoding phototransduction enzymes compromise specific aspects of photoreceptor function. In some cases, however, there is a more nefarious outcome. Mutations in some phototransduction genes also cause photoreceptors to die by apoptosis. For example, mutations that interfere with expression of Pde catalytic subunits cause cGMP to accumulate. Elevated cGMP stabilizes the open state of cGMP-gated channels so that Ca^{2+} flows in and accumulates to excessive concentrations in the photoreceptor. Excess Ca^{2+} has been linked to apoptosis. Mutations that raise the concentration of

Ca^{2+} required to inhibit guanylyl cyclase also cause apoptosis, probably through a similar mechanism.

Mutations in the enzyme that synthesizes cGMP also cause apoptosis, although the mechanism by which apoptosis is induced surely must be different. Without guanylyl cyclase, cGMP is not made, channels remain closed, and the inward flux of Ca^{2+} is reduced. Abnormally low levels of Ca^{2+} may also be linked to apoptosis. Continuous illumination of photoreceptors, as well as mutations in rhodopsin that cause persistent activation of the phototransduction pathway, also induce apoptosis, perhaps by a similar mechanism. Mutations in the genes encoding rhodopsin kinase and arrestin, proteins required to inactivate phototransduction, do not cause apoptosis in complete darkness. However, in normal lighting conditions these types of mutations allow unbridled phototransduction and ultimately apoptosis.

Other types of mutations are lethal to photoreceptors as well. Mutations that interfere with protein folding or transport cause rhodopsin to accumulate in the inner segment of the cell. Accumulation of protein in the wrong compartment of a photoreceptor cell may be another trigger for apoptosis. Normal expression of proteins with specific structural roles can also be critical for survival. Peripherin/RDS is a protein required for normal disc morphology in rods and for proper infolding of the plasma membrane in cones. In the absence of peripherin, rod morphology is compromised and apoptosis ensues. Photoreceptor apoptosis can also be stimulated by mutations that block the activity of transcription factors needed to express important photoreceptor-specific genes.

Not all mutations in phototransduction genes induce apoptosis. Mutations that block expression of transducins in rods and cones block the normal phototransduction process, but they do not cause photoreceptors to die. Mutations that prevent the expression of GCAP and recoverin genes also do not trigger degeneration of photoreceptors.

Conclusion

Phototransduction is a useful model for G-protein-mediated signal transduction. Biochemical investigations of the pathway have been facilitated by the abundance of phototransduction proteins, which are highly concentrated in the outer segments of photoreceptors. The ability to use genetic manipulations to investigate phototransduction has been facilitated by the nonessential nature of vision. This has empowered investigators of phototransduction with the ability to perform in-depth analyses of biochemical and physiological consequences of mutations in photoreceptor genes. Knowledge gained from biochemical, genetic, and physiological studies of phototransduction provides important insights about vision and about other G-protein-mediated signaling pathways.

Introduction

Synapse formation is a highly regulated process resulting in morphologically distinct subcellular structures in the pre- and postsynaptic sites to transmit and receive signals, respectively. At the presynaptic site, synaptic vesicles are clustered around the electron-dense projections near the synaptic plasma membrane. Although individual synaptic boutons exhibit tremendous variability in morphology and size, synapses from the same type of neurons share common characteristics and a given type of neurons often displays a stereotyped pattern of synapses. In 2000, three independent studies reported the identification of two homologous proteins in *Drosophila* and *Caenorhabditis elegans*, known as Highwire (Hiw) and RPM-1 (Regulator of Presynaptic Morphology-1), respectively. Loss of function in these genes causes specific alterations in the stereotyped synapse patterns and synapse organizations. Both invertebrate proteins are othologous to a human protein Pam (Protein associated with Myc), which was identified in 1998 as a binding protein for the Myc oncogene. Nearly all sequenced genomes of multicellular organisms contain a homologous member (see the Tree Families database website). I here refer this conserved protein family as the PHR proteins to honor the original members (Pam/Highwir/RPM-1) and the presence of a unique motif within the family. It is now established that a conserved function of the PHR proteins is to act as an ubiquitin E3 ligase. PHR proteins have been shown to regulate multiple signaling pathways involving mitogen-activated protein kinases (MAPKs), bone morphogenetic protein (BMP) pathway, adenylate cyclase, and the tuberous sclerosis complex (TSC).

PHR Protein Structure and Gene Expression

The PHR proteins are giant (Figure 1). *C. elegans* RPM-1, the smallest member, has 3766 amino acids; *Drosophila* Hiw, the largest, has 5233 amino acids. Given the size of the proteins, the degree of sequence conservation is remarkable. The N-terminus of these proteins has an RHD (RCC1 homology domain). RCC1 is a guanine exchange factor for the Ran guanosine triphosphatase (GTPase) and is composed of seven repeats, forming a seven-bladed propeller structure. The RHD domain in PHR proteins is often separated into two regions RHD1 and RHD2. Following RHD is a conserved region that contains two repeats of 90 amino acids, referred as PHR repeats because they are unique among the PHR proteins. The most conserved region is in the C-terminus, which contains a zinc finger B-box, a RING finger, and shares over 50% amino acid identity from *C. elegans* RPM-1 to human Pam. The vertebrate PHR proteins have a Myc binding domain in the middle. This region in Pam has been shown to be variable due to alternative splicing. Several additional predicted domains, including leucine zipper, nuclear localization signal, and a histone binding protein homologous domain, are also found only in the vertebrate PHR proteins.

Expression studies of mRNA and functional tagged reporter genes for Hiw and RPM-1 show that both proteins are predominantly expressed in the nervous system and are enriched in presynaptic terminals. Expression of RPM-1 or Hiw in presynaptic neurons also rescues the mutant phenotypes. Neither protein is detectable in the nucleus, even when it is overexpressed. Within the presynaptic terminals, the proteins seem to reside in a unique region because co-immunostaining with antibodies against proteins for synaptic vesicles, presynaptic active zone, and several synaptic membrane proteins exhibits very little overlap. This expression domain was initially called the presynaptic periactive zone, based on the studies in *Drosophila* neuromuscular junctions (NMJs). However, the original Hiw antibody was recently shown to recognize a different protein. Thus, the precise subcellular location for Hiw and RPM-1 at synapses remains to be characterized.

The zebra fish Esrom and vertebrate PHR proteins are broadly expressed in many tissues and are most abundant in the nervous system. In embryos, Pam and Phr1 mRNA are detected in the hippocampus, dendate gyrus, cerebellum, retina, spinal cord, dorsal root ganglia (DRG), and cranial ganglia, with high levels around the major synaptogenesis period. Pam and Phr1 mRNAs are also upregulated in the postnatal nervous system and persisted into adulthood. The data on the vertebrate PHR proteins are controversial, depending on the antibodies and cell type. The full-length Pam protein is ~510 kDa. However, two antibodies detect Pam at 450 and 350 kDa, with the latter being predominant in postnatal nervous system. Another antibody that appears to be enriched in some schizophrenic patients reacts with Pam and detects a protein of 60 kDa, which has been suggested to be a proteolytic product of Pam. In the DRG neurons, Pam is not found in the nuclei and appears to be present in the cytoplasm and axons; in the adult cortex, it is localized to nuclei and axon bundles in all layers.

Figure 1 Schematic comparison of Pam, Hiw, and RPM-1. Domain structures are marked. NLS, nuclear localization signals; PHR, Pam/Highwire/RPM-1; RHD, RCC1 homology domain.

Mutant Phenotypes for PHR Genes

The phenotypic analysis of mutant animals provides the first important clues for the function of the PHR protein family. Given the large size and the broad expression of these proteins, it is not surprising that a range of defects are observed and that the terminal phenotypes seem to vary depending on the neuron types and the organisms.

C. elegans neurons have simple morphologies and form *en passant* synapses at defined regions along axons. The positions and the ultrastructural features of the synapses exhibit neuron type specificity. *rpm-1* mutants were isolated from several genetic screens that relied on a synaptic vesicle reporter gene to visualize the morphology and pattern of synapses of different neurons. The motor neurons innervate body-wall muscles and form regularly spaced synaptic boutons along the entire or a segment of the axon. In *rpm-1* mutants, the motor synaptic boutons are irregular in size and in distribution (Figure 2). Within a single presynaptic terminal, the total number of synaptic vesicles is reduced, and frequently, numerous presynaptic dense projections are present. The mechanosensory neurons form synapses through short axonal branches. In *rpm-1* mutants, these synaptic branches frequently do not form, leading to a failure of synapse formation (Figure 2). Moreover, the mechanosensory axons continue to grow beyond their normal termination sites, resulting in an overshooting phenotype. Similar phenotypes are seen for several types of motor and sensory neurons. Despite the synaptic defects, *rpm-1* mutant animals are viable and exhibit nearly normal movement.

Drosophila larval motor neurons elaborate terminal branches on reaching a muscle surface, and each terminal branch forms synaptic boutons of a characteristic pattern (Figure 3). During larval development, the motor terminals undergo a regulated growth in branch and bouton numbers to match the increase in muscle surface. *hiw* mutants were originally identified by screening for flies with walking deficits. In *hiw* mutant larvae, the motor terminals exhibit excessive branching, or synaptic overgrowth, increasing synaptic bouton numbers two- to fourfold and covering twice more synaptic area (Figure 3). However, individual synaptic boutons are smaller than those in wild type. The synaptic content measured by antibody staining to synaptotagmin and neurotransmitter transporter is reduced. Electrophysiological recordings also show that the quantal size and quantal content from the mutant synapses are reduced.

The zebra fish gene *Esrom* was isolated through a large-scale screen for aberrant retinal topographic mapping defects. In wild-type fish, retinal axons from the anterior eye are fasciculated until they reach the posterior tectum. In *esrom* mutants, the anterior axons branch in the anterior tectum and fail to map to the posterior tectum (Figure 4). Some retinal axons also show segregation and fasciculation defects. In addition, *esrom* mutant fish have reduced yellow pigmentation as the result of defects in the biosynthesis of pteridine.

The mouse gene *Phr1* resides on chromosome 14 within the piebald deletion complex, a region syntenic with human chromosome 13q22 that contains the Pam gene. A compound deficiency that deletes *phr1* and two neighboring genes causes animals to die at birth due to respiratory defects. In these mutant mice, the phrenic nerve is thin and has large varicosities at the axon ends. At the NMJs, nerve terminals overshoot and sprout beyond the postsynaptic receptor plaque (Figure 5). Based on the expression pattern of *phr1* and the two neighboring genes, these defects are probably due to a specific loss of *Phr1* function. The report that an antibody shows preferential reactivity with Pam in schizophrenic patients suggests a potential link between Pam and human diseases. In the adult

Figure 2 Synaptic defects in *C. elegans rpm-1* mutants: (a, b) synapses for the GABAergic motor neurons in the wild type; (c, d) synapses for the GABAergic motor neurons in *rpm-1* mutants; (e, f) mechanosensory neurons in the wild type; (g, h) mechanosensory neurons in *rpm-1* mutants. In wild-type animals in (a, b), the SNB-1::GFP marker forms uniformly shaped fluorescent puncta (arrows) that are evenly distributed along the nerve process (a) and in most synapses there is only one prominent electron-dense projection (arrow) within a cluster of synaptic vesicles (b). In the *rpm-1* mutants in (c, d), the SNB-1::GFP puncta are enlarged and irregular (arrowheads in (c)) and several presynaptic projections (arrows) are often present within a single cluster of synaptic vesicles (d). In the wild-type animals in (e, f), PVM neurons (arrow) terminate just posterior to the ALM cell body (e) and extend an axon branch (arrownhead in (f)) to the synapse on to the ventral cord neurons. In the *rpm-1* mutants in (g, h), PVM axons fail to terminate (g) and the synaptic branches are usually absent (h). ALM, anterior lateral microtubule; GABA, γ-aminobutyric acid; GFP, green fluorescent protein; PLM, posterior lateral microtubule; PVM, posterior ventral microtubule. Figure 3 NMJ defects in *Drosophila Highwire* mutants wild-type larva; (b) *hiw* mutant larva. Shown are third instar larvae stained with anti-Syt to reveal the presynaptic branches and boutons. In wild-type larvae (a), muscle 4 is innervated by two motor neurons (MN4a and MN4b). In *hiw* mutants (b), both motor terminals are present on muscle 4, but contain many more branches and boutons. NMJ, neuromuscular junction. Reproduced from Wan HI, DiAntonio A, Fetter RD, Bergstrom K, Strauss R, and Goodman CS (2000) Highwire regulates synaptic growth in *Drosophila. Neuron* 26: 313–329, with permission from Elsevier.

rat spinal cord, inhibition of Pam appears to enhance nociceptive behaviors.

Thus, the analysis of the mutant phenotypes supports an important role of PHR proteins in the precision of synapse pattern and architecture. Genetic studies using temperature-sensitive assays showed that at least some of the defects arise from initial differentiation and that, in the case of *hiw*, it is also required throughout larval development. One interpretation of the mutant phenotypes is that PHR proteins are required for the stabilization of nascent synaptic architecture. In the absence of PHR proteins, nascent synapses are not developed to its maturity; different neurons then respond differently by sprouting, overgrowth, or withdraw from synaptic contacts.

Functions of PHR Proteins

Compared to many newly identified protein families, our understanding of the signal transduction pathways regulated by, or interacting with, the PHR protein has progressed remarkably rapidly. PHR proteins have been shown to function as an E3 ubiquitin ligase to mediate protein degradation. They

Figure 4 Retinal axon defects in zebra fish *esrom* mutants: (a) wild-type retina; (b) *esrom* mutant retina. Shown are optic tectum of 4-day-old zebra fish, with retinal axons labeled with DiI (red) and DiD (blue). In the wild-type retina (a), axons from the anterior region of the eye project to the posterior tectum, and axons from the posterior arborize in the anterior tectum. In the *esrom* mutant retina (b), anterior axons defasciculate and arborize anteriorly. *esr*, *esrom* mutant; *wt*, wild type. From D'Souza J, Hendricks M, Le Guyader S, et al. (2005) Formation of the retinotectal projection requires Esrom, an ortholog of PAM (protein associated with Myc). *Development* 132: 247–256.

Figure 5 NMJ and sensory neuron defects in candidate Phr1 mutant mice: (a) NMJs from the phrenic nerve in wild-type E14.5 embryo; (b) NMJs from the phrenic nerve in 9ThW/1Arg mutant E14.5 embryo; (c) NMJs from the phrenic nerve in wild-type E18.5 embryo; (d) NMJs from the phrenic nerve in 9ThW/1Arg mutant E18.5 embryo; (e) sensory axon terminals in wild-type E18.5 embryo; (f) sensory axon terminals in 9ThW/1Arg mutant E18.5 embryo. At E14.5, in wild types (a), NMJs have terminals (green) overlying AChR-rich plaques (red) on the muscle fibers; in mutants (b), some terminals overgrow beyond the receptor plaques (lower arrowhead) and some have varicose morphology (upper arrowhead). At E18.5, in wild types (c), NMJs are more robust and the receptor plaques are more condensed; in mutants (d), NMJs show similar maturation, but the nerve terminals exhibit sprouting beyond receptor plaques. At E18.5, the mutants (f) show terminal sprouting and the terminal axons have numerous varicosities (arrowhead) and are either more elaborately branched or less fasiculated. Scale bar = 40 μm (a, b, e, f), 11 μm (c, d). AChR, acetylcholine receptor; E, embryonic day; NMJ, neuromuscular junction. From Burgess RW, Peterson KA, Johnson MJ, Roix JJ, Welsh IC, and O'Brien TP (2004) Evidence for a conserved function in synapse formation reveals Phr1 as a candidate gene for respiratory failure in newborn mice. *Molecular and Cell Biology* 24: 1096–1105.

negatively regulate the dual leucine zipper MAPK kinase kinase, a BMP pathway, the tuberin–hamartin complex, and adenylate cyclase.

The presence of a RING domain at the C-terminus predicts that the PHR protein may have an ubiquitin ligase activity. Several pieces of evidence support this role. First, multiple naturally occurring loss-of-function mutations disrupt or eliminate the RING domain in *rpm-1*, *hiw*, and *esrom*. A transgene expressing a Hiw protein in which the key Cys residues in the RING domain are mutated causes a dominant negative effect. Second, Hiw mutant phenotypes

can be partially suppressed by overexpression of a de-ubiquitin enzyme *fat facet*. Third, an F-box protein, FSN-1, binds RPM-1. *fsn-1* mutants exhibits a range of synapse defects similar to that in *rpm-1*. RPM-1 and FSN-1 are also present in a protein complex with Cullin and Skp, suggesting that these proteins may function in a manner similar to Skp/Cul/F-box type E3. Fourth, the RING domain of Esrom is able to catalyze ubiquitination *in vitro*. Moreover, the RING domain of RPM-1 can stimulate ubiquitination of its substrate, DLK-1.

What are the targets for the PHR E3 ligase activity? The answers to this question have come from powerful forward genetic screens in *C. elegans* and *Drosophila*. One way to interpret the defects in *rpm-1* or *hiw* mutants is that they could arise from prolonged actions of targets as the result of failure in protein degradation. Then, mutations eliminating, or impairing the action of, the substrates could restore normal synaptic pattern in *rpm-1* or *hiw* mutants. Screening for such suppressor mutations in *C. elegans* and *Drosophila* led to the identification of a dual leucine zipper MAPK (DLK), DLK-1 and Wallenda, respectively. Loss-of-function mutations in either DLK alone do not cause detectable defects but strongly suppress the synaptic defects in *rpm-1* and the synaptic overgrowth defects in *hiw*. Consistent with being a target of E3 ligase activity, the elevated expression of DLK-1 or Wallenda in otherwise wild-type background causes synaptic defects resembling those in *rpm-1* or *hiw*, respectively. In *rpm-1* or *wallenda* mutants, the levels of DLK-1 or Wallenda at synapses are upregulated. Moreover, biochemical studies in cell culture conditions show that RPM-1 can bind DLK-1 and that the RING domain of RPM-1 can stimulate DLK-1 ubiquitination. Together, these studies establish an evolutionarily conserved mechanism by which RPM-1 and Hiw act as an E3 ligase to downregulate the DLK MAPK at the synapses.

Interestingly, the MAPKs downstream of DLK-1 and Wallenda appear to have diverged in *C. elegans* and *Drosophila*. In *C. elegans*, loss-of-function mutations in the MKK-4 MAPKK and a p38 MAPK PMK-3 were isolated as suppressors of *rpm-1*. Genetic studies indicate that these two kinases act downstream of DLK-1, with PMK-3 as the downstream MAPK. On the other hand, in *Drosophila*, a c-Jun N-terminal kinase (JNK) homolog may act as the downstream MAPK, but it is not yet known which MAPKK acts downstream of Wallenda. Both *C. elegans* PMK-3 and *Drosophila* JNK MAPKs are localized in nuclei, suggesting that the interaction between RPM-1/Hiw and DLK-1/Wallenda at synapses is transduced to the nucleus. Supporting this idea, the expression of a dominant negative Fos, a known target of JNK, in Hiw mutants partially suppresses the synaptic overgrowth. Thus, the synaptic defects in *rpm-1* or *hiw* are, in part, due to improper gene expression at the transcriptional level.

Three other pathways have been implicated in PHR protein functions. Screening for Hiw binding partners by a yeast two hybrid assay identified the Smad protein Medea (Med). Med acts downstream of a presynaptic BMP signaling pathway. Loss of the BMP signaling in motor neurons causes terminal undergrowth such that the NMJ size is small and neurotransmitter release is reduced. Activation of BMP signaling in *hiw* mutants leads to further synaptic expansion, which implies a negative regulation of the BMP pathway by Hiw. However, mutants lacking both *hiw* and BMP signaling exhibit complex phenotypes that are also consistent with the interpretation that Hiw and BMP pathways function in parallel. In fact, phospho-MAD, a major readout of BMP signaling, is not upregulated in *hiw* mutants, and the neuronal expression of a constitutive active BMP receptor that leads to increased phospho-MAD does not lead to synaptic overgrowth. It is not known whether the binding of Med by Hiw leads to degradation of Med. Thus, it remains to be resolved how Hiw interacts with the BMP and Med pathway.

The C-terminal of Pam has been shown to bind TSC2/hamarin. TSC1/tuberin and TSC2 can co-immunoprecipitate with Pam from rat brain protein extracts. In primary cultured cortical neurons, Pam and TSC1/2 show co-localization along the neurites and in growth cones, although in cell bodies Pam is found in the nuclei and TSC is seen at perinuclear locations. A functional test of this interaction was conducted in the *Drosophila* eye. Overexpression of *Drosophila* TSC1 or TSC2 causes small eyes, which were enhanced in *hiw* mutants, suggesting that Hiw may negatively regulate the TSC complex. It remains to be addressed whether this regulation occurs through the E3 ligase activity or other functions of Hiw.

At present, the only known binding partner for the N-terminal of PHR proteins is adenylate cyclase V (AC V), which binds the RHD domain of Pam. Both full-length Pam and RHD domain alone can potently inhibit AC V, AC VI, and AC I. In serum-starved HeLa cells, Pam appears to reside in the endoplasmic reticulum. On treatment with sphingosine-1-phosphate (S1P), Pam translocates to the plasma membrane and inhibits AC activity. S1P is a natural ligand for G-protein-coupled receptors known as endothelial differentiation genes (EDGs). S1P-induced translocation and activation of Pam can be inhibited by pertussis toxin, implying the involvement of G_i. Pam translocation may also require protein kinase C activation and phospholipase C. The functional significance of

the interaction of Pam with AC in neurons was tested in a spinal nociceptive assay. In rat spinal cord and DRGs, Pam expression is upregulated following peripheral nociceptive stimulation by zymosan or formalin. Animals treated with an infusion of Pam antisense oligonucleotides to decrease the endogenous Pam expression exhibited an increase of nociceptive behavior following formalin injection.

Although Pam was originally identified by its binding to the transcriptional activation domain of c-myc, little is known about the role of Pam in nonneuronal cells. A microarray analysis of genes differentially expressed in quiescence and senescence cells showed that Pam is downregulated in both young quiescent and senescent cells. Until an appropriate animal model is developed, the precise roles of Pam and its mammalian counterparts remain unclear.

Conclusion and Perspectives

Within 8 years since the identification of Pam, the first member of the PHR protein family, our understanding of the functions of these conserved proteins has progressed rapidly. The genetic studies of the invertebrate members have identified important players interacting with PHR proteins. Strong evidence supports a definite function of these proteins in ubiquitin-mediated protein degradation at the synapse. Yet many questions remain. For example, the presence of RPM-1 or Hiw at synapses is quintessential for the normal regulation of synapse formation and growth. However, we know nothing about how these proteins get to synapses in the first place and how they change the micro-environment to facilitate synapse formation. The seemingly diverse effects associated with each gene in different neurons in different organisms are particularly puzzling. It is possible that PHR proteins endow synapses with morphological and functional diversity through targeting diverse sets of substrates in different neurons. Or they may act on the same signaling pathways; yet, due to other intrinsic properties, specific types of neurons respond to a common signaling in a different manner. It is clear that downregulation of DLK MAPK cascade is crucial for normal synapse formation in *C. elegans* and *Drosophila*. However, little is known about the signals activating DLK kinase; such signals could include positional cues or synaptic target recognition information. Because loss of function in the DLK pathway does not lead to overt synaptic defects in *C. elegans* or *Drosophila*, more work is needed both to define the normal roles of the DLK pathway and to understand why its inhibition by PHR proteins is so critical for normal synaptogenesis. Moreover, not all the mutant phenotypes of *hiw* or *rpm-1* are suppressed by inactivation of the DLK cascade, implying the presence of unidentified pathways. Given the giant size and multiple protein interaction motifs of PHR proteins, more signaling pathways will certainly be found to interact with these proteins. Last, but not the least, the generation of critical animal models is necessary for defining the function of mammalian PHR proteins. Understanding the synapse-specific roles of PHR proteins may hold the keys to our understanding of the sophisticated tasks that different neurons execute, in light of a uniformity of synapse structures.

Phrenology

C G Gross, Princeton University, Princeton, NJ, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Phrenology is the doctrine that intellectual abilities and personality traits are localized in discrete regions of the cerebral cortex and the magnitude of these abilities and traits is reflected in the overlying skull – in bumps on the head. Although viewed as quackery today, phrenology was a significant medical and popular movement in the first half of the nineteenth century. Furthermore, it had a major effect on the development of modern neuroscience.

In this article, we consider the founders of phrenology, Franz Joseph Gall (1758–1828) and his associate JC Spurzheim (1776–1852); the basic tenets of phrenology and their sources; the impact of phrenology in the lay and scientific communities; and, finally, the role of phrenology in the development of modern neuroscience.

Gall and Spurzheim

Gall was born in Germany and had a Catholic upbringing, although eventually his works were placed on the Index and he was denied a Catholic burial. He received his MD from the University of Vienna and had a successful practice with many famous patients in Vienna and Paris. He wrote and lectured extensively but never held an academic post. In fact, he often had trouble with civic, church, and medical authorities and was accused of atheism, materialism, and immorality. His lectures provided a high income and he does seem to have had a somewhat flamboyant lifestyle. Spurzheim started collaborating with Gall as a medical student in Vienna in 1800 and continued to do so for another 13 years. For the rest of his life, Spurzheim lectured and wrote on phrenology and never practiced conventional medicine.

Gall and Spurzheim made a number of significant anatomical advances that were essentially independent of their phrenological system. They viewed the nervous system, including the brain, the spinal cord, and peripheral nerves, as a hierarchy of interconnected ganglia. This was in contrast to the dominant view since Galen in which the brain was central and the spinal cord and nerves were appendages. They were the first to trace by blunt dissection sensory and motor pathways. The previous dissection technique from Vesalius onward was to make horizontal sections from rostral to caudal. This would reveal the ventricular structure thought to be so important but provide little clue as to the hierarchical organization of the nervous system or the course of neural input or output. The more empirical findings of Gall and Spurzheim included distinguishing cortical gray and white matter; differentiating projection, association, and commissural fibers; tracing the origins of most of the cranial nerves; the first description of postembryonic myelinization; establishing the pyramidal decussation; and the realization that the human brain is convoluted to save space. They produced the first accurate illustrations of the cerebral cortex.

Phrenology: Central Tenets and Methods

Gall and Spurzheim viewed the brain as an elaborately wired machine for producing behavior, thought, and emotion and the cerebral cortex as a set of organs for carrying out these functions. Their phrenological system attempted to relate these psychological functions to the organs of the cerebral cortex – to relate brain and behavior. Phrenology was based on four assumptions: (1) intellectual abilities and personality traits are differentially developed in each individual, (2) these abilities and traits reflect faculties that are localized in specific organs of the cerebral cortex, (3) the development or prominence of these faculties is a function of the activity and therefore the size of the cortical organs, and (4) the size of each cortical organ is reflected in the prominence of the overlying skull (i.e., in cranial bumps). Although they viewed the faculties as 'innate,' they thought they could be modified by experience, especially by education.

These otherwise reasonable hypotheses had one principal fatal flaw: the nature of the evidence. Gall and Spurzheim relied almost entirely on obtaining supportive or confirmatory evidence. They collected large numbers of skulls of people whose traits and abilities were known, examined the heads of distinguished savants and inhabitants of mental hospitals and prisons, and studied portraits of the high and low on various intellectual and affective dimensions. Throughout, they were seeking confirmation of their initial hypothesis usually deriving from a few cases. For example, the idea for a language organ in the frontal lobes come from Gall's experience as a school boy of a classmate who had a prodigious verbal memory and protruding eyes (being pushed out by a well-developed frontal lobe, Gall thought). The idea for an organ of destructiveness (or carnivorous instinct) came from the skulls of a parricide and of a

murderer that were sent to him, from noticing its prominence in a fellow medical student who "was so fond of torturing animals that he became a surgeon," and from examining the head of a meat-loving dog he owned. All their methods were used to seek confirmations; contradictions were explained away.

Gall and Spurzheim gave cogent reasons why the use of experimental lesions in animals (or 'mutilations' as they called them) or the study of brain-injured humans was inadequate, by them, to test their ideas. The state of anatomical knowledge was insufficient to remove a single organ. The organs were interconnected so that removal of one could alter the function of another. Animals would often live only a few days after surgery with the available methods. Generalizing from animals to humans was hazardous. Previous studies had not examined complex cognitive or emotional function in animals but only such things as 'sensibility' or irritability. Needless to say, however, when a clinical case that supported their view was brought to them, they would cite it as further confirmatory evidence.

Ideas on Brain Function before Phrenology

One source of Gall and Spurzheim's ideas was the Swiss anatomist Charles Bonnet (1720–93), who suggested that the brain might be an "assemblage of different organs." Another was the German philosopher JG Herder (1744–1803), who argued that every function must have a bodily organ responsible for it. At this time, physiognomy, the assessment of personality and character by examination of the features of the face, was a widespread practice and in a sense Gall and Spurzheim were transferring this to the top of the head.

Gall and Spurzheim's assigning of various psychological functions to organs of the cerebral cortex was variance with the prevailing view, deriving from Aristotle (384–22 BC), of the unity of the mind. There were a few intimations of punctate localization of psychological function in the brain before Gall and Spurzheim, such as by Erasistratus of Alexandria (*c*. 280 BC), Galen of Pergamon (129–200), Thomas Willis (1621–75), Pourfour du Petit (1674–1741), and Emanuel Swedenborg (1688–1772). However, these views were unknown or totally ignored in the beginning of the nineteenth century. Rather, the prevailing view was that of Albrecht von Haller (1708–77), who dominated physiology through his monumental textbooks and many followers. He concluded that all parts of the cortex were equivalent because he had found that mechanical and chemical stimulation of the cortex had the same null effect everywhere. He thought that "the greater part of the cortex consists of mere vessels."

Before Gall, the cerebral cortex was usually pictured in a uniform fashion, often looking like intestines, a comparison originally made by Erasistratus. By contrast, the illustrations of cortex by Gall and Spurzheim are strikingly accurate (**Figure 1**).

The only previous suggestion that the cerebral cortex was not uniform is structure was by Francisco Gennari (1752–97). As a medical student, he noticed and reported that a white line in the cortex was especially prominent and sometimes double in the posterior part of the cortex.

Gall and Spurzheim Go Separate Ways

The term 'phrenology' was never used or approved by Gall. Originally, he used the term 'craniology' then 'organology' and, finally, 'functions of the brain' or 'brain physiology' to describe his theory of punctate localization of psychological function in the brain. In 1813, Spurzheim separated from Gall and moved to England, where he substituted the term phrenology which seems to have been of American or British origin. There were a number of differences between Gall's organology and Spurzheim's phrenology, which continued to develop after they separated. Gall was much more tentative in naming functions, often giving several terms and long description and a more approximate location, whereas Spurzheim was satisfied with a single term and a 'precise' location. Gall had 27 organs (19 or which were found in animals), whereas Spurzheim extended them to 32–37 with sharper boundaries (cf. **Figures 1 and 2**); later phrenologists, such as Combe, added more. Gall continued to emphasize empirical observation, whereas Spurzheim became increasingly speculative and used phrenology as a way of predicting future behavior. Furthermore, Spurzheim was much more interested in applying the phrenology to social reform and to the treatment of mental disease. The term phrenology was generally applied to both sets of ideas.

Phrenology met with considerable opposition from political and religious authorities, particularly on the European continent, largely because it was viewed as implying materialism and determinism and denying the unity of the mind (and soul) and the existence of free will. On the other hand, phrenology spread widely, particularly in the United States and Great Britain, both as a medical doctrine and as a 'pop' psychology. As a medical doctrine, it influenced the diagnosis and treatment of mental and neurological disease. It generated widespread interest both among the general populace and among such writers and

Figure 1 The Roman numbers refer to the organ's qualities as follows. Organs common to men and animals: I, instinct of reproduction; II, love of offspring; III, friendship; IV, self-defense and courage; V, carnivorous instinct, tendency to murder; VI, cunning, cleverness; VII, ownership, covetousness, tendency to steal, love of authority; VIII, pride, arrogance, haughtiness; IX, vanity, ambition, love of glory; X, caution, forethought; XI, memory of things and facts, educability; XII, sense of places and spaces; XIII, memory and sense of people; XIV, memory of words; XV, sense of language and speech; XVI, sense of color; XVII, sense of sound, music; XVIII, sense of numbers, mathematics; XIX, sense of mechanics. Organs in man alone: XX, wisdom; XXI, sense of metaphysics; XXII, satire, witticism; XXIII, poetical talent; XXIV, kindness, compassion, morality; XXV, mimicry; XXVI, religion; XXVII, firmness of purpose, obstinacy, constancy. These accurate and aesthetic drawings of the cerebral cortex are from volume 1 of Gall FJ and Spurzheim JC, *Anatomie et Physiologie du Systême Nerveux en Général, et du Cerveau en Particulier, Avec des Observations sur la Possibilité de Reconnaître Plusieurs Dispositions Intellectuelles et Morales de l'homme et des Animaux, par la Configuration de Leurs Têtes,* 4 vols. with atlas of 100 engraved plates (Schoell, Paris, 1810–19) (Gall is sole author of vols. 3 and 4).

savants as Honore de Balzac, Charles Baudelaire, George Eliot, August Comte, Horace Mann, Alfred Russell Wallace, and George Henry Lewis. In fact, it rapidly became a popular fad and drawing room amusement, particularly in Great Britain and the United States. Phrenological societies and journals continued to flourish in both countries well into the twentieth century.

Affective faculties		Intellectual faculties	
Propensities	Sentiments	Perceptive	Reflective
Desire to live	10 Cautiousness	22 Individuality	34 Comparison
* Alimentiveness	11 Approbativeness	23 Configuration	35 Causality
1 Destructiveness	12 Self-esteem	24 Size

	21 Imitation	33 Language	

Figure 2 In comparison to Figure 1, note that the locations of the faculties are more specific, as are their names. Phrenological head is from Spurzheim JG (1834) *Phrenology or the Doctrine of the Mental Phenomenon*. Boston: Marsh, Capen & Lyon.

Flourens Attacks Gall

In the scientific world, the most important and influential critique of Gall came from Pierre Flourens (1794–1867). A technically brilliant experimenter, Flourens quickly rose in the French scientific establishment and at the age of 35 was elected to the French Academy of Science, which had rejected Gall. Starting in the 1820s and continuing for more than 20 years, Flourens carried out a series of experiments on the behavioral effects of brain lesions, particularly with pigeons. Flourens reported that lesions of the cerebrum in pigeons had devastating effects on willing, judging, remembering, and perceiving. However, he found that the site of the lesion was irrelevant: all regions of the cerebrum contributed to these functions. The only exception was vision in that a unilateral lesion produced only contralateral blindness, but again there was no localization within the hemisphere. These holistic results tended to eclipse Gall's ideas of punctate localization, but only in scientific circles and only temporarily.

Flourens' finding of cognitive losses after cerebral lesions was actually a confirmation of Gall's emphasis on the cognitive role of the cortex, a viewpoint that had been virtually absent before Gall. The cortex was termed a 'superadded' structure lying hierarchically and physically above the highest sensory structure, the thalamus, and the highest motor structure, the corpus striatum. The general idea that the thalamus had major sensory functions and the corpus striatum major motor functions was generally accepted by the mid-nineteenth century on the basis of a number of studies involving tracing sensory and motor tracts from the periphery and making experimental lesions in animals.

This view of the 'higher' functions of the cortex, common for the period, combines Haller's view of the insensitivity of cortex and both Gall's and Flourens' attribution of 'higher faculties' but neither sensory nor motor functions to the cortex.

Broca 'Confirms' Gall

Despite the bitter attacks of Flourens, Gall's idea of punctate localization and even many of his specific localizations, such as language in the frontal lobes and sexuality in the cerebellum, continued to be actively debated in the mid-nineteenth century.

At least in the scientific community, the supposed correlations between skull and brain morphology were quickly recognized as erroneous. Yet, Gall's ideas stimulated the search for correlations between the site of brain injury and specific psychological deficits in patients as well as in experimental animals. Reports of such correlations were published in both the phrenological and the mainstream neurological literature, and the question of the localization of psychological function in the brain was hotly debated at scientific meetings.

Thus, in 1848, JB Bouillard (1796–1881), a powerful figure in the medical establishment and a supporter of Gall, offered a cash prize for a patient with major frontal lobe damage who did not have a language deficit. The debate about localization reached a climax at a series of meetings of the Paris Societe d'Anthropologie in 1861. At the April meeting, Paul Broca (1824–80), a founder of the society, announced that he had a critical case on this issue. A patient with long-standing language difficulties, nicknamed 'Tan' because that was all that he could say, had just died. The next day, Broca displayed his brain at the meeting and indeed it had widespread damage in the left frontal lobe (actually much more widespread than today's 'Broca's area'). He presented several similar cases in the next few months. Not only did Broca's cases finally establish the principle of discrete localization of psychological function in the brain but also the discovery was hailed as a vindication of Gall. Broca himself had regarded Gall's work as "the starting point for every discovery in cerebral physiology in our century."

Conclusions

Despite its absurdities and excesses, phrenology facilitated the development of the study of the brain and behavior in several ways: by stressing that the human mind could be subdivided into specific functions and that specific brain mechanisms underlay specific mental abilities and traits, by emphasizing the importance of the cerebral cortex in mental activity, and by stimulating a great surge of research on the psychological effects of human brain damage and of experimental lesions in animals. After Gall, less radical divisions of brain function, such as those of Flourons, were much more readily accepted. The search for organs in the cerebral cortex led directly to cytoarchitectonics and myeloarchitectonics, attempts to distinguish cortical areas on the basis of structure, and to the tracing of sensory pathways to specific cortical areas. The phrenologists also influenced the development of physical anthropology: they were the first to develop methods and instruments for measuring the cranium.

The cytoarchitectonic, positron emission tomography, functional magnetic resonance imaging, and other imaging maps of the cerebral cortex that are now ubiquitous in neuroscience textbooks bear more than a coincidental resemblance to phrenological charts. They are the direct descendants of the ambitious, albeit heavily flawed, program of phrenology to relate brain structure and behavior.

Piccolo and Bassoon

J Juranek, Columbia University Medical Center, New York, NY, USA
K Mukherjee, UT Southwestern Medical Center at Dallas, Dallas, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neurons communicate with one another and with their target cells via specialized cell–cell contact sites called synapses. The term synapse was coined in 1906 by Sherrington, and it referred only to the well-distinguished axo-dendritic junctions in central nervous system. In current terminology, synapse implies many kinds of neuronal contacts such as gap junctions (electrical synapses), end plates, and varicose axon terminals of the central nervous system (chemical synapses).

Communication at chemical synapse requires the transformation of electrical activity, the propagating action potential, into chemical signals, the neurotransmitters released from the presynapse at specialized sites. At the ultrastructural level, these presynaptic specializations are characterized by electron-dense projections referred to as active zone; a term coined by Couteaux and Pecot-Dechavassine in 1971. Active zones are formed by a large number of proteins – including cytoskeletal proteins, scaffolding proteins, voltage-gated Ca^{2+} channels and cell adhesion molecules.

Recently, active-zone-specific proteins belonging to five different families have been identified and termed CAZ (cytomatrix of active zone) proteins. These include Munc13s/Unc13 (1995), Rims (1996), Piccolo/Aczonin (1996), Bassoon (1998), Liprin αs/Syd2 (1998), and ELKS/ERC/CAST1 (2002). These proteins are thought to play an essential role in neurotransmission by defining release sites, anchoring Ca^{2+} channels, and coordinating the exo-endocytotic cycle of synaptic vesicles in the presynaptic region.

Domain Structure and Molecular Interactions of Piccolo and Bassoon

Piccolo and Bassoon were isolated in the second half of the 1990s in an expression library screen of rat brain cDNA using antibodies raised against synaptic junctional protein preparations. These are unusually large (Piccolo, 530 kDa; Bassoon, 420 kDa), structurally related, multidomain proteins that are considered central to the assembly and functional organization of the active zone in vertebrates. Unlike other CAZ proteins, these two molecules do not have any orthologs in either *Caenorhabditis elegans* or *Drosophila melanogaster*. However, several proteins containing similar domains have been found in these animals, and it is plausible that they perform similar functions to Piccolo and Bassoon in invertebrates.

The proteins share ten regions of high sequence similarity, called Piccolo Bassoon homology (PBH) domains. The PBH1 and PBH2 domains contain two double zinc-finger motifs, which have low homology with those of Rab3 interacting molecules (RIMs) and Rabphilin-3A. The PBH4, -6, and -8 domains contain coil-coiled (CC) motifs. The remaining PBH domains seem to be unique to these two proteins because they do not share homology with any known proteins. In addition, Piccolo contains one PDZ (PSD, Dlg, ZO-1) domain, two C2 domains (C2A and C2B) at the C-terminus and one glutamine heptad (Q) domain at the N-terminus. Bassoon contains one Q domain at C-terminus and is posttranslationally modified by myristoylation at its N-terminus. Due to sequence similarity, it has been suggested that Piccolo might be acylated at the N-terminus as well (**Figure 1**).

Piccolo and Bassoon, through their multiple domains, interact with various partners at the presynapse, making them ideal scaffolding molecules. The zinc finger domains of Piccolo and Bassoon are known to interact with double-prenylated rab 3A and synaptobrevin receptor PRA1. It has been speculated that such interactions *in vivo* might be important for trafficking of synaptic vesicles at the active zone. Both Piccolo and Bassoon, with their third CC motif, interact with another CAZ protein ELKS, and with two members of C-terminal binding protein (CtBP) family: CtBP1 and CtBP2. In the ribbon synapses of the mammalian retina, Bassoon interacts with RIBEYE, a CtBP2 retinal homolog. In addition, Piccolo interacts with cyclic adenosine monophosphate (cAMP)-guanidine nucleotide exchange factor II (GEFII) via its PDZ domain, with F-actin binding protein (Abp1) via its Q domain, and with G-coupled receptor kinase interactors (GIT) proteins through a region between CC1 and CC2. It interacts with profilin via a polyproline tract. The C2A and C2B domains of Piccolo interact with voltage-dependent L-type Ca^{2+} channel (α-1C). Piccolo, via its C2A domain, is capable of homodimerizing as well as heterodimerizing with RIM, another CAZ protein in a Ca^{2+}-dependent manner (**Figure 1**). The Ca^{2+} affinity of this domain, as well as its capability to dimerize is regulated by alternative splicing. The functional relevance of these interactions are not yet clear. Piccolo C2 domain exhibits a low affinity to Ca^{2+}. It has been suggested that Piccolo may act as a low-affinity Ca^{2+}

sensor at the presynaptic site and might regulates synaptic short-term plasticity.

Subcellular Localization of Piccolo and Bassoon in Mammalian Tissues – Morphological and Biochemical Studies

Bassoon and Piccolo are localized at the presynapse in the central nervous system. These molecules, in general, exhibit a uniform presynaptic distribution. However, bipolar ribbon synapses lack Bassoon, with only Piccolo present at the active zone. Localization of the proteins in two different systems (hippocampal cell cultures and fixed central neuronal tissues) was restricted to the limited area of presynaptic electron-dense projections. Outside the central nervous system, both proteins have been observed in somatic neuromuscular junctions (Figure 2(a)). In addition, Bassoon, along with ELKS, has been found in autonomic varicose nerve terminals (synapses *en passant*) in the vas deferens, which are devoid of any pre- or postsynaptic specializations (Figure 2(b)). Piccolo has even been detected in pancreatic β cells, where it is coexpressed with ELKS. It has been suggested that the ELKS–Piccolo/Bassoon interaction might be of functional relevance in these cells. The broader distribution pattern of these proteins suggest that their role is not limited to being scaffolding molecules at the active zones of chemical synapses; however, more comprehensive studies are required to confirm this notion.

Piccolo and Bassoon Transport and Active Zone Assembly

Presynapse can organize itself within 30–60 min of the initial axodendrite contact. Such rapid formation requires a rapid delivery of the molecular elements to the presynaptic region, specifically at the nascent active zone site. It has been postulated that active zones are preassembled in the soma of neurons, transported *en bloc* by axonal transport in the form of specific transport vesicles, and then inserted by fusion with the presynaptic plasma membrane. Indeed, the presence of such dense-core vesicles has been documented. These vesicles, also called the Piccolo transport vesicles (PTV), contain other CAZ proteins such as RIM and Munc13 but is negative for synaptic vesicle proteins such as synaptophysin. Piccolo and Bassoon co-localize with *trans*-Golgi network (TGN) markers in neuronal culture. Moreover, the inhibition of vesicle exit-form Golgi impairs the transport of Bassoon out of cell soma, indicating that PTVs are generated in the TGN. Association of Bassoon to the TGN has chiefly been attributed to an atypical TGN binding domain encompassing residues 2088–2564 of Bassoon, although N-terminal myristoylation might contribute as well. PTV vesicles exhibits some degree of heterogeneity in their composition of proteins, possibly explaining such heterogeneity in mature active zones. It is still to be elucidated whether vesicular transport of the CAZ proteins is the only way of their delivery to the synapse. Morphological studies on the developing rat cerebellar cortex

Figure 2 Localization of Piccolo and Bassoon: (a) presence of Piccolo and Bassoon in the neuromuscular junction of diaphragmatic muscle, analyzed by immunofluorescence of rat diaphragm sections. The end plates were identified by counterstaining the nicotinic receptor using bungarotoxin (green channel); (b) localization of Bassoon in varicosities of rat vas deferens using immunoelectronmicroscopy (peroxidase method), the varicosities are easily identifiable by the presence of numerous synaptic vesicle. revealed a striking difference between Piccolo and Bassoon distribution at postnatal day (P)5 but not P20, which suggests differential trafficking of these proteins, at least in the cerebellum. Moreover, the abundant distribution of these proteins at both the aspects (perikaryonal and axonal) of ligated sciatic nerves suggests bidirectional transportation of Piccolo and Bassoon. It is unknown whether Piccolo and/or Bassoon are upstream to the recruitment of other active zone proteins. In Bassoon mutant mice, the localization of other CAZ proteins remains unchanged. This could either mean that other CAZ proteins are recruited independently to the active zone or that the function of Piccolo and Bassoon are redundant in this context. Systematic analysis of Piccolo/Bassoon double knockout mouse would yield further information regarding their role as scaffolds at the active zone.

Genetic Studies of Piccolo and Bassoon – Overview of Their Function

The large size of Piccolo and Bassoon together with their relative insolubility are major hurdles toward understanding the biochemical and physiological role of these proteins. Downregulation of Piccolo using antisense approach in pancreatic cells pointed to a function of this protein in exocytosis. Although transfection experiments might be informative, conclusive

results will likely come from experiments targeting the genetic disruption of Piccolo and/or Bassoon.

In this context, the Bassoon mutant mouse with part of exon 4 and the entire exon 5 replaced by a *lacZ/neomycin* cassette have been of immense help. In these mice, the central portion of Bassoon (amino acids 505–2889), including an unconventional TGN binding domain, has been deleted. Although the remainder protein (180 kDa) is translated, it is mislocalized and mostly soluble. Biochemical studies revealed that the absence of Bassoon from the presynapse did not alter the levels or presynaptic localization of other CAZ proteins, except Piccolo. The compensatory increase of Piccolo level by 40% indicated a functional overlap between the two proteins. The mutant mice are viable; however, ~50% die during the first 6 months, possibly as a result of epileptic seizures. These mice suffered from general clonic seizures for up to half a minute, having up to four attacks a day. Electroencephalograph (EEG) recordings showed high-frequency (24 Hz) spikes with high amplitude and synchronicity paralleling the seizures. Overall, no anatomical changes were observed at gross light microscopic and ultrastructural levels. However, manganese-enhanced magnetic resonance imaging (MRI) revealed a significant increase in the overall volume of the brain. Most of this increase is contributed by an increase in the size of the hippocampus and cortex. Electrophysiological data demonstrated abnormalities in glutamatergic release. The readily releasable synaptic vesicle pool (RRP) and excitatory postsynaptic current (EPSC) amplitudes were significantly reduced, but the release probability, RRP refilling, and synaptic plasticity were unaltered. The functional studies from the Bassoon mutant mice suggests that a significant number of glutamtergic synapses are nonfunctional in these mice. These results suggest that Bassoon might play an important role in release from the glutamatergic nerve endings rather than affecting the actual development of the synapse or scaffolding of the active zone. In the ribbon synapse, a specialized glutamatergic nerve ending, the presynaptic organizational function of Bassoon is more apparent because the ribbons are not attached to the active zone in Bassoon mutant mice. This morphological aberration is associated with abnormal synaptic transmission and abnormal dendritic arborization of the neuron postsynaptic to ribbon synapse. The disintegration of the ribbon synapse can be traced directly to the interaction of Bassoon with the CtBP2 homolog RIBEYE. The RIBEYE–Bassoon interaction is responsible for the anchoring of the ribbons to the active zone in the ribbon synapses, enabling the proper functioning of these synapses.

The limited loss of function and 50% survival of the Bassoon mutant mouse suggest that it might be a regulatory molecule, but with no fundamental role in neurotransmission. However, it should be kept in mind that the remaining part of Bassoon, although not correctly localized, could perform some functions. In addition, Piccolo, with a shared domain structure with Bassoon, might partly compensate for the lack of this protein, as evidenced by the compensatory increase in its expression. Piccolo-null mice exhibit a Mendelian distribution of survival, with no obvious lethality or any other apparent phenotype. However, the mutant mice are considerably smaller than wild-type littermates. Bassoon/Piccolo double mutant mice exhibit a perinatal lethality, further strengthening the notion that these two proteins might have overlapping functions. Piccolo has additional domains, especially the C2 domains, which are capable of binding Ca^{2+}; therefore, the survival studies do not exclude an additional role for Piccolo. The survival of single mutant mice for both Piccolo and Bassoon does however, point out that neither of these molecules by itself plays an entirely indispensable role in either synapse formation or neurotransmission. Further characterization of the double mutants would reveal the reason for neonatal lethality and shed light on the functions of these giant proteins.

Pineal Gland and Melatonin

R J Reiter and D-X Tan, The University of Texas Health Science Center, San Antonio, TX, USA

© 2009 Published by Elsevier Ltd.

For decades, the pineal gland (epiphysis cerebri) was considered a functionless vestige of the brain. This concept changed when Aaron B. Lerner, in the late 1950s, discovered a new molecule, melatonin, in bovine pineal tissue. Since then, the pineal gland, via the secretion of melatonin, has been functionally linked to virtually every organ in the body. Indeed, its actions may be more ubiquitous than any other organ of internal secretion.

Macroscopic and Microscopic Anatomy

Although it derives embryologically from two anlage, the pineal gland is an azygous organ that forms a major portion of the epithalamus. In the human, the gland is situated under the corpus callosum in the free margin of the falx cerebri. It is dorsally attached to the brain stem at the junction of the diencephalon and mesencephalon and lies between the superior colliculi. The gland is surrounded by coalescing veins that drain the neighboring neural structures; these veins join to form the straight sinus. Because of its position near the center of the brain between the cerebral hemispheres and due to the close proximity of the mass of blood vessels, the gland is difficult to approach surgically. The pineal gland exhibits large variations in size in terms of its weight and averages about 120 μg. The gland size does not vary with gender.

Microscopically, the pineal gland is composed of modified neurons referred to as pinealocytes and glial cells. Postganglionic sympathetic nerves terminate near the pinealocytes. The human pineal gland typically accumulates hydroxyapatite deposits (i.e., calcifications frequently referred as acervuli or 'brain sand') throughout life. Once thought to be limited to the pineal gland of elderly individuals, these deposits, as revealed by currently available imaging techniques, begin forming in the adolescent years. The gland also may contain one or more cysts. Neither the calcified deposits nor the cysts are known to directly compromise the function of the pineal gland. Only in exceptional cases where a cyst enlarges to the point of rupture does it become problematic.

Blood Supply

The blood supply to the pineal gland is particularly perfuse. On a per-gram basis, the gland possesses a capillary bed more dense than virtually any other organ; this morphological feature portends a highly metabolically active organ. The arteries entering the pineal gland are tributaries of the posterior choroidal vessels, which are terminal branches of the bilateral posterior cerebral vessels. The venous drainage is into the large cerebral venous sinus that surrounds the gland.

Innervation

The primary functional innervation of the pineal gland is postganglionic sympathetic fibers whose cell bodies are in the superior cerebral ganglia situated deep to the bifurcation of the common carotid arteries in the neck. The postganglionic fibers follow blood vessels to reach the pineal gland where, just before they penetrate the organ, they form distinct nerves, the nervi conarii. Within the gland the fibers ramify and the terminals make contact with pinealocytes, the functional units of the pineal.

The preganglionic fibers that terminate in the superior cervical ganglia are located in the intermediolateral cell column of the first several thoracic cord segments. These neurons receive neural signals from the suprachiasmatic nuclei (SCN, or biological clock) via the paraventricular nuclei. The SCN are innervated by a specialized portion of the optic nerve, the retina hypothalamic tract, whose cell bodies are modified ganglion cells in the inner layer of the retina. Via these complex neural connections, the pineal gland is apprised of the photoperiodic state of the individual, that is, either light or dark (Figure 1).

Functionally, the pineal gland is inextricably dependent upon its sympathetic innervation. Interruption of the neural pathway at any point between the SCN and the pineal gland abolishes all known functions of the organ.

Melatonin Synthesis

The exclusive function of the pineal is the synthesis and secretion of the chemical messenger melatonin (*N*-acetyl-5-methoxytryptamine). The mechanisms and processes involved in the production of melatonin are generally well known. The dietary precursor of melatonin is the amino acid tryptophan, which is taken up into pinealocytes from the capillaries that perfuse the gland. Tryptophan, is converted to the monoamine serotonin (5-hydroxytryptamine) in a two-step process. Serotonin is then *N*-acetylated, a step catalyzed by the enzyme serotonin-*N*-acetyltransferase (NAT), to form *N*-acetylserotonin. This latter molecule is then *O*-methylated by hydroxyindole-*O*-methyltransferase

Figure 1 Neural corrections between eyes and the pineal gland and the cellular mechanisms which mediate the nighttime synthesis of melatonin from serotonin. (HIOMT) with the resultant generation of melatonin (Figure 1).

Uniquely, melatonin production in the pineal gland occurs only at night during darkness. During the night the SCN, via the nerve network described previously, signals the postganglionic neurons in the pineal to release norepinephrine (NE) onto the pinealocytes. NE acts on both β-adrenergic and α-adrenergic receptors to mediate a cascade of signal transduction events that culminate in the conversion of serotonin to melatonin (Figure 1). While the enzyme NAT was initially thought to be rate-limiting in the production of melatonin, recent data suggest this may not always be the case.

Once generated, melatonin quickly passively escapes the pinealocytes both into the capillary bed and directly, or indirectly, possibly into the cerebrospinal fluid (CSF) within the third ventricle. This latter process is achieved via the pineal recess, an outpouching of the third ventricle.

Given that melatonin is produced primarily during darkness, blood and CSF melatonin levels are significantly higher at night than during the day. The duration of elevated melatonin in these fluids is proportional to the duration of the dark period to which the individual is exposed. Likewise, light exposure at night, what is generally referred to as light pollution, if sufficiently bright and the proper wavelength, rapidly curtails pineal melatonin synthesis and fluid melatonin values drop precipitously.

Melatonin Levels in Bodily Fluids

Although there are organs in addition to the pineal gland that synthesize melatonin, only the pineal gland releases significant quantities of the indole into the blood and CSF. Because of melatonin's low production in the pineal during the daily light period, its daytime levels in bodily fluids are uniformly low (in the low pg ml^{-1} range). At night, blood levels increase markedly. The amplitude of the nighttime rise in blood melatonin varies considerably between individuals and is genetically determined. The peak melatonin levels in the blood normally range from 50 to 200 pg ml^{-1}. CSF levels of melatonin at night may be much higher. The rhythm of melatonin in bodily fluids in terms of its amplitude is highly uniform from one night to the next.

Effects of Age on Pineal Melatonin Production

In infants, the pineal does not exhibit a pronounced day/night melatonin rhythm until several months after birth. During childhood the nocturnal rise in melatonin is at its maximum. After adulthood is achieved, the production of pineal melatonin wanes and the nocturnal amplitude is diminished. This decline with age continues with the result that elderly subjects may lack a day/night difference in circulating melatonin levels. There is some evidence that certain diseases may be associated with unusually low melatonin values.

Functions of Melatonin

Once in bodily fluids, melatonin has access to every cell in the organism. The indole crosses all morpho-physiological barriers, for example, the blood–brain barrier. Melatonin is highly lipid soluble and readily enters cells where it seems to be distributed within all subcellular compartments.

Melatonin has both receptor-mediated effects as well as actions that are receptor independent. The major membrane receptors have seven transmembrane-spanning domains, are G-protein linked, have a nanomolar affinity for melatonin, and seem to be very widely distributed. The SCN have a particularly high density of melatonin receptors. The membrane receptors commonly identified in mammals including humans are classified as MT1 and MT2. The signal transduction pathways of the membrane melatonin receptors involve a pertussis toxin-sensitive G-protein which reduces intracellular cAMP. Several pharmacological agonists and antagonists of these receptors have been identified.

In addition to membrane receptors, melatonin also acts via intracellular binding sites/receptors. In the cytoplasm, melatonin binds to calmodulin, and nuclear binding sites have also been demonstrated. The specific consequences of the receptor-mediated actions of intracellular melatonin are not well defined.

Besides receptor-dependent actions, melatonin functions as a direct free-radical scavenger. This function requires only that melatonin be in the vicinity of a free radical when it is generated.

Melatonin and Seasonal Reproduction

One of the first discovered functions of the melatonin rhythm was the ability of this cycle to mediate seasonal changes in reproduction. Given that the duration of nocturnal melatonin levels varies with seasonal changes in photoperiodic length, the melatonin message functions as a calendar to signal the changing seasons. This information is utilized by animals that reproduce seasonally to alter their reproductive capability accordingly. The melatonin signal in this scheme is a passive message, with the organism using the signal to its own advantage. Some animals are functionally most competent and mate during long days, while others do so during short days of the winter. In both cases, the changing duration of the melatonin peak impels these annual cycles. Some species, such as humans, are continuous breeders.

Melatonin and Circadian Functions

One of the major functions of the melatonin rhythm seems to be to strengthen and/or synchronize circadian rhythms via an action on the SCN; in this case the melatonin rhythm functions as a clock. Whereas the loss of the rhythmic melatonin cycle may not totally disrupt circadian organization, subtle desynchrony of a variety of physiological functions as well as slower re-entrainment of activity rhythms may occur when the circadian melatonin signal is absent.

Melatonin, when administered exogenously, influences either directly or indirectly the phase and/or period of the SCN. This chronobiotic property of melatonin is used to manipulate the sleep/wake cycle and to assist individuals in recovering from jet lag. The ability of melatonin to modify circadian rhythmicity is a major function of melatonin.

Melatonin as an Antioxidant

Melatonin is a direct free-radical scavenger and an indirect antioxidant. As a scavenger it deftly neutralizes a variety of reactive oxygen species (ROS) and reactive nitrogen species (RNS). It directly detoxifies hydrogen peroxide, hypochlorous acid, singlet oxygen, nitric oxide, and the highly toxic hydroxyl radical and the peroxynitrite anion (Figure 2). Melatonin functions in this capacity by electron donation, which is a typical means of detoxifying radicals by antioxidants. When melatonin interacts with ROS/RNS, a series of metabolites are formed, among which are cyclic-3-hydroxymelatonin (c3-OHM), N^1-acetyl-N^2-formyl-5-methoxykynuramine (AFMK), and N^1-acetyl-5-methoxykynuramine (AMK) (Figure 3). Each of these products is likewise a highly efficient free radical scavenger which greatly magnifies the antioxidant activity of melatonin. This series of reactions is referred to as melatonin's free-radical scavenging cascade.

In addition to functioning as a direct free-radical scavenger, melatonin also stimulates, likely via receptor mechanisms, a number of antioxidative enzymes which are vitally important for reducing oxidative damage. Thus, melatonin stimulates gene expression and activity of the superoxide dismutases, glutathione peroxidases, and glutathione reductase. Furthermore,

Figure 2 Formation of free radicals and radical products. Oxygen-(red), nitrogen-(blue), and chlorine (orange)-based toxic reactants are shown. The most reactive of these products are the hydroxyl radical (•OH) and the peroxynitrite anion ($OONO^-$). MPO, myloperoxidase; SOD, superoxide dismutase.

melatonin promotes the activity of the rate-limiting enzyme in glutathione (GSH) synthesis, that is, gamma-glutamylcysteine synthase. GSH is an important intracellular antioxidant. Some of these actions may be mediated via the metabolites that are formed when melatonin detoxifies radicals and radical products.

Nitric oxide synthase, which controls the formation of nitric oxide, can be a pro-oxidative enzyme. Nitric oxide couples with the superoxide anion radical to generate the devastating toxic peroxynitrite anion (Figure 2). One of the melatonin metabolites, AMF, inhibits nitric oxide synthesis, thereby reducing generation of the peroxynitrite anion and limiting oxidative damage.

Melatonin as an Oncostatic Agent

Melatonin has two potential functions in reducing the incidence of cancer: it prevents free-radical

Figure 3 Melatonin (red) and the numerous metabolites that are formed when the indole reacts with free radicals and related products. AMK, N^1-acetyl-5-methoxykynuramine; AMMC, 3-acetamidomethyl-6-methoxycinnolinone; AMNK, N^1-acetyl-5-methoxy-nitrokynuramine; CAT, catalase; CYTO C, cytochrome C; Hb, hemoglobin; HRP, horse radish peroxidase; IDO, indoleamine-2,3-dioxygenase; MPO, myloperoxidase; ROS, reactive oxygen species; UV-B, ultraviolet-B.

damage to the genome (DNA), thereby limiting the initiation of cancer, and it reduces the growth rate of established tumors. In reference to the latter, melatonin has several means to stymie growth and cellular proliferation of cancer cells. Some of these actions include melatonin's ability to curtail the uptake of growth factors, for example, the omega-6 fatty acid linoleic acid, by cancer cells; this action is accomplished via membrane melatonin receptors. Other mechanisms whereby melatonin may reduce the growth of cancer cells include reducing endothelin-1 production; this molecule is produced in abundance by many cancer cells and it promotes the vascularization of tumors which they need for survival. Also, melatonin inhibits telomerase activity in cancer cells. This enzyme maintains the telomeres of linear eukaryotic chromosomes. These physical extensions are key in maintaining the integrity and stability of chromosomal structure, and, as a consequence, they also render cancer cells very hardy. Finally, antisteroidal actions of melatonin may contribute to the ability of the indole to reduce cell proliferation of hormone-dependent cancers. In particular, this action of melatonin is germane to estrogen-responsive breast cancer and testosterone-sensitive prostate cancer.

Melatonin Regulation of Immune Function

Melatonin is produced in at least some immune cells, and its interactions with this system are pleomorphic. In general, the immunomodulatory effects of melatonin are beneficial to the organism and are mediated potentially by both membrane receptors and nuclear binding sites. Melatonin has direct effects on humoral and cellular immune responses. In general, it reduces proinflammatory cytokine/chemokine production by limiting the translocation of nuclear factor kappa-B to the nucleus and its binding to DNA. Under conditions where the immune system is already hyperactive, for example, in some autoimmune diseases, melatonin's use may be counterindicated.

Concluding Remarks

The discovery of melatonin in the pineal gland occurred roughly 50 years ago. The rhythmic production and secretion of this organ are essential to some of its functions. However, melatonin's actions are far greater than originally envisaged. This functional diversity includes actions that are mediated via receptors on the membranes of many cells (and possibly via intracellular binding sites). Additionally, melatonin has receptor-independent functions, as typified by its ability to directly scavenge ROS and RNS. Some of melatonin's functions are carried out by metabolites of the indole which are generated when melatonin functions as a free-radical scavenger. It seems almost certain that the full functional repertoire of melatonin still has not yet been uncovered. Considering this functional diversity, the pineal gland must not be overlooked as an essential, pluripotent, and beneficial organ.

Pituitary Gland (Cell Types, Mediators, Development)

G V Childs, University of Arkansas for Medical Sciences, Little Rock, AR, USA

© 2009 Elsevier Ltd. All rights reserved.

Location and Anatomy

The pituitary gland, also called the hypophysis, lies in a bony depression at the base of the skull called the sella turcica (Turkish saddle, because of its shape). It is protected by dura mater, called the diaphragma sella. The location of the human pituitary gland can be pinpointed if one points to one's nose and draws an imaginary diagonal line up the nostril into the brain. This is actually the route used by neurosurgeons to access the pituitary and remove tumors.

The pituitary gland in humans is approximately the size of a pea and is made of two types of glandular tissue – the adenohypophysis and the neurohypophysis. The adenophyphysis includes a large region that faces the front of the body (anterior or ventral) called the anterior lobe, or the pars distalis. It also includes a collar of cells around the stalk called the pars tuberalis and clusters of cells attached to the neurohypophysis called the pars intermedia. Figures 1 and 2 illustrate the divisions and subdivisions of the hypophysis.

The neurohypophysis includes a region that faces the back of the body (dorsal or posterior), called the posterior lobe or the pars nervosa. It also includes the connection to the brain, which is made up of nerve fibers and vessels, called the infundibular stalk. The neurohypophysis broadens as it connects to the brain, resembling a funnel, which is how the stalk got the name. This broad area at the top of the stalk is a highly vascular region called the median eminence. The funnel-shaped anatomy inspired the Greek physician, Galen, to develop a theory of fluid circulation from the ventricles of the brain in 130–200 AD, which proposed that fluid was funneled from the third ventricle through the infundibular stalk to the pituitary. After the pituitary filtered the fluid, it was sent out the nose as mucus. This theory was believed for centuries and, in 1543, Andreas Vesalius named the pituitary after the Latin word for mucus, *pituita*.

Anterior Pituitary Cell Types

The anterior pituitary has been considered the master gland because its various cell types regulate endocrine organs and systems throughout the body. However, the pituitary cells are subject to regulation both from factors in the hypothalamus and from feedback by specific target organs.

The earliest light microscopic studies distinguished pituitary cell types by their reactions with different colored dyes. These trichrome stains differentiated three types of cells. The red cells were called acidophils, the blue cells were called basophils, and the colorless cells were called chromophobes. Historians now recognize that the term basophil was actually a misnomer because these early trichrome stains included only acid dyes. True basophilia, which is dependent on areas of ribosomes in the cytoplasm, could not be detected by these dyes. Nevertheless, the terms basophil and acidophil persist, especially in the description of different types of pituitary tumors. Later studies focused on immunolabeling to identify the hormone content in the individual cell types, which helped alleviate the confusion in terminology. The periodic acid Schiff reagent (PAS) was also used to distinguish pituitary cells that produced glycoprotein hormones. Electron microscopic studies identified the cells on the basis of secretory granule size and shape.

Somatotropes

Somatotropes produce growth hormone (GH) or somatotropin, are round–ovoid, and are missing in dwarf animals. They are distinguished by an acidophilic cytoplasm and, when viewed at the electron microscopic level, by densely packed, medium-sized granules (350 nm). In all species, they are the most abundant hormone-producing cell in the anterior pituitary, representing 30–50% of the cell population. GH cells separate in fractions of pituitary cells containing medium-sized cells.

GH is a protein hormone of 191 amino acids (22 kDa) that has anabolic and metabolic functions throughout the body. First discovered as a product of an acidophilic tumor in 1900 by Benda, Harvey Cushing established that this overactive tumor caused acromegaly, a disease associated with increases in bone mass and disfiguration. Evans and Long injected animals with pituitary extracts and caused gigantism, thus proving the hypothesis that the pituitary produces a GH.

GH is best known for its regulation of growth in length of long bones, by regulating the liver's production of insulin-like growth factor-1 (IGF-1), also known as somatomedin. IGF-1 stimulates growth in length of bones at the epiphysial plate. Gigantism results when there is a GH-secreting tumor before puberty.

Figure 1 Flow diagram showing the two main parts of the pituitary gland (hypophysis) and their unique regions.

Figure 2 Pituitary gland in the human showing different regions of each lobe.

GH also plays important anabolic roles in building muscle and bone and normalizing metabolic functions, including the regulation of insulin. It is one of the few pituitary hormones to decrease dramatically during aging, which is correlated with frailty in the elderly. GH secretion is upregulated by exercise, which prevents frailty.

Lactotropes

Lactotropes, or prolactin cells, are acidophils, staining bright red with erythrosine or carmosine. The animal models in which they could best be studied were lactating or pregnant animals because their pituitaries showed enlarged, bright red prolactin cells. Lactotropes produce the polypeptide hormone prolactin, which has 199 amino acids (24 kDa). Prolactin was discovered by Oscar Riddle, who described lactation-inducing effects of anterior pituitary extracts. Prolactin is best known for the stimulation of the growth and function of the mammary gland. Its exact role in the male is poorly understood. More than 300 separate functions for this hormone have been described in a number of species.

Lactotropes have been distinguished by their angular or stellate shape and content of irregularly shaped secretion granules. In rodents, they contain the largest granules of all the pituitary cell types. The granules exhibit irregular, dumbbell shapes. In humans, the granules are smaller; however, they still retain their pleomorphic shapes. Lactotropes also display stacks of lamellar rough endoplasmic reticulum. In normal animals, lactotropes represent approximately 15–26% of the pituitary cell population, with more lactotropes in females. In cell separation studies, prolactin cells separate with the smallest cells. A subset of estrogen-sensitive somatomammotropes that contain both GH and prolactin has been identified.

Thyrotropes

Thyrotropes are among the least abundant of the pituitary cell types, representing 6–10% of the normal pituitary cell population. They produce the 28 kDa glycoprotein hormone, thyroid-stimulating hormone (TSH), which regulates thyroid follicular cells to produce thyroxine or triiodothyronine. Thus, TSH ultimately regulates the body's metabolic rate.

TSH activity from the pituitary was first described in 1926 by Eduard Uhlenhuth, who showed that injections of bovine pituitary extracts caused the enlargement of thyroid gland follicular cells. TSH, a glycoprotein, was purified in the 1960s and found to have two subunits, an α and a β subunit. The α subunit has a structure shared with both gonadotropins, and the structure of the β subunit confers the biological specificity of the TSH molecules.

Thyrotropes are basophils and stain with the PAS reagent. TSH cells are distinguished by their content of very small secretory granules (100–150 nm in diameter) and dilated profiles of rough endoplasmic reticulum. Thyrotropes separate with the fractions containing the largest cells. However, some active thyrotropes may be found among the smallest cells. Thyrotropes enlarge following removal of the thyroid (thyroidectomy) and develop vacuoles, which are dilated sacs of rough endoplasmic reticulum.

Corticotropes

In human pituitaries, corticotropes are basophils. These cells are also PAS positive because they produce a glycoprotein prohormone called pro-opiomelanocortin (POMC). POMC has 241 amino acids (30 kDa) and can be enzymatically cleaved to produce smaller polypeptides, including adrenocorticotropin (ACTH), α- or β-melanotropin (melanocyte-stimulating hormone (MSH)), β-endorphin, and met-enkephalin. ACTH

stimulates glucocorticoid production and secretion by the adrenal cortex (zona glomerulosa cells), playing a vital role in the stress response. It also stimulates the production of dehydroepiandosterone from the adrenal cortex. β-Endorphin provides our own source of analgesia, relieving pain and having a calming influence. It is the source of the runner's high experienced during exercise. MSH stimulates the dispersion of the pigment in skin cells, called melanocytes. It is more important in lower mammals, however, and is the main product of the intermediate lobe.

The early search for the corticotrope began with a description of Cushing's disease, which is caused by high levels of the adrenal hormone cortisol. Harvey Cushing associated this disease with pituitary basophilism. In 1933, Collip and co-workers isolated and characterized the hormone that regulated cortisol, ACTH. It is now known that Cushing's disease can arise directly from an adrenal tumor or indirectly from a pituitary ACTH-secreting tumor.

In humans, corticotropes are distinguished by abundant 300 nm secretory granules. They are large, prominent, and become filled with filaments in response to glucocorticoid feedback. Other large mammals have well-granulated corticotropes, similar to those in humans. In contrast, corticotropes in mice and rats have not been as easy to detect. Studies of adrenalectomized rats or mice in the early 1970s showed that corticotropes in the rat are stellate, with peripherally arranged granules approximately 200–250 nm in diameter. They represent approximately 10% of the anterior pituitary population and separate with the population of small or medium-sized pituitary cells.

Gonadotropes

Gonadotropes are classified as basophils. They also are PAS positive because their two gonadotropin hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), are both glycoproteins (33–38 kDa). Both gonadotropins have two subunits–an identical α subunit, which has 92 amino acids, and a β subunit that confers biological specificity to each of the gonadotropin molecules. The α subunit is identical to that in TSH as well. The LH β subunit has 121 amino acids and that for FSH has 118 amino acids.

LH bioactivity was identified when Zondek and Ascheim reported that urine extracts from pregnant women stimulated the formation of corpora lutea (thereby showing luteinizing activity). FSH bioactivity was discovered by Zondek, who reported that extracts of the urine from postmenopausal women influenced follicular development. A regulatory link between the pituitary and gonads was discovered as early as the 1920s when Evans and Long treated rats with anterior pituitary extracts and produced corpora lutea in ovaries, indicating ovulation. The pituitary origin of the stimulatory substance was confirmed in 1926 by PE Smith, who showed that ovarian atrophy, following removal of the pituitary, was reversed by pituitary transplants.

We now know that LH stimulates the final maturation of the oocyte and ovulation. FSH stimulates the development of follicles. In males, LH, also called interstitial cell-stimulating hormone, stimulates the production of testosterone by interstitial or Leydig cells. FSH is also important in the stimulation of cells that support sperm development.

In most species, gonadotropes include an ovoid or a round subset that separates with the largest pituitary cells and is distinguished by two populations of granules scattered between dilated profiles of rough endoplasmic reticulum. The granules may be 200 nm or as large as 500–600 nm. A second subset of gonadotropes is more angular and contains a population of medium-sized granules. This subset separates with medium-sized cells, is prominent in cycling females, and may also contain GH. A third subset of gonadotropes is small and sparsely granulated, resembling corticotropes; these cells may contain ACTH and gonadotropins.

The gonadotrope population can be distinguished cytochemically by its content of LH and/or FSH or by its expression of receptors for the neuropeptide gonadotropin-releasing hormone (GnRH). It can also be distinguished when it enlarges after castration, becoming filled with vacuoles of rough endoplasmic reticulum. Approximately 50–75% of gonadotropes express both gonadotropins (bihormonal) in normal animals, although there are species differences in the proportion of bihormonal and monohormonal cells. Gonadotropes detected by dual labeling for both gonadotropins or for GnRH receptors represent approximately 15% of pituitary cells in normal rats. Gonadotropes may shift their morphology with their secretory state, and after losses in stores from surge secretory activity, some cells may be detected only by their content of mRNA.

Multifunctional Anterior Pituitary Cells

Sensitive cytochemical and assay techniques have identified pituitary cell types that express multiple hormones. A well-established example of a bihormonal expression pattern is represented by the subset of cells that produce both growth hormone and prolactin, which can be regulated to produce more prolactin by estrogens. Other examples include the

co-expression of POMC by gonadotropes early in postnatal development and the transitional expression of gonadotropins by GH cells during the reproductive cycle.

Increasing evidence supports a hypothesis that not all pituitary cells are terminally differentiated. A survey of the literature will lead the reader to evidence for the co-expression of as many as four hormones by a single cell. This calls into question the original dogma that each pituitary cell type produces only one hormone, and it shows the potential of the anterior pituitary population to retain sets of cells that may serve as precursor or stem cells. This potential may allow the anterior lobe cells to support the body efficiently, when multiple systems are required, bringing online extra cells to enhance a given cell population.

Folliculostellate Cells

A network of stellate cells that are electrically coupled to one another (and perhaps to other glandular cells), called folliculostellate cells, have been described in pituitaries from many species yet they remain somewhat mysterious. They stain with a glial cell marker, glial fibrillary acid protein, and S-100 protein. They also contain a number of other hormones, growth factors, and cytokines that regulate specific pituitary cells. They form follicles with other folliculostellate cells. Their electrochemical coupling is by way of gap junctions, which suggests the capacity for rapid communication in the anterior pituitary along a cellular network.

The folliculostellate cells are chromophobic cells, showing little, if any, evidence for staining with the classical tinctorial stains. In cell separation experiments, they separate in clusters along with the largest cells. Their content of specific hormones, growth factors, and cytokines suggests that they may somehow support the growth and maintenance of hormone-bearing anterior pituitary cells. Their electrical coupling and capacity to communicate may provide a rapid means of mobilizing cells to fully support a particular function. This network could signal major secretory events, such as the LH surge from gonadotropes or the rapid responses to stress by corticotropes.

Regulation of Anterior Pituitary Cells

Blood Supply

The architecture of the blood vascular system has evolved to support the regulation of the anterior pituitary cells. Most of the anterior pituitary blood is brought in from the superior hypophysial arteries, which branch from the internal carotids and the posterior communicating branch from the circle of Willis. These vessels penetrate the stalk–median eminence before they supply the anterior pituitary and form a capillary plexus that provides increased surface area for nerve fiber endings in the median eminence. From this capillary bed, blood is collected into several long portal veins that extend down the stalk to penetrate the anterior pituitary. These portal veins then branch into another capillary bed that supplies the anterior pituitary cells. The capillaries drain into the sinus venosus (venus sinuses in the dura mater).

This portal system architecture provides a focused vascular route for the transport of hormones and other regulatory factors to pituitary cells. The hormones are secreted from nerve endings in the median eminence, and this direct route prevents them from being diluted by the entire bloodstream. Consequently, only miniscule amounts of active hypothalamic hormones are needed to regulate the cells. These regulatory hormones were identified in studies by the laboratories of Roger Guillemin and Andrew Schally, who received the Nobel Prize for their discoveries. They had to use purified fractions from 200 000 to 500 000 sheep hypothalami to obtain sufficient material for biological effects.

Regulators

The regulatory hormones are produced by neurons that are distributed in clusters (nuclei) throughout the hypothalamus. The hormones are stored in secretory granules, which are sent down axons to nerve endings that lie along the capillaries in the median eminence. There, they are released into the blood supply that is collected and transported to the anterior pituitary by the portal veins. Before their identities were confirmed, they were called releasing factors; however, most are now called releasing hormones, named after their principal anterior pituitary target cell.

Growth hormone cells (somatotropes) are stimulated by a neuropeptide produced in the arcuate nucleus of the hypothalamus, called GHRH. It is a 44-amino-acid peptide that is released in pulses into the pituitary portal circulation, bringing about pulses of GH. It was actually discovered and isolated while Michael Thorner was treating an acromegalic patient, who had a GHRH-secreting pancreatic tumor. He sent the tumor tissue to Wiley Vale and Roger Guillemin for isolation and purification of GHRH.

Somatotropes are also regulated by an inhibitor called somatostatin. A polypeptide that is produced by the cells in the periventricular nucleus of the hypothalamus, it was discovered by Guillemin in 1973 from an extract of more than 500 000 sheep hypothalami. Somatostatin inhibits GH secretion and the actions of GHRH. Peaks of somatostatin

are assayed during the lowest points of the GH and GHRH pulses.

Thyrotropes are regulated primarily by thyrotropin-releasing hormone (TRH), which is a tripeptide hormone produced in small neurons (parvocellular) in the paraventricular region of the hypothalamus. These neurons are very sensitive to temperature. Cold- and heat-sensing neurons provide information to the TRH neurons that secrete TRH into the pituitary blood supply to stimulate TSH. TSH then stimulates the thyroid to upregulate metabolism and stimulate shivering and other responses to cold.

Prolactin cells are regulated by dopamine, which is a chronic inhibitor of this hormone, providing a clamp on the cells until prolactin is needed during pregnancy and lactation. The search for a prolactin stimulatory hormone is ongoing, although researchers have shown that TRH has stimulatory actions on lactotropes. The chronic inhibition by dopamine has provided chemotherapeutic tools that help control the growth of prolactin-secreting tumors.

Corticotropes are regulated by corticotropin-releasing hormone (CRH), a 41-amino-acid peptide that is produced by parvocellular neurons in the paraventricular nucleus of the hypothalamus. Another neuropeptide with potent stimulatory actions on corticotropes is arginine vasopressin (AVP). CRH and AVP work synergistically on anterior pituitary corticotropes. CRH neurons are highly sensitive to stress and their rapid release of CRH provides the stimulus for corticotropes to produce and release ACTH and β-endorphin. ACTH, in turn, stimulates the production of adrenal cortisol, which is needed for the flight-or-fight response.

Gonadotropes are regulated by a neuropeptide called GnRH, or LH-releasing hormone, which is a decapeptide. The search for a separate hormone for FSH is ongoing, although candidates have been reported. Produced by neurons scattered in the preoptic and anterior regions of the hypothalamus stretching back to the arcuate nucleus, GnRH is secreted in pulses and stimulates both LH and FSH synthesis and release. GnRH pulses may be driven by various factors, including gonadal steroid hormone feedback and neurotransmitters such as the polypeptide products of the *KISS1* gene, called kisspeptins. Rapid pulses of GnRH favor the release of LH and slower pulses of GnRH favor the release of FSH.

The previous discussion focused on the major neuropeptides from the hypothalamus. Other factors affect pituitary cells, including feedback from target organ products as well as locally produced cytokines and growth factors. Some are produced by the pituitary cells and may represent sources of paracrine or autocrine regulation.

Pars Tuberalis

The pars tuberalis consists of anterior lobe basophils (gonadotropes and thyrotropes) that have formed an incomplete collar around the infundibular stalk. Their expression of melatonin receptors and proximity to the suprachiasmatic nuclei make them candidates for responses to light and dark stimuli (photoperiodicity). These cells may be regulated by melatonin from the pineal and they express specific clock genes. Folliculostellate cells have also been described in the pars tuberalis as having close associations with GnRH-containing nerve fiber endings. This may link responses to photoperiodic stimuli to the reproductive system via this cellular network.

Pars Intermedia

The pars intermedia forms along the region of contact between the anterior and posterior lobes. In adult humans, it remains only as nests of basophilic cells embedded in the posterior lobe. In lower mammals, it remains well developed. The cells form lobules, and nerve fibers may grow into these groups of cells and form connections. A subset of MSH-producing corticotropes is found in the intermediate lobe of most mammals. In humans, this region is well developed before birth.

Intermediate lobe cells produce POMC; however, in lower mammals their enzymatic activities cleave the molecule to produce α-MSH, which is an important regulatory hormone for pigment-bearing melanocytes. Intermediate lobe cells may also be involved in neurogenic stress responses such as that caused by sound, although the amount of biologically active ACTH is relatively low.

Posterior Pituitary

The posterior lobe of the pituitary is largely made of nerve fibers, with supportive astrocytic glial cells, called pituicytes. This lobe was formed by the expansion of the fiber tract containing axons from neurons in the hypothalamus. This downgrowth remains connected to the hypothalamus by the infundibular stalk.

The posterior lobe has a blood supply that is largely separate from that of the anterior lobe. It stems from branches of the inferior hypophyseal artery, which arise from the internal carotids. They penetrate the posterior lobe and form a capillary bed, which then empties into the venous system and the sinus venosus.

The fibers in the posterior lobe originate from neurons in two sets of nuclei in the hypothalamus. One set includes the large neurons (magnocellular) in the paraventricular nuclei, which lie along the lateral

walls of the third ventricle. The other set of magnocellular neurons are in the supraoptic nuclei, which lie over each optic tract. The neurons in both paraventricular and supraoptic nuclei produce either oxytocin or vasopressin.

Oxytocin and vasopressin are produced and stored in secretory granules in separate neurons in most cases. The granules travel down the axons to the pars nervosa. There, they may be stored in nerve endings or in expanded regions called Herring bodies along the pars nervosa capillaries.

Oxytocin and vasopressin are nonapeptides that were discovered, isolated, and synthesized in 1953 by Vincent du Vigneaud, who won the Nobel Prize in Chemistry in 1955. Oxytocin is critical for the support of uterine contractions during labor and contractions of specialized muscle-like cells in the mammary gland during lactation. Its role in the male is not certain, although it may play a role in smooth muscle actions during ejaculation or the transport of sperm. It is also known as a bonding or mothering hormone.

Vasopressin or antidiuretic hormone (ADH) has two names because of dual functions. As ADH, it stimulates water retention by actions on the kidney collecting tubules. As a blood pressure regulator (vasopressin), it constricts arterioles. Both actions ultimately raise blood pressure. Oxytocin and vasopressin were originally derived from a common gene, called vasotocin, which is still found in lower animal species.

Embryologic Development of the Pituitary (Hypophysis)

Rathke first described the origin of the pituitary gland in 1839 and the structure that gives rise to the anterior pituitary bears his name. Rathke's pouch appears at approximately the third week of embryonic life in the human from a group of cells in the anterior part of the neural plate, which are precommitted to become the anterior pituitary, the nasal cavity ectoderm, and the olfactory placode. Regions adjacent to the anterior neural ridge in the diencephalon will become the hypothalamus, infundibulum, and posterior pituitary. These contiguous regions will begin to regulate one another and send projections of their tissue to meet and form the hypophysis.

The hypothalamus produces important factors that drive the organogenesis of the pituitary. One of these is called thyroid transcription factor or T/ebp (also called Nkx1.1 or TitfI). T/ebp stimulates the ventral diencephalon and the developing infundibulum to secrete another important growth factor, fibroblast growth factor 8 (Fgf8). Fgf8 stimulates the thickening of the pituitary placode along the roof of the mouth and then stimulates the formation and upgrowth of Rathke's pouch. Figure 3 shows this process.

Another important factor needed for full Rathke's pouch development is bone morphogenetic protein 4 (Bmp4), which is also expressed in the ventral diencephalon. Bmp4 promotes the development of the pouch and expression of one of its first early gene products, Isl1. Isl1 will stimulate the production of the first anterior pituitary hormone subunit, the α subunit, which is found in thyrotropes and gonadotropes.

Thus, the formation and upgrowth of Rathke's pouch is stimulated by the hypothalamus and infundibulum. The anterior wall of Rathke's pouch then thickens to form the adenophyphysis. Figure 3(b) shows that as Rathke's pouch is growing up and filling in with new cells, structures from the neurohypophysis grow down from the hypothalamus. The expansion of the fiber tracts forms the pars nervosa, which remains connected to the brain via the infundibular stalk. Eventually, Rathke's pouch loses its connection with the oral epithelium (Figure 3(c)).

Development of Anterior Pituitary Cells

If the gene expression discussed previously is proceeding with the correct sequence and timing, the definitive Rathke's pouch grows up and its anterior wall becomes filled in by the rapid proliferation of cells, which are the precursor cells to the anterior pituitary (Figures 3(b) and 3(c)). The ventral diencephalon produces a protein called Wnt5a, which helps with the development of the shape of the pituitary. At the same time, the oral epithelium and the ventral diencephalon produce Sonic hedgehog protein (Shh) to influence early development of the pouch as well as later regional specification that allows the differentiation of each of the cell types.

The first sets of cells to form produce the α glycoprotein subunit, shared by thyrotropes and gonadotropes. These cells form the precursor population for all other pituitary cell types. They are influenced by important transcription factors, a few of which are discussed here. Pitx1 directly activates the α subunit promoter and is important for its continued function even in the adult. It is also highly expressed in the pars tuberalis, early in development, which may relate to the concentration of basophils that are found in this region.

Another gene that is vital for the normal appearance of several pituitary cell types is *Lhx*3. In mutant mice that do not make Lhx3, Rathke's pouch can develop, but cells with α subunit, TSH, and GH do not appear and the appearance of LH is also delayed.

Figure 3 Embryologic development of the pituitary gland. (a) The anterior pituitary arises from the roof of the mouth as Rathke's pouch. The posterior pituitary is a downgrowth from the diencephalon. (b) Rathke's pouch continues to grow up toward the infundibulum. Its anterior (ventral) wall thickens as the anterior pituitary cells proliferate. (c) The adenohypophysis loses its connection with the roof of the mouth and lies anterior to the neurohypophysis. See **Figure 1** for the different regions of each lobe. (d) The developing pars distalis has regions of specification that allow each cell type to develop normally. The most dorsal region, attached to the pars nervosa, contains MSH cells (pars intermedia). This is separated from the remaining adenohypophysis by Rathke's cleft. The regions from ventral to dorsal contain gonadotropes, thyrotropes, and lactotropes/somatotropes. A separate population of thyrotropes (called the rostral tip thyrotropes) develop independent of Pit-1 regulation. Corticotropes develop in the opposite region. These regions are maintained by gradients of growth and transcription factors.

Humans deficient in *Lhx3* show losses in GH, prolactin, TSH, and gonadotropins.

Prop1 has been called the prophet of Pit-1 because its appearance precedes that of Pit1, another transactivation factor that is vital for the appearance of GH, prolactin, and TSH cells. The Ames mouse is an important example of a mutation in *Prop1*. Its pituitary gland is reduced by 85% and there are major reductions in gonadotropes, thyrotropes, somatotropes, and lactotropes.

Previously mentioned are some of the early genes that must be expressed for the birth and differentiation of each of the pituitary cell types. However, to make certain that each cell type develops normally, there is a regional pattern of sequestration. This allows the somatotropes, lactotropes, and most of the thyrotropes to develop in the dorsal regions of the pituitary (pointing toward the back of the body). The gonadotropes, corticotropes, and a subpopulation of thyrotropes develop in ventral regions (pointing toward the front of the body). **Figure 3(d)** shows the regions in which each of the cell types develop.

The reason for this sequestration is simple. Factors that regulate the differentiation of gonadotropes may inhibit the differentiation of somatotropes, thyrotropes, and prolactin cells. Hence, regional separation ensures that each cell type develops normally. The regions are initially formed by gradients of protein transcription factors. Early in development of the anterior pituitary there is a ventral-to-dorsal (back-to-front) graded pattern of expression of bone morphogenic hormone 2 (Bmp2), which was stimulated by the Shh secreted by cells in the roof of the mouth. In other words, regions closest to the oral epithelium have the highest concentration of Bmp2 because of their proximity to the Shh-producing cells. This Bmp2 gradient opposes a dorsal-to-ventral (back-to-front) graded pattern of Fgf8. Recall that Fgf8 was stimulated by factors coming from the infundibulum and the hypothalamus. Thus, the dorsal part of the Rathke's pouch produces more Fgf8.

The presence of high levels of Fgf8 in dorsal regions and high levels of Bmp2 in ventral regions induces specific sets of transcription factors needed for each

group of hormone-bearing cells. Fgf8 in the dorsal regions promotes the production of Prop1 and Pit1, which is important for somatotropes, prolactin cells, and a subpopulation of Pit1 responsive thyrotropes. It also represses the production of Isl1, which drives the production of α subunit.

Bmp2 in the ventral regions, along with Isl1, initially promotes the development of the α subunit and its maintenance in ventral regions. Isl1 production is also maintained in this region, and this leads to the formation of a rostral group of thyrotropes that are not dependent on Pit1 (Figure 3(d)). Eventually, Bmp2 must be inhibited to promote the development of protein factors leading to the birth of gonadotropes. One of these proteins is Gata2.

Gata2 inhibits the expression of Pit-1. Thus, to allow the development of the Pit-1-dependent somatotropes, thyrotropes, and lactotropes, Fgf8 induces the expression of Pax6, which suppresses Gata2 expression in the dorsal regions. In ventral regions, Pax6 is low and Gata2 can therefore be optimal for the development of gonadotropes. Thus, the gradient isolates the optimal environment for the selective development and differentiation of each of the cell types.

Figure 3(d) also shows that corticotropes develop from a lineage completely separate from that of other cell types. They initially appear at the ventral base of Rathke's pouch. After their numbers are enhanced by special factors, a fraction of these cells express Pitx1, which works synergistically with a factor called Tpit that is present only in POMC-expressing cells. This action initiates POMC cell differentiation and POMC transcription. Other factors involved in the enhancement of POMC cells include LIF and the NEUROD1/PanI heterodimer.

These early development events ensure that individual cell types are born and develop normally during embryonic development. Studies have demonstrated some common lineages because families of hormone-bearing cells are dependent on common transcription factors (e.g., somatotropes, thyrotropes, and lactotropes). There is interesting heterogeneity among cell types, such as the ventral- and dorsal-derived thyrotropes.

It is important to recognize that after birth, most of the anterior lobe is filled with a mixture of pituitary cells. In the human, basophils predominate in ventral and medial regions and the acidophils are more numerous in posterior and lateral regions of the pituitary. However, in other species, such as rats, these regions of concentrations are not as obvious. Furthermore, the development of multipotential cell populations suggests further modification as the animals mature after birth. Some of this modification may occur after pubertal development and may be driven by gonadal steroids. Thus, although it is clear that early developmental events support the one cell–one hormone hypothesis, it is also evident from studies of adult pituitaries that the anterior lobe retains sufficient plasticity to allow remodeling of the cell types in order to support multiple systems.

Introduction

While we can think of plasticity in the nervous system in two broad domains, neuronal and behavioral, the two are inexorably linked in that any behavioral plasticity must arise from underlying forms of neuronal plasticity. The initial suggestion of a role for new or induced gene expression in plasticity derives from the behavioral domain. Beginning with studies in the early 1960s on the effects of pharmacological inhibitors of protein synthesis on learning and memory, it has become clear that long-lasting forms of plasticity require gene expression. The primary finding, which has been replicated in species as diverse as *Drosophila*, *Aplysia*, and mice, is that when an inhibitor of protein synthesis, such as anisomycin, is administered during the initial learning, the animals develop normal memory recall 1 h after training, but the memory is dramatically reduced when measured at 24 h. The amnestic effects of protein synthesis inhibitors have led to the suggestion that initial learning involves changes in preexisting proteins, but that the stabilization of these molecular changes over 24 h requires the synthesis of new proteins. These new proteins are presumed to be induced during the initial learning and to exert their effects of over a period of hours to consolidate the initial, transient, cellular changes that underlie short-term memory into a long-lasting or permanent form. This is supported by the fact that inhibition of protein synthesis at the later, 24 h, time point does not impact memory. The process by which short-term memories are stabilized into long-term memories, in a protein synthesis-dependent manner, is often referred to as memory consolidation, or molecular memory consolidation, to distinguish it from the more prolonged changes in the anatomy of memory that involve hippocampal function.

A number of basic questions arise from the initial observation that new gene expression is required for memory consolidation: What are the specific genes induced during synaptic or behavioral plasticity? What are the cellular mechanisms for regulating induced gene expression? What are the cellular plasticity processes that these genes act on to stabilize long-term memories? Are these induced genes required for the consolidation of long-term memory? Advances in molecular and genetic technology over the past two decades have allowed these questions to be addressed to some extent. This progress has produced an outline of transcriptional signaling mechanisms linking initial molecular and synaptic events to gene expression, neuronal plasticity, and behavioral memory.

What Are the Specific Genes Induced during Synaptic or Behavioral Plasticity?

Current models of memory formation in the mammalian brain postulate that neuronal activity-dependent forms of synaptic plasticity play a critical role. In order to look for genes that might be induced by neuronal activity, studies in the late 1980s focused on seizure-induced gene expression. The first gene identified as responding to seizure activity was the protooncogene *cfos*. The *cfos* gene is induced within minutes after the onset of seizure activity, but its expression is transient, returning to baseline levels within several hours. Subsequent screening using differential hybridization techniques or, more recently, expression profiling on DNA microarrays has identified approximately 60 genes that show rapid induction in response to high-level neuronal activity. The activity-induced genes represent a wide variety of molecular domains, from transcription factors to growth factors and components of the cytoskeleton. The identity of these genes does not provide any clear insight into common molecular mechanisms that they might subserve.

The activity-dependent genes, such as *cfos*, are induced not only by high-intensity seizure activity but also by artificial electrical stimulation and environmental stimuli. The most widely studied form of synaptic plasticity in the mammalian nervous system is long-term potentiation (LTP). LTP is an activity-dependent form of synaptic strengthening which has many features that make it an attractive candidate as a cellular mechanism of memory. LTP is typically induced by brief bouts of high-frequency stimulation, which have also been shown to effectively induce rapid expression of many of the same genes discovered in seizure screens.

At the behavioral level, many of these activity-regulated genes have been used to map neuronal activation in response to environmental stimuli. *cfos* is perhaps the most widely used marker of neuronal activity, as it has relatively low baseline expression and strong sensitivity to neuronal activity in a wide variety of brain regions. It has replaced, to a large extent, other techniques for mapping brain activation, such as 2-deoxyglucose labeling. Two other seizure-induced

genes that have been used widely for mapping activity patterns in the brain are *zif268*, encoding a zinc-finger transcription factor, and *arc*, encoding a cytoskeletal-associated protein. Both of these genes have slightly different anatomical distributions and sensitivity to neuronal activity. The properties of *arc* gene expression have allowed it to be used to assess neuronal activity at two different time points. Experiments using this approach have shown that when animals are exposed repeatedly to the same environmental contingencies they induce *arc* expression in the same neurons, indicating that the gene induction is clearly reporting environmentally relevant neuronal activity rather than nonspecific global activity.

What Are the Cellular Mechanisms for Regulating Activity-Induced Gene Expression?

The cellular mechanisms for induction of gene expression by neuronal activity have been studied extensively. While genes such as *cfos*, *zif268*, and *arc* can be induced by a variety of stimuli using different second-messenger signaling mechanisms, the primary signal in neuronal activity-induced gene expression is Ca^{2+}. The Ca^{2+} can derive from two primary sources, voltage-sensitive Ca^{2+} channels that become active when neurons are depolarized and *N*-methyl-D-aspartate (NMDA)-type glutamate receptors, which require both synaptic activity and membrane depolarization for their activity. In a typical cortical pyramidal neuron during high-frequency firing, both pathways will be active.

The transduction of this Ca^{2+} signal into transcriptional activation is significantly more complex. The majority of studies have been carried out in cell culture using artificial depolarization of neurons and using *cfos* to report gene expression. One of the difficulties in these studies is that a primary Ca^{2+} signal in neurons can activate a wide variety of second-messenger signaling pathways as shown in Figure 1. Ca^{2+} increases cAMP levels through stimulation of a Ca^{2+}-dependent form of adenylate cyclase. Ca^{2+} also activates the extracellular signal-regulated kinase/mitogen-activated kinase (ERK/MAPK) signaling pathway through ras activation. Finally, there are protein kinases that are directly activated by Ca^{2+}/calmodulin binding, such as Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and CaMKIV. Each of these signaling pathways has been demonstrated to impact,

Figure 1 Molecular signaling in activity-dependent gene regulation. Neuronal activity produces an increase in Ca^{2+} primarily through the activation of *N*-methyl-D-aspartate receptors (NMDARs) and voltage-gated Ca^{2+}channels (vCCs). Ca^{2+} can be activated at least in three different second-messenger signaling pathways that converge on the nuclear transcription factor cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB) to induce gene expression. AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor; AdC, adenylate cyclase; CaMKIV, Ca^{2+}/calmodulin-dependent protein kinase IV; CBP, CREB-binding protein; ERK, extracellular signal-regulated kinase; MSK1, mitogen- and stress-activated kinase 1; PKA, protein kinase A.

to some degree, the induction of *cfos* by neuronal activity. The relative contribution of each of these signaling pathways to gene expression is likely dependent upon the pattern and time course of the neuronal activity-induced Ca^{2+} signal as well as the subcellular location of that signal. The interaction of these complex signaling mechanisms would in turn control the pattern of gene induction in response to given type of stimulation.

Although there are many transcription factors that respond to the various second-messenger signaling pathways, the cAMP response element-binding protein (CREB) has been studied in the most detail and plays a clear role in activity-induced gene expression. CREB is a transcription factor that was initially discovered based on its response to cAMP. Functional activation of CREB requires phosphorylation at a specific serine residue (Ser133), which can be mediated by the cAMP-responsive protein kinase A (PKA). The same serine residue is a target for phosphorylation by CaMKIV and by a downstream MAPK pathway component, mitogen- and stress-activated kinase 1 (MSK1). In this way multiple different second-messenger signaling pathways that are activated by Ca^{2+} can converge on a single target molecule to regulate transcription. The DNA-binding element for CREB is found in the promoter for the *cfos* gene, as well as in many other genes that are regulated by neuronal activity. This element alone, in a synthetic promoter construct, can confer responsiveness to neuronal activity to cis-linked genes.

What Are the Cellular Processes That These Genes Act on to Stabilize Long-Term Memories?

If new gene expression is required for the consolidation of long-term memories, what might be the cellular processes that underlie its role in memory? This is a component of the larger, and not clearly answered, question of what cellular mechanisms underlie memory. Initial progress on both of these questions has been made in invertebrate model systems such as *Aplysia*. Kandel and his colleagues have analyzed a form of simple learning in this marine mollusk at the behavioral, circuit, cellular, and molecular levels. Sensitization memory in *Aplysia* shows the same dependence on translation, for the conversion from short-term to long-term forms, that is seen in many other species and behavioral paradigms. The underlying cellular changes for this memory appear to be an increase in synaptic efficacy in the specific motor circuit that controls the behavior. In a critical series of experiments, Kandel showed that the synaptic change had the same sensitivity to protein and RNA synthesis inhibitors as did the behavioral memory. That is, when protein synthesis was inhibited during the induction of synaptic plasticity, a short-term form of the plasticity occurred but lasted only a few hours. In the absence of protein synthesis blockade, the synaptic plasticity is stabilized and maintained for more than 24 h. This striking concordance between behavioral memory and a cellular plasticity mechanism suggests that this may be the means by which memory consolidation functions at the cellular level. It also provided the first suggestion that gene expression changes may be critical for neuronal as well as behavioral forms of plasticity.

The cellular plasticity in *Aplysia* is not activity dependent but is mediated by serotonin-induced activation of adenylate cyclase. So while the plasticity in *Aplysia* does not require neuronal activity, it recruits one of the same second-messenger signaling pathways that is activated in the induction of *cfos* by action potential firing in mammalian neurons. *Aplysia* contains CREB homologs that act similarly to mammalian CREB. Blocking CREB-dependent transcription in *Aplysia* neurons produces an effect similar to blocking all transcription or translation, in that the long-lasting synaptic plasticity is inhibited while the short-lasting form is unaffected.

In mammals, the neuronal activity-dependent form of synaptic plasticity, LTP, is commonly studied in the hippocampus, either in the intact brain with implanted electrodes or *in vitro* in brain slices. LTP is induced artificially by high-frequency stimulation, resulting in a prolonged increase in the strength of the stimulated synapses that, in the intact brain, can last for weeks. Most of the molecular and pharmacological studies of LTP have focused on the brain slice preparation. In this preparation, if transcription or translation is pharmacologically blocked during the high-frequency stimulation used for induction, there is an effect similar to that discussed previously for *Aplysia* synaptic plasticity – a short-lasting form of LTP is produced, which then returns to baseline over several hours.

The nature of the transcriptional requirement for LTP has been investigated in an interesting series of experiments by Morris and Frey; their findings suggest that the products of activity-induced gene expression in the nucleus are functionally delivered only to synapses that were recently active. This process is sometimes referred to as 'synaptic tagging' and is supported by the following observations. If synapses are stimulated weakly, this induces a short-lasting potentiation that is not dependent on new gene expression. However, if those same neurons were previously stimulated strongly to induce gene expression, then the short-lasting potentiation is converted into a long-lasting LTP. The suggestion is that the

weak stimulation has molecularly altered or tagged the synapses in such a way that they can now make use of activity-induced genes, if the genes are available within the cell. The strong stimulation of the neurons, at a distinct set of synapses, provides that transcriptional signal.

Advances in techniques for genetic manipulation of the mouse, such as gene knockout and transgenesis, have allowed the functional role of specific molecules to be tested in the intact mammalian brain. The role of CREB has been tested using this approach. Mice in which the CREB gene has been deleted or inhibited through expression of a dominant-negative transgene show deficits in long-lasting LTP, while the short-lasting form remains intact. Several of the genes that are rapidly induced by neuronal activity, most notably those for the transcription factor zif268 and the cytoskeletal-associated protein arc, have been knocked out and produce similar LTP phenotypes.

These results demonstrate that in both vertebrate and invertebrate systems, forms of synaptic plasticity that are thought to underlie long-term memory formation show requirements for new gene expression that parallel what is seen at the behavioral level for long-term memory. While this provides a suggestive framework for how one might understand the role of activity-induced gene expression in long-term memory (i.e., the induced genes are necessary to stabilize the synaptic plasticity that in turn stabilizes the memory), this is certainly an oversimplification. It is clear from many studies that there is not a simple relationship between LTP and behavioral memory. LTP is an artificially induced phenomenon of which there are a number of different types, some of which do not require new gene expression. Moreover, there are a number of examples in which transcriptionally dependent forms of LTP can be impaired genetically or pharmacologically while memory remains relatively intact.

Are These Activity-Induced Genes Required for the Stabilization of Long-Term Memory?

The generation of genetically altered mice carrying mutations in the various activity-induced genes or in the signaling molecules important for their induction has allowed the possibility for linking specific genes to behavioral memory. One of the first studies of this type came from *Drosophila*, which, like the other species discussed, shows a requirement for new protein synthesis for the stabilization of long-term memory. Genetic studies in *Drosophila* have identified genes involved in the cAMP signaling pathway in the formation of memory using a simple Pavlovian conditioning paradigm. Using dominant-negative inhibitors of CREB, Tim Tully and his colleagues showed that expression of the CREB inhibitor impaired long-term memory while sparing short-term memory. Strikingly, they went on to show that expression of a CREB activator allowed training paradigms that normally produced only short-term memory to then induce a long-lasting memory. These results suggest that CREB, which, as discussed previously, is a critical mediator of neuronal activity-induced gene expression and long-lasting forms of synaptic plasticity, is also a critical regulator of the conversion of short-term into long-term forms of behavioral memory.

Similar studies have been carried out in mice. Alcino Silva and his colleagues studied a line of mice in which CREB expression was reduced through a genetic manipulation. They found that long-term memory was selectively impaired in these mice. However, the interpretation of phenotypic alterations, particularly behavioral alterations, in genetically modified mice, in which the genetic lesion is present for the entire developmental history of the animal, can be complex. For example, is the phenotype directly due to the loss of the gene of interest or to compensatory changes in the expression of other genes, or in the development of the circuitry underlying the behavior? CREB is a member of a class of related transcription factors and it was found that in the CREB mutant mice there was a compensatory upregulation in other members of this gene family. Was the phenotype indirectly due to this change in the balance of expression in CREB family members?

To address these issue, a number of groups have used inducible genetic manipulations. In this case, the animals can be allowed to develop normally and the genetic change is induced in the adult just prior to behavioral testing. This should preclude any developmental abnormalities and minimize the chances for compensatory changes that could alter or mask the phenotype. This approach was taken for CREB signaling using inducible expression of a dominant-negative transgene that targeted broadly the CREB family of transcription factors. Even when CREB was inhibited as little as 6 h prior to behavioral training, the same pattern of memory impairment, short-term intact/long-term impaired, was observed. Thus, in both *Drosophila* and mammals, using the most precise genetic manipulations available, it appears that the transcription factor CREB is a critical mediator of the stabilization of short-term into long-term memory.

Transcription is not a simple process involving single molecules, but requires the recruitment of many proteins into a complex on the DNA. Transcription is also sensitive to chromatin structure and the covalent

modification of DNA and proteins within chromatin. Among the important components of this process are the transcription coactivators, which serve to link specific transcription factors like CREB to the recruitment of the more general transcriptional machinery. In addition, these molecules can serve to alter the structure of chromatin through the covalent modification of histones to a state that facilitates transcription. One of these transcription coactivators is the CREB-binding protein (CBP). The CBP gene has drawn interest since it was identified as the underlying genetic alteration in Rubinstein–Taybi syndrome, a rare disorder in humans that is characterized by both developmental and cognitive abnormalities. Two recent studies examined CBP function in behavior using inducible genetic modification. It was found that even when the gene was inhibited only in adult animals, it caused a deficit in long-term memory similar to that seen with CREB inhibition. This suggests that some of the cognitive phenotypes observed in the human disorder may be due to an acute requirement in the adult for normal CBP function.

In addition to linking CREB to the recruitment of the general transcriptional machinery, CBP functions as an enzyme to modify chromatin structure by acetylating histones. This histone acetylation allows the chromatin to assume an open structure needed for effective transcription. Surprisingly, the behavioral effects of genetic CBP inhibition could be overcome with pharmacological agents that elevate histone acetylation nonspecifically. This demonstrates not only the critical role for chromatin structure modifications in the transcriptional regulation of long-term memory, but also suggests a possible pharmacological intervention in disorders, such as Rubinstein–Taybi, that result from disruption of this process.

The role of CREB-based transcription in the stabilization of long-term synaptic and behavioral plasticity is clear. What of the signaling pathways that activate CREB and the 60 or so activity-induced genes that have their expression mediated by CREB? Here the players are more numerous and the results less clear. Mutant mice have been engineered to disrupt each of the three major upstream signaling pathways to CREB activation (Figure 1) – Ca^{2+}-dependent adenylate cyclase, ERK/MAPK, and CaMKIV – with mixed results. Complete elimination of the Ca^{2+}-responsive cyclase leads to a phenotype in both LTP and behavioral memory that is similar to that seen with protein synthesis inhibitors, but not a complete phenocopy. Knockout of CaMKIV leads to a strong reduction in *cfos* inducibility and a deficit in protein synthesis-dependent LTP lasting more than 1 h. Surprisingly, however, the knockout fails to produce similar major changes in long-term behavioral memory. Finally, the ERK/MAPK signaling pathway contains the most components and is the most difficult to dissect. Pharmacological inhibitors of ERK/MAPK signaling have been shown in many studies to disrupt memory and synaptic plasticity. Mutation of an upstream effector of ras function (the neurofibromatosis gene, *NF1*) similarly produces deficits in long-term memory. However, mutations of some of the more downstream effectors have produced conflicting results. This type of complexity is not surprising given the diverse interactions between these very general cellular signaling pathways. As discussed previously, the induction of gene expression likely results from the contribution of each of these signaling pathways, and the impairment of one pathway might be expected to lead to compensation by the others under certain conditions.

The activity-induced genes are numerous and their individual roles in behavioral plasticity have been less well studied. Three of the activity-induced genes that appear to have an influence on memory are the transcription factor gene *zif268*, the brain-derived neurotrophic factor gene *BDNF*, and the cytoskeletal-associated protein gene *arc*. In the case of *zif268* and *arc*, mice carrying a deletion in the gene are viable to adulthood, allowing behavioral testing in which the animals show the selective impairment in long-term memory with sparing of short-term memory that is characteristic of protein synthesis inhibitors. The deletion of the *BDNF* gene produces a severe developmental phenotype. However, one recent study used antisense oligonucleotides to block *BDNF* expression specifically in adult animals and found a similar phenotype. Thus, the individual disruption of three neuronal activity-induced genes, representing distinct categories of molecular function, produces behavioral phenotypes that are similar to that produced with the general blockade of new gene expression.

Summary and Future Directions

A simple framework has been provided for understanding the role of gene expression in neuronal and behavioral plasticity. In summary, the transcription factor CREB plays a critical role, integrating multiple upstream signaling pathways into the increased transcription that is necessary for the stabilization of long-lasting synaptic plasticity and memory. In invertebrates CREB functions primarily by responding to direct cAMP signals. In the mammalian nervous system the critical role of CREB is in integrating multiple molecular signaling pathways that are activated by neuronal activity. Each of these pathways is stimulated by a primary Ca^{2+} signal that occurs when neurons are depolarized, allowing activation of both

NMDA receptors and voltage-dependent Ca^{2+} channels. The response to neuronal activity involves the transcriptional activation of about 60 different genes with diverse functions.

The signaling pathways and the molecular and temporal dynamics of activity-induced gene expression are reasonably well understood. The clear deficiency is in understanding the cellular processes on which these genes act. The questions for the future concern how the activity-induced genes effect synapses, how they stabilize synaptic changes, and whether these synaptic changes completely account for their role in long-term behavioral plasticity.

Plasticity of Intrinsic Excitability

R Mozzachiodi and J H Byrne, The University of Texas Medical School, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

During the past several decades, analyses of the cellular and molecular mechanisms underlying memory formation and maintenance have led to the widespread view that memory storage is largely due to persistent experience-dependent changes in synaptic efficacy. However, an accumulating body of work indicates that learning also leads to persistent changes in intrinsic neuronal excitability. These changes are due to modifications of membrane conductances and can affect electrophysiological properties, including the resting potential, the input resistance, the shape and the threshold of the action potential, and the discharge frequency.

In this article, we review some of the earlier work illustrating plasticity of intrinsic excitability produced by experience, together with some more recent findings. In addition, we discuss the implications of these results and the extent to which changes in synaptic efficacy and changes in intrinsic excitability can both contribute to memory storage.

Changes in Intrinsic Excitability Produced by Learning and Experience

Research over the past three decades has discovered modifications in the intrinsic membrane properties occurring in invertebrates and vertebrates following different forms of nonassociative and associative learning.

Invertebrate Models

Alkon and collaborators were the first to report that classical conditioning (i.e., the learned ability to associate a predictive stimulus with a subsequent salient event) altered the excitability of the photoreceptors in the nudibranch mollusk *Hermissenda crassicornis*. The positive phototaxis that the animal normally exhibits in response to illumination was reduced when the animal was trained with multiple paired presentations of light (conditioned stimulus; CS) and rotation (unconditioned stimulus; US), which activates the vestibular system. This form of learning was associative and the suppression of phototaxis, the conditioned response, persisted for weeks. Classical conditioning produced changes in several membrane properties of the type B photoreceptors, which are the primary sensory neurons of the CS pathway. The type B photoreceptors are excited by light and also by synaptic drive from the statocyst cells, which are part of the vestibular system activated by rotation. The changes produced by classical conditioning included increases in input resistance, spontaneous firing and spike activity in response to current injection, and generator potentials evoked by the CS. Importantly, these changes persisted when the synaptic input to the photoreceptors was removed. Voltage-clamp analysis of the type B photoreceptors revealed that pairing-specific changes in several ionic currents were the biophysical substrate of the altered membrane properties just mentioned. Classical conditioning decreased two K^+ currents, a rapidly activating and inactivating K^+ current (I_A) and a Ca^{2+}-activated K^+ current ($I_{K,Ca}$), and also increased a voltage-dependent Ca^{2+} current. These biophysical changes were consistent with the increase in excitability observed in the type B photoreceptors following classical conditioning, because a reduction of I_A and $I_{K,Ca}$ would tend to produce an enhanced depolarization and increased spike activity in the photoreceptors in response to the presentation of light. The pairing-specific increase in intrinsic excitability was observed for several days following conditioning. Also, the magnitude of the increase in excitability was positively correlated with the degree of phototactic suppression, thus suggesting a causal relationship between the biophysical changes in the type B photoreceptors and the expression of the conditioned response.

Following the results observed in *Hermissenda*, other learning-related changes in intrinsic excitability were identified in other invertebrates, including annelids and mollusks. In the leech *Hirudo medicinalis*, habituation and sensitization, two forms of nonassociative learning, altered in opposite directions the intrinsic excitability of an identified neuron. *Hirudo* exhibits a defensive withdrawal reflex that consists of whole-body shortening in response to light touch of the skin. This reflex can be habituated, when it is repetitively evoked, or sensitized, when a strong, noxious stimulus is delivered. Sensitization, which is mediated by serotonin (5-hydroxytryptamine; 5-HT), requires the activity of a group of electrically coupled interneurons called the S cells. Sensitization increased the input resistance of the S cells as well as their spike threshold and the number of action potentials evoked by intracellular depolarization. These effects were mimicked by exogenous application of 5-HT. Conversely, habituation produced a decrease in intrinsic excitability. These results indicate that in the leech bidirectional changes in intrinsic excitability represent

cellular correlates of two distinct forms of nonassociative learning.

The marine mollusk *Aplysia californica* has been probably the most extensively used invertebrate model to study the cellular and molecular mechanisms of learning and memory. Several examples of experience-dependent changes in intrinsic excitability have been reported in *Aplysia* following both nonassociative and associative learning of simple defensive reflexes as well as associative learning of more complex behaviors such as feeding. Long-term (24 h) sensitization of the tail-siphon withdrawal reflex was associated with facilitation of the sensorimotor neuron synapse as well as changes in the biophysical properties of the tail sensory neurons. The intrinsic changes included increases in the excitability and in the after-depolarization following either a single spike or a burst of action potentials. Voltage-clamp analysis revealed that long-term sensitization reduced the net outward current in the tail sensory neurons, which is consistent with the increased excitability observed in these neurons following learning. Interestingly, long-term sensitization training also altered the biophysical properties of tail motor neurons. These changes included a more hyperpolarized resting membrane potential and a decrease in the threshold for spike initiation. The changes produced by long-term sensitization in the sensory neurons resembled those induced by short-term sensitization, thus suggesting that the phenotype of the expression mechanism for the short-term memory is preserved for the long-term memory.

In *Aplysia*, classical conditioning also produced changes in the intrinsic excitability of sensory neurons. In a simplified preparation of the *Aplysia* siphon-withdrawal reflex, classical conditioning led to an increased input resistance and excitability of the siphon sensory neurons. Interestingly, the changes in intrinsic excitability, as well as the pairing-specific strengthening of the sensorimotor neuron synapses, were restricted to the sensory neurons that were activated by mechanical stimulation of the siphon (i.e., on-field neurons), thus providing CS specificity to the expression of the conditioned response. The presence of biophysical as well as synaptic changes following both nonassociative and associative learning suggested the intriguing hypothesis that the same cellular phenotype underlying nonassociative learning may also serve as physiological substrate for associative memory.

In *Aplysia*, the cellular mechanisms of associative learning of complex behaviors were also studied using appetitive forms of classical and operant conditioning (i.e., the learned ability to associate an expressed behavior with the consequences). Both operant and classical conditioning altered the biophysical properties of neuron B51, a key element of the feeding neural circuitry, but the changes were remarkably different. Operant conditioning increased the input resistance and decreased the burst threshold of B51, resulting in an overall increase in intrinsic excitability, whereas classical conditioning did not alter the input resistance, but increased the burst threshold of B51, resulting in a decrease in intrinsic excitability. These findings provided a biophysical substrate to the hypothesis that, at the cellular level, operant and classical conditioning are mediated by fundamentally different mechanisms. The decreased excitability in B51 was counterintuitive because classical conditioning enhances feeding in response to the CS and also strengthens the CS-evoked excitatory drive to B51. However, the analysis of the responsiveness of B51 to the CS after training revealed that classical conditioning indeed facilitated the recruitment of B51, indicating that the factors that enhanced the recruitment of B51 overpowered the diminished excitability. Although experimental evidence is needed, the pairing-specific decrease in the excitability of B51 might represent an adaptive mechanism to help shape the CS specificity produced by classical conditioning.

Although most of the effects of learning on the membrane properties involved changes in input resistance and/or altered threshold for action potential initiation resulting in modulation in intrinsic excitability, other forms of intrinsic modifications were described as a result of experience in mollusks. For example, as mentioned previously, long-term sensitization in *Aplysia* was associated with an increase in the resting potential of the motor neurons. In the pond snail *Lymnaea stagnalis*, long-term memory for appetitive classical conditioning of feeding, induced by repetitive paired presentations of mechanical stimulation of the lips (CS) and application of sucrose as a feeding stimulant (US), was associated with a persistent depolarization in the modulatory neuron CV1a involved in the initiation of feeding movements. The pairing-specific depolarization of CV1a was positively correlated with the fictive feeding response to the CS in reduced preparations from conditioned animals, but it was not associated with any change in other membrane properties such as input resistance, spike threshold, or spike frequency. The time course of the persistent depolarization also mirrored the duration of retention of long-term memory. This pairing-specific depolarization would render CV1a more likely to fire in response to the CS and allow the CS to more effectively generate feeding responses.

Vertebrate Models

The first evidence of experience-dependent changes in neuronal excitability in a vertebrate model system was reported by Brons and Woody in 1980. These authors used a conditioning paradigm in the cat in which repetitive paired presentations of an auditory click (CS) and a glabella tap (US), which evoked an eyeblink response, led to the appearance of the conditioned response consisting of a combined eyeblink and nose twitch. Cellular analysis conducted in the sensory–motor cortical areas and in the facial nucleus of awake cats revealed that classical conditioning was associated with an increased excitability as measured by the minimum amount of injected current necessary to evoke an action potential. An increase in input resistance was also measured in neurons of the facial nucleus. Although the increase in neuronal excitability lasted for at least 4 weeks following training, the difference between conditioned and control animals became significant only after 25 days. Also, the persistence of the increased excitability, once the conditioned response was extinguished, indicated that this mechanism was not directly implicated in the formation and retention of the conditioned response. A detailed analysis of the biophysical substrate of the increased excitability has not been pursued.

Several other examples of experience-dependent changes in intrinsic excitability were identified in vertebrate models. In the rabbit, delay eyelid conditioning, which is performed using a tone as CS and a coterminating air puff as US, depends on the activation of both the cerebellar cortex and cerebellar deep nuclei. Recordings from Purkinje cells revealed a reduced spike threshold and a reduced afterhyperpolarization (AHP) evoked by burst of spikes in slices from conditioned animals when compared to control animals. The AHP that follows action potentials is an important determinant for the firing activity of neurons, and a pairing-specific reduction of its amplitude is consistent with an increased excitability observed following classical conditioning. Importantly, these changes were long-lasting (up to 30 days), restricted to defined microzones of the cerebellar lobule HVI, and the degree of reduction in spike threshold positively correlated with the conditioned response in the paired animals. Another form of classical conditioning is trace eyelid conditioning, which requires the hippocampus, and occurs when a trace interval is imposed between the CS offset and the US onset. Cellular analysis of trace eyelid conditioning revealed that hippocampal pyramidal neurons in the CA1 and CA3 areas from conditioned animals exhibited a greater number of spikes evoked by depolarizing current injections and a decreased AHP due to a reduction in the Ca^{2+}-dependent K^{+} current underlying the AHP, as compared to control animals. These changes were consistent with a pairing-specific increase in excitability. Although the increased excitability was similar to that found following delay conditioning, it was not restricted to a specific area, but it was instead widespread through the dorsal hippocampus, and also could not be detected 7 days after training when the memory for trace eyelid conditioning was still retained. These findings indicate that it is unlikely that this transient increased excitability in hippocampal neurons constitutes a part of the memory trace itself, but it could represent a mechanism through which the hippocampal circuit is set in a more permissive state for input-specific synaptic modification to occur during memory formation. A similar learning-dependent reduction in AHP also occurred in CA1 pyramidal neurons in the dorsal hippocampus following a spatial learning task that depends on the hippocampus.

In rats, pairing-specific enhancements in both CS-evoked synaptic drive and neuronal excitability (i.e., increased input resistance and reduced amount of injected current necessary to elicit an action potential) were measured *in vivo* in neurons from the lateral nucleus of the amygdala of anesthetized rats trained with a conditioning paradigm during which an odor (CS) was repetitively paired with a footshock (US). The synaptic and the intrinsic changes were both prevented when dopamine signaling, which is relevant for amygdala-dependent forms of learning, was pharmacologically blocked in the lateral nucleus of the amygdala. These results are important because they indicate that both synaptic and intrinsic plasticity occur together during memory formation.

Changes in intrinsic excitability have been found also in vertebrates following operant conditioning tasks. In monkeys, operant conditioning of the spinal stretch reflex is associated with changes in the intrinsic properties of the motor neurons. The spinal stretch reflex is among the simplest vertebrate reflexes and is largely mediated by a monosynaptic pathway between Ia afferent neurons and alpha motor neurons. Because this reflex is influenced by descending activity from supraspinal structures, it can be operantly conditioned and animals can learn to gradually increase or decrease this reflex or its electrical analog, the H-reflex. In particular, operantly conditioned decrease in the H-reflex in monkeys was associated with an increase in the depolarization needed for the spinal motor neuron to fire and a decrease in its conduction velocity. These apparently intrinsic changes were consistent with the hypothesis that a positive shift in motor

neuron firing threshold and a consequent increase in the depolarization needed to reach that threshold could contribute to weaken the magnitude of the H-reflex following operant conditioning. Recent modeling studies proposed that a positive shift in the activation of voltage dependence of Na^+ channels might represent the biophysical substrate for the operantly conditioned decrease in the H-reflex.

Changes in excitability produced by operant conditioning were also reported in rats following an olfactory discrimination task. Rats were trained to discriminate pairs of odors for a water reward. Several consecutive days of training were required for a rat to successfully discriminate between a first pair of odors, but once the rat reached good performance, its ability to learn to discriminate between a new pair of odors improved dramatically and only 1 day was needed to achieve good performance. This phenomenon is called rule learning, because the animal acquires a rule to perform rapidly and efficiently in the olfactory task that is independent of the memory of any particular odor. Cellular analysis revealed that spike frequency adaptation and AHP amplitude were both reduced in pyramidal neurons of the rat olfactory cortex following olfactory discrimination training when compared to naive or pseudo-trained animals. These changes were detected 1–3 days after training, but they decayed to baseline values by 5–7 days after training. It has been speculated that this example of increased excitability is not *per se* a mechanism of memory storage, but it might be involved in rule learning, setting the neural circuits in the piriform cortex in an excitable, more permissive state for activity-dependent synaptic modifications to occur.

Activity-Dependent Modulation of Intrinsic Excitability

In addition to learning tasks *in vivo*, intrinsic excitability can be modulated also by patterns of electrical stimulation of neurons and neural pathways. Depending on the protocol of stimulation, some of these patterns of neuronal activity may induce either an enhancement or reduction of synaptic strength, termed long-term potentiation (LTP) and long-term depression (LTD), respectively. LTP, which is probably the most studied example of activity-dependent modulation of synaptic efficacy, can be induced in several areas of the vertebrate brain, including the hippocampus, the amygdala, the neocortex, and the cerebellar cortex, and is commonly considered to be a mechanism underlying aspects of learning and memory. Because several forms of LTP and LTD can be induced in isolated brain slices, the biochemical cascades underlying these forms of neuronal plasticity can be analyzed.

Although most of the work on LTP has focused on the mechanisms underlying the persistent augmentation of synaptic efficacy, several lines of evidence indicate that, at least in some cases, LTP is also accompanied by modifications in intrinsic excitability. Bliss and Lømo, who first described LTP in the dentate area of the rabbit hippocampus in 1973, also reported an increase in the population spike (i.e., the extracellularly recorded signal representing the summation of the evoked action potentials in postsynaptic neurons) accompanying LTP, which could not be entirely explained by the LTP-evoked increase in the population excitatory postsynaptic potential (EPSP). This nonsynaptic component of LTP was termed EPSP-to-spike potentiation, or E-S potentiation. The mechanisms underlying E-S potentiation are still subject to some debate. Two hypotheses have been developed to explain this phenomenon: an LTP-induced decrease in the ratio of inhibitory to excitatory drive, and an LTP-induced increase in the intrinsic excitability of the postsynaptic neurons through modulation of voltage-dependent channels. Several lines of evidence indicate that a reduction in the ratio of inhibitory to excitatory drive is not sufficient to account for the E-S potentiation, thus pointing to a role for LTP-induced intrinsic plasticity, the consequence of which would lead to a higher efficiency of EPSP-to-spike coupling. One example, which suggests the modulation of voltage-dependent channels as a mechanism underlying the increased excitability accompanying synaptic LTP, has been reported in hippocampal CA1 pyramidal neurons. In these neurons, a pattern of synaptic inputs paired with postsynaptic spikes induced long-term-increase of intrinsic excitability concurring with synaptic LTP. The increased excitability was manifested as a decrease in the action potential threshold that was attributable to a shift in the activation curve of voltage-gated Na^+ channels. This form of enduring increase of intrinsic excitability shared a similar signaling pathway with the late phase of synaptic LTP, which included the requirement of activation of glutamate receptors of the *N*-methyl-D-aspartate (NMDA) type, the influx of Ca^{2+}, the activity of Ca^{2+}/calmodulin (CaM) kinase II, and changes in protein synthesis.

Interestingly, the modulation of the EPSP-to-spike coupling appears to be bidirectional. In the CA1 region of the hippocampus, LTD, normally induced by low-frequency patterns of electrical stimulation, was accompanied by a reduction of the E-S coupling. This reduction of the E-S coupling was largely due to a decrease in the intrinsic excitability of hippocampal

cells. Therefore, opposite modulation of the synaptic strength is associated with bidirectional changes in E-S coupling, which reflect bidirectional modifications of intrinsic excitability.

Other examples of activity-dependent changes in intrinsic excitability produced by synaptic activation have been reported in different brain areas. For example, in the rat entorhinal cortex, a brain region involved in the acquisition and retention of working memory, persistent graded increases in firing frequency were induced in pyramidal neurons by repetitive excitatory synaptic activation. These sustained levels of firing could be either increased or decreased in an input-specific manner and relied on activity-dependent changes of Ca^{2+}-dependent cationic current. This intrinsic ability of the neurons in the entorhinal cortex to generate graded persistent activity has been proposed as a cellular mechanism for working memory. Another example of modulation of intrinsic excitability induced by synaptic activation has been reported in the cerebellar cortex. In this brain region, high-frequency stimulation of the mossy fiber-to-granule cells pathway led to LTP and was also accompanied by a persistent enhancement of intrinsic excitability of granule cells, which was associated with increased input resistance and decreased spike threshold. Neurons of the cerebellar deep nuclei also exhibited a rapid, synaptically driven, increase in their intrinsic excitability, which required Ca^{2+} influx through activation of NMDA-type glutamate receptors. However, in this case, the pattern of synaptic stimulation used to activate these neurons did not produce any facilitation of the synaptic input. This latest example indicates that modulation of intrinsic excitability can be expressed without the occurrence of changes in synaptic function, thus providing a contribution to the information storage independent from synaptic plasticity.

Recent findings indicate that changes in intrinsic excitability may not require synaptic activation. For example, a train of high-frequency intracellular depolarizations delivered to pyramidal neurons in layer V of the primary visual cortex produced an enduring increase in intrinsic excitability. This change in excitability required Ca^{2+} entry during neuronal activity and did not affect the passive membrane properties, thus suggesting the involvement of voltage-dependent channels. Another example of synaptic-independent modulation of intrinsic excitability has been reported in hippocampal CA1 pyramidal neurons. In these neurons, a pattern of suprathreshold repeated intracellular stimulation, called theta-burst firing, produced a decrease in somatic excitability, which was due to an upregulation of the hyperpolarization-activated cationic current I_h. This decrease in excitability was prevented by Ca^{2+} chelators, by low concentrations of tetrodotoxin (which blocked backpropagation of action potentials from the soma to the dendrites), and by NMDA receptor antagonist even in the absence of synaptic activation. These findings suggest that during theta-burst firing, backpropagating action potentials would lead to Ca^{2+} influx through the NMDA receptor, which, in turn, would increase the I_h via a mechanism mediated by CaM kinase II.

Interestingly, recent findings indicate that the synaptic drive needs not be excitatory to induce an increase in intrinsic excitability. Recordings from spontaneously firing neurons in the medial vestibular nucleus indicate that brief periods of inhibitory synaptic input, or direct membrane hyperpolarization, triggered a long-lasting increase in both spontaneous firing rate and firing responses to intracellular depolarization. This increase in excitability, termed firing rate potentiation, was due to a decrease in cytosolic Ca^{2+}, which reduced CaM kinase II activity, maximal in spontaneously active vestibular neurons, and, in turn, downregulated BK-type $I_{K,Ca}$. This novel form of neuronal plasticity might contribute to motor learning in the vestibuloocular reflex.

The intrinsic changes produced by patterns of neuronal activity are not restricted to ion channels. Modulation of the activity of membrane transporters has also been reported. For example, interneurons of the rat dentate gyrus exhibited a long-term depolarization of their resting membrane potential after high-frequency stimulation of the perforant path that was attributed to an activity-dependent change in the rate of the electrogenic Na^+ pump function. This activity-dependent depolarization, which occurred in the absence of any potentiation of the excitatory synaptic input, required the rise of intracellular Ca^{2+} and the activation of glutamate receptors of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) type, but not of those of NMDA type. As a result of the depolarization, the interneurons of the dentate gyrus responded with action potential discharge to previously subthreshold EPSPs even in the absence of synaptic potentiation, thus indicating an increase in the E-S coupling. Activity-dependent changes in the function of the electrogenic Na^+ pump have also been found in invertebrate neurons. In *Hirudo*, low-frequency repetitive stimulation of touch (T) sensory neurons led to a lasting increase in the amplitude of the AHP produced by the firing discharge, which is due to an increase in the activity of the electrogenic Na^+ pump. The modulation of the Na^+ pump activity was regulated by both the influx of Ca^{2+} during neural activity and the release of Ca^{2+} from intracellular

stores. In addition, phospholipase A2 and the downstream activation of arachidonic acid metabolites, derived from the 5-lipoxygenase pathway, were necessary for the increase of the AHP amplitude. Interestingly, the increase of the AHP amplitude was associated with a persistent depression of the synaptic connection between T cells and their follower neurons. This synaptic depression may be a cellular mechanism contributing to short-term habituation.

Plasticity of Intrinsic Excitability as a Mechanism for Memory Storage: Hypotheses and Lines of Evidence

The general motif that emerges from the preceding examples is that several different learning tasks, nonassociative and associative, as well as activation of neurons and neural pathways, induce changes in the biophysical properties of neurons in both invertebrate and vertebrate model systems. These neurophysiological correlates have been identified at the level of sensory neurons, interneurons, and motor neurons.

What is the functional relevance of these changes? In some case a direct role for the intrinsic plasticity in memory storage could be proposed. For example, in *Aplysia* and *Hermissenda,* because the loci of plasticity induced by classical conditioning were found at the level of the first central relay in the circuits controlling the responses, neuron-wide changes in intrinsic excitability in response to the conditioned stimuli appear to be an appropriate memory mechanism to express and retain the conditioned response. However, in other cases the changes in intrinsic excitability failed to correlate, or correlated poorly, with the learned behavioral changes, thus making it difficult to assess their contribution to the storage of memory. Although additional results are required, one hypothesis is that some of the intrinsic changes may not function as part of the engram itself, but they may represent either adaptive mechanisms to shape the stimulus specificity of the learned response (as in the case of classical conditioning of feeding in *Aplysia*), or mechanisms through which a neural circuit is set to a permissive state to facilitate the occurrence of the synaptic modifications necessary for memory formation (as in the case of trace eyelid conditioning in rabbits or olfactory operant conditioning in rats).

Another issue that requires more investigation is the extent to which the changes in intrinsic excitability are complementary to experience-dependent modifications in synaptic efficacy. The majority of theoretical models of memory storage have been largely based on persistent experience-driven changes in synaptic function. It is because of certain unique properties of the synapses, such as associativity and input-specificity, that systems of memory storage based on changes in synaptic strength have a potentially massive storage capacity. In contrast, global changes in intrinsic excitability would theoretically alter the throughput of all the synaptic inputs impinging to a given neuron. If this is the case, memory mechanisms based on neuron-wide altered intrinsic excitability would have a lower storage capacity and would be less versatile compared to systems of memory storage based on changes in synaptic strength.

Some recent results may help to reconcile differences between models of memory storage based on synaptic and models based on intrinsic plasticity. Patch-clamp techniques and simultaneous Ca^{2+} imaging that allow for recordings from individual dendrites have revealed that the induction of LTP was accompanied by a local increase in dendritic excitability that favored backpropagation of action potentials into that dendritic region, with a subsequent boost in the Ca^{2+} influx. A shift in the inactivation curve of a transient A-type K^+ current was found to account for the enhanced excitability. Importantly, the activity-dependent increase in dendritic excitability was localized at, or in the vicinity of, the synaptic site, which was potentiated in an input-specific manner following electrical stimulation. Local increase in dendritic excitability could facilitate enhanced propagation of synaptic potentials toward the site of action potential initiation. Therefore, enhancement of local excitability could contribute to the higher efficiency of coupling between synaptic potentials and spike as observed following LTP induction.

Although validation in *in vivo* preparations is required, these findings indicate that changes in intrinsic excitability can be induced to restricted membrane compartments and can be co-expressed with changes in synaptic efficacy in a manner that affects signal integration locally and can preserve input specificity.

Summary

Data collected over the past decades in both vertebrate and invertebrate model systems indicate that learning and memory as well as patterns of electrical stimulation of neurons and neural pathways not only alter synaptic function but also produce changes in intrinsic excitability. These changes in intrinsic excitability can be neuron wide or restricted to specific membrane compartments, such as the dendrites, thus affecting neuronal function and signal integration either globally or locally. Although ascertaining the functional relevance of certain changes in intrinsic excitability in the context of a given form of learning

has not been always successful, and in several cases the role of intrinsic plasticity still remains elusive, lines of evidence suggest that experience-dependent changes in intrinsic excitability may function as part of the engram itself, or as adaptive mechanisms to shape the stimulus specificity of the learned response, or also as mechanisms through which a neural circuit is set to a permissive state to favor the occurrence of the synaptic modifications necessary for memory formation and retrieval.

Pleasant Touch

A B Vallbo, H Olausson, and J Wessberg, Goteborg University, Goteborg, Sweden

Pleasant Touch – A Fundamental Affectionate Variable

It is a universal experience that bodily contact between individuals is a powerful means of nonverbal communication. Skin-to-skin touch may have a very strong emotional impact, immediate as well as long term. The affective potential of bodily contact is perhaps most apparent in erotic and parent–child relations, although touching is a potent means to convey empathy and relieve anxiety in less intimate personal contacts as well. Even a passing touch offered by a friend or an empathic nurse may give great reassurance to a person in fear, distress, or agony. Robin Dunbar stated wisely that a touch may be worth a thousand words. Further, in positive excitement we like to raise the feeling of shared joy, for instance, by hugging the teammates after a goal. On the other hand, the erotic potential of bodily contacts implies a barrier which in many situations makes us abstain from touching another person.

It was shown long ago by Harlow and co-workers that pleasant touch is essential to provide affection and security in early childhood. Studies of baby monkeys left in distress because they were deprived of their native mothers led to the conclusion that contact comfort is a very potent factor for the baby to develop affectionate responses, reassurance, and love for the mother. In fact, contact comfort was found to be even more powerful than nutrition.

Although a number of sensory mechanisms, as well as psychological factors are probably involved in most situations when we convey positive emotional signals by bodily contact, it is obvious that cutaneous touch is a significant element. The focus of the present account is on highly sensitive cutaneous sense organs which respond to light touch, particularly the unmyelinated tactile (CT) afferents which might have a specific role in this context. With regard to semantics, the term 'tactile' in this account solely refers to the finding that the afferents respond intensely to light touch, whereas the term does not refer to central effects related to haptics.

Tactile Afferents in Human Skin

The canonical view of human physiology is that light touch is signaled by large and fast conducting myelinated Aβ-afferents alone. However, in the last decades it has been demonstrated that human skin is also innervated by unmyelinated afferents responding to light touch (CT-afferents). They conduct impulses at a speed of about $1\,\mathrm{m\,s^{-1}}$ whereas Aβ-afferents are about 50 times faster (see Figure 1). Six different kinds of Aβ-afferents with separate physiological properties have been identified in human skin in addition to the CT-afferents (Table 1).

The distinct difference in receptive field size and topography is illustrated in Figure 2 for the main types of tactile afferents encountered in the hairy skin of the forearm. Corresponding illustrations for glabrous skin units may be found in Kandel, Schwartz, and Jessel's textbook. Receptive field structure as assessed with an objective method provides convincing evidence for unit identification and separation in distinct groups, although additional observations are essential, for example, conduction velocity and selective sensitivity to hair movements.

There is an interesting regional difference with regard to Aβ and CT innervation in man. CT-afferents have been demonstrated in face, forearm, hand dorsum, and thigh, suggesting that they are present all over the hairy skin. However, they have not been found in the glabrous skin of the hand in spite of numerous microenurography explorations of this area. Hence, it seems reasonable to conclude that they are lacking in the glabrous skin. Although there is no method to properly assess the proportion of CT-afferents out of total number of tactile units, it is a recurring experience in microneurography experiments that CT-afferents are encountered at least as often as Aβ-afferents in nerves innervating the forearm skin. However, there are indications that CT-afferents may be less common in the lower leg.

It should be pointed out that unmyelinated tactile afferents were demonstrated long ago in the hairy skin of various animals but they have not been found in the pad skin which corresponds to the glabrous skin in man – where CT-afferents are lacking as well. In animals the unmyelinated tactile afferents are often denoted as low threshold mechanoreceptive C-afferents (C-LTM). For long it was assumed that this system of afferents had faded away in the process of evolution from rat, rabbit, and cat to man until microneurogaphy demonstrated CT-afferents in man in the beginning of the 1990s.

Functional Properties of CT-Afferents

The CT-afferents are equally sensitive to skin deformation as many of the Aβ-afferents. They respond to

Figure 1 Microneurography recording of two single afferents to light touch, that is, a fast conducting Aβ-afferent and an unmyelinated CT-afferent. (a) Target point for touch stimulus and microneurography recording site from the lateral antebrachial cutaneous nerve in the upper arm. (b) Microneurography record and time course of tap stimulus showing an early burst of nerve impulses in the Aβ-afferent and a late burst in the CT-afferent. Distance between target area and recording site was 247 mm implying a conduction velocity below 1 m s^{-1} of the CT-afferent. The threshold of the CT-afferent as tested with von Frey monofilaments was 1.3 mN. (c) Nerve impulses from the record in (b) displayed on an expanded timescale to highlight the different impulse shape of the Aβ-afferent (SAI type) and the CT afferent. Reproduced from Wessberg J, Olausson H, Wiklund Fernstrom K, and Vallbo AB (2003) Receptive field properties of unmyelinated tactile afferents in the human skin. *Journal of Neurophysiology* 89: 1567–1575, with permission from The American Physiological Society.

Table 1 Mechanoreceptive afferents in human nerves from glabrous and hairy skin

Sensory endings and afferent unit acronyms		
Glabrous skin	*Hairy skin*	*Adaptation*
Merkel SAI	Merkel SAI	Slow
Ruffini SAII	Ruffini SA II	Slow
Pacini FA II (PC)	Pacini FA II (PC)	Fast
Meissner FAI (RA, QA)	Hair follicle unit	Fast
	Field	Fast
	C-tactile CT (CLTM)	Intermediate

The separate unit types were identified on the basis of microneurography recordings in man while types of end organ were inferred on the basis of physiological and morphological studies in various species. Slow and fast adaptation refers to the presence or lack of sustained response to stationary skin deformation. Most acronyms refer to adaptation properties (fast, rapid, quick, or slow adaptation). Acronyms within parenthesis have mainly been used in studies of nonhuman species. All afferents listed are myelinated and fast conducting (Aβ fibers) except CT units which are unmyelinated (C-fibers). The table includes highly sensitive afferents but not nociceptive afferents that may respond weakly to innouous skin deformation. The table entries refer to glabrous skin of the hand and hairy skin of the forearm and are based on recent investigations. However, there are microneurography studies suggesting a somewhat different innervation pattern in particular skin regions, the existence of subgroups, and one or two additional mechanoreceptor types.

indentation forces in the range 0.3–2.5 mN as tested with von Frey monofilaments and they produce high-frequency trains of action potentials (50–100 impulses s^{-1}) to pleasant touch stimuli. It should be recalled that maximal impulse frequency recorded from afferent C-fibers is about 100 impulses s^{-1}. In contrast, Aβ-afferents may fire close to 1000 impulses s^{-1}. It is of interest that, in addition to these two groups of sensitive tactile afferents, some of the nociceptive afferents may respond to innocuous touch as well. However, their sensitivity is low and their response to pleasant touch is minimal, usually not more than one or two impulses.

While CT-afferents share the high sensitivity with the Aβ-afferents, the physiological properties of the two groups differ in most other respects. Aβ-afferents fall in two distinct groups with regard to response to steady-state skin deformation (Table 1). The fast adapting units do not respond at all, that is, they lack static sensitivity altogether, while the slowly adapting units provide a continuous discharge for minutes or more. Actually, many Ruffini units may be firing continuously for life. In contrast, the CT-afferents have intermediate adaptation properties. They respond initially with a burst of high impulse rate, while the rate often falls to zero after a few seconds of sustained indentation. The discharge may then reassume after another few seconds, then wax and wane to finally stop altogether. CT-afferents lack the potential of the Aβ-afferents to code fast events. They respond well to slowly moving stimuli but poorly to brisk movements and vibration. Hence, their dynamic response range is limited to low frequencies. Stimuli which are particularly efficient to evoke a massive CT-input are slowly moving, caress-like stimuli over large skin areas with the hand or a broad artist paintbrush. A prominent feature of the CT-afferents is that they are highly fatigable. When identical stimuli are repeated, the first stimulus usually evokes a much larger response than the following. This feature suggests that the system is particularly interested in novel events. When a local skin deformation is released, CT-afferents may produce an after-discharge that may last for many seconds. However, the duration varies a lot even within the individual unit depending on temperature, previous history, and other nondefined factors. An additional and unique feature of the CT-afferents

Figure 2 Receptive field topography of five kinds of tactile afferents in the hairy skin. Data from four representative Aβ-afferents and two different CT afferents (see **Table 1**). Note difference in scale for the hair and field units. The colors represent intensity of afferent firing from zero to maximal rate of the particular trial. Peak rates fall in the range 35–60 impulses s^{-1}. Gray areas which fill up the SAII box represent continuous spontaneous activity of the afferent. (Aβ afferents) Adapted from Vallbo AB, Olausson H, Wessberg J, and Kakuda N (1995) Receptive field characteristics of tactile units with myelinated afferents in hairy skin of human subjects. *Journal of Physiology* 483: 783–795, with permission from Blackwell Publishing. (CT-afferents) Reproduced from Wessberg J, Olausson H, Wiklund Fernstrom K, and Vallbo AB (2003) Receptive field properties of unmyelinated tactile afferents in the human skin. *Journal of Neurophysiology* 89: 1567–1575, with permission from The American Physiological Society.

is that the response of the individual afferent is not as consistent and predictable as with individual Aβ-afferents but may vary from one test series to the next for no obvious reason.

The response features of the CT-afferents as outlined above all converge toward the interpretation that the system is not designed to code accurately and consistently intensity and time course of skin deformations. These are functions which are essential for discriminative touch. In daily life, the tactile system continually captures details of temporally and spatially variant skin deformations. As a result we can readily perceive more complex features, for instance, the direction of a stimulus moving along the skin and we can discriminate the intensity of component indentations which are closely adjacent in time and space to assess shape and surface structure of objects. Altogether, it seems evident that the CT-afferents lack response properties required for serving discriminative touch.

Significance of conduction velocity The high conduction velocity of the myelinated Aβ-afferents is a feature which is essential for discriminative touch, as well as for guidance of motor activities. Hence, the low conduction velocity of the CT-afferents precludes these roles. First, the long delay (0.5–1.0 s) from stimulus to impulse arrival in the brain is hardly compatible with accurate integration with signals from fast Aβ-afferents and other sensory systems, for example, vision and hearing, that is, forms of integration which are often essential for guidance of

motor activities. Second, the documented interfiber variation in conduction velocity around $1\,m\,s^{-1}$ implies that the set of impulses in the sample of CT-afferents excited by a local touch would be widely dispersed in time when arriving to the brain. As a result, the CT-afferents produce a temporally blurred account of the peripheral event compared to that of the Aβ-system. Hence, the slow conduction velocity of the unmyelinated nerve fibers implies an additional argument against the CT-system having a role in discriminative touch.

CT-Afferents – Functional Hypotheses

The physiological properties of the CT-afferents as presented above seem to rule out the possibility that the system plays an essential role in discriminative and motor aspects of cutaneous mechanoreception. Hence, it is of interest to consider what other functions might justify the presence of a slow system with selective sensitivity to light touch. Which functions might afford the deficiencies of the CT-system in coding peripheral events, yet be biologically significant enough to justify the preservation of a parallel tactile system in addition to the fast and accurate Aβ-system?

Tickle Hypothesis

For long, the low threshold mechanoreceptive C-afferents were discussed as a system accounting for the sensation of tickle. This idea proposed by Zotterman in 1939 was largely based on his observation that unmyelinated tactile afferents in the cat may produce long-lasting after-discharges when a skin indentation was released. The tickle hypothesis was then reiterated in a number of successive publications as late as in the 1990s. However, in microneurogaphy studies of human CT-afferents, it has been found that the duration of after-discharge does not match the duration of tickle sensations, nor is the impulse rate of CT-afferents related to the intensity of tickle sensation. Moreover, subjects who lack Aβ-afferents but have preserved small fiber functions (see below) are not aware of being tickled in the affected skin areas. These findings indicate that the sensation of tickle is dependent on Aβ-afferents rather than on CT-afferents.

Maintenance of Cortical Maps

Studies in nonhuman subjects (cat and flying fox) have suggested that unmyelinated mechanoreceptive afferents may play an essential role in the complex processes of shaping and maintaining the map of body surface in the somatosensory cortex areas. The hypothesis is based on observations of how these maps are modified with amputations and other injuries. In relation to a possible role of CT-afferents in this context, it seems significant that the unmyelinated afferents involved in body surface mapping are sensitive to capsaicin. Since human CT-afferents are not sensitive to capsaicin, it seems reasonable to conclude that the CT-afferents are not main candidates for cortical map design.

Affective Touch Hypothesis

Although poor coding accuracy is a serious drawback in discriminative functions, an area where these deficiencies are readily affordable is the limbic realm. Considering the potential roles of light touch in relation to limbic functions, it seems reasonable to single out one function of particular interest, that is, tight physical contact with conspecifics, in the first place with your mother, later in life with your partner and children. We all strongly feel now and then that skin wants skin. These considerations led to the affective touch hypothesis, implying that the essential role of the CT-system is to convey pleasant aspects of light touch, particularly in skin-to-skin contact with affiliative human beings. It should be emphasized that this does not imply that CT-afferents are the only afferents that may contribute or give rise to limbic touch effects, as will be discussed in a later section.

Responses to Activation of the CT-System

To test the affective touch hypothesis and explore the functional role of the CT-system, it is desirable to activate the CT-afferents selectively without activating Aβ-afferents. Unfortunately, this is not possible in normal subjects although stimuli designed to give different proportions of Aβ- or CT-input have been tested.

It has been demonstrated in proper psychophysical tests that a slowly moving touch stimulus ($1–5\,cm\,s^{-1}$) which is particularly effective to activate CT-afferents is more pleasant than a fast-moving stimulus. Vibratory stimuli which activate Aβ-afferents very efficiently, but CT-afferents only weakly, are rated as less pleasant than slowly moving touch stimuli. These observations are consistent with the hypothesis that CT-afferents are more important for the feeling of pleasant touch than are Aβ-afferents. Although findings of this nature are consistent with the affective touch hypothesis, more pertinent data have been obtained from a few subjects, who suffer from a very rare neurological deficiency (sensory neuronopathy syndrome), implying that they lack Aβ-afferents from large parts of the body. As a consequence, it is reasonable to assume that their sole tactile afferents are unmyelinated CT-afferents.

Psychophysical Responses

Two subjects with sensory neuronopathy syndrome are well described in the literature. They have been studied extensively over the years particularly with regard to motor functions. It has also been reported, although more in passing, that they lack tactile sensibility. This observation was consistent with the prevailing view at that time that tactile sensibility is lacking altogether when Aβ-afferents are nonfunctioning. This view, in turn, was largely based on experiments in normal subjects which suggested that tactile sensibility is lacking when the Aβ-afferents had been selectively blocked by sustained pressure onto the nerve.

However, when it became evident that human skin is supplied with a system of unmyelinated afferents sensitive to light touch, it became pertinent to reexamine the tactile sensibility of neuronopathy subjects using more refined approaches. Rigorous psychophysical tests were pursued to study if the neuronopathy subjects were at all able to detect touch stimuli which were particularly designed to evoke massive CT-inputs. It was found, in 2-alternative-force-choice (2-AFC) tests, that subjects lacking Aβ-afferents readily detected such stimuli applied to the forearm skin where CT-afferents are abundant. In contrast, they failed altogether to detect the same kind of stimuli applied to the glabrous skin of the hand where CT-afferents are lacking. A difference of similar kind was found between the two skin regions in the neuronopathy subjects when detection threshold was assessed using von Frey monofilament. Relatively weak monofilaments which give a pure sensation of touch in normal subjects were readily detected in the hairy skin but not in the glabrous skin. Here much stronger stimuli (4–8 times stronger) were required for detection. Moreover, the neuronopathy patients reported that these strong stimuli gave rise to a sharp and marginally painful sensation, suggesting that detection in the palm was based on nociceptive input. In contrast, sensations with threshold von Frey monofilament in the hairy skin lacked all elements of pain or sharpness suggesting that detection was based on afferents sensitive to innocuous stimuli. It should be emphasized that, in normal subjects, there is no difference between the two skin regions in this respect, that is, thresholds for detection of monofilament stimuli are identical in the hairy and glabrous skin. Further, thresholds are generally lower than in the neuronopathy subjects, suggesting detection by Aβ-afferents in normal subjects. An additional highly relevant finding is that the neuronopathy subjects are unable to detect vibratory stimuli which are known to a give a poor excitation of CT-afferents but a massive activation of several kinds of Aβ-afferents.

Although these observations agree that CT-afferents may well account for detection of touch stimuli in subjects lacking Aβ-afferents, it has been more difficult to obtain a clear and consistent apprehension of the quality of the sensation perceived when CT-afferents are selectively stimulated. Still, a number of interesting features emerged, when the qualitative characteristics of the sensation were explored.

First, it was obvious that the sensation associated with a massive and selective CT-input was very weak, vague, and inconsistent when slowly stroking a broad and soft artist paintbrush along the forearm of the neuronopathy subjects. In some trials, the subject reported no sensations at all. In others, they reported a sensation of light touch which was barely detectable and difficult to mentally catch and describe in detail. In this context it should be noticed that stimulus detection in a psychophysical 2-AFC test does not prove that the stimulus is very clearly perceived. The weakness and vagueness of the sensation are further illustrated by the fact that conscious perception of CT-stimulus varied from one occasion to the other and between the two subjects as well. In fact, one of the two subjects (GL) reported that she began to feel more touch sensations in daily life, once she had had the experience of touch perception from the affected skin areas and had become aware of the possibility. Although the two neuronopathy subjects were not able to give a clear and detailed description of the sensation evoked by CT-stimulation, some consistent features of the quality emerged, namely that the sensation had no tint of pain, tickle, or itch. Further they reported that the sensation elicited by CT-stimulation was slightly or moderately pleasant.

Brain Responses

When functional magnetic resonance imaging (fMRI) was used to study brain response to touch stimuli (Figure 3) in normal and neuronopathy subjects lacking Aβ-afferents, the findings indicated that different sensory areas are activated by the fast (Aβ) and the slow (CT) tactile systems from the hairy skin. In normal subjects pleasant touch activated the classical somatosensory areas SI and SII as well as insular cortex, notably the posterior part of the contra-lateral insula. Somatosensory areas SI and SII are known to be significant for discriminative touch whereas insular cortex is a region of great interest in relation to affective mechanisms, because it is considered to house a gateway from sensory systems to the emotional systems of the frontal lobe. When similar stimuli were applied to subjects lacking Aβ-afferents, no activation was found in the somatosensory areas whereas the posterior insular region was activated.

Figure 3 fMRI responses (BOLD) to pleasant touch stimuli. (a) Response in posterior and middle insular region to selective stimulation of CT-afferents in a neuronopathy subject lacking large myelinated Aβ-afferents. In this subject light touch produced no BOLD response in somatosensory areas SI and SII, whereas similar stimuli regularly activate these two areas in normal subjects. (b) BOLD response in orbitofrontal cortex to pleasant touch stimuli of the palm in normal subjects (group data). BOLD, blood-oxygen level dependent. (a) Unpublished. (b) Adapted from Rolls ET, O'Doherty J, Kringelbach ML, et al. (2003) Representations of pleasant and painful touch in the human orbitofrontal and cingulated cortices. *Cerebral Cortex* 13: 308–317, with permission from Oxford University Press.

The conclusion is that the unmyelinated CT-afferents project toward the emotional systems (insular cortex) but less or not at all toward the discriminative–cognitive systems (classical somatosensory areas SI and SII). This observation seems to provide an essential support for the affective touch hypothesis.

To what extent the tactile Aβ-afferents project toward the emotional systems along with the CT-afferents has not been widely explored. However, it seems likely that this may be the case, because pleasant touch stimuli of the palm, where CT-afferents are lacking, give rise to fMRI responses in a target area for insular efferents in orbitofrontal cortex involved in more complex emotional mechanisms. It remains to be explored whether a projection of tactile Aβ-afferents to emotional centers is unique for the palm or is true for other skin areas as well. It may be speculated that Aβ-afferents from the palm have obtained an affective role because CT-afferents are lacking here. Anyway, it seems clear that affective aspects of touch are not always dependent on CT-afferents alone.

The physiological properties of the CT-afferents as well as the psychophysical and fMRI responses to selective activation of the unmyelinated tactile system converge toward a limbic-emotional role of the system. The affective touch hypothesis implies that the essential role of the CT-system is to provide or support emotional, hormonal, and behavioral responses to skin-to-skin contact with conspecifics. On the other hand, it seems likely that a natural perceptive-emotional response to pleasant touch is dependent on the combination of afferents from the two tactile systems, because selective CT-stimulation fails to evoke anything like a full sensation of pleasant touch. The combination of CT- and Aβ-afferents is obviously required for the complete feeling of pleasant touch in the hairy skin. It is also pertinent to recall a general principle regarding emotional responses. The intensity and even the quality of the emotional response evoked by a particular stimulus is highly dependent on contextual factors, as well as state of deprivation, that is, to what extent your desire with regard to the particular emotion has recently been satisfied or not. Obviously, your sense of pleasure is intense when you hug and touch your partner after weeks of separation, whereas you are not particularly pleased when touched by an unknown person in a crowd.

It may be asked why evolution has retained a separate system of unmyelinated afferents for social-emotional touch. Why could this role not be handled by the Aβ-afferents? It is difficult to deny that they could – and, in fact, they do in the glabrous skin of the hand.A particular reason for preservation of the CT-system is that unmyelinated afferents are parsimonious because they take up little space in the peripheral nerves.

CT-System – A Branch of an Interoceptive Afferent System

In a wider perspective, the CT-system may be regarded as a branch of a large afferent system which is basically concerned with your own body rather than external events, as conjectured by Craig. The basic role of the interoceptive system is to continuously watch the condition of body tissues, as well as physiological and chemical variables within the body. Interoceptive afferents have particular access

to brain centers which control affective, hormonal, autonomic, and behavioral responses with effects to readjust adverse conditions and keep variables within desired ranges. The ultimate aim would be to keep the cell, the individual, and the species going. Included in the interoceptive system are afferents related to perception of pain, itch, temperature, air hunger, vasomotor flush, hunger, thirst, and a range of visceral sensations, as well as afferents which are essential for the subconscious control of physiological variables, such as blood pressure and concentration of blood gases.

The peripheral afferents of the interoceptive system consist of small diameter nerve fibers (thin myelinated Aδ and C fibers) with projections to the superficial lamina of the dorsal horn in the spinal cord and nucleus of the solitary tract. In this context it is interesting that touch sensitive unmyelinated afferents (C-LTM) have been shown to project to lamina I and II in several mammalian species, consistent with the interpretation that they belong to the interoceptive system. However, apart from this finding, connectivity studies of CT-afferents or homologs in other species are unfortunately lacking altogether in the literature.

At higher levels the small fiber afferents are tightly linked to amygdale and hypothalamus and, at cortical levels, to the insular region, primarily the posterior and middle parts. Moreover, there are indications that the anterior insular cortex on the nondominant side constitutes a still higher level housing a re-representation of the interoceptive image of the entire body. This representation of the physical self is postulated to constitute a basic foundation of mental consciousness.

The role of the CT-units as an afferent branch of a system guarding the well-being of the body would be to signal pleasure and reassurance as you are close to your parents, lover, kin, or friends. There are indications that pleasant bodily contacts promote hormonal responses, that is, endorphin and oxytocin, which contribute to the feeling of well-being, confidence, and calmness.

Bodily Contact

Although the affective touch hypothesis implies that the particular role of the CT-system is to promote emotional, hormonal, and behavioral responses to pleasant physical contact with conspecifics, it is obvious that a number of other sensory channels are important as well. Interesting observations of social and biological roles of tight bodily contacts in nonhuman species have been reported.

A particular kind of bodily contact is grooming. At first sight it appears that grooming has a hygienic role alone. However, Dunbar has demonstrated in monkeys that it has an affective and social role as well. Obviously, the groomee is very pleased with the procedure even though the handling is often quite tough. Grooming increases the production of endorphin in the groomee. Dunbar has also found that monkeys spend much more time in grooming than required from hygienic point of view. It is particularly interesting that the time spent on grooming is larger, the larger the social group. The bottom line conclusion is that an essential role of grooming is to promote affectionate attachment between individuals and hence to keep the group together.

The caring pattern of the mother in handling her young infants has a profound influence on the development of the child. Epidemiological studies in man have demonstrated that adverse conditions in early childhood tend to increase stressful and nonsocial behavior in the adult. Biological mechanisms that might be significant for this phenomenon have been explored in rats by Meaney and co-workers. Individual rat mothers differ with regard to caring pattern. Some are very active, spending a lot of time licking and handling their pups. Others are more passive in that respect. The caring pattern has a profound effect on epigenetic mechanisms related to the expression of stress hormone receptors in the brain. In the end, the offspring of active mothers become less stress sensitive, more curious, and exploratory than the offspring of passive mothers. Interestingly, these differences are permanent and remain in the adult, although they are partially modifiable.

Although it remains to be explored to what extent the CT-system is involved in affective response to bodily contacts in a social context, like grooming and mother's care of her baby, there is no question that the CT-system is activated in these situations. The affective touch hypothesis implies that the CT-system is one of several communication channels accounting for responses to bodily contacts which engage perceptive, hormonal, autonomic, and behavioral mechanisms and might range from immediate pleasure, joy, and reassurance in sex to the postnatal development of your children's stress coping profiles.

Population Codes: Theoretic Aspects

W J Ma and A Pouget, University of Rochester, Rochester, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neurons encode in their spike trains features of the external world, internal states of the organism, or motor commands. Understanding the nature of the neural code is a key step toward understanding how the brain computes. In this article, we focus on one type of neural code, known as population codes, which are used to encode many features throughout the nervous system.

A population code is a way of representing information about a feature through the simultaneous activity of a large set of neurons sensitive to the feature. This set is called a population. A population code is useful for increasing the organism's certainty about a feature as well as for encoding multiple features simultaneously.

In most studies of population codes, the activity of a neuron is quantified either by the number of spikes it emits or by the average rate of spike emission (firing) over a given time interval. The response of all neurons in a population to a stimulus is called the population response or the population pattern of activity. It can encode information about one or more stimulus features. In the case of a visual stimulus such as a moving image, a feature could, for instance, be contrast, orientation, color, shape, speed, identity, or utility. A stimulus feature of interest is itself often also referred to as a stimulus; we follow this terminology.

An important aspect of population codes is the stochastic nature of neuronal responses. This is unlike what is found in a computer, for example, in which words are mapped deterministically onto strings of zeros and ones. There is only one word that corresponds to a given string and vice versa. In contrast, in the brain, the mapping from stimulus to population response is probabilistic. When the same stimulus is presented multiple times, the population response will in general be different each time. As a consequence, different stimuli can elicit the exact same population response, although generally with different probabilities.

The probabilistic mapping from stimulus to population response is called the encoding of the stimulus. The reverse process is decoding – obtaining a stimulus estimate from a given population response.

In this article, we first discuss encoding and give examples of population codes. Modeling the process by which neurons encode information is a prerequisite for the development of decoding techniques because decoding can often be thought of as a mathematical inverse to the encoding process. Next, we describe various decoders along with their performance and their connection to the encoding models. Finally, we address recent developments and open issues. Throughout the article, we consider an example in which the stimulus feature of interest is orientation, which takes values between 0° and 180°, but none of our conclusions is specific to this particular choice of feature.

Encoding

Encoding is the mapping from stimulus to population response. Since the response is variable, this mapping is probabilistic. Describing encoding therefore requires specifying a probability distribution over responses. This distribution will change on varying the stimulus and is therefore a conditional distribution, where the conditioning is on the stimulus. Such a distribution is also called a generative model or a noise model.

Tuning Curve Plus Noise

The response of each neuron in a population to a stimulus is typically characterized as the sum of a mean response and a noise term, both of which may depend on the stimulus. The mean response of a single neuron upon varying the stimulus value is characterized by a tuning curve. Let us consider a population consisting of N neurons, labeled by an index $i = 1, \ldots, N$. We denote the mean response of neuron i to stimulus s by $f_i(s)$. On a single trial, when a stimulus s is presented, the activity of neuron i can be written as:

$$r_i = f_i(s) + \eta_i(s)$$

where $\eta_i(s)$ is zero-mean, possibly stimulus-dependent noise. Tuning curves are usually either bell-shaped or monotonic. If the tuning curve is bell-shaped, the neuron has a preferred stimulus value (i.e., one to which its mean response is highest). Figure 1(a) shows the tuning curve and the noise of a neuron responding to orientation. In this example, the tuning curve is described by a circular Gaussian (von Mises distribution),

$$f_i(s) = Ae^{B\cos(2(s-s_i))} + C$$

where A, B, and C are constants representing amplitude, narrowness, and baseline, respectively, and s_i is the preferred orientation of neuron i. Neurons often have broad tuning curves (in our example, B would be low). This might be surprising if the goal is to encode a stimulus with high precision. However, we will see that this is the strength of population coding: even

Figure 1 Example of encoding a stimulus in a population code for orientation. (a) Response of a single neuron as a function of stimulus orientation. The line represents the mean activity (tuning curve), which is described by a circular Gaussian. The maximum response was set to 15 spikes/s. This neuron has a preferred orientation of 90°. The shaded area contains responses within one standard deviation from the mean. Variability is taken to be Gaussian with variance proportional to the mean, with negative values set to zero. In this example, the constant of proportionality between mean and variance (Fano factor) is 0.8. (b) Tuning curves for all six neurons in the population. Population code typically involves thousands of neurons, but only six are shown here for clarity. The neurons' preferred orientations were chosen to be equally spaced, with a spacing of 30°. The tuning curves are broad and overlapping. (c) Population response to a contour oriented at 80°. The six neurons are labeled by their preferred orientation. The red circles indicate the mean response of the neurons to this stimulus. The red line shows the mean responses if there were many more neurons. The blue circles show an example of a response on a single trial. (d) Variance as a function of the mean response on a log–log plot. A straight line with slope 1 indicates that variance is proportional to the mean. The red line corresponds to a Poisson process, in which the variance is equal to the mean. The blue circles are the neurons in our example. Since we chose the constant of proportionality to be 0.8, these circles lie below the line of a Poisson process.

when tuning curves are broad and variability is large, stimuli can be encoded with high accuracy because every neuron contributes a piece of information. Figure 1(b) shows tuning curves for all neurons in a population of six.

Single-Neuron Response Distribution

To go beyond the description of mean response plus noise, one can describe the full response distribution of a neuron. The noise distribution is completely unrelated to the shape of the tuning curve. Common assumptions for the response distribution of a neuron are a Poisson distribution (for spike counts) and a normal distribution (for the number of spikes per second). A Poisson distribution is a one-parameter discrete distribution. The probability of a neuron i showing activity r_i in response to stimulus s is given by

$$P(r_i|s) = \frac{e^{-f_i(s)} f_i(s)^{r_i}}{r_i!}$$

In a Poisson process, the probability at each time step of a neuron firing a spike is independent of the probability at the previous time step. For large means (greater than approximately 10), a Poisson distribution is well approximated by a normal distribution with variance equal to the mean.

Normally distributed neural variability has the form

$$P(r_i|s) = \frac{1}{\sigma_i(s)\sqrt{2\pi}} \exp\left[-\frac{(r_i - f_i(s))^2}{2\sigma_i(s)^2}\right]$$

where $\sigma_i(s)$ is the possibly stimulus-dependent standard deviation. The rationale behind a normal distribution is that neuronal variability is due to the combined effect of a large number of stochastic processes. Both distributions are not fully satisfactory in describing observed neuronal variability: normal distributions assign nonzero probability to negative responses, whereas Poisson distributions are limited to a ratio between variance and mean equal to 1.

This ratio, also called the Fano factor, is experimentally found to take values between 0.3 and 1.8.

The example in Figure 1 uses for each neuron Gaussian variability with variance proportional to the mean, with negative values set to zero. Neurons are assumed to be independent. Figure 1(c) shows a sample population response and the mean population response to a stimulus oriented at 90°. Figure 1(d) shows the relation between variance and mean for the variability chosen here, compared to a Poisson process.

Population Response Distribution

To describe the probabilistic response of an entire population, we need to make assumptions about the joint responses of neurons. The simplest assumption is that all neurons respond independently from each other. Then, the population response distribution is the product of the response distributions of the neurons in the population. That is, if we denote the population response by a vector $\boldsymbol{r} = \{r_i\}_{i=1,\ldots,N}$, its distribution is

$$P(\boldsymbol{r}|s) = \prod_{i=1}^{N} P(r_i|s)$$

This is also called the likelihood function of s. However, responses of neurons in a population are usually not independent of each other but, rather, exhibit noise correlations. A positive pairwise correlation implies that when the activity of one of the neurons in the pair on a given trial is above its mean, the activity of the other neuron is likely to also be above its mean. Population responses with pairwise correlations are typically modeled by a multivariate normal distribution with a nondiagonal covariance matrix. The off-diagonal elements of this matrix measure the pairwise correlations. Experimentally, it is very difficult to measure a covariance matrix for a large number of neurons because of the large amount of data needed. Some data are available for pairwise correlations and they clearly indicate that many neurons have positive correlations. However, the form of the joint probability distribution over a large population of neurons, and particularly whether this distribution can be approximated by a multivariate Gaussian distribution, is unknown.

Higher-order correlations can be described mathematically but are experimentally even more difficult to measure. Consequently, few studies have attempted to measure or investigate higher-order correlations.

Examples of Population Codes

Population codes are believed to be widespread in nervous systems. In electrophysiological experiments, a population response is normally recorded from multiple nearby electrodes in a particular brain area. Population codes have been studied most widely in sensory systems. For instance, in primary visual cortex (V1) and area V4 of the macaque, population codes exist for orientation, color, and spatial frequency. In the hippocampus in rats, a population code exists for the animal's body location. A population code for spatial location in a visual scene or of the body of the organism is also called a topographic map. The cercal system of the cricket has a population code for wind direction. The secondary somatosensory area (S2) in the macaque has population codes for surface roughness, speed, and force. The postsubiculum in rat contains a population code for head direction. Primary motor cortex (M1) in macaque uses populations coding for direction of reach. Even abstract concepts such as number appear to be encoded by population codes in the prefrontal cortex.

Another Encoding Scheme: Encoding Probability Distributions Explicitly

When the encoding schemes described in the previous section were first developed, the central assumption was that a population code encodes a single value at any given time (e.g., the orientation of a contour). Subsequently, several authors noted that population codes might encode probability distributions instead of single values. Encoding probability distributions is a particularly intriguing idea because it would allow the nervous system to perform statistical inference, a very powerful approach when performing computations in the presence of uncertainty. As discussed later, it is in fact possible to recover a probability distribution from a population code from the 'tuning curve plus noise' encoding model described previously.

There also exist other encoding models that naturally lead to decoders that return probability distributions. These are encoding schemes in which the mean response of each neuron is directly a function of the probability that the stimulus is the preferred stimulus of the neuron. This function could, for instance, be a scaled version of the probability:

$$f_i(s) = A \cdot \Pr(s = s_i)$$

where A is a constant. It could also be a linear function of its logarithm,

$$f_i(s) = [A \log \Pr(s = s_i) + B]_+$$

where A and B are constants, and $[x]_+ = x$ if $x \geq 0$ and 0 otherwise. Such codes are sometimes called explicit codes for probability distributions. In explicit codes, neural variability is merely a nuisance and its form has no particular meaning.

Decoding

In order to assess the amount of information contained in a neural population, experimentalists recording

neural activity need to be able to obtain a stimulus estimate from the pattern of activity in that population on a single trial. This process is called decoding and can be regarded as the inverse of the encoding process.

In this section, we review several popular decoding techniques. As discussed later, these methods differ in the reliability of the stimulus estimates they produce. An optimal decoder is one that recovers all the information available in the population activity, where information is defined as Fisher information. Thus, using an optimal decoder is a way to determine the information available in a given population code.

The issue of decoding a neuronal population is not only relevant for experimentalists but also important for any computation performed by downstream neurons. Generation of a motor command is an example of obtaining a single estimate based on sensory information encoded in a population. The accuracy of such a computation is limited both by the accuracy with which sensory input is encoded (i.e., the amount of Fisher information available) and by the performance of the brain's decoding method (i.e., the amount of Fisher information extracted). Therefore, the issue of decoding population codes is central not only to analysis of neural data but also to our understanding of how neural computations are being performed.

Fisher Information

The next section reviews various decoding methods for population codes. These methods differ by two criteria: how much data they require and their performance. In general, the more data required, the better the results. However, how can one quantify the performance of a decoder? The performance is determined in part by the noise in the encoding process. Because of this noise, the neural activity is guaranteed to vary from trial to trial even when the stimulus is maintained constant. As a result, any decoder of this neural activity will return estimates that also vary from trial to trial. To evaluate the performance of a particular estimator, it is common to examine two quantities related to the probability distribution over the estimate: the bias and the variance. The bias, which is the difference between the average estimate and the actual stimulus value, indicates any systematic misestimation. The variance of the stimulus estimates quantifies the variability in the estimate from trial to trial and is inversely related to the reliability of the estimate. Ideally, a decoder should have zero bias and minimal variance. A general result, known as the Cramer–Rao bound, specifies the smallest variance that can be achieved by any estimator. It can be calculated from the bias of the estimator and an estimator-independent quantity called the Fisher information for the population code. Fisher information is defined in terms of the conditional probability distribution describing the population response:

$$J(s) = \left\langle \left(\frac{\partial}{\partial s} \log P(\boldsymbol{r}|s) \right)^2 \right\rangle$$

where $\langle \cdot \rangle$ is the expected value taken over $P(\boldsymbol{r}|s)$. $P(\boldsymbol{r}|s)$ corresponds to the encoding process, as discussed in the previous section. Note that Fisher information is not a function of a particular response since $\mathbf{r}$ is averaged out. Instead, it measures the quality of an encoding model. Fisher information provides a lower bound on the variance $\sigma_{\hat{s}}^2$ of any estimator. Specifically, the variance of an unbiased estimator $\hat{s}$ of s is guaranteed to satisfy

$$\sigma_{\hat{s}}^2 \geq \frac{1}{J(s)}$$

A generalization of this formula exists for biased estimators. The variance of an estimator also determines the smallest change in the stimulus that can be reliably discriminated. If the variance is small, the estimator can be used to detect tiny changes in s. Accordingly, there is a natural link between Fisher information and discrimination threshold: Fisher information is inversely proportional to the square of the discrimination threshold of an ideal observer of the neural activity, or equivalently, it is proportional to the square of the sensitivity d' of an ideal observer:

$$J(s) = \frac{d'^2}{\delta s^2}$$

where d' is the sensitivity (a measure of performance), and δs is the distance between the two stimuli to be discriminated. For the case of independent Poisson neurons, Fisher is easily calculated to be

$$J(s) = \sum_{i=1}^{N} \frac{f_i'(s)^2}{f_i(s)}$$

where $f_i'(s)$ is the derivative of the tuning curve. This equation implies that the neurons that fire most (for which the stimulus is near the peak of their tuning curves) contribute little to the Fisher information because the slope of the tuning curve is small near the peak. Conversely, neurons that respond with intermediate activity, on the side of the tuning curves where the slope is high, contribute maximally to Fisher information. Intuitively, it is clear that the slope of the tuning curve matters in discrimination tasks: Where the slope is high, a small change in the stimulus will cause a large change in mean activity.

Decoders

A decoder takes the population response $\boldsymbol{r}$ as input and produces an estimate $\hat{s}$ of the stimulus s as output.

Decoders can be divided into two categories: those that take the form of neural variability into account and those that do not. The performance of various decoders discussed here is compared in Figure 2 for the example from Figure 1.

Peak response decoder or winner-take-all decoder Suppose that each neuron in the population has a preferred stimulus value. Then, when the population responds to a stimulus, a simple estimator of the stimulus is the preferred stimulus value of the neuron with the highest response:

$$\hat{s}_{\mathrm{WTA}} = s_j : j = \underset{i}{\operatorname{argmax}}\ r_i$$

This very simple decoder disregards the information in all other neurons, is highly sensitive to neuronal variability, and cannot return values intermediate between the preferred stimuli of the neurons. Therefore, it will generally not perform well. However, it only requires knowledge of the preferred stimulus of each neuron, which can be measured experimentally with very few trials.

Weighted-average or population vector decoder A better decoder is obtained by computing a weighted average of the preferred stimulus values of all neurons, with weights proportional to the responses of the respective neurons. Each neuron 'votes' for its preferred stimulus value with a strength proportional to its response:

$$\hat{s}_{\mathrm{WA}} = \frac{\sum_{i=1}^{N} r_i s_i}{\sum_{i=1}^{N} r_i}$$

Although this method performs quite well in many cases, it does not take the form of neuronal variability into account. On a circular stimulus space – for instance, when the stimulus is orientation or motion direction – the equivalent of this method is called the population vector.

Template-matching decoder We can ask the question for which stimulus value s the observed population response is closest to the mean population response generated by s. That is, we match the observed population response with a set of templates (mean population responses for different s). As an error measure, we use the sum-squared difference. This gives the decoder

$$\hat{s}_{\mathrm{TM}} = \underset{s}{\operatorname{argmin}} \sum_{i=1}^{N} (r_i - f_i(s))^2$$

This decoder also does not take the form of neuronal variability into account, but it uses more than only the preferred stimulus values of the neurons.

Maximum-likelihood decoder An important method that does take the form of neuronal variability into account is the maximum-likelihood decoder. This decoder computes the probability that a stimulus value elicited the given population response, and it selects the stimulus value for which this probability is highest:

$$\hat{s}_{\mathrm{ML}} = \underset{s}{\operatorname{argmax}}\ P(\boldsymbol{r}|s)$$

Figure 2(a) shows a histogram of maximum-likelihood estimates obtained from decoding 1000 trials of the population considered in Figure 1. If the number of neurons in the population is large, the maximum-likelihood estimate is unbiased and under some conditions also achieves the Cramer–Rao lower bound. If the noise is independent and normally distributed with fixed variance, the maximum-likelihood decoder is identical to the template-matching decoder. If the tuning curve is

Figure 2 Decoding responses of the population of six neurons of Figure 1. (a) Histogram of maximum-likelihood estimates obtained from 1000 trials of the population responding to an orientation of 90°. The standard deviation of this histogram is the estimation error. (b) The estimation error over 1000 trials as a function of stimulus orientation for several decoders. From top to bottom, the graphs correspond to the peak response decoder (green), the template-matching decoder (purple), the population vector (red), and the maximum-likelihood decoder (cyan). The lowest graph (blue) indicates the Cramer–Rao bound. All decoders are unbiased in this example. Since actual populations usually contain many more than six neurons, estimation errors will be much smaller.

Gaussian and noise is independent Poisson, the maximum-likelihood estimate equals the weighted average.

The problem with this method is that $P(\boldsymbol{r} \mid s)$ must be known with high precision; that is, one needs to measure the tuning curves and the noise distribution of the entire neuronal population. This typically requires a large data set, especially if pairwise correlations are needed.

Bayesian decoders Bayesian decoders use Bayes' rule to express the probability of a stimulus given a response, $P(s \mid \boldsymbol{r})$, as the normalized product of the probability of this response given a stimulus, $P(\boldsymbol{r} \mid s)$, and the prior probability of the stimulus, $P(s)$:

$$P(s|\boldsymbol{r}) = \frac{P(\boldsymbol{r}|s)P(s)}{P(\boldsymbol{r})}$$

The prior probability reflects knowledge about the stimulus before the population response is elicited, and it can have been generated on the basis of previous experience. The probability distribution obtained in this way is referred to as the posterior probability distribution over the stimulus. When the number of neurons is large, this distribution is usually a narrow normal distribution. It can be collapsed onto an estimate by taking the value that has the highest posterior probability; this is called the maximum *a posteriori* (MAP) estimator:

$$\hat{s}_{\mathrm{MAP}} = \underset{s}{\operatorname{argmax}}\ P(s|\boldsymbol{r})$$

Alternatively, the posterior distribution can be collapsed onto an estimate using a loss function $L(s, s')$, which indicates the cost of reporting an estimate s' different from the true value s. The Bayesian estimate is then the value that minimizes the cost averaged over the posterior distribution:

$$\hat{s}_{\mathrm{Bayes}} = \underset{s}{\operatorname{argmin}} \int L(s, s')P(s'|\boldsymbol{r})\mathrm{d}s'$$

If the loss function is the squared error, the Bayesian estimate is the mean of the posterior distribution. For Gaussian posteriors, it is therefore equal to the MAP estimate. If the loss function is the absolute error, the Bayesian estimate is the median.

Like the maximum-likelihood estimator, this approach can be difficult to use in practice because it requires knowledge of $P(\boldsymbol{r} \mid s)$, which is data-intensive.

Neural implementation Decoding is not only of interest to scientists attempting to determine the function of a neural population but also important to the brain. The brain faces the task of generating motor output on the basis of information encoded in a population pattern of activity. The optimal strategy for many cost functions is to pick the motor command that corresponds to the MAP estimate of the stimulus. Recurrent neural networks with population codes have been shown to be able to compute these estimates in some simple cases, but there is still no general theory of Bayes-optimal computations and learning in neural circuits.

Decoding Probability Distributions

As mentioned previously, several groups have proposed that population codes may encode full probability distributions over the stimulus instead of single values $\hat{s}$. The Bayesian decoder described in the previous section falls in this category. Given an observed pattern of activity, it returns a full distribution over the encoded stimulus, denoted $P(s \mid \boldsymbol{r})$. However, this is not the only way to decode a probability distribution from a population code. Other approaches are possible depending on the nature of the encoding steps. Previously, we described several encoding models in which the mean activity of a neuron is directly related to the encoded probability of its preferred stimulus. If this is the case, the decoder should be designed to invert this encoding process. Such decoders are significantly more complicated because they ultimately involve computing a probability distribution, or an estimate, not just over s but over all possible probability distributions over s. The difficulty derives from the fact that even when s is a scalar and therefore lives in a one-dimensional space, the space of probability distribution over s has infinitely many dimensions. Several approximations have been designed to deal with this problem.

Discussion and Open Issues

We have discussed two general ways of encoding information in population codes and evidence for population codes in the brain. We described several methods for obtaining a stimulus estimate from a population response, as well as a new view in which the entire posterior distribution is computed.

An issue we have not addressed is how the performance of a population code can be improved. Population codes and their neuronal decoders can change in ways that are directly coupled to changes in behavior. For instance, attention can serve to improve the performance of a population code by increasing the amount of information that is retained between consecutive stages of processing. The phenomenon of perceptual learning, in which observers reduce the variance of their performance (i.e., their stimulus

estimates) through practice, is thought to be due in part to a similar improvement and in part to an improvement of the decoder used by the brain for the task-relevant population. The mechanisms through which learning can improve population codes are the subject of ongoing research, both empirical and theoretical.

An open issue in population coding is the impact of correlated variability in a population code on the information contained in it. Part of the debate concerns identifying which quantity is suitable to measure this information. Measures in the literature are all based on either Fisher information or Shannon information. The former has the advantage that it is computed for a particular stimulus and has an interpretation in terms of the performance of an ideal observer in a discrimination task. Another part of the debate centers around the assertion that what matters for behavior is not the information that is present in correlations but, rather, the information that would be lost if correlations are neglected in decoding. Evidence shows that neglecting correlations between pairs of neurons in decoding causes only a small loss in Fisher information. An important caveat is that even small correlations can have a significant effect in large populations. In cases in which correlations are important for decoding, a further question is how they can be modeled with a tractable number of parameters – and from an organism's standpoint, how they can be learned. Analyzing empirical population data with a range of decoders will help to elucidate the role of correlations.

Most studies of population codes ignore any information that might be present in spike timing. However, spike timing is known to be important in several perceptual tasks, such as sound localization, and simultaneous firing of large numbers of neurons – synchrony – has even been proposed as an operational principle of the brain. Studies have begun to investigate population coding for dynamic stimuli, which involves decoding population spike patterns, but much work remains to be done on this topic.

Although this article only discussed issues related to coding and decoding, it is important to keep in mind that population codes in the brain are used for computation, which eventually controls behavior. Interestingly, population codes are particularly well suited to optimal nonlinear computations because they provide basis functions. These basis functions can be recombined linearly to implement a very large class of nonlinear computations. Moreover, when embedded in recurrent networks, these computations can be nearly optimal in a Bayesian sense. The latest studies on this topic focus on whether these codes can be used to perform any kind of Bayesian inference, a type of inference that provides a robust approach to computation in the presence of uncertainty.

Despite these open questions, there is little doubt that population codes are a powerful and general way of carrying information in neuronal activity. Closely integrated experimental and theoretical work is needed to fully understand how population codes perform computations and how their decoders are implemented in neural circuitry.

Population Coding

A Berkowitz, University of Oklahoma, Norman, OK, USA

© 2009 Elsevier Ltd. All rights reserved.

Population coding is the idea that nervous systems rely on the activity of a large number of relatively imprecise neurons, rather than one or few highly precise neurons, to perform a given function. Each neuron in the large population typically is coarsely or broadly tuned to a particular parameter, rather than sharply tuned, yet the population as a whole usually generates precise outputs.

Early History of the Idea

Trichromatic Theory of Color Vision

Thomas Young was probably the first to suggest population coding. In 1802, he devised this hypothesis to explain how the retina represents the color or wavelength of light at each location:

> As it is almost impossible to conceive of each sensitive point of the retina to contain an infinite number of particles, each capable of vibrating in perfect unison with every possible undulation, it becomes necessary to suppose the number limited, for instance, to the three principal colours, red, yellow, and blue . . . each of the particles is capable of being put in motion more or less forcibly by undulations differing less or more from a perfect unison.

Although Young could not examine the responses of individual retinal 'particles,' modern studies confirm his hypothesis.

Population Coding May Increase Precision

The idea that a large number of coarsely tuned neurons can collectively encode a parameter more precisely than a small number of sharply tuned neurons arose soon after the first electrical recordings were made from individual sensory neurons by Edgar D Adrian in 1926. In 1928, Adrian wrote,

> The accuracy of localization will naturally depend on the number of receptors of the same type in the area which contains the stimulated region. . .. If there is much overlapping in the areas supplied by the terminal branches of different fibres it might be possible to localize the stimulus more exactly by comparing the relative intensities of discharge in the different fibres.

Population Coding as Democracy

A valuable analogy between population coding and political governance was developed early on: single-neuron coding is like a monarchy, whereas population coding is like a democracy. A monarch might make decisions faster, more wisely, and more consistently than a democracy (depending on the monarch), but the collective voting of a large group may be more reliable. For example, if a monarch were to go insane or be assassinated, the entire country would be in peril. Similarly, if an important neural function were dependent on the activity of one neuron, any malfunction or injury to that neuron could jeopardize the animal's life. In contrast, a democracy or a population code would be more resilient in response to injury of several members, due to the redundant inputs of remaining members. Also, in any given election, a minority of members may cast the 'wrong' vote without disrupting the outcome.

William James proposed in 1890 that our consciousness is associated with a single 'pontifical' neuron. Sir Charles S Sherrington, however, considered and rejected this idea in 1941:

> We might imagine this principle pursued to culmination in the final supreme convergence on one ultimate pontifical nerve-cell. . . . It would secure integration by receiving all and dispensing all as unitary arbiter of a totalitarian state. . . . But . . . the nervous system does not integrate itself by centralization upon one pontifical cell. Rather it elaborates a million-fold democracy whose each unit is a cell.

Localized versus Distributed Functions

There has been a long debate about whether the control of a particular behavioral function is associated with one region of the central nervous system (particularly the cerebral cortex) or instead is widely distributed. Localization of function was initially suggested in the late eighteenth century by the phrenologists, beginning with Franz Joseph Gall, who associated human mental functions with particular bumps on the skull. Later, physician-scientists who are now more respected argued for localization of function based on specific behavioral deficits in patients with brain lesions. Others, however, including Marie-Jean-Pierre Flourens in the early nineteenth century and Karl Lashley in the early twentieth century, argued for distributed function based on the lack of deficits in general tasks in many animals and humans with localized cortical lesions.

To some extent, the debate about single-neuron coding versus population coding mirrors the older debate about localization of function versus distributed function. There are important differences, however. One difference is in the level of analysis: a number of neurons versus an entire brain region. A second difference is that a functional neuronal

population is not necessarily constrained to a small and distinct brain area and may be intermixed with populations mediating other functions. A third difference is in the type of function associated with a neuronal population. Earlier studies typically associated one behavior or trait, such as spoken language or aggressiveness, with one cortical area. Recent studies typically associate a neuronal population with a function that is used in multiple behaviors and thus may term the group of neurons a module.

The Alternative: Single-Neuron Coding

To elucidate population coding, it may help to consider its opposite – single-neuron coding. This is the idea that related neuronal inputs converge massively onto a single neuron and/or diverge massively from the neuron, which signals a complex event by its activity alone.

Decision Neurons

For example, sensory neurons whose activity signals the presence of a predator could converge onto a single 'decision' neuron, which in turn could quickly and efficiently trigger a coordinated movement to move the animal away. Such an organization occurs in a marine mollusk (the dorsal ramp interneuron in *Tritonia*), in crayfish (the lateral and medial giant interneurons), and in fish (the Mauthner neuron), although crayfish and fish have an additional neuronal population that can evoke similar movements when the need is less urgent or when the decision neuron has been damaged.

Grandmother Cells

Individual neurons have also been found that respond optimally to a complex and significant object, such as a prey item (e.g., a 'bug detector' in frogs), beginning with experiments in the 1950s. Neurons in a particular part of a songbird's forebrain were later found to respond optimally to playback of that bird's own song and not nearly as well to the same song in reverse or to a conspecific's song. A subset of these cells has been found to be extraordinarily precise temporally as well, firing action potentials reliably within a period of approximately 10 ms just before the animal produces a particular song syllable. Beginning in the late 1960s, neurons in the inferotemporal cortex of monkeys and humans were found to respond optimally to a visually presented hand or face. In recent work, some appeared to respond optimally to a single person's face, regardless of the size, viewpoint, lighting, etc. Since it is not practical to present every possible visual stimulus in such experiments, however, it is possible that the selectivity of these neurons is not as limited as it appears. Such cells have been termed 'grandmother cells,' the idea being that a particular cell might be activated by the sight of one's grandmother and by nothing else.

Hybrid Coding Schemes

Population coding in its narrowest sense involves a large population of broadly tuned neurons, whereas single-neuron coding in its narrowest sense involves one highly specialized neuron for each function. If instead there are multiple grandmother cells, for example, one such cell would be sufficient to signal the sight of one's grandmother, but it would not be necessary since other grandmother cells would remain in the event of injury. Thus, this type of organization might be considered a hybrid between single-neuron and population coding, in which many cells contribute to each function but each such cell is sharply, rather than broadly, tuned and all the cells in this group have the same tuning. In 1972, Horace Barlow argued that the idea of a single, 'pontifical cell'

> should be replaced by a number of 'cardinal cells.' Among the many cardinals only a few speak at once; each makes a complicated statement, but not, of course, as complicated as that of the pontif if he were to express the whole of perception in one utterance.

This idea might be termed few-neuron or oligoneuron coding and considered intermediate between single-neuron and population coding.

The opposite of oligoneuron coding would be a hybrid organization in which a single neuron is responsible for a perception or behavior although the neuron is not highly specialized. This is essentially the idea of the lower envelope principle, which arose from studies beginning in the 1960s correlating sensory perceptions with the tuning curves of individual neurons. The idea is that the brain only uses inputs from the one neuron that is most sensitive to (and thus most strongly activated by) each stimulus. This hypothesis has been supported for perceptual discrimination of the direction of visual motion in primates, but there have been few other experimental tests of it.

Population Coding Is Widespread

Examples of Broad Tuning

A key feature of population coding, narrowly defined, is that each cell in the population is coarsely or broadly tuned. Many examples of broadly tuned neurons have been described, from sensory neurons to premotor neurons, in diverse invertebrates and vertebrates. Figure 1(a) shows an early example. This primate superior colliculus neuron fired action potentials

Figure 1 Examples of broadly tuned neurons. (a) Single-unit recordings from an individual neuron in the primate superior colliculus during saccades (arrow) to visual targets at varying angles. (c) Reproduced from Miller JP, Jacobs GA, and Theunissen FE (1991) Representation of sensory information in the cricket cercal sensory system. 1: Response properties of the primary interneurons. *Journal of Neurophysiology* 66: 1680–1689, with permission. (d) Reproduced from Berkowitz A (2001) Broadly tuned spinal neurons for each form of fictive scratching in spinal turtles. *Journal of Neurophysiology* 86: 1017–1025, with permission.

before and during saccadic eye movements in a relatively wide range of directions. Nonetheless, the cell fired fastest (and longest) for saccades directed at approximately 150° and progressively less for saccades at progressively different angles. In other words, this cell, which is typical of collicular cells, coarsely encodes a particular saccade direction. The coarseness of tuning was surprising because saccades are quite precise. The authors proposed, however, that the collective activity of the population of coarsely tuned cells results in precise and accurate saccades.

A tuning curve can be produced by graphing a cell's action potential rate as a function of any quantitative parameter. Sharply tuned cells have a sharp peak for one value of the parameter and drop to baseline levels for all larger or smaller parameter values. In contrast, broadly tuned cells respond in varying degrees to a wide range of parameter values. Sensory neurons can be either sharply or broadly tuned, and they can even be sharply tuned to one parameter and broadly tuned to another. For example, each cone photoreceptor is effectively sharply tuned to a light's location but broadly tuned to its wavelength (**Figure 1(b)**). In contrast, olfactory sensory neurons are thought to display only broad tuning to parameters of an odorant molecule (except cells that are selectively responsive to a pheromone).

Further along in sensory processing, cells may be tuned to sensory parameters that are already coded at the periphery (e.g., light wavelength or location, or sound frequency) or instead tuned to sensory parameters that must be computed. For example, neurons in the inferior colliculus of birds (especially well studied in owls) and mammals are tuned to the location of a sound, which is not coded in the cochlea but must be computed from differences in sound timing and intensity in the two ears.

Although sensory neurons can be broadly tuned (and most motor neurons are effectively broadly tuned since they are active during a wide variety of movements, but conventionally they are not described this way), most studies of population coding have focused on neurons within the central nervous system, between sensory neurons and motor neurons, which may be termed interneurons. Some examples of broadly tuned interneurons are shown in **Figures 1(c)** and **1(d)**. Four of the identified sensory interneurons on each side of the body of a cricket collectively respond to wind from all directions behind the cricket and lead to escape movements (**Figure 1(c)**). A sample of four interneurons from the spinal cord of a turtle collectively respond to tickling across one side of the body surface and contribute to hindlimb scratching movements (**Figure 1(d)**). These examples illustrate how a small number of broadly tuned interneurons can effectively cover a large parameter space.

Other examples of broadly tuned interneurons include leech somatosensory interneurons that lead to local bending movements; neurons in the midbrain of weakly electric fish and sound-producing fish that are tuned to the difference in frequency between their own electric field or vocalization and that of their neighbors; rat somatosensory cortical neurons that respond to whisker contact; bat midbrain and cortical neurons tuned to combinations of auditory parameters of the echolocation pulse and echo; cat spinocerebellar neurons that respond to the position or direction of a whole limb; and primate neurons tuned to a variety of sensory and motor parameters in several parts of the visual, somatosensory, auditory, and motor cortices, among many others.

Encoding of Multiple Parameters

Broadly tuned interneurons often encode more than one parameter simultaneously. For example, multisensory neurons in the superior colliculus of birds (especially evident in owls) and mammals encode both the visual and the auditory location of an object; these neurons are arranged in a map of space. Similarly, neurons in the rat hippocampus respond optimally when the animal is in a particular location in space, having (at least) two-dimensional coordinates. Primate motor cortical neurons are often broadly tuned to the activity of one or more muscles, as well as movement amplitude, force, velocity, and direction, to varying degrees. Thus, W Thomas Thach noted in a 1978 study that "all the types of neurons that were looked for were found, in nearly equal numbers." These parameters are normally correlated with one another, and although tasks have been designed to distinguish among them, different investigators have argued in favor of different movement parameters as primarily coded. Some cells are tuned to related sensory and motor parameters, such as movement toward a location to which there is sensory tuning.

In the previous cases, the encoded parameters are closely related conceptually. In other cases, parameters that are not intuitively related are apparently encoded by the same population. For example, many primate motor cortical neurons are broadly tuned to both the direction of an upcoming hand movement and the relative timing of a visual stimulus within a sequence of stimuli. One of these encoded parameters appears to be a component of motor planning and the other of memory. It has been argued that a population may collectively encode parameters that are not at all evident in the activity of individual neurons. Songbird and monkey studies also indicate that the parameters encoded by a population may change, and this may contribute to sensorimotor learning.

A related finding is that individual interneurons can contribute to generating multiple, distinct kinds of behaviors, such as swimming and shortening in leeches, distinct phases of rhythmic digestive movements in crustaceans, swimming and struggling in tadpoles, and scratching and swimming in turtles. Thus, multifunctional populations of neurons mediate many behaviors, especially rhythmic behaviors.

Encoding and Decoding

Whatever parameters are encoded in population activity, signals must be extracted from the population to be of any use to the animal. Thus, downstream neurons must 'read out' or decode population activity. One possibility is that decoding results in an explicit representation of a key feature in the environment (e.g., your grandmother) or a motor command (e.g., an escape movement). In this case, population coding at one stage of processing leads to single-neuron or oligoneuron coding at another stage. A second possibility is that a population encoding sensory parameters directly causes a second population to encode appropriate motor parameters, without any explicit or intermediate representation between them. A third possibility is that multiple populations interact to determine activity in yet another population. In this scenario, the brain uses a series of populations to compute new parameters, eventually producing a distributed motor command in a population of premotor interneurons. A process such as this is probably involved in coordinate transformations. Thus, a visual stimulus is initially represented in retinocentric coordinates, but subsequent processing may lead to coding in head-centered, body-centered, and even extrinsic space coordinates, prior to specifying motor output in joint angle or muscle activity coordinates.

In most cases, it is very difficult to determine whether or how the nervous system actually decodes the activity of a population of neurons. Regardless of how the nervous system does it, having a convenient decoding algorithm allows one to assess whether a given parameter is effectively encoded in a population's activity. Efficient decoding algorithms will also be critical to the success of human prostheses, the movements of which are controlled by decoding the activity of chronically monitored neuronal populations.

The Population Vector

One type of decoding algorithm is called the population vector. The idea is that each cell is broadly tuned to a certain value of the parameter of interest, for example, the direction of an upcoming hand movement. The cell's tuning curve can be approximated as a cosine function of the angle between the cell's 'preferred direction' (i.e., the direction of arm movement for which the cell fires at its highest rate) and the direction of the actual upcoming arm movement. The activity of each cell prior to each hand movement can then be represented as a vector, with the vector angle equal to the cell's preferred direction and the vector length proportional to the cell's increase in firing rate from its baseline level. The population vector is calculated as the sum or average of the vectors of all the cells recorded. It has a direction close to that of the monkey's actual hand movement (**Figure 2(a)**). This shows that hand movement direction is effectively encoded in the activity of motor cortical neurons and that, however the nervous system actually decodes this activity, the behavioral result is similar to what would be produced by population vector decoding. In later experiments, a monkey was trained to rotate a handle 90° counterclockwise from a reference angle given by a visual stimulus. In this case, the population vector gradually rotated from the stimulus direction to the movement direction (**Figure 2(b)**), perhaps revealing a neural correlate of mental rotation.

Other investigators, however, have used mathematical or computational approaches to argue that the predictive success of the population vector of cells' preferred directions does not necessarily imply that motor cortical neurons primarily encode hand movement direction. Motor cortical cells might instead encode muscle parameters, such as shortening velocity. Hand movement direction is typically correlated with muscle parameters and thus the hand-direction population vector should predict arm movements accurately in any case.

The population vector is just one of many possible decoding algorithms and is a special case of linear decoding algorithms. Modeling a neuron's tuning curve with a cosine may be inaccurate and may eliminate valuable information. Other decoding algorithms, such as maximum likelihood estimation and Bayesian inference, have been shown to extract more information from population activity and thus may approach more closely what an ideal observer could decode, but it is unclear whether real nervous systems ever implement such algorithms.

Information Theoretic Approaches

Empirical discoveries of broadly tuned neurons have inspired theoreticians to study population coding using mathematical and computational modeling approaches. Many of these studies have utilized information theory, a branch of probability and statistics, to assess quantitatively the amount of information encoded in a population as well as the efficiency of

Figure 2 Population vector from monkey motor cortical recordings. (a) Single-cell vectors (light purple) for one direction of hand movement (yellow) and the population vector computed from them (orange). (b) During the reaction time of a mental rotation task, the population vector rotates from the stimulus direction (blue) to the movement direction (red). Eight stimulus directions are shown. (a) Reproduced from Georgopoulos AP, Schwartz AB, and Kettner RE (1986) Neuronal population coding of movement direction. *Science* 233: 1416–1419, with permission. (b) Reproduced from Georgopoulos AP, Taira M, and Lukashin A (1993) Cognitive neurophysiology of the motor cortex. *Science* 260: 47–52, with permission.

various decoding algorithms. These studies have led to several general conclusions, as well as several ongoing debates.

Broad tuning can increase accuracy One conclusion is that given a fixed number of neurons, broadly tuned neurons encode stimulus features more accurately than sharply tuned neurons, effectively because more neurons are activated (and hence 'vote') during each stimulus. This conclusion from mathematical and modeling approaches in the 1980s mirrored Adrian's intuition in 1928. For example, computational modeling of electrosensory processing in weakly electric fish demonstrated that the output of a population of broadly tuned sensory neurons (and thus the animal's behavior) can have greater precision than that of any individual member of the population. This phenomenon, termed 'hyperacuity', has since been demonstrated experimentally in weakly electric fish and bats. (One caveat, however, is that it is difficult or impossible to rule out experimentally that there is some neuron, not yet recorded, with a sensitivity that matches the behavioral sensitivity.)

Subsequent theoretical studies suggested that broader tuning does not necessarily lead to greater accuracy (depending on how the neurons' activity is affected by factors other than the encoded variable), but the relative accuracy of broad tuning compared to sharp tuning always increases with the number of different parameters each neuron codes for (or, in other words, the dimension of the encoded variable). In a population of neurons tuned to three or more parameters, broader tuning is predicted to provide greater accuracy. Moreover, a population in which different neurons display different kinds of tuning (e.g., different shapes or widths of tuning curves) can encode a parameter more accurately than a population with uniform tuning properties. In some cases, such as the coding of electric image amplitude and width by neurons in weakly electric fish, the optimal tuning is broad for one parameter and sharp for the other. Finally, computational modeling approaches have demonstrated that systems with widely distributed coding are more resilient, responding to increasing injury with 'graceful degradation' rather than complete failure (perhaps providing the basis for the relative insensitivity to specific cortical lesions noted by Flourens and Lashley).

The effects of noise One theoretical advantage of using a large population of broadly tuned neurons, rather than a smaller population of sharply tuned neurons, is that variability in neuronal activity unrelated to the encoded variable, often termed noise, tends to be reduced more by averaging across a larger population. In general, for neurons with minimal noise, each neuron provides maximal information for stimuli along the steep flanks of its tuning curve, but for noisy neurons, each provides maximal information for stimuli at its peak. However, noise can have multiple sources. Noise due to stochastic events (e.g., ion channel openings and closings) occurs independently in each of the neurons investigated. In this case, the larger the population averaged, the greater

the noise reduction. Other sources of noise, however, may be correlated among neurons due to common inputs not directly related to the encoded parameter. In this case, noise amplitude is not reduced by averaging, so broader tuning does not necessarily provide greater accuracy. It might be possible, however, to monitor this correlated noise via a separate population, which could then be used to subtract out correlated noise from the main population. Evidence for such a scheme has been found in experiments on weakly electric fish.

In some cases, however, correlations among neurons in the exact timing of their action potentials may themselves carry important information. This kind of population coding can only be examined by recording from multiple neurons in the population simultaneously. The extent to which nervous systems encode information through such temporal correlations is a matter of vigorous debate, with assessments of the additional information ranging from negligible to substantial.

Empirical Tests of Population Coding

Regardless of what information is encoded in the activity of a population of neurons, does the nervous system actually use this information, and if so, how? Downstream neurons might rely on the most active single neuron within the population (the lower envelope principle). There might even be competition within the population, such that the most active neuron inhibits all others (winner-take-all). In this case, the winner would effectively have a veto over other population outputs. Alternatively, the activity of each member of the population might contribute to the output (e.g., by vector averaging or vector addition). Finally, nervous systems might preferentially use signals from simultaneously active neurons so that fine-scale temporal correlations are critical. To address these issues experimentally, one must perturb population activity in a controlled manner and compare the resulting downstream activity or behavior to that predicted by each decoding scheme. This kind of experiment has been feasible in only a few systems.

One fortuitous example is the monkey superior colliculus and its control of saccades. This structure is organized into a map of saccade angles and amplitudes. If one electrically stimulates a particular site, a particular saccade results. One can then inject a local anesthetic into the same location (**Figure 3(a)**). If the nervous system uses only the activity of the most highly active neurons (winner-take-all), the local anesthetic should eliminate all visually evoked saccades toward the location previously evoked electrically (**Figure 3(a)**, arrowhead). In fact, the monkeys generated such saccades accurately. Saccades to other targets, however, were misdirected in a particular pattern: saccades to targets nearer than the electrically evoked saccade were too short, whereas farther saccades were too long, and so on. Thus, the monkeys actually use the activity of neurons in most or all of the colliculus. Movements were perturbed by the absence of 'votes' from the anesthetized region, in accordance with a vector-averaging algorithm.

Another area of the monkey brain, the medial temporal cortex (MT), contains cells selective for the direction of motion of a visual stimulus. Monkeys were given a visual stimulus moving in one direction

Figure 3 Experimental tests of population decoding algorithms. (a) Monkey saccades from the fixation point (+) toward target lights before (open squares) and after (solid squares) an injection of lidocaine into the superior colliculus; the injection was into the site that evoked the saccade shown by the arrow. (b) Leech bending movement directions evoked by a particular touch stimulus (left), electrical stimulation of a particular sensory neuron (middle), and these two kinds of stimulation together (right). In both cases, the resulting movement directions are consistent with vector averaging of the contributions of all the cells involved. (a) Reprinted by permission from Macmillan Publishers Ltd: *Nature*, Lee C, Rohrer WH, and Sparks DL (1988) Population coding of saccadic eye movements by neurons in the superior colliculus. *Nature* 332: 357–360. (b) Reprinted by permission from Macmillan Publishers Ltd: *Nature*, Lewis JE and Kristan WB Jr. (1998) A neuronal network for computing population vectors in the leech. *Nature* 391: 76–79.

while experimenters electrically stimulated an area of MT that codes for a very different visual motion direction. The monkeys were trained to make a saccade toward one of eight lights to signify their perception of motion direction. Monkeys tended to choose one or the other of the directions indicated by the two simultaneous stimuli but not an intermediate direction, consistent with a winner-take-all decoding mechanism. In a different experiment, however, monkeys were trained to make eye movements to track moving visual stimuli. While the monkeys did so, the experimenters electrically stimulated a site in MT. The electrical stimulation predictably biased, but did not overrule, ongoing eye movements, consistent with vector summation or averaging but inconsistent with winner-take-all decoding. Taken together, these findings suggest that activity in a single population of neurons may be decoded differently by different downstream populations mediating different tasks.

Other fortuitous examples involve small invertebrate systems in which individual neurons can be repeatedly identified and manipulated from one animal to the next. For example, crayfish escape from a sudden touch via a tail flip. A posterior stimulus excites the lateral giant neuron, which causes a forward tail flip; an anterior stimulus excites the medial giant neuron, which causes a backward tail flip. The type of tail flip produced depends on whether the lateral giant or the medial giant fires an action potential first, because each causes inhibition of the other. Stimulation of one of these neurons alone reliably elicits a complete tail flip. Thus, this is a winner-take-all mechanism. (Nonetheless, there is also a distributed population of non-giant neurons that can mediate tail flips in other behavioral contexts.)

The case is quite different for several bilateral pairs of giant interneurons (GIs) in the cockroach, which respond to a wind puff from the right by generating an escape movement to the left. Experimenters reversed this movement decision by stimulating a left GI simultaneously with the right wind puff, causing right turns instead. Movement directions could be predicted from the GI's total number of action potentials, regardless of their exact timing, suggesting that temporal correlations do not contribute critically to the movement decision in this case. Moreover, a higher rate of action potentials in a stimulated GI shifted turning direction by a larger amount, consistent with vector averaging or summation but inconsistent with winner-take-all decoding.

Finally, four P sensory neurons in the leech, acting via interneurons, cause local bending of the body wall away from a touch stimulus. Some interneurons activated during a touch-elicited bend have effects on motor neurons that are antagonistic to the bend produced by the system as a whole (i.e., these cells may be 'outvoted' by the rest of the population). Experimenters electrically stimulated one P cell while touching a body wall location that evoked a response in a different P cell. The two stimuli individually caused bends differing by almost 180°, but the two together produced a bend that was intermediate in direction (**Figure 3(b)**), consistent with population vector decoding but not winner-take-all decoding.

Porphyria: Acute Intermittent

W N Arnold, University of Kansas Medical Center, Kansas City, KS, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The various metabolic disturbances that are characterized by excessive synthesis of porphyrins or related compounds collectively are known as porphyrias. Carriers of these diseases are prone to excrete elevated concentrations of the porphyrins and related chemicals in their urine and feces. Abnormal excretion has no intrinsic medical import, but is a reflection of high concentrations of the compounds circulating within the body, and therein lies the potential for neurological abnormalities (due to porphyrin precursors), cutaneous photosensitivity (due to porphyrins), or both, depending upon the particular type of porphyria. Acute intermittent porphyria (AIP) belongs to the first subcategory. The overly produced compounds are δ-aminolevulinic acid (an amino acid) and porphobilinogen (PBG) (a pyrrole), which are intermediates on the metabolic pathway to porphyrin and eventually heme. The symptoms of AIP are all neurological. Increased sensitivity of the skin to sunlight is not observed with this type of porphyria because porphyrins do not accumulate.

'Acute' refers to the rapid onset, and abrupt cessation, of expressed symptoms. 'Intermittent' indicates the periodicity, which is typical, and emphasizes the distinct periods of normalcy, which usually intercede between medical crises. The expression of symptoms depends upon lifestyle, and the adverse effects of malnutrition and exposure to alcohol are well documented. Also, many therapeutic drugs which normally are useful and well-tolerated by the general population will initiate medical crises or provoke relapses in AIP patients. Fortunately, the disease is usually manageable by the avoidance of precipitating factors. The partial deficiency in one enzyme, PBG deaminase, is the underlying cause for the manifold derangements of the AIP patient under crisis. Most of the chemicals that are precipitating factors act by depleting the cytochrome P450 pool in the liver. When considered together, exacerbation factors and latent illness provide a prime example of the influence of the environment on the expression of symptoms due to a congenital disease.

Clinical Manifestations of AIP

Children who are AIP gene carriers remain clinically latent and symptoms rarely occur before puberty. The peak decade for onset of symptoms is from age 20 to 29 years (somewhat higher for males than females), but the disease sometimes remains latent throughout a lifetime. Among those who do express symptoms, there are patients who also have a deficiency in hepatic steroid 5-reductase. How this is acquired or related to AIP is not clear, but it is not due to abnormal porphyrin metabolism *per se*. A close correlation between elevated hormone-binding globulin and clinical expression of AIP has also been demonstrated. Indeed, it has been suggested that certain drugs may precipitate AIP attacks in part because they act through the endocrine system.

Tabulations of the most common hallmarks of AIP emphasize abdominal pain and other gastrointestinal complaints, symptoms referable to the peripheral and central nervous systems, and signs of autonomic neuropathy including tachycardia and hypertension. Porphyria-induced hypertension can cause early-onset renal failure. Bladder dysfunction may result in urinary retention. Effects on optic nerves or the occipital lobes leading to blindness (amaurosis), drooping of both upper eyelids from paralysis of the third cranial nerve (bilateral ptosis), dilation of one pupil, and involuntary rapid, rhythmic eyeball movements (nystagmus) have all been documented for AIP cases. Sexual impotence has occasionally been reported. Signs and symptoms are so varied that individual illnesses may mimic several other diseases. Premonitory symptoms include restlessness and irritability. Attacks develop rapidly. Resolution may occur in days or sometimes weeks, in an unpredictable fashion, but subsequent recovery is then often quite rapid. Convulsions occur in only 10% of all AIP cases, but when they do many of the normally effective antiseizure drugs may adversely affect the outcome. The nature of the disease with respect to both onset of crises and outcome makes an acute attack of AIP particularly frightening because patients can become almost completely paralyzed during severe episodes. The most common cause of death from AIP is respiratory paralysis.

The Biochemical Lesion in AIP

Almost any cell in the human body can engage in synthesis of heme, because heme is not only vital to hemoglobin but also for the cytochromes involved in so many aspects of metabolism. However, the organ of primary concern for AIP is the liver, where two-thirds of the heme that is produced normally is incorporated into the various types of cytochrome P450, and an even larger proportion attains during the induction of P450s. The AIP patient has a vulnerable heme

Figure 1 The heme pathway in acute intermittent porphyria (AIP). The dashed arrow from heme up to the first enzyme, δ-aminolevulinic acid (ALA) synthetase, indicates that the concentration of this enzyme, which normally limits the rate of heme synthesis, is influenced by the size of the heme pool (see text for details). In the structures depicting porphobilinogen and uroporphyrinogen III the acetate and propionate residues are indicated as (A) and (p) respectively.

pathway. The neurological problems associated with medical attacks are a consequence of disruption in the heme pathway and the transient accumulation of toxic compounds. An abbreviated representation of the metabolic pathway for heme synthesis is shown in Figure 1.

The key enzyme for our purposes is PBG deaminase, which directs and catalyzes the joining together, head to tail, of four molecules of PBG to form hydroxymethylbilane. This intermediate is subject to nonenzymatic tetrapyrrole ring closure, to form uroporphyrinogen I, but in the presence of another enzyme, uroporphyrinogen III cosynthetase, the major product is uroporphyrinogen III. The process is further complicated by a compartmentalization within cells; thus the early and final steps occur within mitochondria whereas the intermediate events proceed in the cytosol. Traffic of molecules in and out of the mitochondrion is part of the overall process and one aspect of orchestration for the overall pathway. The first enzyme, δ-aminolevulinic acid (ALA) synthetase, catalyzes the reaction which has the most influence on the actual rate of heme synthesis. This enzyme is present in lower amount than any of the subsequent enzymes. In part, this is due to rapid degradation of ALA synthetase within the cell, and it must be continually manufactured. Therein lies a major control feature, because heme, the end product of the pathway, causes both a repression (lower rate of synthesis of the enzyme) and an inhibition (lower catalytic rate of the existing enzyme) of ALA synthetase. Also, the synthesis of this key enzyme can be partially blocked by high glucose intake, thus helping to explain the ameliorating effect of a high-carbohydrate diet on AIP attacks, and the adverse effect of malnutrition or fasting.

One of the first lines of clinical treatment (whatever the precipitating factor) is concentrated glucose infusion. The molecular connection has now been

explained as mediated by a coactivator of nuclear receptors (PGC-1α), which influences both glucose metabolism and the first enzyme in hepatic heme synthesis. Thus PGC-1α is a key factor in the elevation of gluconeogenesis in the fasted liver as well as the increased expression of ALA synthetase. The activator and the enzyme are coregulated during fasting and feeding. . However, it is worth noting that some steroids will induce the synthesis of ALA synthetase as much as 40- to 50-fold and that many drugs also exert their adverse effects independently of the PGC-1α connection.

The individual with AIP has about one-half of the normal amount of PBG deaminase, the third enzyme in the heme pathway. This is the basic, inherited defect. Because PBG deaminase is not rate limiting to the overall pathway, 50% of normal is sufficient for unstressed AIP patients to supply their heme needs. This explains the lack of symptoms for latent AIP patients and the intervening periods of normalcy for patients who have experienced episodes of sickness. It also accommodates the observation that hemoglobin synthesis (in the bone marrow) is not compromised by a partial deficiency in PBG deaminase, and anemia is not a sign of AIP. Exacerbation factors exert their effect by increasing the synthesis of ALA synthetase. The combination of an increase in the first enzyme, which is normally rate limiting, and a preexisting partial block in the third enzyme, PBG deaminase, causes a large increase in the two intermediate metabolites, ALA and PBG. Under these circumstances, their excretion in the urine is significantly increased. Freshly voided urine is a normal color, but with time PBG polymerizes to form porphobilin, which imparts a reddish-brown appearance to aged specimens. Direct light accelerates this process. Urine which has aged internally due to bladder dysfunction may already be discolored when released with a catheter, although the color is sometimes mistaken for urinary bleeding. In contradistinction to the conception that 'port wine urine' is the 'telltale' sign of AIP, it is worth emphasizing that many carriers, with or without medical attacks, have never remarked upon abnormally colored urine.

Neurological Manifestations in AIP

While the overproduction of ALA and PBG is clearly a prerequisite for neurological problems, the mode of action is not completely understood at this time; at least three working hypotheses have been offered. First, ALA or PBG (or a yet-to-be-identified derivative) may be toxic to the nervous system. Increasing amounts accompany acute attacks and, even though increased excretion is sometimes seen in latent cases, neurological dysfunction *per se* never occurs when porphyrin precursor excretion is normal. ALA is structurally similar to γ-aminobutyric acid, a neurotransmitter, and ALA may interfere with γ-aminobutyric acid receptors on nerve cells. An important reservation here is that neither ALA nor PBG can easily cross the blood–brain barrier. A second suggestion arises from investigations of chemically induced hepatic heme depletion in the rat, wherein it was found that liver tryptophan 2,3-dioxygenase (a heme-containing enzyme) activity is lowered. This impairment spares tryptophan degradation, increases the concentration of tryptophan served to the central nervous system, and thus increases serotonin turnover. In the experimental system, exogenous heme reversed the effect whereas tryptophan potentiated it. The serotonin mechanism may play a role in the neurological disturbances associated with AIP. Third, if the vulnerable pathway for heme also operates in the nervous system, there may be more direct neurological effects. Regardless of mechanism, the two forms of useful therapy, namely high-carbohydrate feeding and hematin infusion, both act by suppressing the synthesis of ALA synthetase.

Chemical Exacerbations

Many drugs are metabolized in the liver by a system which involves the endoplasmic reticulum and cytochrome P450. This heme protein is subject to destruction by a free-radical reaction during the detoxification process, and the induction of P450s by drugs and xenobiotics further increases consumption to the point of becoming a drain on the heme pool. Excessive alcohol ingestion leads to a proliferation of endoplasmic reticulum in liver cells, and part of the ethanol ingested is metabolized therein via a cytochrome P450-mediated system. In this manner, alcohol and other drugs which lower the heme pool are thought to exert their influence on the overall pathway by derepressing (hence increasing) the synthesis of ALA synthetase. In the AIP patient, with half of the normal amount of PBG deaminase, the insult may be too great and toxic levels of ALA and PBG may develop. One system that was developed expressly to test potential porphyrinogenic drugs depends upon measuring the induction of ALA synthetase in fetal chicken liver cells that have been exposed to test compounds. Early examples of AIP were revealed as a response to new drugs – initially the hypnotic sulfonal, later barbiturates, and subsequently many other drugs, alcohol, and sundry organic compounds. Some steroid metabolites precipitate attacks, and endogenous changes may account for crises at puberty, for the earlier

onset with females, and for the relationships with the menstrual cycle and oral contraceptives. Other exacerbating factors include infections and malnutrition. Low-carbohydrate and low-protein diets are especially detrimental, and fasting can precipitate an attack of porphyria. A study in Scotland indicated an association between smoking and the induction of repeated attacks in patients already diagnosed with AIP.

Genetics

Barker and Estes, in 1912, were the first to note that AIP runs in families. The extensive studies of Paul Waldenström in 1957 in Sweden firmly established the inherited nature. The disease follows an autosomal dominant pattern of inheritance; if one parent is a carrier then on the average 50% of the children will bear the defective gene. However, the penetrance is variable, with only a fraction of the carriers usually expressing the disease. The enzymatic lesion is PBG deaminase and the gene for the enzyme is localized to the distal long arm of chromosome 11. Mutation within this gene leads to a defective protein product, one that has no PBG deaminase activity. This aberrant product in about 80% of cases does not survive long enough within cells to be detected by reaction with antibodies to the normal protein. Most of the remainder of cases exhibit a defective protein that cross-reacts with appropriate antibodies. A very small group apparently overproduces a different aberrant protein or (more likely) makes an altered protein that has a longer life by resisting cellular degradation. Whether this heterogeneity accounts for differences among patients in the susceptibility to exacerbation factors, and the clinical presentation, remains to be elucidated.

Famous Patients

King George III of Great Britain suffered from intermittent attacks of mental derangement which have been attributed to a form of porphyria by Macalpine and Hunter. A good case for acute intermittent porphyria was initially presented, although these authors later seemed to favor another type, variegate porphyria, because of some less well-documented claims of skin sensitivity in the subject. The illness of Vincent van Gogh has been attributed by Loftus and Arnold in the early 1990s to a toxic psychosis, and acute intermittent porphyria is the best working hypothesis. The artist suffered from severe and manifold neurological problems ranging from gastrointestinal pains to fits with hallucinations. His condition was exacerbated by his lifestyle, which was marked by inadequate nutrition, abuse of alcoholic beverages, chronic smoking, and environmental stress. His several debilitating crises were of abrupt onset and rapid resolution, and their initiation often coincided with exposure to factors now known to provoke attacks in AIP patients. The age of onset of symptoms and the incidence of mental illness in the van Gogh family also support this working hypothesis. It is clear that Vincent van Gogh was both productive and creative in spite of his illness, not because of it. Some diseases with the potential for severe neurological involvement are not incompatible with creativity.

Concluding Remarks

The intervals between presenting symptoms and the correct diagnosis of AIP have been reported to range from several months to years. Because of their psychoses, carriers may be institutionalized, and many of these individuals are never properly diagnosed. The incidence of AIP is about 1 in 50 000 within all ethnic groups (about 1 in 10 000 in Sweden). Because penetrance is low it is generally assumed that the rate for the aberrant gene is underestimated. In this context, it is also worth noting that when psychiatric institutions were surveyed for AIP, order of magnitude increases in rate compared with local populations were observed, due to the revelation of previously undiagnosed cases. Because abdominal pains are frequent, AIP patients are often referred to the surgical ward and come under the knife unnecessarily. Many otherwise useful drugs will actually precipitate attacks and add to the suffering. Lists of safe drugs and also those to be avoided by AIP patients are published, and if correctly managed the AIP patient can lead a happy and productive life. Elucidation of the mechanisms involved in this particular congenital disease serves to emphasize by contrast the importance of metabolic orchestration to health. An adenoviral vector has been used to augment a deficiency of PBG deaminase in the liver of an AIP mouse model. The expressed enzyme enabled the animal to avoid ALA and PBG accumulations which were otherwise encountered in the model in response to a phenobarbital challenge. A gene therapy for AIP in humans may be possible in the future.

Positron Emission Tomography (PET)

M Reivich, University of Pennsylvania, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Positron emission tomography (PET) allows quantitative measurements of regional physiological and biochemical processes to be made *in vivo* in humans. The approach consists of labeling a tracer with a positron-emitting radionuclide, the administration of this tracer to the subject, the determination of the three-dimensional distribution of the positron activity in the organ being studied by means of a positron emission tomograph, and the quantitation of the parameter under study by means of a suitable mathematical model. Frequently, the arterial input function – that is, the time course of change of the concentration of the tracer in the arterial blood – also needs to be measured in order to quantitate the parameter of interest.

The positron is a particle with a positive charge and a mass equal to that of an electron. After the emission of the positron from a radioactive nuclide, the particle interacts with an electron and the two particles undergo the process of matter–antimatter annihilation in which their masses are converted into electromagnetic radiation in the form of two photons, each with an energy of 511 keV, which travel in directions nearly 180° apart. It is the detection of this annihilation radiation by the PET scanner that is used to produce an image of the distribution of the positron activity in the tissue.

The detection and collimation of the annihilation radiation in PET devices is achieved by having an array of radiation detectors in which two detectors on opposite sides of the array are electronically connected by a coincidence circuit such that an event is registered only if both detectors sense the annihilation photons virtually simultaneously. These events are then reconstructed into an image of the distribution of these annihilation events within the organ of interest using algorithms similar to those developed for computerized tomography (CT) scanners.

Radiopharmaceuticals

The most frequently used positron-emitting radionuclides are isotopes of oxygen, nitrogen, and carbon (commonly occurring constituents of organic molecules), as well as fluorine. The specific isotopes used are oxygen-15, nitrogen-13, carbon-11, and fluorine-18 with half-lives of 2, 10, 20, and 110 min, respectively. These short half-lives permit the administration of relatively large doses of radioactivity to the subject with radiation exposures within established safe limits. They also mean that these radionuclides must be produced close to where they will be used, requiring a cyclotron or other accelerator on site.

The development of tracers for physiological and biochemical measurements in the brain with PET has focused mainly on labeled compounds to measure local cerebral blood flow, cerebral blood volume, oxygen consumption, glucose consumption, protein synthesis, neurotransmitter receptor properties, tissue proliferation, tissue pH, gene expression, and drug distribution. Table 1 provides a representative list of these tracers.

In addition to cyclotron-produced positron emitters, many potentially useful positron emitter generator systems have been developed. These systems offer convenient access to a choice of positron emitters with a wide range of half-lives and a variety of chemical properties for use in the preparation of labeled tracer molecules. The most commonly used positron emitter generator systems are ^{68}Ge/^{68}Ga and ^{82}Sr/^{82}Rb.

PET studies have added significantly to our understanding of metabolic and physiological processes in the human brain in both normal and pathologic conditions.

Sensory and Cognitive Stimuli in Normal Subjects

The effects of various sensory and cognitive stimuli on regional cerebral blood flow (rCBF) and metabolism have been examined. Monaural auditory stimulation elevates the metabolic rate for glucose in the temporal cortex contralateral to the stimulated ear. A tonal memory test has also been examined. In the tonal memory test, significant increases in glucose metabolism were found in the right posterior superior and middle temporal cortices. Those subjects employing a nonanalytic strategy for remembering the sequence of tones had higher metabolic rates in the right frontal and parietotemporal regions. In those subjects using an analytic approach, higher metabolic rates occurred in the left posterior superior temporal cortex. Similar differential effects have been seen in studies of memory with auditory presentation of facts. Subjects using the strategy of silently rehearsing the facts to themselves activated left frontal and right cerebellar regions. Subjects using the strategy of creating a vivid visual image of the facts showed activation of the prefrontal, intraparietal, and posterior superior parietal regions.

Several studies of the effects of visual stimulation on local cerebral glucose metabolism have been

Table 1 Representative PET tracers

Function	*Tracer*
Blood flow	^{11}C-iodoantipyrine
	$C^{15}O_2$
	$H^{15}O_2$
Blood volume	$C^{15}O$
	^{11}CO
Oxygen metabolism	$^{15}O_2$
Glucose metabolism	^{18}F-fluorodeoxyglucose
	^{11}C-deoxyglucose
Protein synthesis	^{11}C-leucine
	^{11}C-methionine
D_2dopamine receptors	^{11}C-raclopride
	^{18}F-*N*-methylspiroperidol
	^{11}C-spiroperidol
D_1 dopamine receptors	^{11}C-SKF 38393

Tissue proliferation	^{11}C-purines, nucleotides, and nucleosides
	^{11}C-putrescine
Tissue pH	$^{11}CO_2$
	^{11}C-dimethyloxazoladine

reported. In the visual cortex contralateral to the stimulated hemifield, a significant increase in metabolism was observed. When the visual stimulus was limited to the central 20° (macular region) of one hemifield and the peripheral 60° of the other hemifield, increases in metabolism in the macular and peripheral representations of the visual fields in the visual cortex were observed. Tactile stimulation produces an increase in metabolism in the contralateral postcentral gyrus and surrounding areas.

The effects of cognitive tasks have been studied. Verbal and spatial tasks produced the expected increase in metabolism in the left and right hemispheres, respectively, mainly in the superior temporal and inferior parietal regions. In addition, there were significant differences in the laterality of metabolism in the frontal eye fields of the prefrontal cortex which may be related to a postulated neural network that links cognitive activity with motor orientation.

Studies of episodic memory using a semantic analysis strategy have demonstrated involvement of the left inferior prefrontal cortex. In another study involving the recollection of previous events, increases in blood flow were seen in the right dorsolateral prefrontal cortex and the anterior portion of the premotor area as well as the left anterior cingulate gyrus and in the parietal lobes bilaterally. These findings may reflect the operation of a neuronal network involving prefrontal and parietal cortical regions subserving memory-related processes.

The temporary storage and manipulation of information is thought to be processed in a system termed working memory. This system consists of an attentional controller and the central executive, aided by two subsidiary systems – the visuospatial sketchpad and the phonological or articulatory loop. The visuospatial sketchpad holds and manipulates visual images, and the phonological or articulatory loop performs a similar function for speech-based information.

Verbal storage tasks result in activations in left posterior parietal cortex and three frontal sites (Broca's area, the left supplementary motor, and the premotor area). PET studies also have shown that subvocal rehearsal of phonological information is neurally implemented by left hemisphere speech areas, including Broca's area, the premotor area, and the supplementary motor area.

The central executive is assumed to be responsible for the attentional control of working memory. When a task requires processing the contents of working memory, the dorsolateral prefrontal cortex is activated.

It seems likely that visual and spatial information is handled by regions of the brain separate from those handling verbal information. Spatial information is represented more dorsally (superior parietal cortex) than object information (inferior temporal cortex). Other studies suggest that object information also appears to be more left lateralized in the ventrolateral frontal cortex (VLFC) with spatial information in the right VLFC.

Studies of patients with focal lesions have demonstrated the importance of medial temporal and diencephalic regions in long-term memory (LTM) tasks. Imaging studies have demonstrated frontal cortex activation during LTM tasks that are related to memory encoding and retrieval. The left frontal cortex (predominantly VLFC and less so dorsolateral frontal cortex (DLFC)) is activated during verbal encoding and the right frontal cortex during visuospatial encoding. Memory retrieval has been postulated to involve two main stages: specification of

search parameters and verification of memories retrieved. Imaging studies suggest that these two stages activate VLFC and DLFC, respectively, more so on the right than the left.

Cerebrovascular Disease

PET has provided important data concerning the pathophysiological events occurring after a stroke. Measurements of rCBF and metabolism have provided useful information in staging the severity of tissue injury and predicting outcome as well as showing alterations in these parameters in response to therapy.

The relationship between metabolism and flow in the acute stroke patient may also provide prognostic information. The oxygen extraction fraction (OEF), which is the ratio of oxygen consumption to blood flow, may be an index of the severity of tissue injury. Early in the patient's course, cerebral metabolism may be normal but flow reduced and manifest by an elevated OEF. This disproportional decrease in flow compared to metabolism has been termed 'misery perfusion.' There may be some critical level of increased OEF beyond which tissue ischemia leads to irreversible damage. A reduction in oxygen metabolism from the normal level of 3.75 ml $100\,g^{-1}\,min^{-1}$ to a level of 1.25 ml $100\,g^{-1}\,min^{-1}$ or a reduction of flow to approximately 12 ml $100\,g^{-1}\,min^{-1}$ has been reported to be associated with infarcted irreversibly damaged tissue. An ischemic penumbral region has been defined in which flows are at a level within the threshold of functional impairment but morphologic integrity is preserved (i.e., a flow between 12 and 22 ml $100\,g^{-1}\,min^{-1}$) and which has the capacity to recover if perfusion is improved. In the penumbral region, there is a cerebral metabolic rate of oxygen ($CMRO_2$) >1.4 ml $100\,m^{-1}\,min^{-1}$ and an OEF >0.7. The extent of the penumbra is large if measured in the first hours of ischemia and smaller if measured later. It has been demonstrated that spontaneous neurologic recovery after stroke is significantly related to the volume of penumbric tissue that escapes infarction.

In some patients within a few hours following a stroke, flow may be increased relative to oxygen metabolism, with a resulting decrease in OEF. Again, flow and metabolism are uncoupled but now in the opposite direction, which has been termed 'luxury perfusion.' A later phase of hyperemia between 10 and 20 days following a stroke may occur, which is due to capillary hyperplasia in tissue undergoing cavitation. The prognostic significance of luxury perfusion is unclear, but in some studies it has been associated with good recovery of the tissue and a good clinical outcome. The later hyperemic phase, however, seems always to be associated with infarction. In the chronic phase, approximately 1 month after the ictus, there may be recoupling of flow and metabolism but at a reduced level.

Central benzodiazepine receptor ligands have been suggested as a marker of neuronal integrity that can identify irreversibly damaged tissue irrespective of the time elapsed since the onset of ischemia. In patients with acute ischemic strokes studied within 3–16 h of onset, cortical regions with decreased ^{11}C-flumazenil (FMZ) binding predicted final infarcts seen on magnetic resonance imaging (MRI) or CT scans. The predictive value of reduced FMZ binding was comparable to that of regional $CMRO_2$ reduction less than 1.4 ml $100\,g^{-1}\,min^{-1}$. Studies with ^{18}F-fluoromisonidazole, a tracer that is trapped within hypoxic cells with still active metabolism, have demonstrated viable tissue in the peri-infarct region as long as 42 h after a stroke. This evidence of relatively long-lasting penumbral tissue suggests that the time for therapeutic intervention may be protracted in some patients and that PET studies may be able to identify those patients.

PET studies have also shed light on the mechanisms of recovery of function following a stroke. It has been a consistent finding in several studies that increased glucose metabolism and blood flow occurs in the ipsilateral sensorimotor cortex as well as in the contralateral primary and secondary sensorimotor cortices with movements of the paretic hand after recovery from stroke compared to normal hand movement (Figure 1). PET studies of rCBF have shown in patients recovering from aphasia that during speech there are areas of activation both in the right hemisphere and in spared left hemispheric regions (Figure 2). Thus, there is evidence of neural plasticity playing a role in functional recovery after stroke.

In patients with carotid artery disease, the presence of an increased OEF is a powerful predictor of future stroke. Reversal of a focal increase in OEF has been demonstrated following endarterectomy or superficial temporal artery to middle cerebral artery anastomosis in patients with transient ischemic attacks.

Hemodynamic and metabolic abnormalities may be present in the tissues distant from an ischemic area which appear normal on CT or MRI scans. These remote effects are presumed to be secondary to metabolic alterations produced by the decrease in axonal input to the region and have been termed diaschisis. Such changes have been documented in the contralateral cerebellar hemisphere, the non-ischemic hemisphere, as well as ipsilateral cortical regions outside the area of infarction. PET studies have shown that there is a relationship between the resolution of diaschisis and subsequent recovery.

Figure 1 rCBF activation study in a patient who had recovered well after right-sided paresis due to a subcortical stroke. Shown are areas activated more than in ten normal subjects when they are all making movements with the right hand. The patient shows more activation in the left primary sensorimotor cortex and in secondary sensorimotor areas, all contralateral to the recovered hand (right). Also ipsilaterally(left), secondary sensorimotor areas are activated more than in the normal subjects. Reproduced from Rijntjes M and Weiller C (2002) Recovery of motor and language abilities after stroke: The contribution of functional imaging. *Progress in Neurobiology* 66: 109–122, with permission from Elsevier.

Figure 2 rCBF study showing regions activated by a verbal task in six normal subjects (top) and six patients who had recovered from Wernicke's aphasia (bottom) due to a stroke in the left posterior language regions. All subjects and patients were strongly right-handed. The right hemispheres are shown on the left and the left hemispheres on the right. In the normal subjects, there was activation in the anterior and posterior language regions in the left hemisphere, with weaker activation in homologous areas of the right hemisphere. In the patients, the left posterior language region was destroyed, so no activation was present there. There was still activation in the left frontal language region. Homologous regions in the right hemisphere are activated stronger than in the normal subjects. Reproduced from Rijntjes M and Weiller C (2002) Recovery of motor and language abilities after stroke: The contribution of functional imaging. *Progress in Neurobiology* 66:109–122, with permission from Elsevier.

Changes in flow, metabolism, and receptor binding in acute stroke patients in response to therapeutic interventions have been shown to occur and to correlate with functional recovery.

Cerebral Tumors

PET measurements can play an important role in the evaluation and management of patients with brain tumors, including the grading of tumors, determination of prognosis, and the differentiation of recurrent tumor from radiation necrosis.

Measurements of cerebral glucose metabolism have been used in an attempt to grade the malignancy of brain tumors *in vivo*. This approach is based on evidence in the literature suggesting that there is a progressive increase in the degree of anaerobic glycolysis of a glioma the higher its grade. A positive correlation between glioma grade and glycolytic activity as measured by the ^{18}fluorodeoxyglucose (FDG) technique has been observed (Figure 3).

FDG–PET has also been useful in determining prognosis in patients with brain tumors. PET can more accurately predict the degree of malignancy of a tumor than CT or MRI, and PET has also been

Figure 3 Differentiation between low- and high-grade glioma. In low-grade gliomas (WHO °II) glucose metabolism is similar to white matter (arrows) and amino acid uptake is only moderately increased. In high-grade gliomas (WHO °IV) both glucose metabolism and amino acid uptake are increased. Reproduced from Jacobs AH, Kracht LW, Gossmann A, et al. (2005) Imaging in neurooncology. *NeuroRx* 2: 333–347, with permission.

shown to predict survival in patients with gliomas more accurately than either CT or MRI.

FDG uptake has been shown to be useful in distinguishing between radiation necrosis and tumor recurrence, which is typically difficult with either CT or MRI. In general, areas of radiation necrosis are hypometabolic, whereas tumor recurrence appears hypermetabolic. However, accumulation of FDG in infiltrating macrophages may obscure this delineation. [^{11}C]methionine is better suited in this regard and differentiates between tumor recurrence and radiation necrosis with high sensitivity and specificity.

FDG–PET has also been used to determine tumor response to radiation and/or chemotherapy and patient survival. Patients whose tumors have decreased glucose metabolism after radiation therapy tend to have a better prognosis than those who do not show such a response (Figure 4).

[^{11}C]methionine has been used to help determine the fields for radiation therapy because the tumor volume depicted by [^{11}C]methionine is larger than that depicted by MRI. Benodiazepine receptors are increased in brain tumors compared with normal brain, and thus [^{11}C]flumazenil, a benzodiazepine antagonist, has been useful in depicting tumor volume as well.

Movement Disorders

Parkinsonism is a feature of a number of neurodegenerative diseases, including Parkinson's disease (PD), multiple system atrophy (MSA) and progressive supranuclear palsy (PSP). Separating these various parkinsonian syndromes using clinical criteria alone can be difficult. Discrimination of these various disorders is important in view of differences in prognosis and therapy. These syndromes can be differentiated partially on the basis of the involvement of different components of the dopaminergic system.

Figure 4 Parameters of interest in the noninvasive diagnosis of brain tumors. Alteration of the blood–brain barrier and the extent of peritumoral edema are detected by MRI. Signs of increased cell proliferation can be observed by means of multitracer PET imaging using [^{18}F]FDG, [^{11}C]MET, and [^{18}F]FLT as specific tracers for glucose metabolism, amino acid transport, and DNA synthesis, respectively. Secondary phenomena, such as inactivation of ipsilateral cortical cerebral glucose metabolism, may be observed and are of prognostic value. Reproduced from Jacobs AH, Kracht LW, Gossmann A, et al. (2005) Imaging in neurooncology. *NeuroRx* 2: 333–347, with permission.

The major cause of parkinsonism is PD, accounting for 60–85% of all cases. In PD presynaptic uptake of ^{18}F-dopa is significantly decreased in the striatum, being most marked in the posterior part of the putamen while being relatively preserved in the caudate (Figure 5). In patients with atypical parkinsonism (lack of resting tremor and poor response to dopaminergic drugs), both the caudate and putamen are equally affected. Studies of ^{18}F-dopa appear to be sensitive enough to detect preclinical PD. The rate of decline in ^{18}F-dopa uptake over time is significantly faster in PD than in normals. Studies of ^{18}F-dopa have been used to assess the role of genetics versus environment in PD. Studies of nigrostriatal dysfunction in monozygotic and dizygotic twins showed significantly higher concordances in the monozygotic twins which argue strongly against an environmental factor and for a genetic cause of PD.

D_2 receptor binding is decreased in the caudate in advanced PD but otherwise is usually normal. Striatal D_1 receptors have been examined and found to be unchanged. Studies of the dopamine transporter also show a more pronounced reduction of striatal binding in the putamen than in the caudate which correlates with disease severity. Presynaptic monaminergic vesicular transporters are decreased in the putamen more than the caudate in PD patients compared to elderly normal subjects.

Abnormalities in rCBF response to motor tasks have been reported in PD patients. Some of these abnormalities can be normalized after dopaminergic medication, pallidotomy, or subthalamic nucleus stimulation. A generalized decrease in rCBF has also been reported without a concomitant decrease in $CMRO_2$, which has been postulated to be due to vasoconstriction secondary to loss of dopaminergic innervation of the cerebral vessels.

In PD patients, although inconsistent results have been reported for regional glucose metabolism, most studies have shown a generalized decrease involving the cortical and subcortical regions. There is a lack of correlation between changes in glucose metabolism and clinical findings of rigidity or tremor. In patients with PD and dementia, there is a global decrease in glucose metabolism but with more severe hypometabolism in temporoparietal areas.

PET studies have been used to examine the effects of various forms of treatment of PD. For example, following intrastriatal transplantation of human embryonic mesencephalic tissue, striatal ^{18}F-dopa uptake increases and is correlated with graft survival.

MSA accounts for up to 10% of patients with parkinsonism and is poorly responsive to dopaminergic medication. In patients with MSA, presynaptic uptake of ^{18}F-dopa and dopamine reuptake sites are decreased in the putamen and caudate. Striatal D_2 receptor binding is also decreased in patients with MSA, as is vesicular transporter binding. Both ^{18}F-dopa uptake and D_2 receptor binding correlate with motor impairment. Glucose metabolism in patients with MSA is also decreased in the putamen and caudate. In addition, significant reductions in metabolism are present in the premotor and motor cortex, the thalamus, and the cerebellum.

Figure 5 Reduced striatal [^{18}F]-dopa uptake is present in PD compared to normal subjects. The reduced [^{18}F]-dopa uptake is more pronounced in the putamen with relative sparing in the caudate nucleus. Reproduced from Thobois S, Jahanshahi M, Pinto S, Frackowiak R, and Limousin-Dowsey P (2004) PET and SPECT functional imaging studies in Parkinsonian syndromes: From the lesion to its consequences. *Neuroimage* 23: 1–16, with permission from Elsevier.

In patients with PSP, ^{18}F-dopa uptake is significantly reduced, involving both the caudate and the putamen. However, there is no correlation between levels of ^{18}F-dopa uptake and motor disability, unlike in PD and MSA. D_2 receptor binding sites are also decreased in the caudate and putamen, as are striatal dopamine transporters. A pattern of alterations in glucose metabolism is seen in these patients, which is similar to that seen in MSA but with less pronounced frontal lobe and striatal hypometabolism.

PD patients can be distinguished from MSA and PSP patients with PET studies of the dopamine system. In untreated PD patients, presynaptic function (F-dopa uptake and dopamine transporter and vesicular transporter binding) is impaired, whereas postsynaptic function (D_2 receptor binding) is normal or increased; in MSA and PSP, both pre- and postsynaptic functions are impaired. A decrease in striatal glucose metabolism also clearly distinguishes PD from MSA.

In Huntington's disease (HD), striatal ^{18}F-dopa levels are normal but D_2 receptor binding in the caudate is decreased. This decrease is correlated with the duration of illness. Subjects at risk for HD have normal D_2 receptor binding. Glucose metabolism in HD patients is decreased in the caudate nucleus even when the CT scan is normal and can precede the onset of symptoms in people at risk for HD. There is also evidence that glucose metabolism is reduced in the cerebral cortex in HD patients and that the severity and duration of symptoms correlate with the decrease in metabolism in cortical and subcortical regions.

Psychiatric Disorders

Depressive Disorders

Patients with manic-depressive disorders have been found to have abnormalities in glucose metabolism in the left anterolateral prefrontal cortex, inferior temporal cortex, and basal ganglia. The severity of depression correlates with the decrease in left frontal metabolism. In addition, in bipolar depressive patients compared to unipolar patients, a decrease in glucose metabolism has been observed in the frontal cortex (hypofrontality). In patients with bipolar depression, global glucose metabolism is decreased in the depressive phase, whereas in unipolar patients global metabolism is within normal limits. In addition, bipolar patients in the hypomanic phase tend to have normal glucose metabolism. Thus, FDG–PET studies might be useful in distinguishing unipolar from bipolar depression, which would be important in regard to the patient's treatment and prognosis. An increase in glucose metabolism with treatment of depression has been observed in bipolar and 'mixed' manic-depressive patients.

Studies of serotonin receptor binding in the cortex using ^{11}C-methylspiperone have shown an inverse relationship between the severity of depression in stroke patients and spiperone binding in the left temporal cortex. Serotonin transporter binding measured with PET and ^{11}C-McN 5652 was found to be reduced in the amygdala, midbrain, and ventral striatum in depressed patients in one study, whereas it has been reported to be increased in the thalamus and right cingulate and left frontal cortices in other studies. Blood flow has also been reported to be decreased in cortical regions, more so on the left, in depressed patients.

Schizophrenia

In untreated schizophrenic patients during resting conditions, decreases in glucose metabolism have been observed in frontal and temporal cortex and in central brain regions. The presence of frontal hypometabolism does not appear to be specific for this disorder because patients with affective disorders also demonstrate this finding.

Presynaptic dopamine metabolism has been studied in schizophrenic patients with ^{18}F-dopa and found to be abnormal. In one study, a significantly increased dopa uptake was found in the posterior cingulate and a significantly decreased uptake in the ventral striatum compared to normal control subjects. In other studies, dopa uptake has been reported to be increased in the striatum as well as in the prefrontal cortex. The vesicular monoamine transporter has been studied with ^{11}C-dihydrotetrabedazine and found to be normal in the striatum.

Quantitative studies of D_2 receptors in schizophrenic patients have revealed contradictory results. Differences in the ligands used (^{11}C-*N*-methylspiperone and ^{11}C-raclopride, respectively), the experimental strategy, and the patient populations as well as differences in the dopamine receptor subtype affinities of the two ligands might explain these discrepant results. Two meta-analyses have shown an increase in D_2 density in the striatum in schizophrenic patients. Further work is needed to resolve this important question. A few studies have examined striatal D_1 receptors in schizophrenic patients and found them to be unchanged from those in normal subjects. Studies of D_1 receptors in the prefrontal cortex in schizophrenic patients have produced contradictory results.

Schizophrenic patients treated with antipsychotic drugs have a significant fraction of the D_2 receptors in the striatum occupied by the drug. Some of the

antipsychotic drugs also occupy the D_1 receptors, as measured with ^{11}C-SCH 23390.

Postmortem studies have shown decreased serotonin 5-HT_{2A} receptors, increased 5-HT_{1A} receptors, and decreased serotonin transporter in the prefrontal cortex of schizophrenic patients. PET studies of serotonin receptor changes in schizophrenic patients have been performed using ^{18}F-setoperone and ^{11}C-*N*-methylspiperone and have found no significant differences from normal control subjects. However, one study using ^{18}F-setoperone did reveal a significantly lower 5-HT_{2A} binding potential in the frontal cortex in neuroleptic-naive schizophrenic patients. No PET studies have examined 5-HT_{1A} receptors or the serotonin transporter in schizophrenia.

PET studies are also being used to help determine the appropriate dose of drugs as well as in the development of new drugs to treat psychiatric illnesses.

Aging and Dementia

rCBF and oxygen metabolism measured with PET methods have demonstrated a significant decline with aging in these parameters in gray matter with relatively little change in white matter. Regional cerebral glucose metabolism has also been reported to decrease with aging, with the frontal cortex showing a greater decrease than other cortical regions. Other investigators, however, have failed to detect any statistically significant difference in regional cerebral glucose consumption between normal young subjects and normal elderly subjects.

Studies of the dopaminergic system have shown an age related decline in D_1 and D_2 receptors in the striatum, frontal cortex, temporal cortex, and thalamus of the order of 10% per decade (**Figure 6**). Studies of monoamine oxidase B have demonstrated a significant increase with age in many brain regions, including the frontal, parietal, and temporal cortices, the thalamus, basal ganglia, pons, and cerebellum. Serotonin (5-HT_{2A}) receptor binding has also been reported to decrease with aging (**Figure 7**).

In patients with Alzheimer's disease (AD), studies have shown a decrease in glucose and oxygen consumption as well as a decrease in rCBF compared to normal elderly subjects. These studies also showed a significant correlation between the degree of cognitive impairment and the reduced metabolic rate as well as a good correlation between the patient's cognitive deficits and the location of the metabolic abnormalities. The typical pattern of decreased metabolism that is seen most prominently affects the parietotemporal association and posterior cingulate cortices and later the parietal cortex with extension to the frontal cortex in advanced disease, with relative sparing of the primary sensorimotor cortices, thalamus, basal ganglia, and cerebellum. A multicenter study showed that decreased glucose metabolism in the parietotemporal, prefrontal, and posterior cingulate cortices is diagnostic of mild to moderate AD with 93% sensitivity and specificity, and even in very mild AD sensitivity was 84% and specificity was 93%. In addition, the pattern of metabolic abnormalities enables one to distinguish AD from

Figure 6 Loss of dopaminergic activity in aging is illustrated in the study of [^{11}C]FLB 457, a dopamine D_2 receptor ligand, in a young (age 25 years) and an old (age 70 years) healthy woman. The images are scaled to an equal radioactivity in the reference region (the cerebellum). Reproduced from Kaasinen V and Rinne JO (2002) Functional imaging studies of dopamine system and cognition in normal aging and Parkinson's disease. *Neuroscience and Biobehavioral Reviews* 26: 785–793, with permission from Elsevier.

Figure 7 [^{18}F]altanserin PET images in young normal (age 20 years), elderly normal (age 66 years), and Alzheimer's disease (AD; age 67 years) subjects. Images are normalized to the cerebellum, an area with few 5-HT_{2A} receptors. Cortical 5-HT_{2A} binding is greater in the young subject compared to the elderly subject. The Alzheimer's patient exhibits diffusely lower 5-HT_{2A} binding than both the young and elderly controls. Reproduced from Meltzer CC, Smith G, DeKosky ST, et al. (1998). Serotonin in aging, late-life depression, and Alzheimer's disease: The emerging role of functional imaging. *Neuropsychopharmacology* 18: 407–430, with permission.

other forms of dementia. Frontotemporal dementia (Pick's disease) shows a more severe frontal and temporal hypometabolism, dementia with Lewy bodies demonstrates more severe occipital hypometabolism in addition to the parietotemporal hypometabolism, whereas vascular dementia is characterized by diffuse hypometabolism in cortical, subcortical, and cerebellar regions. Depression can lead to memory impairment without dementia but is associated with a more global reduction in glucose metabolism with accentuation in the frontal lobe.

Studies of protein synthesis using L-[^{11}C]methionine have shown that in patients with AD protein synthesis is also decreased compared to age-matched normal subjects and is proportional to the severity of the dementia. Detectable impairment of protein synthesis prior to any clinical signs suggests that this may be a sensitive probe for the evaluation of neuronal metabolic integrity at a very early stage of the disease.

PET neuroreceptor studies using ^{11}C-nicotine in patients with AD have shown a decrease in the low-affinity nicotine receptors in the temporal and frontal cortices and a significant correlation with the Mini-Mental State Examination Score.

Reduced acetylcholine activity has also been observed in the parietotemporal cortex in AD as well as a loss of serotonin receptors in the temporal and frontal cortex (Figure 7).

Epilepsy

Because of its ability to measure functional changes in the brain, PET has great potential in the study of epilepsy, a disorder in which changes in neural discharges usually unassociated with structural alterations are present. In patients with a generalized seizure disorder, CBF and metabolism are normal interictally. Ictally, a global increase in CBF occurs during generalized seizures, with a postictal decrease in CBF. Similar changes occur in cerebral metabolism.

In patients with partial epilepsy, it has been found that in the interictal period glucose metabolism and cerebral perfusion are reduced in the region corresponding to the epileptic focus. Ictal studies have shown an increase in both these parameters in these regions. The area of hypometabolism typically extends well beyond the area of pathologic abnormality to include the entire temporal lobe. Studies with ^{11}C-flumazenil, which binds to the γ-aminobutyric acid

Figure 8 Comparison of ^{18}FDG PET (a) and ^{11}C-FMZ PET (b) in a patient interictally with complex partial seizures. (a) ^{18}FDG PET shows extensive hypometabolism in the left temporal lobe, affecting both the medial temporal cortex (arrow) and the inferior and lateral (double arrow) temporal neocortex. (b) ^{11}C-FMZ PET shows a circumscribed decrease of ^{11}C-FMZ volume of distribution (Vd) in the left medial temporal lobe (arrow). (c) Statistical analysis with statistical parametric mapping (SPM99) shows a significant decrease of FMZ-Vd in the left anterior hippocampus compared with 21 controls. The statistical map is overlaid on the patient's MRI; the color scale shows the *t* value. Reproduced from Tai YF and Piccini P (2004) Applications of positron emission tomography (PET) in neurology. *Journal of Neurology, Neurosurgery, & Psychiatry* 75: 669–676, with permission.

central benzodiazepine receptor complex, in these patients often show a smaller region of abnormality (Figure 8). Occasionally, the FMZ–PET study will be abnormal, whereas the FDG–PET study or MRI is normal in these patients. FMZ–PET is more sensitive and accurate in delineating the seizure focus than FDG–PET. Interictally, decreased glucose metabolism and FMZ binding have also been observed. The presence of thalamic involvement has a strong lateralizing value, particularly when cortical abnormalities are subtle. FDG–PET should be considered as the first-line PET investigation in patients with temporal lobe epilepsy with a strictly normal MRI, and FMZ–PET could be proposed in the subgroup of patients whose FDG–PET failed to reveal focal hypometabolism.

In patients with extratemporal lobe epilepsy, interictal FDG–PET, in general, has proven to be a reliable test for identifying dysfunctional cortical regions of hypometabolism that correspond to the location of epileptic foci. FDG–PET in cases of frontal lobe epilepsy has show a sensitivity and accuracy of 92–96% and 74–78%, respectively. A comparison of FDG– and FMZ–PET studies in patients with frontal lobe epilepsy showed a good correlation between location of FMZ–PET abnormalities and epileptic focus identified by surface and intracranial electroencephalogram (EEG) with subdural electrodes. Furthermore, FMZ–PET abnormalities were more restricted that those delineated with FDG–PET.

In patients with generalized forms of epilepsy, interictal PET studies usually do not demonstrate lateralized or localized cortical abnormalities. During frequent absence seizures, however, marked generalized hypermetabolism as well as a global increase in CBF may be present.

Several other PET tracers have been examined for their potential usefulness in detecting epileptic foci – for example, histamine H1 receptor binding, opioid receptor binding, *N*-methyl-D-aspartate receptor activity, and serotonin synthesis. Focal increases of these tracers have been observed in various forms of epilepsy; however, the results are preliminary.

Gene Therapy

Several approaches to gene therapy are being tested using a variety of vectors and therapeutic genes. All rely on the same rationale: genetically engineering a target tissue to produce a new therapeutic protein. This requires the selective introduction of genes into a target tissue using a vector. Such vectors include adenovirus, retrovirus, DNA–protein complexes, and liposomes. The vector has several roles: it delivers the gene across the cell membrane into the nucleus and drives expression of the gene to produce the therapeutic protein.

One major approach in cancer gene therapy that has been extensively investigated is the use of enzyme/prodrug systems, such as herpes simplex virus thymidine kinase/ganciclovir (HSVtk/GCV), which introduce a drug-activating enzyme. Phosphorylation by the viral kinase triggers the therapeutic effect of GCV. The viral kinase activates the drug to a monophosphate. Subsequent phosphorylation of the monophosphate by cellular kinases leads to inhibition of DNA synthesis and cancer cell death.

PET studies in mice using a PET scanner designed for small animal studies (2 or 3 mm in plane resolution) have demonstrated the feasibility of HSV1-tk as a reporter gene and ^{18}F-GCV as an imaging

reporter probe. The liver, which is the primary site of adenovirus uptake after intravenous administration, was visualized only in the mice receiving Ad.HSVtk compared to those receiving a control virus. There was a significant correlation between the HSVtk enzyme activity in the liver and the ^{18}F-GCV activity in the liver. Since it has been shown that there is a strong correlation between ^{18}F-GCV uptake *in vitro* and the growth inhibition in response to pharmacological doses of GCV, the uptake of ^{18}F-GCV may be not only a marker for gene transfer and expression of HSVtk in tumors but also a predictor of response to therapy.

Figure 9 Imaging D_2R and HSV1-tk PET reporter genes in the same animal. A mouse carrying C6-stb-tk+ tumor (right) and D_2R (left) was imaged by micro-PET for HSV1-tk reporter gene expression using FPCV and D_2R reporter gene expression using FESP. Highly specific localization of FPCV and FESP was observed in tumors expressing HSV1-tk and D_2R genes, respectively. Reproduced from Iyer M, Barrio JR, Namavari M, et al. (2001) 8-[^{18}F]Fluropenciclovir: an improved reporter probe for imaging HSV1-tk reporter gene expression *in vivo* using PET. *Journal of Nuclear Medicine* 42: 96–105, with permission.

Fluoro-penciclovir (^{18}F-FPCV) has also been shown to be a useful imaging reporter probe. *In vitro* studies have shown that accumulation of ^{18}F-FPCV is greater compared to ^{18}F-GCV in C6 cells expressing HSVtk. The use of FPCV as a reporter probe should allow a greater imaging sensitivity.

Another tracer that has been studied is fluoro-hydroxy-propoxy methyl guanine (^{18}F-FHPG). It has been evaluated in *in vitro* and *in vivo* studies which suggest that ^{18}F-FHPG is a potential *in vivo* PET imaging agent for monitoring gene incorporation and expression. Comparison of FPCV and ^{18}F-fluro-hydroxymethyl-butyl guanine (FHBG) as reporter probes in studies of transgenic mice expressing HSV1-tk in the liver showed that there is significantly greater hepatic accumulation when using FHBG. A mutated form of HSV1-tk, HSV1sr-39tk, which phosphorylates GCV and penciclovir more efficiently than thymidine, has been shown to have improved sensitivity for imaging reporter gene expression using a probe which is a derivative of penciclovir, FHBG.

Figure 10 PET imaging of endogenous p53 activation. Transaxial PET images through the shoulder (a and c) and pelvis (b and d) of two rats are shown. A nontreated animal is shown on the left and a BCNU-treated animal on the right. Both animals had three SC tumor xenografts: U87p53TKGFP (test) in the right shoulder, U87 wild-type (negative control) in the left shoulder, and RG2TKGFP (positive control) in the left thigh. The nontreated animal on the left shows localization of radioactivity only in the positive control tumor (RG2TKGFP); the test (U87p53TKGFP) and negative control (U87 wild-type) tumors are at background levels. The BCNU-treated animal on the right shows significant radioactivity localization in the test tumor (right shoulder) and in the positive control (left thigh) but no radioactivity above background in the negative control (left shoulder). Reproduced from Doubrovin M, Ponomarev V, Beresten T, et al. (2001) Imaging transcriptional regulation of p53-dependent genes with positron emission tomography *in vivo*. *Proceeding of the National Academy of Sciences of the United States of America* 98: 9300–9305, with permission.

Another reporter gene technique is based on the expression of a transmembrane receptor as the reporter gene and its labeled receptor ligand as the marker. One application of this method uses the dopamine D_2 receptor and ^{18}F-fluoroethyl-spiperone (^{18}F-FESP) as a ligand which, unlike most HSV1-tk substrates, rapidly crosses the blood–brain barrier. The vectors used in these studies were either an adenovirus carrying the D_2R reporter gene (Ad-D_2R) or a control adenovirus expressing β-galactosidase (Ad-βGal). In studies in mice administered either Ad-D_2R or Ad-β Gal intravenously, given ^{18}F-FESP 2 days later, and then imaged, only those animals given Ad-D_2R showed significant activity in the liver. The ^{18}F activity in the liver was proportional to the levels of hepatic D_2R-dependent ^{3}H-spiperone binding. Studies in which the D_2R antagonist butaclamol was administered 2 or 3 days after Ad-D_2R administration further demonstrated the specificity of the ^{18}F-FESP reporter probe for imaging the D_2R reporter gene. An example of the use of the HSV1-tk and D_2R reporter genes is shown in Figure 9. A mutant D_2R that uncouples signal transduction while maintaining affinity for FESP has been reported. Other receptor-based reporter gene systems involve the somatostatin receptor subtype II (SSTr2) and the sodium iodide symporter (NIS).

The monitoring of patients undergoing gene therapy may be improved with the ability to determine repetitively and noninvasively where the transferred DNA is being expressed and to what extent expression occurs over time.

In addition to use in gene therapy, reporter gene imaging can be used to visualize endogenous biological processes such as transcriptional regulation of gene expression as well as specific intracellular protein interactions. For example, endogenous expression of p53 has been imaged *in vivo* using a retroviral vector bearing the *cis*-p53/TKGFP reporter system in which a reporter gene for herpes simplex virus type 1 thymidine kinase was placed under the control of an artificial *cis*-acting p53-specific enhancer and the PET reporter probe fluoro-deoxy-arabinofuranosyl-[^{124}I]iodouracil. In this study, DNA damage produced by *N*,*N*′-bis (2-chloroethyl)-*N*-nitrosourea (BCNU) administration caused upregulation of p53 transcriptional activity which could be imaged with this reporter system (Figure 10).

Posterior Parietal Cortex and Arm Movement

A Battaglia-Mayer and R Caminiti, Università di Roma, Rome, Italy

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Cortical control of arm movement to visual targets (reaching) is the result of the cooperative interplay of a constellation of parietal and frontal areas and of their reciprocal corticocortical connections (Figure 1). This network is considered the main substrate for a recurrent mechanism underlying planning, execution, and control of arm movement. The posterior parietal cortex (PPC) plays a crucial role in this process. Parietal operations seem necessary for the visual-to-motor transformation underlying reaching and for the control of the congruence between motor plans and actual movement, thanks to efferent copies of motor commands from frontal cortex and reafferent signals from the sensory periphery. PPC is also crucial for the online control and adjustment of reaching, whenever requested by task demands. The premotor and motor areas of the frontal lobe, for their direct access to the spinal cord, are essential to address motor commands to the motor periphery and, through efferent cortical connections, corollary signals to other brain regions, including PPC. These frontal areas can participate in the birth of visually guided arm movements by elaborating signals about the state of the motor system to predict the sensory consequences of a motor command, thus creating the basis for an internal model of the desired movement.

These concepts stem from the cross-fertilization of results coming from different neuroscience disciplines, such as psychophysics, behavioral neurophysiology, neuroanatomy, and neuropsychology. Psychophysical studies in humans have set the background for interpreting novel neurophysiological results, mostly addressed at the elucidation of the dynamic properties of neurons in different areas of the parietofrontal system, studied in alert behaving monkeys. Neuroanatomical investigations have provided the necessary substrate for understanding the input–output relations in this cooperative distributed system, while the neuropsychological analysis of patients with brain lesions has been essential to determine whether, and to what extent, the integrity of parietal operations is essential for different aspects of reaching.

The Essential Features of Reaching in Psychophysical Analysis

Reaching consists of a coordinated eye–hand movement toward an object of interest. If target eccentricity is around 15° of visual angle, eye movement is accompanied by head movement. The onsets of activation for eye, head, and arm muscles largely coincide in time. However, because the inertias of the eye, head, and arm differ, the eye moves first, followed by the head, and then by the hand. Therefore, the initial motor command addressed to arm muscles is based on extrafoveal signals. However, at the onset of arm movement, the eye has normally landed on the target, and foveal information can be used for updating the motor command and later on for the visual control of the final hand shaping. Preventing eye or head movements results in a severe inaccuracy of reaching. In addition, eye position signals, from proprioception or efferent copies of eye movement, contribute essential information since their manipulation results in typical reaching errors.

The movement of the arm is a consequence of motion at the shoulder and elbow joints. These motions result from the torques exerted on the joints by the combined contraction of a large number of muscles acting on them, and they depend on movement trajectory and velocity, gravity, and inertial and Coriolis forces. This phase of reaching, characterized by a large amplitude movement that brings the hand close to the target, is followed by corrective adjustments of smaller amplitude, mostly at the wrist and finger joints, that depend on the orientation, geometry, and physical properties of the target. When reaching is made in different direction of space, a significant correlation exists between the activities of the different muscles set in motion, suggesting that they act in a synergic fashion, that is, through a coordinate activation with defined time sequences. The time-varying profiles of a limited number of muscle synergies well explain the overall pattern of muscle activity during fast reaching, regardless of different loads imposed or arm posture.

During arm movements, the hand occupies different positions in space at different times, and this defines the hand trajectory. The trajectory of free arm movements in three-dimensional (3-D) space is slightly curvilinear, and its shape is independent of movement speed, arm orientation, or external loads.

Figure 1 The parietofrontal network underlying arm movement. Brain figures of the medial (top) and lateral (bottom) views of the macaque monkey's brain, showing the regions of parietal (yellow), premotor frontal and cingulate (green), and motor (red) cortices where cell activity is related to arm movement. The inset of the brain figure on the right is an unfolding of the intraparietal sulcus (IPS), necessary to display the areas (gray shading) forming the medial and lateral banks of the sulcus. Similar unfolding is shown for the cortex of the parieto-occipital (POS) and cingulate (CiS) sulci. The blue arrows indicate the main reciprocal association connections that define the parietofrontal network. Thin broken lines indicate the architectonic borders between cortical areas. In the medial view, POS and CiS indicate parieto-occipital and cingulate sulcus, respectively. In the lateral view, LS, STS, SF, IPS, CS, PS, and AS indicate lunate, superior temporal, Sylvian, intraparietal, central, principal and arcuate sulci. Areas V6A, PGm, PEc, MIP (medial intraparietal), PEa, and PE are part of the superior parietal lobule. Areas Opt, PG, PFG, PF, LIP (lateral intraparietal), and AIP (anterior intraparietal) are part of the inferior parietal lobule (IPL). In the frontal lobe, areas F2, F4, and F5 on the lateral aspect of the hemisphere and the supplementary motor area (SMA) on the medial wall are the frontal premotor areas that project to primary motor cortex (M1). In the CiS, the dorsal (CMAd) and ventral (CMAv) cingulate motor areas are two premotor fields that project to M1. CMAr indicates the rostral cingulate motor area. S1, primary somatosensory cortex; V6, visual area VI; V6A, visual area VIA.

Therefore, it is believed that the trajectory is a movement invariant encoded by the central nervous system, in front of the exuberance of degrees of freedom that characterize movement.

Reaching movements display a typical bell-shaped velocity profile, with an accelerating and a decelerating phase. Therefore, during movement, hand velocity never remains constant. The particular shape of this otherwise invariant profile will depend on the trade-offs imposed by the different contexts in which movement is performed and by the variable that in each context has to be optimized, such as (minimizing) jerk, (maximizing) stiffness, (minimizing) energy expenditure, and so forth.

The accuracy of reaching movements is maximal when the hand starting position is located in front and around the reacher's midline, when movement is of small amplitude, and when it is directed straight ahead rather than in other directions. The faster the movement, the less it is accurate, a principle known as speed–accuracy trade-off. Changing speed also affects joint movement dynamics and requires a rescaling of the joint torques.

Visual Information Is Essential to Reaching

Arm movements are typically guided by vision, from target localization in space to visual control of movement trajectory and final shaping of the hand necessary

to match the physical properties of the target object. The visual direction of a target is mapped in retinotopic coordinates, whereas encoding its distance requires the combination of retinal disparity and fixation distance information, such as eye vergence angle, accommodation, and vertical disparity. The angle of vergence is the most important one, particularly within the near space, where the vergence range is roughly equal to the arm length. Therefore, this information might be used to specify the distance of arm movement as well. This is also suggested by ontogenetic considerations since manual reaching in infants develops at the same time as binocular control. Reaching is more accurate when vision of the arm is allowed than when it is prevented. However, this seems to depend, not only on visual feedback from the moving arm, but also from visual motion cues arising from active arm movement. These mechanisms seem to rely on peripheral vision, while the final preshaping of the hand near the target occurs under the control of central vision.

Coordinate Transformation Underlying Reaching

The vector of desired hand movement is defined by the difference (motor error) between the target and the hand location. Although hand position can be encoded in retinal coordinates, outside the visual field it is defined by proprioception and by efferent copies of the motor commands. In the process of combining information about target and hand position, the endpoint of arm movement has to be transformed from retinal to allocentric or egocentric coordinates, probably through a cascade of transformations. It is believed that these transformations carry behavioral errors of different types: (1) constant errors, measuring the systematic deviation of the mean endpoint of movement from the target; (2) variable errors, reflecting the variance of the individual movement endpoints around the mean; and (3) local distortions, indicating the degree of similitude between the configuration of the targets and that of the movement endpoints. In recent years, psychophysical studies have devoted significant attention to the analysis of reaching errors since they may reveal the internal representations and coordinate transformations used to specify the endpoint of reaching. An emerging view is that the frame of reference used to specify arm movement is task- and context-dependent. A few examples follow.

During arm movements toward visible virtual targets or to memorized locations, the specification of the final hand position occurs in terms of direction and distance from the eyes. This implies that a combination between eye and hand information enters into a common egocentric binocular frame of reference. When vision of the hand is not allowed, the axes of maximum variability are rotated around the body. When a discrepancy between the actual and the visually perceived hand position is introduced at one location in space, participants learn a visuomotor remapping over the entire workspace within a spherical coordinate system that specifies the azimuth, elevation, and distance of the hand relative to the eyes. These data support the hypothesis of a multistage transformation, from viewer-centered to head- and shoulder-centered coordinates. Furthermore, the existence of hand-centered commands for movement based on combination of target and hand signals is revealed by the additional variability observed along movement direction. When targets are located in a structured space, the endpoint position of reaching can be specified in object-centered or allocentric coordinates. Cognitive processing, such as prior information on the spatial relationships between targets that will be presented in sequence along a virtual line, also affects the representation of endpoints of reaching. In such instances, the pattern of errors reveals coexisting egocentric and allocentric representations. In conclusion, the frame of reference used to specify the endpoint for reaching is not fixed but depends on the available sensory information, task constraints, structure of visual scene, and cognitive context.

Eye–Hand Coordination

When human participants are asked to make pointing movements to visual targets presented in a sequential fashion, they cannot initiate a saccade to any given target until the hand has reached the previous one. This functional coupling between eye and hand movements is internal and does not depend on vision, since it also occurs when vision of the moving arm is prevented. In addition, saccades are faster when they occur within a coordinated eye–arm movement. When considering continuous movements, changing the gain of eye pursuit results in a change in the subsequent hand movements. Thus, in some instances the angle of gaze indicates the target direction for the hand, and in other cases hand movement affects eye movements.

Studies of eye–hand coordination in naturalistic settings confirm the importance of eye information for guiding hand movement. For instance, during tea making, in spite of the constellation of targets in the visual scene, the eyes always move to the object that will be manipulated, leading hand movement by about half a second; in addition, the eyes often move to a new location before the manipulation of the first object is completed so as to control the state of important variables such as the level of water in the teapot, the level of sugar available, and so forth.

Reaching to Moving Objects: The Neural Basis of Interception Movements

A different aspect concerns reaching to nonstationary targets, that is, interception of moving objects. To intercept a moving object, knowledge of where and when its impact with the hand will occur is essential. Temporal estimations for interception can be achieved as hypothesized by the τ model; that is, an interception movement begins when the ratio between the retinal size of an approaching object to its rate of change reaches a critical (τ) threshold. A more comprehensive formulation of this theory generalizes the model to movement control under virtually all conditions and redefines τ as the time to closure of the gap existing between the effector and the target, at the current gap closure rate. It is worth stressing that a common type of interception consists of catching free-falling objects. Studies in humans have suggested that during this task, the brain uses an internal model of gravity that takes into consideration not only the object's velocity, but also its gravitational acceleration. However, interception of a moving target on a video monitor, therefore with no real mass to interact with, occurs assuming a nonaccelerated motion, even when motion is accelerated.

Encoding Arm Movement by the PPC

General Properties of Parietal Reach Neurons

The study of the relationships between neural activity and arm movement in the PPC began in 1975 with the seminal study by Mountcastle and his collaborators. In area 5 of the superior parietal lobule (SPL) and area 7 of the inferior parietal lobule (IPL), they described the properties of a population of neurons that were active with purposeful projection of the arm toward targets of interest located within the immediate peripersonal space. These neurons ceased to fire if targets were moved out of reaching distance or when the animal was making an arm movement in absence of a specific motivation (i.e., reaching for food if it was not hungry, or for water if it was not thirsty). These reaching neurons were far less active or totally silent during passive arm movements imposed on the animal by the experimenter or during passive manipulation of skin, joints, and deep muscle receptors. Thus, the main feature of reaching neurons emerging from these early studies was the conditional and context-dependent nature of their activity, characterized by a nonobligatory relationship with arm movement. Subsequent studies, in line with those originally made in primary motor cortex, have demonstrated that the activity of reach neurons in both SPL and IPL varies in a broad fashion with direction of arm movement and that encoding of movement direction resides in a population code. Similarly, reaching neurons in PPC are influenced by arm position and by the visuospatial signal concerning target location in space. It is interesting that the activity of most parietal reach neurons is also influenced by the position and movement direction of the eye. This modulation by combined eye–hand information can be observed during reaction time and movement time of fast reaching, as well as during the delay interval occurring between the presentation of a visual signal instructing the animal about the direction of the future movement (or the location of a memorized target) and the onset of movement. Reaching-related activity in SPL is influenced by binocular eye vergence signals and is therefore well suited for encoding reaching distance in 3-D space. Therefore, the main feature of parietal reach neurons is their combinatorial nature. An example of this is offered by the different influence and weight of eye and hand signals on neural activity. On this basis, three main classes of combinatorial neurons have been identified in the IPL (Figure 2): hand-dominant, whose neural activity is mostly determined by hand signals; eye-dominant, whose activity is mostly influenced by eye signals; and eye–hand cells, with neural activity equally influenced by eye and hand information.

There exists a fundamental difference between the directional tuning properties of neurons in the SPL and IPL. In the former, the preferred directions of individual cells, obtained from different epochs of

Figure 2 Combinatorial cell types in area 7a. Spike density functions (SDFs) of neural activity for three different cells, each studied during eye movement (green), hand movement (blue), and coordinated eye–hand movement (red) tasks. SDFs are aligned to the go signal (vertical interrupted line). From Battaglia-Mayer A, Mascaro M, and Caminiti R (2007) Temporal evolution and strength of neural activity in parietal cortex during eye and hand movements. *Cerebral Cortex* 17(6): 1350–1363.

different tasks, cluster within a restricted part of space, the global tuning field (Figure 3), an ideal visuomotor frame to dynamically combine eye and hand signal in a directionally congruent fashion, and therefore a possible substrate for eye–hand coordination, in its many different forms. In IPL, instead, only 25% of the cells display a global tuning field, and neuronal activity seems more intensely modulated when the hand moves toward the fixation point, therefore in a more selective form of eye–hand coordination than those apparently subserved by the SPL. At the population level, in the SPL, the distribution of the eye–hand preferred directions computed during different epochs of different tasks covers the directional continuum in a uniform fashion, whereas in the IPL it is highly skewed toward the contralateral space (Figure 4).

Understanding Actions and Motor Intentions by Parietal Neurons

There are action sequences that, although characterized by the same basic movements, have different goals, such as when one reaches out to grasp and eat an apple or to place it in a box. In the monkey IPL, a class of parietal neurons discharges differently

Figure 3 The global tuning field (GTF) of two parietal neurons. When eye and/or hand movements are made in eight different directions under different task conditions, the preferred directions (colored arrows) of individual parietal neurons cluster within a limited part of space, referred to as GTF. In each GTF, the thick dark grey arrow indicates the mean vector (MV), that is, the orientation in space of the neuron's tuning field. The length of the MV is directly proportional to the sharpness of the tuning field. Thus, the GTF of the cell on the left is sharper then that on the right. Yellow refers to a saccadic eye movement task (MTe, eye movement time; THTe, eye target holding time), red to a combined eye–hand movement task (RTh, hand reaction time; MTh, hand movement time; THTeh, combined eye–hand holding on target), blue to a hand movement task requiring central fixation (MTh, hand movement time; THTh, hand holding on target), green to an instructed delay task that separates eye from hand movement in time. This task was performed in light (light green) and dark (dark green) condition (RTe, MTe, eye reaction and movement time, respectively; RTh, MTh, hand reaction and movement time; Del indicates the delay period, when the eye is on the target and the hand is preparing to move; THTeh refers to combined eye–hand holding on the target). Modified from Battaglia-Mayer A, Ferraina S, Mitsuda T, et al. (2000) Early coding of reaching in the parietooccipital cortex. *Journal of Neurophysiology* 83: 2374–2391.

Figure 4 Spatial orientation of the mean vectors of the global tuning field of neurons in (a) the superior parietal lobule (SPL) and in (b) the inferior parietal lobule (IPL). Notice the uniform distribution of the mean vectors in SPL, while in IPL they point mainly toward the contralateral part of space (mean vector of the distribution points to 6°), relative to the hemisphere (left) of cell recording. In (b) the red arrow indicates the mean vector of this distribution. Modified from Battaglia-Mayer A, Mascaro M, Brunamonti E, and Caminiti R (2005) The overrepresentation of contralateral space in parietal cortex: A positive image of directional motor components of neglect? *Cerebral Cortex* 15: 514–525.

depending on the monkey's action goal. These neurons, located in area PFG, also discharge differently when the monkey observes the experimenter performing the same motor sequence with different goals. It has been hypothesized that these parietal mirror neurons encode the agent's motor intention and, therefore, are part of a network involved in motor intention and action understanding. This network involves the area PFG and ventral premotor area F5 (Figure 1).

Parietal Mechanisms for Online Control of Hand Movement Trajectory

Human and nonhuman primates are able to make fast online correction of hand movement trajectory if the visual information that guides movements is changed, such as when the target location is suddenly displaced. In such circumstances, the human or other primate will not reach the first target but will produce a curved trajectory toward the new target location (Figure 5(a)). Movement can also be corrected when the human or other primate is not aware of the shift in target position, that is, during an ocular saccade, or when vision of the arm is occluded, as well as in deafferented patients with loss of proprioception in all four limbs. It has been hypothesized that to perform online corrections, the brain might use a feedback mechanism based on motor outflow, as well as sensory information, such as retinal error.

In humans, transient inactivation of PPC function by transcranial magnetic stimulation (TMS) interferes with the ability to perform fast correction of hand movements when the target location changes in space and prevents learning of a new dynamic if reaches are made in a velocity-dependent force field. Lesion of the PPC leads to optic ataxia (OA), a difficulty of visual control of arm movements. A case report of one OA patient with bilateral PPC lesion documents the patient's marked inability to produce smooth corrections of hand trajectory in response to a sudden change of target location in space (Figure 5(a)).

So far, only a few cell recording studies have been devoted to the activity of cortical cells during online movement corrections. In the primary motor cortex, neural activity is influenced by signals about the change of movement direction to a visual target, consisting of a truncation of the discharge pattern typical of the movement to the first target and of its replacement by a discharge pattern associated with the

Figure 5 (a) When a visual target jumps from its original position, A, to a new location, B, during arm reaction or movement time, normal participants smoothly correct their hand movement trajectory (red broken line) from A to B, while parietal patients are incapable of this in-flight correction and complete the movement to the first target before directing the hand to second one (red continuous line). Blue and green lines are trajectories of direct movement to A and B, respectively. (b) The neural activity of a parietal neuron during a similar change of hand trajectory due to a jump from target 1 to target 8 and vice versa (gray sphere at the center of the cube is the origin of hand movement). Both the neural activity (shaded gray curves) and the hand velocity signal (solid black curves) are aligned to the beginning of hand movement (vertical dashed line). The triangles indicate the time of target presentation, and the thick horizontal lines correspond to periods of eye movements. Neural activity was modulated with the direction of hand movement and was correlated with hand velocity, leading it by an average of 65 ms. Note the presence of a double peak in the neural activity, preceding the two peaks in the hand velocity profile. Hand paths for target 8 to 1 are depicted inside the cube. This cell was not active in an eye control task (not illustrated). Modified from Battaglia-Mayer A, Archambault PS, and Caminiti R (2006) The cortical network for eye-hand coordination and its relevance to understanding motor disorders of parietal patients. *Neuropsychologia* 44(13): 2607–2620.

Figure 6 (a) Egocentric coding of target and hand position within a spherical coordinate system by neurons in parietal areas PE and PEa (superior parietal lobule). Azimuth is indicated by the angle χ, elevation by ψ, distance by φ or by the length of segment ρ. (b) Monkeys were trained to point to a visual target (violet) by making movements of constant amplitude from one of three different starting points (yellow) in one of eight possible directions. Targets denoted by pairs of numbers (e.g., 2, 11) could be reached from two different starting points. Each neuron is best tuned to the changes in one spatial coordinate of the target relative to the body: in (c) to the azimuth (neural activity increases monotonically from right to left); in (d) to distance (the closer the hand, the greater the activity); in (e) to elevation (increasing with downward movements). The wire frames correspond to the three workspaces depicted in (a), with the corners indicating the position of the wrist relative to the monkey at the end of the movement to the corresponding target. Red bars denote the activity averaged during movement time; green bars, the activity predicted by a linear model of final wrist position in shoulder-centered spherical coordinates. Modified from Lacquaniti F, Guigon E, Bianchi L, Johnson PB, Ferraina S, and Caminiti R (1995) Representing spatial information for limb movement: The role of area 5 in the monkey. *Cerebral Cortex* 5(5): 391–409.

movement to the second target. Motor cortex is linked to SPL areas both directly and indirectly through dorsocaudal premotor cortex. In humans, during sensorimotor adaptation, the perturbation of premotor cortex activity through TMS results in a reduction of online corrections of reaching dependent on vision. The information used by motor cortex for online control of hand movement trajectory originates, at least in part, in the SPL. Here, cell activity has been studied in alert monkeys trained to make regular reaches, as well as quick corrections of hand movement trajectories, in response to a sudden jump of a visual target in 3-D space (**Figure 5(b)**). After target jump, while the eye completes the saccade to the first target and then moves to the second one, the hand smoothly changes its movement trajectory to the first target and moves toward the second one. In spite of absence of any difference in the early phase of movement trajectory in the perturbed versus the nonperturbed trials, target jump promotes an early change of neural activity in a good proportion of SPL cells. Such change, predictive of the future correction of movement trajectory, mainly influences the activity of a population of parietal neurons encoding hand tangential velocity (**Figure 5(b)**). These neurons change their firing frequency in a way that leads by a variable time the abrupt change in hand velocity occurring shortly before the change of trajectory. Some of these cells, as well as other parietal neurons in the SPL, also fire after the change of direction, suggesting that in PPC predictive signals coexist with feedback information concerning ongoing movement. Thus, parietal neurons can control and promote fast changes of hand trajectory at all times during arm movement.

Coordinate Frames for Reaching in the PPC

An approach inspired by the results of psychophysical studies in humans has shown that SPL in monkeys can be the substrate for an egocentric representation of hand position and movement since its neural activity is tuned in a body-centered reference frame, whose coordinates defined the azimuth, elevation, and distance of the hand relative to an origin centered on the shoulder or on the eyes (**Figure 6**). The analysis of neural activity through multiple-task approaches favors the existence of allocentric representations of reaching in the most caudal part of the SPL. Other studies suggest that encoding reach plan in PPC

occurs in eye or in hybrid eye–hand coordinates and that a direct transformation between these frames might occur. During copy tasks, encoding of movement seems to occur in hand coordinates. Thus, multiple representations of reaching have so far been described in PPC. It is believed that the exact nature of these representations is task-dependent.

Parietal Cortex and Interception of Moving Targets

The cortical mechanisms of interception have been studied in parietal and motor cortex of alert monkeys trained to intercept targets moving circularly with real or apparent motion or to remain immobile during target motion. It was found that the activity of most parietal cells was influenced by the direction of stimulus motion and acceleration and by the time elapsing between the target onset and its arrival and the interception point, that is, target motion time. Neural activity types dependent on the stimulus motion predominated in parietal area 7a, and those linked to hand movement were more common in the motor cortex. Decoding of spike trains showed that embedded in area 7a's neural activity is a signal concerning the target position in real and apparent motion conditions. This signal is important for initiating an interception movement. A population of cells was found to be task-specific, being activated during interception of moving targets, and not during movement to stationary target. Therefore, the distributed system underlying interception in the primate's cerebral cortex consists of gradients in which different neural activity types relevant to the task are represented at all nodes of the network, although with different strength.

For one to better understand the neural mechanisms of reaching to moving objects, knowledge of how different types of object motion influence neural activity is essential. Optic flow exerts a significant influence not only, as already known, on PPC but also on motor cortical cell activity, with expanding flow fields as the most effective stimuli in driving neural activity. In area 7a the proportion of cells sensitive to visual stimuli is higher than in motor cortex, while in the latter the sensitivity to expanding flow fields is twice that in PPC. This type of optic flow provides information about the direction of an object moving toward an immobile observer and can also be useful when self-motion and object motion interact, such as when avoiding obstacles or intercepting visual targets during locomotion. Parietal cells sensitive to optic flow do not display sensitivity to radial motion of objects moving toward or away from the fovea. Thus, encoding of object motion in the PPC might reside on separate parallel mechanisms, segregated in different populations of neurons, one based on optic flow information and related to global motion, another on opponent vector organization and mostly devoted to local motion analysis.

Finally, concerning the above-mentioned hypothesis that interception is based mostly on an internal model of gravity, functional neuroimaging indicates that the gravitational acceleration in visual motion is encoded within a distributed network centered on the so-called vestibular parietotemporal cortex. This information probably influences the motor cortex through the premotor areas of the frontal lobe.

Multiparametric Encoding of Arm Movement Variables by Parietal Neurons

In the SPL, the study of the time-varying correlation of neural activity with different arm movement parameters has shown a significant correlation with movement direction, position, amplitude, velocity, and acceleration. Velocity encoding has also been described for slow continuous movements, such as those required in a copy task. The question of whether neural activity in PPC relates to movement kinematics only, or to movement dynamics as well, has long been debated. In the SPL, cell activity seems invariant to external loads applied to the limb, suggesting that this part of PPC is a central node of the network involved in encoding arm movement in kinematic terms. In the IPL, reaching-related activity is broadly tuned to arm movement direction and position.

The Temporal Relationships between Neural Activity and Arm Movement in Parietal Cortex

The temporal relationships between neuronal activity and behavioral events can shed light on the role and position of PPC in the chain of events leading from target localization to arm reaching, in other words, from vision to movement. It is generally assumed that neural activities leading movement onset can reflect the motor command, while those occurring around and after movement initiation reflect corollary signals and/or the sensory feedback from the moving arm.

In the majority of cells of both the SPL and IPL, neural activity precedes arm movement onset (**Figures 7(a) and 7(b)**) by a variable time, and a good proportion of cells fire around or during movement. When the same cells are studied during the saccade that brings the eye on the target, in the SPL most of them show a presaccadic nature, but in the IPL they fire after the saccade, thus reflecting an eye position signal. In both the SPL and the IPL, an intriguing result emerges when the population activities relative to eye, hand, or coordinated eye–hand movement are aligned to a common behavioral event, such as

Figure 7 Temporal relationships between neural activity and arm movement in posterior parietal cortex. (a), (b) Distribution of onset times of neural activity relative to hand movement in superior parietal lobule (SPL; (a)) and inferior parietal lobule (IPL; (b)). Vertical broken lines indicate the beginning of hand movement. Percentages in brackets indicate the proportion of cells firing before the onset of hand movement. Thick horizontal bars below the x-axes refer to the beginning of reaction time ± standard deviation. (c) Population spike density functions (PSDFs) of SPL neurons during coordinated eye–hand movement (red), hand movement (blue), and eye movement (green) tasks. (d) PSDFs of IPL cells during coordinated eye–hand movement (red), hand movement (blue), eye movement (green), and in a no-go condition (yellow), in which no movement was required. In (c) and (d), the vertical lines indicate, from left to right, median values of beginning of eye movement time (MT; broken green line, in (c) at 150 ms, in (d) at 164 ms), end of eye MT (solid green, in (c) at 229 ms, in (d) at 188 ms), onset time of hand movement (broken blue line, in (c) at 265 ms, in (d) at 324 ms), end of hand MT (solid blue, in (c) at 400 ms, in (d) at 613 ms). Therefore, the two green lines encompass the median value of the duration of eye MT, and the two blue lines, the median value of the duration of hand MT. In (c) and (d), PSDFs are aligned to the presentation of the visual target, serving in both cases as the go signal for movement. Modified from Battaglia-Mayer A, Mascaro M, and Caminiti R (2007) Temporal evolution and strength of neural activity in parietal cortex during eye and hand movements. *Cerebral Cortex* 17(6): 1350–1363.

the go signal for movement (Figures 7(c) and 7(d)). In such instances, the relative curves display a common temporal evolution and peak, with SPL activity peaking at about 200 ms after go signal (Figure 7(c)), and IPL activity at about 400 ms (Figure 7(d)). In the latter, no activity is observed during a no-go task, which requires no future eye and/or hand movement. Thus, at the population level, parietal neural activity seems to be largely independent of whether a specific effector, such as the eye or the hand or both, will move but rather signals that a movement will occur or is occurring. This temporal signal can represent a common clock that can be used for different types of actions involving the eye, the hand, or their coordinated movement in different order and time sequence. It is worth noticing that there exists a strong correlation between the timing, but not the errors, of eye and hand movement under different task conditions. Interfering with parietal functions through TMS disrupts the natural correlation existing between the amplitude of eye and hand movement during coordinated eye–hand actions.

Corticocortical Circuits Underlying Reaching: Architecture of a Distributed System

In the PPC, reaching is encoded by a multiplicity of cortical areas that, thanks to their reciprocal connections with the premotor and motor areas of the frontal lobe, define a distributed parietofrontal system. The parietal reach regions so far identified, with their

frontal connections, are shown in Figure 1. In each of them, neurons combine retinal, eye, and hand information. However, in the SPL, a gradient of functional properties characterizes these different areas. In the most posterior part of the network (areas V6A and 7m), retinal, eye position, and eye movement information predominate over coexisting hand signals. At intermediate rostrocaudal levels in the SPL (areas PEc, PEa, and MIP), retinal, eye, and hand information influences cell activity in a similar fashion, while at the rostralmost level (area PE), hand position and movement information dominates over coexisting eye influences. These SPL areas project to and receive from different premotor areas and from motor cortex itself. A similar, mirror-image gradient of functional properties exists in the frontal lobe, with parietofrontal connections linking regions displaying similar functional properties. Superimposed on this functional dimension is a second one, related to the nature of the information encoded in the network. Moving from posterior to anterior in the SPL, a transition from preparatory (set- and memory-related) to movement signals occurs. The opposite is observed across premotor and motor cortices. Cells encoding eye and/or hand position information are ubiquitous at all tangential locations of the SPL, so as to form a matrix on which preparatory and movement-related information is embedded and eventually selected on the basis of task demands. Eye and hand position signals are essential under virtually all conditions for planning combined eye–hand movements.

The functional architecture of the parieto-frontoparietal network imposes constraints on the nature of the coordinate transformations underlying visually guided reaching. In fact, this cannot be regarded as the result of coordinate transformations performed by each parietal area in its own private coordinate frame but is the result of a recursive mechanism in which different signals are selected and combined in a context-dependent fashion throughout the network and further elaborated locally, thanks to intrinsic connections.

Consequences of PPC Lesions on Arm Movements

For the properties and position of PPC in the distributed network controlling arm movements, and for its lack of projections to the interneurons and motor neurons of the spinal cord, damage to the PPC results not in primary motor deficits, such as paralysis, changes of muscle tone, and so forth, but in higher-order motor disorders, interpreted as consequences of the disruption of the parietal operations and of their interplay with the premotor and motor areas of the frontal lobe.

In the neuropsychological literature, two of the main arm-movement disorders described after parietal lesion are OA and directional hypokinesia (DH). The first is more common after lesion of the SPL, while the second is classically associated with damage of the IPL.

Lesions of the SPL: OA

In 1909, Rudolf Bálint first described OA as a key feature of a more general syndrome that was a consequence of a bilateral softening of the parietal lobe. As Bálint pointed out, OA produced a profound impairment of his patient's daily activities (Figure 8). In fact, "while cutting a slice of meat . . . which he held with a fork in his left hand, he would search for it outside the plate with the knife in his right hand" (Figure 8, top panel), or "while lighting a cigarette he often lit the middle and not the end" (Figure 8, center panel, left). Bálint pointed out the systematic nature of this disorder, which was evident in the patient's

Figure 8 Schematic drawing of the impairments typical of optic ataxia, as first described by Bálint in a patient with bilateral cortical softening centered on the parietal lobes. For explanations, see text. Original drawings by C Cardone.

behavior when reaching out in his peripersonal space. "Thus, when asked to grasp a presented object with his right hand, he would miss it regularly, and would find it only when his hand knocked against it" (Figure 8, center panel, right). The patient performance in the same tasks was normal when using the left hand (Figure 8, bottom panel), which excluded disorders of visual attention. Furthermore, in the absence of visual control, he could imitate with the right hand passive postures imposed on his left hand, and this excluded apraxic disorders. In Bálint's view, the disorder was specifically dependent on a defective visual control of movement, and he named it OA, in analogy with tabetic ataxia, which was a consequence of a defective somatosensory control of movement resulting from damage of the dorsal columns of the spinal cord. OA impairs not only visual reaching but also hand grip formation and prehension under visual control. In addition, OA patients suffer from a severe disturbance of the spatial and temporal characteristics of online visual control of movement. Corrective movements prompted by changes in target location are delayed, and hand movement trajectory does not show the typical smooth curvature that brings the hand to the new target's location. In these cases, the hand completes the movement toward the location where the target was first presented and then moves toward the new one (Figure 5(a)). Obstacle avoidance during reaching is also impaired. The task-dependent nature of OA is documented by the observation that it occurs during reaching or grasping for real targets, not when pantomiming hand grasping movement of memorized objects.

OA is consequence of bilateral or unilateral parietal lesions. In all instances, arm movement errors mostly occur in the peripheral visual field. Right parietal lesions result in misreaching with one or both hands in the contralateral visual field (field effect). Left parietal lesions cause misreaching with the right hand in both ipsi- and contralateral visual fields (hand effect). When lesions mostly affect the left SPL, or when a rapid correction of movement trajectory is required, OA is not confined to the peripheral visual field but also occurs in central vision.

Lesions of the IPL: Disturbances of the Action Space and DH

In general, the disturbances of the representation of action space in neglect patients is well evidenced by their motor behavior when requested to cross out with a pencil the local components of a global letter in the hierarchical figures of Navon (Figure 9(a)).

Figure 9 Movement disorders of patients with hemispatial neglect from right parietal lesion. The left part of the action space is ignored. (a) Performance when crossing letters forming the Navon figures. Reprinted by permission from Macmillan Publishers Ltd: *Nature* (Marshall JC and Halligan PW (1995) Seeing the forest but only half the trees? *Nature* 373: 521–523.), copyright (1995). (b) Records of eye movements during a visual search task in which participants are required to identify the letter T within a field of distractors. Reprinted by permission from Macmillan Publishers Ltd: *Nature Reviews Neuroscience* (Husain M and Rorden C (2003) Nonspatially lateralized mechanisms in hemispatial neglect. *Nature Reviews Neuroscience* 4(1): 26–36.), copyright (2003).

Under such conditions, while being able to correctly name both local and global components of the figure, thus showing no perceptual impairments, these parietal patients cross out only the local components in the right part of each global figure, ignoring those located on the left.

DH is the hallmark of arm movement disorders of neglect, with which it is generally associated, in patients suffering from right PPC lesions. DH consists of a prolongation of hand reaction time for targets in the contralesional space, especially those requiring arm movement with leftward direction. The disorder is diagnosed when the ispilesional arm is involved. DH is often accompanied by directional bradykinesia and hypometria, characterized by reduced velocity and amplitude of arm movement, respectively. In tasks requiring patients to reach at targets within a field of distractors, the hand of patients with neglect recursively points to the same targets in the right part of the space, as a consequence of the inability to update a motor program on the basis of previous movements. The same occurs when the search is performed through eye movements (Figure 9(b)). In neglect patients, similar disorders are also common in the oculomotor domain and consist of elongation of reaction time when the eye moves toward contralesional targets, reduced saccade amplitude, and eye movement trajectories characterized by a 'staircase' shape.

A Positive Image of OA and DH: Interpreting the Movement Disorders of Parietal Patients from a Physiological Perspective

The study of the dynamic properties of PPC neurons and of their relationships with the premotor cortex via corticocortical connections provides the basis for a positive image of the arm movement disorders of parietal patients. In fact, parietal neurons are influenced by different signals concerning planning and execution of eye and hand movement. A key feature of SPL neurons is their global tuning filed, that is, the invariance of their preferred directions across tasks requiring different spatial relationships between the eye and the hand during movement to visual targets. This spatial congruence of different signals might be regarded as the neural basis of eye–hand coordination. Furthermore, these neurons are part of a network richly interconnected with premotor and motor cortices. Therefore, the reaching disorders of patients suffering from OA is today interpreted as a consequence of the breakdown of the combinatorial mechanisms of SPL parietal neurons and of their interplay with premotor cortex.

In the IPL, one of the main spatial properties of eye- and hand-related cells is the anisotropy of the distribution of their preferred directions, mostly pointing toward the contralateral space. This anisotropy of the directional motor space might explain the difficulty in movement toward the contralateral space that characterize DH in patients with hemispatial neglect.

Introduction

Hands are the most frequently and dexterously used parts of our bodies. This is directly reflected in the disproportionately large representation of hands in the homunculi of the somatosensory and motor cortices. We manufacture and use tools with our hands. The hand is also the most extensively observed part of our own body. We look carefully at our fingertips when we manipulate objects. We look at a distant object and then extend our hand to reach and retrieve it under observation. And occasionally we explore space with our hands instead of using our eyes. Why are primates, especially humans, so intensely interested in their hands?

This article first focuses on the primate hand from the perspectives of its comparative evolution and unique functionality. Brain functions subserving manual behaviors are then discussed from an environmental point of view. Finally, the article considers how eye–hand coordination and the brain functions associated with it are essential for tool use.

The Evolution of the Hand as the Distal Extremity of the Forelimb

The hand is the distal extremity of the forelimb. First, let us consider the significance of this structure from the viewpoint of vertebrate evolution. Forelimbs are thought to originate from the pectoral fins of fish, although this view remains somewhat controversial. With some assistance from other fins, the pectoral fins are responsible for locomotion in fishes – swimming. Later in vertebrate evolution, amphibians and reptiles moved onto the land. Here, fins evolved into limbs to support their bodies against gravity and created the impulsive locomotive forces that enabled these animals to walk forward. In birds (and *Chiroptera*), forelimbs became wings, but they still had a locomotive function – flying. Finally, the major functions of limbs retained for most animals, including most mammals, were those for supporting and moving their bodies in their habitats. Thus, during the entire course of vertebrate evolution, the hands were merely the distal ends of the forelimbs, forming an interface that effectively interacts with the surface of the environment through which the animal moves. Some hands have thin webs of skin between the fingers to move water or have sharp nails at the ends of fingers to scratch and grip the soil, and still others have fluffy feathers for flapping through the air.

In these vertebrate ancestors, forelimbs have always been attached either underneath or at the sides of the trunk, the most effective locations for their primary antigravity and locomotive functions. Thus, limbs were never previously positioned in front of the face, so that these animals never, or rarely, were able to observe their hands. Hence, the control of the forelimb and hand relied exclusively on somatosensory feedback, without visual information for monitoring their motion.

However, primates evolved with dramatic changes to their forelimbs and hands. In order to adapt to the arboreal environment, primate limbs became greatly elongated compared with their trunk, enabling them to efficiently reach for branches. In addition, their hands became enlarged, with flat nails at the fingertips for more secure grasping. Accurate control of the hands as they reached for and gripped branches required that their location and shape in space had to be monitored and confirmed. The hands, at the distal extremities of the elongated forelimbs, had to be constantly moved to positions exactly in front of the face, to bring them under precise spatial control at the center of the visual field.

Eye–Hand Integration in Primates

The primate hand continued to evolve from its original functions in quadrupedal locomotion. In addition to the precise visuomotor coordination of hand and arm movements needed for locomotion in the arboreal habitat, the hand in primates developed an opposing thumb for firmly grasping branches that were visually identified and targeted.

In order to establish the visual functions required for precise reaching and grasping, vision evolved in parallel with the hand. Paired eyes that had been located on the sides of the head in earlier mammals were now on the front of the head and faced forward. This gave primates binocular vision, due to the largely overlapping visual fields of the two eyes, making precise analysis of depth information possible. Binocular vision may have evolved less in other species because it was beneficial for them to secure wider, less overlapped visual fields in two eyes located on each side of the skull. Exceptions to this tendency are the carnivores and raptors that hunt for prey. These animals are different from primates in that

they reach their prey, not by extending their forelimbs, but rather by locomotive jumps.

The hands and visual systems of primates have thus been refined through evolution for coordination, resulting in the emergence of further unique features. Flexible supination and pronation of the forearm allow primates to position the palms of their hands, which are on the bottom surfaces of the limbs, in front of their eyes. Thus, the subtle space structured by precise finger and opposing thumb manipulations is manifested at the center of the binocular visual field, which, with its maximal spatial resolution, is capable of analyzing fine, three-dimensional (3-D) structures. With this visuomanual coordination, abundant somatosensory information about hand–finger shapes can be subjected to visual confirmation. Somatosensory feedback from the hand must originally have contributed to the precise control of locomotive effectors. Moreover, by linking its functioning with vision, the hand has become capable of exploring space through its own sensations – the whole hand has become a sensory organ. Hence, we grope with our hand and thereby feel the shape of space. Alternatively, we can confirm, verify, and inspect visually perceived spatial structures by motor and tactile information acquired through moving the hand and fingers across their surfaces. Primates have now acquired, through eye–hand integration, a flexible, precise, cross-modal (visual plus somatosensory) map of space. This function, never previously possessed by any nonprimate species, reaches its highest level of elaboration in humans.

Somatosensory Traces of Hand Shape

Somatic sensory information about postures, locations, and movements of the hand is detected through millions of receptors distributed throughout the skin, joints, muscles, and other tissues. Each of these receptors responds to a specific physical energy, namely, an adequate stimulus to its receptive fields. Detected information is transformed into sequences of nerve impulses that are conducted through peripheral nerves and specific ascending pathways in the central nervous system. The trains of nerve impulses, without much modification, reach the primary somatosensory cortex (S1), located at the postcentral gyrus occupying the most anterior part of the parietal cortex. The S1 is somatotopically organized. Tactile information is projected onto Brodmann's Area (BA) 3b, whereas joint and proprioceptive information projects onto BA3a. Thereafter, with hierarchical, intracortical processing, these information fragments are integrated and transformed until they gradually become meaningful.

The response properties of BA3 neurons are generally robust and with sharp contrast, resembling those of the primary afferents that innervate their respective receptors. The receptive fields are small, and the submodalities of adequate stimuli (e.g., light palpation, joint displacement, flutter, or vibration) are simple and clear. Hence, the shape or posture of the entire hand could never be estimated merely by observing these simple neuronal responses.

Shifting toward the posterior S1 areas BA1 and BA2, neuronal response properties gradually become complex: receptive fields are larger, with multiple submodalities of adequate stimuli, as if by the gradual convergence of the elementary BA3 responses. Integration in the posterior BA2 is more complex than a summation of elements, characterized by the extraction of spatiotemporal patterns that represent characteristic features of the stimuli across wide areas of the skin surface of the hand. They detect, for example, the orientation of edges, the surface texture of objects being touched, or the direction of their movements. Posterior BA2 neurons also code particular dynamic shapes of the hand and fingers, such as scratching, pointing, or picking. Further, some neurons respond only when the hands are actively touching an object, not when being touched by the object. The function of the latter class of neurons may be to verify the sensations caused by the movement of one's own hands.

In these posterior S1 areas, neuronal response properties become less well contrasted, less robust, and less stable. In the anterior bank of the intraparietal sulcus (IPS), including BA5/7, response properties are particularly difficult to characterize. The somatosensory responses of some of these neurons can be influenced by attentional states or by intervening visual stimuli. There are neurons in the finger region of the anterior IPS area with bilateral receptive fields, via transcallosal interconnections. The receptive fields of these neurons are always strictly symmetrical. These receptive field properties cannot be explained by bottom-up mechanisms, suggesting influences from images about the shape of the hands, perhaps by feedback from higher areas of the association cortex.

Thus, as a result of S1 hierarchical information processing, integration with visual information about the location and shape of the hand should be readily prepared at the gateway to the parietal association area so that the functional representation of hand shape can be generated. Indeed, in the arm region of the parietal BA5 that is posteriorly adjacent to the S1 exist neurons that respond when monkeys assume particular arm postures, when they touch particular parts of the body with their own hands, or when the monkeys watched these actions.

Examination of the Visual Space at Hand

Visual information is first captured by retinal cells, pixel by pixel, and then projected via the medial geniculate nucleus in the thalamus to the primary visual cortex, at the posterior end of the cerebrum. The hierarchical processing of this information then proceeds forward in the cerebral cortex. The part of the visual system relevant to this review is the spatial information processing that takes place along the dorsal stream. To understand the relationships between self and external spatial structures, the processing of optical-flow information that deals with self-motion in space and the processing of 3-D depth information about the nearby space are both crucial. These abilities are well developed in primates to subserve arboreal locomotion using hands, as described above.

How does one perceive oneself moving in space? When something moves in space, the image of that object in the visual field moves. When one looks around, the whole visual image moves. The visual image, however, exhibits peculiar flowlike movements when one moves in space. Thus, in order to analyze our own 3-D movements in space, optical flow information from the wider visual field is needed. Neurons that code optical flow are first found along the dorsal stream in the middle temporal area (MT/V5) of the extrastriate cortex at the temporoparietal junction region in monkeys. However, because receptive fields of these MT/V5 neurons are generally small, the information carried by these neurons is not sufficient for analyzing self-motion.

The medial superior temporal (MST) area is adjacent to and receives direct projections from MT/V5. The receptive fields of MST neurons sensitive to optical flow are large and cover most of the visual field. Rotating movements in 3-D space with changes in depth information can also drive MST neurons. Similar response properties are observed in the ventral intraparietal area (VIP), at the fundus of the IPS. The VIP receives direct inputs from the MT/V5 and integrates these inputs with facial somatic sensations to represent movements in space relative to the face. Considering that the lower half of a monkey's whole visual field is occupied by its own face, these neurons could code self-motion by integrating motion relative to the face and environmental space, using the face as a reference point. Vestibular information also reaches the MST area and the VIP, perhaps contributing to the perception of self-motion in space.

Gross depth information based on optical flow information alone is insufficient for the precise analysis of 3-D structures in nearby space. Detailed 3-D analyses require the binocular parallax information that is generated by two forward-facing eyes. The caudal intraparietal area (CIP), the visual area that possesses neurons specialized for binocular analyses, receives input from V3A. CIP neurons code special 3-D information about features such as slope, depth, and curvature that represent the precise characteristics of the shapes of 3-D objects in the visual space of the hands. Neurons in V3A are also parallax sensitive, but their receptive fields are small and thus probably do not integrate overall shape discrimination in the central visual field. This resembles the relationship between MT/V5 and MST neurons, as described above.

Before bipedal locomotion evolved in humans, primates were able to sit, which freed their forelimbs for executing delicate handwork such as grooming. In doing so, primates position their hands and fingers just in front of their faces, where binocular vision has the highest resolution. There they rotate their hands by supination and pronation of the wrist and shape the fingers and opposing thumbs in a most efficient way. Thus, the evolution of primates has produced the dexterous hand, the delicate binocular eyes, the brain circuitry for processing detailed visual information, and the ability to precisely control hand and finger movements.

Adjustment of Hand Shape with Spatial Structures

In the primate brain, somatosensory and visual information about the hand is thus prepared across the IPS for the formation of cognitive maps of hand shape in space. One aspect of this predominantly visual process occurs in the anterior intraparietal area (AIP) on the posterolateral bank of the IPS, a posterior extension of the area of S1 finger representation. Neurons in the anteromedial bank that faces the AIP across the IPS code particular combinations of shapes of the hand and fingers, but they only sparsely integrate that representation with visual information, in naïve monkeys.

AIP neurons code hand shape when monkeys perform tasks involving precise finger actions such as pinching tiny 3-D knobs or picking up tiny objects from variously shaped small holes. In these experiments, target objects were first shown to monkeys in the light, and then the monkeys were asked to reach for and manipulate these objects either under light or in the dark. AIP neurons discharged when monkeys (1) performed hand and finger actions either in the light or in the dark, but not when just watching the target (motor-dominant neurons); (2) watched the target and executed actions under the light and, though much weaker, even in the dark (visuomotor

neurons); or (3) observed the target or made actions in the light but not in the dark (visual-dominant neurons). These neurons may contribute to shaping the hand prior to actually grasping a target, namely, preshaping. Indeed, patients with damage to this parietal region have difficulties in preshaping while reaching. If activity in this area is blocked by an injection of muscimol (a γ-aminobutyric acid agonist), monkeys are unable to make preshaping movements.

Visual-dominant AIP neurons fire when monkeys look at an object but do not make any actual hand movements. This property resembles the responses of CIP neurons to particular 3-D objects, as described above. Hence, the CIP processes precise 3-D information about objects, and this transformed information is in turn sent to the AIP through its strong, direct projections. Here it is integrated with somatosensory information processed backward from the S1 to match the hand shape to the 3-D shapes of objects that will be grasped with the hand. An efference copy for making hand actions from the ventral premotor area (PMv), through its strong mutual connections to the AIP, may also contribute to this process. Neurons exist in the AIP that appear to memorize the hand shape needed to grip a particular object. The activities of these neurons are sustained during a delay period of several seconds after the monkey has observed the object to be grasped, perhaps coordinating the memory of the shapes of the object and the hand. Thus, visual, somatosensory, and motor information regarding hand shape is integrated in this AIP area in a visually dominant way, with the visual analysis of spatial structures matched and verified through the hand and finger actions needed to trace them.

Optimization of Hand Shape for Tool Use

The ability of the brain to adjust the shape of the hand and fingers to the shape of the object to be manipulated, as described above, is very important when humans attempt to hold and use a tool with the hands. Functional imaging of the human brain reveals that intraparietal areas, including the AIP area described above, are activated when humans see the tool they intend to use, suggesting that humans automatically bring to mind the shape and meaningful hand and finger actions needed to use it. Other cortical areas also commonly activated include the PMv and the superior temporal sulcus area. It is suggested that the PMv represents the actual hand actions needed for tool usage, whereas the superior temporal sulcus represents the semantic meaning of the tool function. Thus, if the brain apparatus for matching hand shape to representations of spatial shape already existed in lower primates, humans could easily adapt these mechanisms for effectively grabbing and using external objects as tools.

Plasticity of Parietal Hand Representation on Tool Use

The mechanisms described above imply that a tool is represented in the parietal cortex through the shape and actions of the hand using it. But is this all there is to it? When we use a tool, it is not just an external object *per se*: we regard it as an object incorporated into part of our body, the externalized hand. The tool becomes a part of the body, but one that lacks direct somatic sensations. The visual appearance of the body, with the tool, must be transformed into a somatosensory representation of the body, in contrast to the AIP, where the visual image of the space is adjusted by the somatosensory representation. In monkeys trained in tool use, that transformation appears to take place in neurons situated in part of the parietal cortex close to somatosensory regions, on the anterior bank of the IPS that faces the AIP across the sulcus. This area is the posterior extension of the S1 forearm representation.

Macaque monkeys do not use tools spontaneously in nature, but they can be trained over a period of about 10 days to use a rake to retrieve distant food items that are beyond the reach of their arms. In naïve monkeys prior to training, only sparse visual inputs were found in the part of the anterior bank of the IPS discussed above. But after tool-use training, bimodal neurons that respond to both somatosensory and visual inputs were found. These neurons appeared to code the image of the hand in space, with the visual receptive field encompassing the somatosensory receptive field. When the latter moves by hand movement, the former follows accordingly.

When a monkey uses tools, these visual receptive fields extend along the axis of the tool to include the tool. This is as though the functional and internal introspection by the monkey using the tool has resulted in the extension of the representation of the distal forearm to incorporate the tool as part of the arm. The brain may do this by matching its representation with the visual appearance of the newly acquired functional forearm. This incorporation of the tool into the mental body image was never induced in monkeys that did not use the object as a tool, even though monkeys were physically holding it. Thus, it is not merely a representation of a material feature of the body but represents a cognitive map of the internal and external space, integrated in a manner

that reflects the mental image of the body shape with respect to its functional significance.

When humans play video games or use teleoperator apparatus with a TV monitor, they experience the introspective projection of their body image onto those appearing on the monitor. Thus, humans accept that the body image projected onto the monitor is part of themselves, in spite of its separation from them. Monkeys have also been successfully trained to perform an action, and even to use tools, by relying only on the image projected on the monitor and without directly viewing the image of their hand. During these behaviors, the visual receptive fields of IPS bimodal neurons, described above, became responsive to the image on the monitor, encompassing the projected image of the hand, including tools if tools were used. When images of the hand (and tools) in the monitor were expanded, shrunk, or dislocated by video effects, the visual receptive fields in the visual space of the monitor changed to match the modified images in the monitor. Thus, somatosensory images of the shapes of the body are not fixed but can be extended to include information presented on the monitor, even though these images are discontinuous and projected some distance from the body. Further, the shapes can be transformed to match an artificially modified visual appearance. These representations are found in the intraparietal cortex.

Plasticity of Parietal Space Representation with Tool Use

In the AIP, neurons match the precise shapes of 3-D space with the shape of the hand. When the shape of the arm and hand is functionally altered by holding a tool, this integration must change accordingly. When the monkey holds to use a rake, the rake becomes an extension, not of the hand itself, but of the functional length of the forearm. Indeed, the bimodal activities in the area posteriorly adjacent to the S1 area of the forearm representation, as mentioned above, were established by training. Thus, the change in the spatial representation produced by holding the rake should include the space reached and explored through forearm movements. This change in the spatial representation was found in the bimodal neurons in that same anterior IPS region.

IPS bimodal neurons with somatosensory receptive fields located on the proximal part of the body (shoulder, neck, or face) had visual receptive fields that covered the reaching distance. Before tool use, the visual receptive fields of these neurons covered only the areas within the reaching distance of hands, whereas after tool use, they expanded to include the extra distance that could be reached by using the tools. Thus, this location appears to contain a process that functionally recalibrates the perceived space, taking the shape of one's own body as a reference. This coding of near versus far space is being studied in brain-damaged patients (particularly those with damage to their parietal cortices). These patients exhibit retardations of body image and peripersonal space, also the phenomena typically observed in patients with somatosensory–visual cross-modal extinction.

Expansion of the Hominid Parietal Cortex in Evolution with Dexterous Tool Use

Higher primates have larger brains than other animals. Which parts of the brain have expanded? In lower mammals such as rodents, the primary cortices occupy most of the cerebrum. In the lower primates, perhaps due to the dramatic improvement in the visual system, especially with binocular vision, the primary visual area expanded first. This expansion was followed by the expansion of the anteriorly adjacent parietal association cortex required for visual processing. The prefrontal cortex emerges, yet remains tiny at this evolutionary stage. Then, with the evolution of the hominids, the next expansion in the cortical area was typically of the parietal cortex, as determined from comparisons of the endocast brains from primitive hominid skulls with the brain of the chimpanzee. At the same time as this parietal expansion, hominin ancestors successively invented various kinds of tools. Whether tool use itself triggered the expansion of the parietal cortex, however, is not known.

During weeks of training in tool use in monkeys, normally weak visual inputs in the IPS area became more evident. The coding of the shape of the body image is modified to include the tools. Corresponding to this phase of training, immediate early genes and neurotrophic factors are expressed in this brain region. Rich arborization and extensions of axons that project onto this area, together with synaptogenesis, are induced. These axons originate from the area of the temporoparietal junction, in the vicinity of the MT/V5 or MST area. This enhanced projection may contribute to the perception of spatial motion relative to the hands, equivalent to the VIP coding in relation to the face, as argued earlier. Hence, demand by tool use may have induced the enlargement of the parietal cortex. In monkeys, the morphological changes in this area could be induced by artificial demand, whereas in hominin ancestors, either there may have been mutational changes that automatically

induced this morphogenesis or the changes were more easily triggered during normal development. These mechanisms remain hypothetical.

Summary and Perspectives

The body structure of primates allowed them to place their hands (the distal extremity of the forelimb) in front of their face. From this position, 3-D structures could be precisely analyzed using precise binocular vision. Demand for such elaborate shaping of hands under visual supervision may have induced the expansion of the parietal cortex in primates. These mechanisms enabled higher primates to handle primitive tools, and then the tool use process *per se* may have triggered further expansion of the parietal cortex. This is the region of the cortex where not only somatosensory and visual inputs but also vestibular and auditory inputs converge. Therefore, it can be characterized as a multisensory cortex. Such parietal multimodal integration may not be limited to interpretations of represented shapes and the meanings of spatial structures. Humans express various conceptual ideas analogously to spatial processes. Humans also express the manipulation of those abstract ideas using the analogy of the body, typically by hand actions (the term 'manipulate' emphasizes this). Thus, the parietal processing of hand shape in space may be directly extrapolated to higher intellectual functions in humans.

Post-Polio Syndrome

E Farbu, Stavanger University Hospital, Stavanger, Norway

Introduction

The first description of new muscular weakness and atrophy several years after acute paralytic poliomyelitis (polio) was given by Raymond and Charcot in 1875, when they reported a 19-year-old man with new atrophy in his shoulder following paralytic polio in childhood. In the following centenary, paralytic polio was considered to be a three-phasic illness with acute muscle weakness, recovery, and a stable phase, and Charcot's observation was not investigated further until several reports of increasing muscle weakness emerged in the 1980s. A clinical description and definition were given by Halstead in 1985 and revised in 1991, and today we have increasing knowledge about the clinical course, possible etiologies, and clinical management. This article reviews the background, features, and management of post-polio syndrome (PPS).

Acute Paralytic Polio

The term poliomyelitis originates from the Greek words *polios* (gray), *myelos* (marrow), and the Latin suffix *itis* (inflammation) and refers to the specific localization of the infection in the anterior horn (gray matter) in the spinal cord. Acute paralytic polio is caused by infection of the poliovirus, which is enterovirus of the Picornaviridae family. There are three serotypes of polio viruses; they were first identified in 1931 and later named PV-1 Mahoney, PV-2 Lansing, and PV-3 Leon. It is believed that paralysis is most common with PV-1. The polio virus is an RNA virus in which the virion consists of a single-stranded RNA genome of positive polarity in a nonenveloped icosahedral protein capsid. In the majority of cases, an immunization with no clinical symptoms takes place, although 1% of the affected persons develop fever and signs of aseptic meningitis and flaccid paralysis. The virus attacks the motor neurons in the anterior horn of the spinal cord, which can cause flaccid muscle weakness if the inflammation is severe enough. The most common localization of weakness is in the lower limbs, but all levels of the spinal cord can be affected, including the upper cervical cord and brain stem, causing respiratory difficulties. A random distribution of the weakness is common.

During the large epidemics in the United States and Europe in the 1940–50s, the mortality rate was about 7%, mainly due to respiratory weakness. Sabin's oral and active vaccine and Salk's inactivated vaccine were introduced in the 1950s, and they were quickly implemented in the industrialized world. This led to a formidable reduction of polio epidemics, and new cases of paralytic polio diminished rapidly. Europe, Australia, and the Americas have now been declared polio-free, with no reported polio cases over the past years. The last case of acute paralytic polio in Europe occured in Turkey in 1998. Despite the worldwide vaccination campaign, there are four countries in Africa and Asia – Nigeria, India, Afghanistan, and Pakistan – where the polio virus is still endemic and new epidemics occur; the number of new polio cases in 2006 was 1912. The poliovirus is highly infectious. Transmission into nonendemic countries occurs, and the mutation rate of the virus is high. Worldwide surveillance and vaccination will therefore be needed for several years before a polio-free world can be achieved.

Only humans are natural hosts for the poliovirus. Little is known about the human factors determining susceptibility for acute polio infection, but it seems that persons with Fcγ receptor IIIA V/V genotype are less susceptible for paralytic polio. Coexisting skeletal muscle injury of other causes could also be a factor, probably by introduction of retrograde axonal transport of the poliovirus.

Recovery

A recovery with improvement of muscle strength takes place after the acute illness; it is due to decrease of the inflammation which may temporarily disable infected but surviving motor neurons. In addition, there is an extensive axonal sprouting and reinnervation by surviving motor neurons and an increase in muscle fiber size among the muscle fibers with existing innervation. The degree of residual weakness may vary considerably due to the extent of neuronal damage, from complete to partial persistent weakness. Normal strength and muscle volume can be found despite a loss of 50% of the motor neurons within one segment, but subclinical signs of motor neuron affection with increased amplitudes on electromyographic (EMG) recordings can be found, confirming the motor neuron affection. Most of the recovery takes place within the first 6 months, but further improvement can be seen up to 2 years after the acute infection. The recovery phase is followed by a stable phase of neuromuscular function which can last for several decades.

Post-Polio Syndrome

Definition and Clinical Description

The first description of PPS dates back to 1875, when Raymond and Charcot reported new muscular weakness and atrophy in a 19-year-old tanner, following "*paralysie essentielle de l'enfance*." This man had marked new atrophy in his shoulder with no signs of other neurological disorder. The subject was not investigated systematically in the next decades, but anecdotal reports raised the possibility that progressive motor neuron diseases such as amyotrophic lateral sclerosis (ALS) could be a late complication following paralytic poliomyelitis. In the 1980s, three decades after the large polio epidemics in the Western world, questions about late complications after paralytic polio were raised again, and PPS was defined and implemented.

Dalakas introduced the term post-poliomyelitis atrophy in 1984 to describe patients with a confirmed history of paralytic polio, partial recovery of function, and at least 10 years with functional stability, signs of residual neurologic damage on neurologic examination characterized by muscular atrophy, weakness, areflexia, and normal sensation in groups of muscle with random distribution, and experience of new muscular symptoms. The term PPS was first used by Halstead in 1985 to cover medical, orthopedic, and psychological problems possibly or indirectly related to the long-term post-polio disability. He redefined and narrowed the description and definition in 1991:

1. Confirmed history of polio
2. Partial or fairly complete neurological and functional recovery after the acute episode
3. Period of at least 15 years with neurological and functional stability
4. Two or more of the following health problems occurring after a stable period: extensive fatigue, muscle and/or joint pain, new weakness in muscles previously affected or unaffected, new muscle atrophy, functional loss, cold intolerance
5. No other medical explanation found
6. Gradual or abrupt onset of new neurogenic weakness

Clinical Features

Patients from all parts of the world report the same symptoms of PPS; muscle weakness, new atrophy, postexercise fatigue, muscle pain, generalized fatigue, muscle cramps, fasciculations, cold intolerance, and joint pain tend to dominate. The new weakness or atrophy may occur in previously affected muscles, but also in muscles with previous subclinical motor neuron affection. The typical clinical pattern is asymmetrical and often scattered weakness, involving several segments of the spinal cord, without any signs of upper motor neuron involvement, and no rapid and severe progressive deterioration. Tendon reflexes are often weakened or absent in the same scattered pattern. Fasciculations can be observed in the affected muscles, but are not generalized. Postexercise fatigue and decreased muscular endurance during activity are frequent and may be present before new weakness or atrophy is detected on examination. This is probably due to changes in the aerobic capacity of the muscle fibers, which are often enlarged with a reduced glycolytic activity. The other symptoms are less specific and may be caused by several other disorders. Muscle pain may be present both in weak muscles and in other healthy muscles as a result of overuse due to compensatory movements. Generalized fatigue is a subjective sense of tiredness, lack of energy, and reduced endurance. It is a subjective symptom which can be caused by several other coexisting disorders which must be ruled out before attributing it to PPS.

The prevalence of PPS varies; it has been reported as affecting from 20% to 80% of previous polio patients, mostly dependent on what population was studied and what criteria applied. Today, we estimate that between 20% and 50% of polio survivors will develop PPS. Risk factors are, first of all, the severity of the acute polio, with patients with severe acute polio at greater risk for PPS. A great recovery with assumptive normal muscle function and strength also increases the risk for later PPS. Patients who acquired acute polio as adolescents or adults seem to be at greater risk than patients who had acute polio in childhood. Frequent muscle activity up to the limit of fatigue and exhaustion is another risk factor.

The diagnosis of PPS is an exclusion diagnosis; the role of the investigation is to rule out every possible cause for the new symptoms and clinical deterioration. As PPS occurs in an aging population, the frequency of other coexisting and non-polio disorders is increasing, indicating that a proper diagnostic workup is needed.

PPS patients may be more susceptible to disorders of the spine if there are weak paravertebral muscles and kyphosis or scoliosis. This could lead to other neurological problems such as radiculopathies and myelopathies, and reduced ventilatory capacity. Degenerative spine disorders without neurological complications may also occur, and can lead to pain and physical inactivity. Compensatory use of presumably healthy muscles may lead to muscle and joint pain, tendonitis, and other overuse symptoms. Degenerative joint disorders are common, particularly in weight-bearing

joints and paretic extremities. Weak muscles with following physical inactivity increase the risk of osteoporosis, and fractures in paretic limbs are not unusual. Use of walking aids such as crutches or splints and braces could increase the risk of peripheral nerve entrapment.

Pathogenesis

Despite large efforts to reveal the exact pathogenesis behind PPS, there is no single explanation which covers the clinical picture seen in PPS. Several neuropathological changes have been described, raising further questions.

Denervation and compensatory mechanisms The deterioration of the neuromuscular function among PPS patients is slowly progressive and strictly focal with scattered involvement of muscle fibers within one motor unit, and there is no generalized motor neuron disorder. Dropout of motor units does occur with a scattered pattern. In PPS, there is an imbalance between degeneration and regeneration of enlarged motor units, causing ongoing denervation, and new muscle weakness occur when the motor neuron is unable to maintain all the nerve terminals and a critical number of muscle fibers become denervated. Longitudinal studies have demonstrated that one motor unit can increase in size up to 20-fold compared to normal size before this imbalance becomes clinically evident with new weakness. Excessive use of the remaining motor units seems to contribute to the increasing size of the remaining motor units.

Healthy individuals lose 1% of their muscle strength after the third decade as a part of the normal aging process. After the age of 60, there is also a decrease in the number of motor units in the spinal cord, where the rate of loss varies between muscles. This normal aging process takes place in post-polio patients and contributes to the muscle weakness, but cannot explain the more pronounced process in PPS.

Muscle fibers Skeletal muscles consist of two types of muscle fibers. Type I fibers ('slow twitch') are dense with capillaries, myoglobin, and mitochondria and can perform aerobic activity for longer periods. Type II fibers are mainly involved in 'fast-twitch' operations, with anaerobic metabolism. Muscle biopsies from PPS patients reveal chronic and acute denervation and acute reinnervation, variable muscle fiber size, and scattered atrophic fibers, but no fiber group atrophy. It has been shown that fiber type I dominates in previous polio muscles, and these fibers have a decreased capillary density and reduced oxidative and reduced glycolytic enzyme activities. This muscle fiber transformation from type II to type I seems to depend on the functional demand on the muscle. In patients with excessive use of motor units (i.e., weight-bearing muscles in the legs), the dominant features are predominance of hypertrophic type I fibers and scattered angulated and rounded atrophic fibers, fiber splitting, internal nuclei, and rimmed vacuoles. If there is less use of the remaining motor units, the frequency of hypertrophic type I fibers is lower, and there is widespread fibrosis and atrophic fibers with vesicular central nuclei, pyknotic central nuclei, vacuoles, and cytoplasmatic bodies, but also normal fibers and hypertrophic fibers. The combination of almost total type I predominance, hypertrophic fibers, and reduced oxidative capacity seems to be unique for polio muscles.

The degree of morphologic changes depends on how extensively the muscle was affected in the acute phase, whether partial or full recovery was obtained, and the functional demand. Increased lymphocytic infiltration in perivascular and perimyseal areas has been found in certain muscle specimens but is not consistent, and there is no evidence of generalized inflammation beyond the muscle membrane in PPS.

Inflammation in cerebrospinal fluid and spinal cord It has been questioned whether a reactivation of the polio virus could be present in PPS. There are no cases of recurrent acute polio, and as the poliovirus has a rapid cytolytic cycle, it seems unlikely that the virus escapes immunologic surveillance and is harbored in motor neurons. In addition, no specific immune response against the poliovirus in the cerebrospinal fluid (CSF) in PPS patients has been confirmed. *In vitro* studies have shown that poliovirus can induce persistent infection in human neuroblastoma cells, and persistent poliovirus has also been found in mouse models, but when examining CSF from PPS patients, no complete match of the amplified sequences has been found, and there is no evidence for presence of the virus in studies employing *in situ* hybridization. There is no confirmed evidence of reactivation of the poliovirus as a cause of PPS, but it is possible that mutant virus particles are present in neural tissue without clinical significance.

The issue of a general immunologic activation has been studied, and oligoclonal IgG bands and antineurofilament antibodies in the CSF have been found in some PPS patients, but the clinical significance is unknown. An alteration in T cells in peripheral blood (CD4+ subsets) has also been demonstrated, indicating a possible immune activation.

Cytokines are proteins which can act as chemical messengers, particularly in the immune response. Inflammatory cytokines such as tumor necrosis factor-alpha

(TNF-α) are mainly produced by macrophages and play an important role in inflammation. Although their functions are not fully elucidated, it is presumed that increased volumes of TNF-α and other inflammatory cytokines such as interferon-gamma (IFN-γ) are detrimental to motor neurons and other nerve cells. Anti-inflammatory cytokines such as interleukin-10 (IL-10) are expressed on monocytes and type T2 helper cells and inhibit the actions of natural killer cells (NK cells), thereby reducing the stress response. Recent studies show that, when examining CSF and peripheral blood in PPS patients, an increased intrathecal expression of mRNA for the inflammatory cytokines TNF-α, IFN-γ, interleukin-4 (IL-4), and IL-10 compared to normal controls is found. Increased TNF-α is also seen when analyzing CSF with enzyme-linked immunosorbent assay (ELISA) tests. It has been shown that intravenous immunoglobulin reduces the expression of the proinflammatory cytokines TNF-α and IFN-γ, whereas the levels of the anti-inflammatory cytokine IL-10 remained unchanged in PPS patients. From this point of view, there is evidence of a low-grade immune response in PPS, but it is not established whether this is due to a defect immune system or is secondary to neurodegeneration, autoimmunity, or an unspecific immune response.

Management

Diagnostic assessment The first priority is to establish the diagnosis and exclude all other possible explanations for the new symptoms. There is no test or clinical sign which can confirm the diagnosis of PPS alone, and a proper diagnostic workup is mandatory, particularly if the symptoms are less specific, such as generalized fatigue, muscle pain, muscle cramps, and cold intolerance. A neurophysiological examination is useful in several aspects. At first, it is important to establish typical motor neuron involvement. This is demonstrated with neurogenic EMG findings and normal sensory findings on nerve conduction studies. Other disorders, such as more progressive motor neuron diseases such as ALS or nerve entrapment and radiculopathies, can also be detected on neurophysiological examination and should be ruled out if clinically suspected. A macro EMG examination can be useful to assess the degree of motor neuron loss, as a normal clinical picture can be found even with a loss of up to 50% of motor neurons.

Supportive therapy There is no effective specific treatment available for PPS, and the cornerstone in management of PPS is supportive therapy. Well-conducted exercises prescribed and supervised by experienced therapists can prevent further decline in muscle weakness and reduce symptoms of muscular fatigue, muscle weakness, and pain in selected PPS patients. Both isokinetic and isometric exercises can be performed, but overuse and fatiguing activities should be avoided. It is important to organize the exercises with intermittent breaks and submaximal work loads, and endurance training can be more effective than strengthening exercises. Training of severe weakened muscles should probably be avoided. If symptoms of excessive fatigue and new weakness occur during the training period, the exercises should be stopped and reevaluated. Supervision and advice from experienced therapists are usually necessary in the beginning. The long-term effects of such training have not been explored, but from a general health perspective it is advisable to perform some form of aerobic training to improve cardiovascular fitness and avoid weight gain, which could lead to worsening of the general condition and add a greater workload to already weak muscles. Training in warm water and in a warm climate is useful for amelioration of several PPS symptoms, particularly if non-swimming exercises are performed.

Reduced respiratory function because of weakness in respiratory muscles or severe kyphosis and/or scoliosis is well treated with noninvasive respiratory aids such as CPAP (continuous positive airway pressure) or BiPAP (bilevel positive airway pressure), both to prevent further decline and to treat an existing underventilation, especially if this occurs during sleep. Training of respiratory muscles can also improve pulmonary function, and general precautions such as stopping smoking, mobilization of secretions, and cough assistance are beneficial. If there is a coexisting obstructive sleep apnea, weight control and avoidance of obesity are important.

Lack of energy and general fatigue can be ameliorated with lifestyle modifications such as the introduction of assistive devices such as proper orthoses, walking sticks, and intermittent or permanent use of a wheelchair. Reorganization of daily activities with frequent rest periods, energy conserving, and work simplification is generally recommended.

If there are other coexisting orthopedic and neurological disorders like degenerative joint and spine disease, they should be treated following general guidelines for the specific disorder. Properly fitted orthoses and calipers are useful to prevent disuse and secondary joint degeneration or nerve entrapments. Surgery should be considered if the orthopedic disorder interferes with activities of daily living. If surgery is indicated, a longer recovery and rehabilitation period may be needed.

Pain in muscles and joints can be reduced by decreasing mechanical stress on joints and muscles with lifestyle changes, use of assistive devices, and

aquatic exercise training. If there is bulbar weakness with dysphagia, instruction on swallowing techniques by speech therapists can be of help.

Patients with PPS have to cope with new loss of function, and sometimes an increase in disability and handicap. This new life situation can cause emotional stress and reduced well-being. To help patients come to terms with their new situation, it is important to reassure them that PPS is not a life-threatening disorder with a rapid progression, like ALS. Regular follow-up in PPS clinics, patient education programs, and group training with other PPS patients can give a more positive experience of the 'self' and prevent a decline in mental status.

Pharmaceutical interventions Several studies on pharmaceutical interventions in PPS with regard to muscle strength, fatigue, pain, and quality of life have been performed. Pyridostigmine (an acetylcholinesterase inhibitor) was found to be effective for fatigue in two pilot studies, but this was not confirmed in larger controlled studies, and there is no convincing evidence that pyridostigmine is helpful in PPS. High doses of prednisolone have been tried to improve muscle strength and reduce fatigue, but no significant effect was seen. In order to reduce fatigue, amantadine has been tried with negative results.

It is presumed that inflammatory cytokines damage motor neurons. From this perspective, intravenous immunoglobulin (IvIg) could be an alternative in PPS, as it reduces the mRNA expression of TNF-α and IFN-γ. Recent controlled studies from Sweden showed that an IvIg-treated group of PPS patients had better performances on muscle strength and a higher vitality score after treatment. One uncontrolled Swedish study showed improvement on vitality when measured on the Quality of Life registration SF-36 after IvIg treatment. A small, controlled Norwegian study found no effect on muscle strength or fatigue after IvIg, but pain improved significantly on two measurements. Further studies on patient subgroups, doses, treatment intervals, and long-term effects are needed before any conclusion on IvIg as a therapeutic option in PPS can be drawn.

Postsynaptic Density/Architecture at Excitatory Synapses

H-C Kornau, Center for Molecular Neurobiology (ZMNH), University of Hamburg, Hamburg, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Excitatory chemical synapses of the central nervous system are highly specialized structures which rapidly convey information from one neuron to the other by means of a soluble neurotransmitter, in most cases glutamate. The neurotransmitter is released from the presynaptic terminal upon action potential-evoked calcium influx, diffuses through the synaptic cleft, and opens ligand-gated ion channels on the surface of the postsynaptic cell, resulting in excitatory postsynaptic currents. Signal reception and processing is achieved in dendrites, which are often contacted by presynaptic terminals of thousands of neurons. Excitatory synapses are mostly located on spines, little mushroom-shaped structures protruding from the dendritic shaft. Dendritic spines form a compartment for processing of the individual synaptic input.

In electron micrographs the presynaptic side is recognized by a high density of neurotransmitter-containing vesicles. On the postsynaptic side of the cleft a characteristic electron-dense thickening of the membrane, extending approximately 30 nm into the spine cytosol, is observed (Figure 1); this thickening, a structure that has attracted the interest of neurobiologists since the 1950s, is called the postsynaptic density (PSD). Given that synapses are crucial for information processing in the brain, the importance of the PSD, as the site where neurotransmitter receptors are connected to intracellular structures and where synaptic processing within each spine is initiated, is obvious. Molecular biology and biochemical approaches have identified many proteins of the PSD, including (1) adhesion molecules, receptors, and channels, (2) scaffolding, adaptor, and cytoskeletal proteins, and (3) signaling/regulatory proteins, including kinases, phosphatases, small GTPases, and similar molecules. Moreover, the studies revealed how these proteins physically interact with each other or with the postsynaptic membrane. Thus, we can draw preliminary models containing some of the major components of the PSD to get an idea of the way this macromolecular protein complex may function and how it is rearranged during development and in processes of synaptic plasticity.

How Postsynaptic Densities Are Studied

Electron microscopy initially identified PSDs as hallmarks of glutamatergic/Gray type I synapses in the central nervous system. PSDs are 25- to 50-nm-thick protein assemblies with a diameter of several hundred nanometers. High-resolution electron microscopy reveals a structured 5-nm-thick sheet, which might form the nucleus of the PSD, as well as filamentous structures which connect it to cytoskeletal elements within the cytoplasm of the dendritic spine and to organelles such as the smooth endoplasmic reticulum at the margin of the PSD. Due to their unique density and their resistance to nonionic detergents, PSDs can be purified as intact, disk-shaped structures by differential centrifugation protocols. These preparations serve as the protein sources for the molecular analysis of PSDs. Initially, individual PSD proteins were discovered by amino acid sequencing of protein bands of such PSD preparations after separation by gel electrophoresis. Alternatively, antibodies were raised against complex PSD preparations and used to screen cDNA expression libraries. Coimmunoprecipitates of known PSD components have been a source for finding new elements of this structure as well. Yeast two-hybrid screening, a genetic screen for interacting proteins, supplied a number of proteins physically binding to glutamate receptors or scaffolding proteins of the PSD. Recently, proteomics, which is generally regarded as a large-scale analysis of proteins in a given sample, involving efficient protein separation and highly sensitive protein identification techniques, has been applied to glutamate receptor complexes and to PSD preparations. The results suggest that the PSD contains several hundred different polypeptides. Mass spectrometry techniques have not only identified these proteins with great sensitivity, they have also allowed quantitative determinations. Thus, for some of the components, we know their stoichiometries. Using scanning transmission electron microscopy on a rat forebrain PSD fraction, the mass of an average PSD was measured and the number of copies of specific PSD proteins derived from their relative mass contributions was determined by quantitative gel electrophoresis (Table 1). Consistent with an independent approach using a green fluorescent protein-based calibration technique, these data suggest that a single PSD contains several hundred copies of each of its major polypeptides.

The Protein Composition of Postsynaptic Densities

Glutamate Receptor Complexes

Glutamate receptors and associated proteins were among the first components identified to be part of

Figure 1 The PSD, a structural element of excitatory synapses. The electron micrograph shows a representative excitatory synapse (Gray type I) at a synaptic spine (s) of an adult mouse hippocampus. Major synaptic structures are the presynaptic bouton (b) filled with synaptic vesicles (diameter ~50 nm), the PSD (arrowheads), and the synaptic cleft in between. The electron micrograph was a kind gift of Dr. Michaela Schweizer, Central Service Facility of Morphology at the ZMNH, University of Hamburg, Hamburg, Germany.

Table 1 Dimensions of a PSD

Mean diameter[a]	~360 nm
Depth[b]	~25–50 nm
Mean mass[a]	~1.1 GDa
Number of PSD-95 molecules[a]	~300

the PSD. Glutamate receptor channels mediate the principal postsynaptic functions – that is, changes in membrane potential upon binding of the excitatory neurotransmitter. The different types of ionotropic glutamate receptors are named for their specific agonists. α-Amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor channels are opened upon glutamate binding alone, whereas *N*-methyl-D-aspartate (NMDA) receptor activation requires simultaneous membrane depolarization (e.g., by activation of neighboring synapses). This depolarization relieves the extracellular magnesium block of the NMDA channel, allowing influx of sodium and, importantly, calcium through the channel pore. Calcium acts as a second messenger within the cell and is important for the induction of synaptic plasticity. A very abundant PSD protein involved in these processes and activated by calcium is calcium/calmodulin-dependent protein kinase II (CaMKII). It is associated with the cytoplasmic region of the NMDA receptor, allowing it to sense the influx of calcium through this channel directly. Subsequent pathways involve a variety of structural rearrangements within the PSD and lead to a change in synaptic efficacy primarily expressed as an altered number of AMPA receptors in the postsynaptic membrane. Both native AMPA and NMDA receptor complexes are associated with a variety of scaffolding/adaptor proteins (e.g., postsynaptic density protein 95), which link the ionotropic glutamate receptors to other integral membrane proteins, to soluble signaling molecules, and to the spine cytoskeleton, and form the core lattice of the PSD. At the margin of the PSD, metabotropic G-protein-coupled receptors for glutamate (mGluRs) modulate the intraspinal calcium level. Proteomics has unraveled individual protein complexes for NMDA receptors, mGluRs, and AMPA receptors.

The NMDA receptor complex is tightly linked to the core of the PSD by a series of adaptor proteins comprising postsynaptic density protein 95 family members (PSD-95; also called synapse-associated protein 90 (SAP90), PSD-93/Chapsyn-110, SAP102, and SAP97), guanylate kinase-associated proteins (GKAPs; also called SAP90/PSD-95-associated proteins, or SAPAPs), and Shanks (also called proline-rich synapse-associated proteins, or ProSAPs) (Figure 2). PSD-95 and its relatives encompass three PDZ domains, an SH3 domain, and a guanylate kinase domain, all of which function as protein–protein interaction domains. They belong to the family of membrane-associated guanylate kinases (MAGUKs), which function primarily at sites of cell-to-cell contact. Employing its PDZ domains, PSD-95 links the NMDA receptor to neuroligins, postsynaptic cell adhesion molecules crucial for synapse formation, and to several signaling molecules, among them neuronal nitric oxide synthase (nNOS) and synaptic GTPase-activating protein (synGAP), an abundant regulator of Ras and Rap GTPases. The GKAPs connect PSD-95 to the Shank

Figure 2 Simplified scheme of the molecular architecture of the PSD. The different types of glutamate receptors are linked to the Shank scaffold, a two-dimensional sheet, either by the PSD-95 family of proteins and by guanylate kinase-associated protein (GKAP) molecules, or by Homer dimers. The Shank scaffold connects the PSD with the spine actin cytoskeleton. The PSD-95 family proteins form a membrane-proximal layer of scaffolds, whereas the Shanks constitute a second, deeper layer. PDZ domains are depicted as blue circles. The C-terminal domains of the glutamate receptor subunits, the PSD-95 family members, as well as the Shanks, recruit numerous signaling molecules to the PSD. The PSD-95 family members connect the PSD with cell adhesion molecules governing the integrity with the presynaptic specialization. The Homer proteins link the metabotropic glutamate receptors (mGluRs) not only to the Shank scaffold, but also to the inositol 1,4,5-trisphosphate receptor within the smooth endoplasmic reticulum. For simplicity, all of these connections were omitted from the scheme. The figure does not reflect the real stoichiometry of the scaffolding proteins. AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor; TARP, transmembrane AMPA receptor regulating protein; NMDAR, *N*-methyl-D-aspartate receptor.

core of the PSD by binding to both the guanylate kinase domain of PSD-95, on one hand, and to the PDZ domain of a Shank molecule, on the other hand. Four closely related GKAP family members show distinct spatiotemporal expression patterns in the brain. Shanks (three related proteins) contain a number of protein interaction domains, including ankyrin repeats, an SH3 domain, a PDZ domain, a proline-rich region, and a sterile alpha allowing them to bind to a variety of proteins. Moreover, by self-association of their SAM domains they are able to form large sheets within the PSD. The resulting dense platform is associated with the actin cytoskeleton, the smooth endoplasmic reticulum, the different glutamate receptor complexes, and other channels and receptors. Shanks are also early components during synaptogenesis.

The three classes of adaptor proteins play a crucial role within the PSD. They form an axis of scaffolds differing in their distance from the plasma membrane (Figure 2): PSD-95 is located approximately 12 nm cytoplasmic to the extracellular face of the postsynaptic membrane, like the C-termini of the NMDA receptor, whereas GKAP and Shank molecules are buried deeper in the cytoplasm (approximately 24–26 nm from the membrane). They recruit a number of signaling molecules to the PSD and connect the PSD with cytoskeletal elements. Proteomic analysis of the NMDA receptor complex has revealed a complexity of more than 100 proteins, including a variety of protein kinases and phosphatases, small G-proteins and their regulators, and other signaling molecules, such as nNOS, phosphatidylinositol 3-kinase (PI3K), phospholipase C-γ, Citron, and Arg3.1/Arc. In addition, several cell adhesion molecules and associated adaptors, including N-cadherins and β-catenin, which regulate dendritic spine morphogenesis, were found in the NMDA receptor complex. Finally, many cytoskeletal proteins are part of this complex.

Type I metabotropic glutamate receptors are located at the margin of the PSD. These G-protein-coupled receptors lead to inositol 1,4,5-trisphosphate (IP_3) production, which consequently activates the IP_3 receptor and induces the release of calcium from intracellular stores. Key molecules of the mGluR protein complex are the Homer proteins, which are expressed from three genes. They can dimerize by a coiled-coil interaction and these dimers connect mGluRs to the Shank backbone of the PSD on the plasma membrane side, and IP_3 receptors in the smooth endoplasmic reticulum to the Shank backbone on the cytoplasmic side, of the PSD. Thus, Homer proteins connect mGluRs and IP_3 receptors to the PSD and link mGluRs and IP_3 receptors, allowing efficient intracellular calcium release upon mGluR activation. In these assemblies the N-terminal EVH domains of the Homer dimers bind to a PPXXF motif in the receptors and to a proline-rich region in Shanks (Figure 2). (The EVH nomenclature derives from 'enabled-VASP (vasodilator-stimulated phosphoprotein) homology.') Interestingly, Homer 1a, an

isoform lacking the coiled-coil domain, which is highly expressed as an immediate-early gene, can compete with the constitutive forms of Homer and thus with the link of mGluRs and IP_3 receptors to the PSD. This may enable the cell to limit the release of intracellular calcium if required. The mGluR5 complex has been also subject to proteomic analysis. It provided a number of additional candidate proteins of mGluR complexes and confirmed the link to Homer, Shank, and IP_3 receptors delineated herein.

AMPA receptors mediate the majority of the fast excitatory neurotransmission in the brain. The efficacy of a synaptic connection is related to the number of AMPA receptors in the postsynaptic membrane. Thus, whereas NMDA receptors are mediating the induction of synaptic plasticity, AMPA receptors are crucial for its expression. The number of AMPA receptors in the postsynaptic membrane is indeed quite variable, ranging from zero to several hundred receptors per synapse, and can rapidly change upon usage of a synapse. AMPA receptors are rapidly cycling between plasma membrane and endosomal compartments. Thus, they need a unique set of associated proteins.

The best documented interaction of AMPA receptors is their binding to the integral membrane protein stargazin. Stargazin was the first member of a family of four differentially expressed TARPs (for transmembrane AMPA receptor regulatory proteins), which function as auxiliary subunits of AMPA receptors. By two independent interaction sites, TARPs regulate both the trafficking and the gating of AMPA receptors. A C-terminal interaction of TARPs with PSD-95 connects AMPA receptors with the PSD and governs the synaptic localization of AMPA receptors (Figure 2).

The rapid cycling of AMPA receptors requires the interaction with AP2 and clathrin. These and *N*-ethylmaleimide-sensitive fusion protein NSF, a multimeric ATPase playing an important role in membrane fusion, bind to specific motifs in the center of the short, intracellular C-termini of selected AMPA receptor subunits. Additional proteins interact with the very C-terminal amino acids of AMPA receptor subunits and affect the synaptic localization of AMPA receptors. These include an adaptor protein termed glutamate receptor-interacting protein (GRIP) and a protein originally identified as a protein interacting with C kinase, PICK1. Both of these proteins bind to the C-termini of AMPA subunits by PDZ domains. GRIPs (two related proteins) harbor seven PDZ domains and thereby can connect AMPA receptors to several cytoplasmic and membrane-standing proteins (e.g., the ephrin receptor). The PICK1 interaction with AMPA subunits is essential for the AMPA receptor endocytosis involved in cerebellar long-term depression.

Proteomic approaches to tackle the composition of AMPA receptor complexes identified a limited complexity as compared to NMDA receptor or mGluR complexes. However, AMPA receptor cycling between plasma membrane and endosomal locations may specifically require transient or weak interactions, which may be lost during purification of the receptor complex.

Multiple interfaces between the individual glutamate receptor multiprotein complexes appear to exist: Homer (mGluR complex) can bind to Shanks in addition to mGluRs and IP_3 receptors, and stargazin (AMPA receptor complex) binds to PSD-95 (NMDA receptor complex). Proteomic studies of PSD proteins have been performed on immunopurifications of glutamate receptors (brain protein complexes purified via peptides derived from the C-terminal sequence of the NMDA receptor subunit 2B, a target of PSD-95 family members) and on purifications of entire PSDs. The data from these different approaches have been compiled as our current view of the PSD composition. They show that in addition to the glutamate receptor complexes connected to the different scaffolding proteins we have to integrate a large number of additional integral membrane proteins, signaling/regulatory proteins, and cytoskeletal elements into our model of the PSD. Although the number of proteins identified in PSD fractions goes into the hundreds, only a few principal types of molecule classes can be covered here.

Integral Membrane Proteins

Independent analyses of the PSD proteome revealed a variety of integral membrane proteins aside from glutamate receptors. These include not only other channels and receptors, but also cell adhesion molecules (e.g., neuroligins and N-cadherin) which directly link the PSD with the juxtaposed membrane specialization on the presynaptic side termed the active zone. Cell adhesion molecules govern several steps of synaptogenesis and may keep the active zone and the PSD in register during structural changes of the synapse.

Regulatory Proteins

The importance of CaMKII as a very abundant PSD protein for the induction of synaptic plasticity has already been mentioned. However, many other types of protein kinases and phosphatases are found in the PSD as well. This is not surprising since phosphorylation and dephosphorylation events often mediate

functional and structural modulation of central nervous system synapses.

Small GTPases of the Ras superfamily, termed Ras and Rap, belong to the most important molecules involved in the integration of biochemical signals in the dendritic spine. Their activity determines the amount of AMPA receptors in the postsynaptic membrane. As GTPases they switch between an active, GTP-bound, and an inactive, GDP-bound, state. Activation requires a specific guanine nucleotide exchange factor (GEF); inactivation requires a GTPase-activating protein (GAP). PSD preparations contain several GEFs and GAPs for Ras and Rap, which themselves differ by the signals required for their activation.

Small GTPases of the Rho family, including Rac and cdc42, directly influence the state of the spine cytoskeleton. For example, adhesion molecule-mediated recruitment of specific Rac GEFs activates Rac and leads to changes in actin polymerization. These GTPases have a strong impact on the morphology of dendritic spines and their regulators are found in PSD preparations.

Cytoskeletal Proteins

The axis of scaffolds in the PSD (PSD-95 family members, GKAPs, and Shanks) is also a nucleus for interactions with the cytoskeleton in the spine. As already indicated in the section on the NMDA receptor complex, PSD preparations contain a variety of cytoskeletal proteins. They include actin, actin-binding proteins, tubulin, spectrin, cortactin, and many others.

The proteomic approaches revealed several hundred different proteins in PSD preparations. However, it should be noted that this does not necessarily reflect the complexity at a single PSD. The protein composition of PSDs in different brain regions as well as in different synapses of a single neuron may considerably differ, and thereby may contribute to the large number of identified proteins.

PDZ Domains

Like all macromolecular protein networks, the PSD is connected by modular protein–protein interactions. Analysis of the interacting protein sequences has revealed the presence of specific domains. A domain frequently found at sites of cell-to-cell contact is the PDZ domain (so named from PSD-95/discs-large/zonula occludens-1), which is present in many different proteins in humans. PDZ domains bind, in most cases, to short peptide motifs at the C-termini of other proteins and are classified according to the sequences they recognize. In addition, some PDZ domains can heterodimerize. The PDZ domain is also central in connecting different components of the PSD (Figure 2). It was first recognized in the prototype PSD scaffolding protein PSD-95 (hence, the name), which contains three N-terminal PDZ domains and uses two of them to bind to the C-termini of NMDA receptor subunits and the third PDZ and other domains to connect the receptor to a variety of PSD components. PDZ domains are essential for the function of many signaling and scaffolding proteins of the PSD. The scaffolding proteins often contain several PDZ as well as other interaction domains, each with a preferred binding partner, allowing the scaffold to coordinate large protein complexes.

Rearrangements of Postsynaptic Densities

Developmental Assembly of Postsynaptic Densities

Most of the synapse formation in the rat central nervous system occurs during the first two postnatal weeks. It is initiated by an interaction between pre- and postsynaptic cell adhesion molecules within the synaptic cleft, including neurexins/neuroligins, cadherins, synCAMs, receptor tyrosine kinases, and others. Among the earliest proteins at synapses are PSD-95 family members and Shanks, suggesting that they play a major role in the assembly of the PSD. Their interactions with the other scaffolding and signaling molecules are thought to promote the formation of the PSD very rapidly. Simultaneously, NMDA receptors are recruited into the PSD, whereas the integration of AMPA receptors into the postsynaptic membrane requires presynaptic glutamate release. Early in development many synapses in the central nervous system lack AMPA receptors and are therefore called silent synapses.

PSDs of postnatal day 2 rats contain already many of the proteins found in adult PSDs. However, during development, specific molecular changes are evident. These include a switch in the expression of NMDA receptor subunits from NR2B to NR2A and, simultaneously, of their interaction partners SAP102 to PSD-95, and an increase of AMPA receptors and CaMKII. Although during synaptogenesis the recruitment of key PSD proteins such as NMDA receptor subunits and Shanks appears to occur in a rather gradual manner, preformed transport packets containing either AMPA or NMDA receptors, or mobile clusters containing PSD-95, GKAP, and Shank, driven by actin transport, have been described. Thus, how the PSD is assembled during synapse formation requires further investigation.

Activity-Dependent Changes at Postsynaptic Densities

The size, protein composition, and structure of the PSD are altered in response to developmental and environmental cues. One cellular model for learning and memory, long-term potentiation (LTP), involves a prolonged strengthening of a synapse in response to a high-frequency input. Calcium influx through NMDA receptors, which are open under these depolarizing conditions, allows activation of a number of signaling molecules of the PSD, including CaMKII, calcineurin, nNOS, and several regulators of small GTPases. The primary result is a change in the phosphorylation pattern of PSD proteins, among them the glutamate receptor subunits. Phosphorylation leads to an altered affinity of binding partners and concomitant stabilization or destabilization of the receptor molecules at the PSD. Activation of small G-proteins can trigger endo- or exocytosis of membrane proteins. As an example, additional AMPA receptor subunits are rapidly inserted into the plasma membrane during LTP, resulting in a direct increase of the postsynaptic response. In contrast, AMPA receptors are removed from the synaptic plasma membrane during long-term depression. Other small GTPases, upon activation, alter the polymerization state of actin in the dendritic spine. Thus, synaptic plasticity involves structural plasticity at the PSD.

In addition to changes in the phosphorylation pattern, receptor localization, and cytoskeleton structure, local translation and targeted protein degradation contribute to the high capability of the PSD to rearrange. Activity-dependent translation of AMPA receptor subunits in dendrites may mediate synapse-specific modifications. The presence of mRNAs for other PSD components (e.g., Shanks) in dendrites suggests their local translation as well. Dendritic protein synthesis may contribute significantly to synaptic plasticity processes.

Posttranslational modifications aside from phosphorylation affect the PSD structure. As an example, PSD-95 family proteins are differentially palmitoylated at two cysteine residues, with important consequences for their clustering ability. Changes in the PSD structure and composition can also result from altered patterns of transcription and splicing in the nucleus. Alternative splicing events affect the interactions of various PSD proteins by adding/removing sequences encoding specific interaction domains or motifs. For example, two forms of PSD-95, a palmitoylated one (see earlier) and one with an N-terminal L27 domain which enables additional interactions of PSD-95, result from alternative splicing. Rearrangements of the PSD may not only result from alterations in the amount or modification of scaffolding proteins, but may also be influenced by their propensity to interact as a result of alterations in the ionic environment. Of interest in this context, it has been shown that the zinc concentration can, at least *in vitro,* directly influence the assembly of Shank fibers, a core element of the PSD.

The Physiological Role of Postsynaptic Densities

What may be the function of this complex protein assembly? Based on its localization and content, the clustering, localization, and regulated trafficking of glutamate receptors, the compartmentalization of different glutamate receptor complexes, the spatial organization of signaling cascades, the dynamic regulation of the cytoskeleton, and the stabilization of the synaptic structure may be some of the roles the PSD plays.

The ordered array of proteins into microdomains of the PSD governs the efficiency of the signal transduction pathways initiated by activation of the different kinds of glutamate receptors. Importantly, the PSD clusters the glutamate receptors at sites directly adjacent to the presynaptic release sites, which is crucial for fast chemical neurotransmission. Its connection to the receptors and cell adhesion molecules and to the cytoskeleton of the dendritic spine allows the PSD to coordinately respond to changes of presynaptic activity with alterations of the structure of the PSD and the morphology of the spine. Numerous links between the amount of PSD scaffolding proteins and the spine density and size as well as the glutamate receptor content of synapses have been experimentally established.

An impaired architecture of the PSD would be expected to affect the balance of excitatory and inhibitory neurotransmission in the central nervous system and, therefore, to cause fatal diseases. However, relatively little is known about the connection between neurological disorders and the dysfunction of the PSD; maybe the high molecular redundancy of scaffolding proteins secures that central synapses will function even if one of the PSD-95 family member, GKAP, or Shank genes is mutated. Nevertheless, the Shank 3 gene is linked to a neurological disorder termed 22q13.3 deletion syndrome, characterized by mental retardation, delayed speech, and dysmorphic features. Mutations and chromosomal rearrangements in loci corresponding to PSD-95 and neuroligin genes are associated with autism. Mental retardation is linked to the genes for several additional PSD components and correlates with an abnormal morphology of dendritic spines and synapses. Therefore, studying the PSD may not only help to understand

mechanisms of synaptic transmission, but may also provide insight into diseases of the central nervous system.

Postsynaptic Development: Neuronal Molecular Scaffolds

E Kim, Korea Advanced Institute of Science and Technology, Daejeon, South Korea

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Neuronal synapses generally fall into two groups, excitatory and inhibitory. Excitatory synapses are mostly present in dendritic spines, which are thorn-like structures on dendrites. Inhibitory synapses are located on dendritic shafts and the cell body. Excitatory synapses are characterized by the presence of an electron-dense thickening in the postsynaptic side known as the postsynaptic density (PSD). The PSD is formed through the assembly of macromolecular postsynaptic protein complexes containing receptors, scaffolds, and signaling proteins.

Postsynaptic development at excitatory synapses is thought to involve an initial axodendritic contact, followed by localization of early postsynaptic proteins and recruitment of additional proteins to permit growth into mature postsynaptic structures. During the past decade, mechanisms underling the assembly and molecular organization of excitatory neuronal synapses have been thoroughly studied. Inhibitory neuronal synapses have received relatively less attention, partly because the wealth of proteins in the PSD has attracted scientific interest. This article focuses on postsynaptic differentiation at excitatory synapses. In particular, it discusses how postsynaptic scaffolds contribute to the assembly, organization, and plasticity of the PSD.

Postsynaptic Scaffolding Proteins

Components of the PSD have been identified by various experimental approaches including mass spectrometry and the use of protein interaction traps such as the yeast two-hybrid system. Proteomic approaches have identified hundreds of PSD components, including membrane proteins, scaffolding proteins, signaling proteins, and cytoskeletal proteins. Proteomic studies have further provided information on relative and absolute amounts the PSD proteins and their phosphorylation.

Here, postsynaptic scaffolding proteins are defined as proteins that are relatively more abundant than are other PSD proteins and that possess various domains for protein–protein interactions. The presence of such domains strongly implies that the proteins are implicated in the assembly and organization of the PSD. Many postsynaptic scaffolds contain the PDZ (PSD-95-Dlg-ZO1) domain, a 90-amino-acid-long module that interacts with the C-terminal PDZ-binding motif of other proteins. The PDZ domain is one of the most common protein domains known, being found in approximately 580 proteins encoded by the mouse genome. PDZ proteins exhibit 1–13 tandem arrays of PDZ domains. PDZ domain-binding motifs are found in a wide variety of proteins, including membrane proteins and signaling proteins. PDZ proteins, due to their ability to interact with other proteins and form macromolecular protein complexes, are found mainly in specialized cell-to-cell junctions, including neuronal synapses and tight junctions.

A well-known PDZ-containing postsynaptic scaffold is PSD-95, which is a family of proteins with four known members: PSD-95/SAP90, PSD-93/chapsyn-110, SAP97, and SAP102. PSD-95 family proteins contain various domains for protein–protein interactions, including three PDZ domains, one SH3 domain, and one GK domain. Splice variants of PSD-95, PSD-93, and SAP97 (PSD-95β, PSD-93ζ, and SAP97β) contain an additional domain, L27, at the N-terminus. Through these domains, PSD-95 binds to a wide variety of proteins and is involved in the assembly and molecular organization of the PSD. Proteomic studies have shown that PSD-95 is one of the most abundant proteins in the PSD. The four members of the PSD-95 family seem to differ in function, with PSD-95 and PSD-93 being more important in synapses and SAP97 and SAP102 playing roles in protein trafficking.

Functionally, transient overexpression of PSD-95 in dissociated neurons increases the number and size of dendritic spines and α-amino-3-hydroxy-5-methyl-isoxazole propionic acid (AMPA) glutamate receptor-mediated synaptic transmission. In hippocampal slices, PSD-95 overexpression drives GluR1 AMPA receptors into synapses, occludes long-term potentiation (LTP), and enhances long-term depression (LTD). Conversely, acute PSD-95 knockdown reduces the ratio of excitatory to inhibitory synapses and suppresses AMPA receptor-mediated synaptic transmission. Transgenic mice with truncated PSD-95 exhibit reduced LTD, enhanced LTP, and impaired spatial learning. These knockout mice show unaltered AMPA receptor-mediated currents, in contrast to acute PSD-95 knockdown, probably due to functional compensation by other PSD-95 family proteins. Indeed, double-knockout mice lacking both PSD-95 and PSD-93 show a markedly reduced ratio of AMPA/*N*-methyl-D-aspartate (NMDA) excitatory postsynaptic currents. Together, these results implicate PSD-95 in the

Figure 1 Schematic diagram of PSD proteins. Domain structures of selected PSD proteins. PDZ domains are shown as dark ellipses. Other domains are indicated: Act1, actin regulatory domain 1; Act2, actin regulatory domain 2; Ank, ankyrin repeats; ArfGAP, Arf GTPase-activating protein; BAR, Bin-Amphiphysin-Rvs domain; C2, calcium/lipid binding domain 2; CaM kinase, Ca^{2+}/calmodulin-dependent kinase (CaMK)-like domain; CC; coiled coil domain; CRIB, Cdc42/Rac-interactive binding; EVH1, ENA/VASP homology domain 1; GH1, GKAP homology domain 1; GK, guanylate kinase-like domain; GKBD, PSD-95 GK binding domain; GRKBD, GRK2 binding domain; kinase, serine/threonine kinase domain; L27, domain initially found in LIN2 and LIN7; PH, pleckstrin homology domain; RapGAP, Rap GTPase-activating protein; RasGAP, Ras GTPase-activating protein; RCB, Rac binding domain; SAM, sterile α motif; SH3, Src homology 3 domain; SHD, Spa2 homology domain; WW, domain with two conserved Trp (W) residues. Proteins: CASK/LIN2; vertebrate homolog of lin2; GIT1, GRK-interacting protein 1; GKAP, GK-associated protein; GRIP/ABP, glutamate receptor interacting protein/AMPA receptor binding protein; IRSp53, insulin receptor tyrosine kinase substrate p53; PICK1, protein interacting with C-kinase; PSD-93, postsynaptic density protein 93; PSD-95, postsynaptic density protein 95; SAP97, synapse-associated protein 97; SAP102, synapse-associated protein 102; Shank, SH3 and ankyrin repeat-containing protein; SPAR, spine-associated RapGAP; S-SCAM, synaptic scaffolding molecule.

regulation of excitatory synapses, dendritic spines, synaptic strength and plasticity, and learning and memory.

Other postsynaptic scaffolds implicated in postsynaptic development are listed in Figure 1. A large number of these scaffolds contain PDZ domains, as does PSD-95, suggesting that PDZ-based interaction is a widespread mechanism for postsynaptic assembly and organization.

Principles Governing Postsynaptic Differentiation

An important question in synapse formation concerns which side of the synapse initiates synapse formation. Some published studies indicate that the assembly of functional nerve terminals precedes postsynaptic differentiation. Time-lapse microscopy and retrospective immunostaining on cultured hippocampal neurons (11–14 days *in vitro* (div)) indicate that contact-induced formation of functional nerve terminals is followed by clustering of postsynaptic proteins including PSD-95 and glutamate receptors in approximately 45 min. Early stage hippocampal neurons (5–7 div) contain nonsynaptic mobile packets with postsynaptic scaffolds such as PSD-95, GKAP/SAPAP, and Shank/ProSAP. Some of these packets are fast moving and can be recruited to PSD-95/GKAP-negative nascent synapses apposed to functional nerve terminals, suggesting that the presynaptic side instructs postsynaptic assembly. However, a proportion of these mobile packets move slowly. These packets contain neuroligin-1, and when they contact axons, they induce functional nerve terminals by recruiting mobile synaptophysin clusters. This suggests that a certain degree of postsynaptic assembly also occurs prior to the formation of functional nerve terminals, and that synaptogenesis occurs in a bidirectional manner.

Presynaptic assembly is thought to be mediated by vesicular intermediates including synaptic vesicle (SV)

precursors and specialized dense-core vesicles known as Piccolo/Bassoon transport vesicles (PTVs). These two types of vesicles carry preassembled complexes of SV proteins and active zone components (scaffolds and plasma membrane proteins), respectively. Notably, active zones are assembled from a small number (typically two or three) of PTVs. A related question is whether postsynaptic assembly also occurs in this manner. Early stage (3 or 4 div) cortical neurons exhibit rapidly moving NMDA and AMPA receptor transport packets similar to the mobile packets of early hippocampal neurons (mentioned previously). This suggests that modular transport of postsynaptic proteins may play a role in early synaptogenesis. However, late-stage (8–13 div) hippocampal neurons exhibit a gradual recruitment of postsynaptic proteins, including NMDA receptors, PSD-95, and Shank. Although reasons for this discrepancy remain to be determined, a possible explanation is that neurons at different developmental stages may have distinct mechanisms of postsynaptic protein assembly.

Induction of Postsynaptic Differentiation

When the presynaptic side induces postsynaptic differentiation, what might be the initiating signals? Neurotransmitters, released from nerve terminals, are good candidates. Neurotransmitters may affect the morphology of dendritic spines and filopodia (long thin protrusions on dendrites), suggesting that the neurotransmitters may instruct synapse formation. However, transgenic mice that cannot release neurotransmitters, due to the absence of the presynaptic protein Munc13 or Munc18, exhibit normal synapse formation. In addition, blockade of neurotransmitter release in cultured neurons does not inhibit synapse development. These data suggest that neuronal activity is not required for synapse formation.

Another possible trigger is transsynaptic adhesion between presynaptic and postsynaptic cell adhesion molecules. Ideally, transsynaptic adhesions should be heterophilic to minimize homophilic adhesions between dendrites and axons. In addition, synaptic adhesion molecules need to permit coupling of adhesion events to induction of synaptic differentiation through the recruitment of various synaptic proteins to the sites of contact. A well-known example of heterophilic and synaptogenic transsynaptic adhesion is that between presynaptic neurexins and postsynaptic neuroligins. Neurexins were originally identified as receptors for α-latrotoxin, a potent neurotoxin from black widow spider venom that induces massive neurotransmitter release from nerve terminals. Subsequently, neuroligin was identified as an endogenous postsynaptic ligand of neurexins. In addition, neuroligin was found to directly interact with the PDZ domains of PSD-95 through the C-terminal tail, providing a novel mechanism of synapse formation.

The neurexin–neuroligin complex promotes synapse formation in a bidirectional manner. Neuroligin expressed in nonneural cells induces presynaptic differentiation in contacting axons of co-cultured neurons. Conversely, neurexin presented on nonneural cells or beads induces the clustering of key postsynaptic proteins in contacting dendrites. Direct aggregation of neuroligins on the surface membrane of dendrites induces similar clustering of postsynaptic proteins. Acute knockdown of neuroligins reduces the number and function of synapses. These results suggest that neuroligin is a key mediator of synapse formation. Interestingly, transgenic mice deficient in three neuroligins (mice with triple knockout mutations of neuroligin-1, -2, and -3) exhibit reductions in synaptic transmission, but their synapse number is not affected. This suggests that neuroligins regulate functional maturation of synapses rather than their formation, although further work in this area is required.

An interesting feature of the neuroligin family is that neuroligin isoforms differentially localize to excitatory and inhibitory synapses. Specifically, neuroligin-2 is mainly found at inhibitory synapses, whereas other neuroligin isoforms are detected at excitatory synapses. Consistent with these observations, direct aggregation of neuroligin-2 on dendrites induces the clustering of gephyrin, an inhibitory postsynaptic scaffold. Acute knockdown of neuroligin-1, -2, and -3 in cultured neurons results in a greater reduction in the function of inhibitory synapses than excitatory synapses. In addition, the neuroligin triple-knockout mice show an increase in the ratio of excitatory to inhibitory synapses. These results suggest that neuroligin-2 regulates inhibitory synapse formation and/or function.

SynCAM is another family of synaptic cell adhesion molecules implicated in excitatory synaptic differentiation. SynCAM family members, expressed in nonneural cells, induce the formation of functional nerve terminals in contacting axons. These terminals have release properties similar to those seen in regular synapses. The C-terminus of SynCAM contains a PDZ-binding motif and associates with synaptic PDZ proteins, including CASK/LIN2 and syntenin. This, together with data from studies on neuroligin (described previously), suggests that synaptic differentiation is mediated by synaptic scaffolds that couple synaptic adhesion events to the recruitment of various synaptic proteins.

When the great diversity of neuronal synapses is considered, synaptogenic adhesion molecules other than neuroligin and SynCAM may act in concert

with postsynaptic scaffolds. NGL, a family of adhesion molecules, interacts with PSD-95 through the C-terminus in a manner similar to the neuroligin–PSD-95 interaction. The extracellular domain of NGL associates with netrin-G/laminet, a GPI-anchored adhesion molecule. The complex of netrin-G, NGL, and PSD-95 is implicated in the regulation of excitatory synapse formation. In support of this idea, NGL presented on nonneural cells or on beads induces presynaptic differentiation in contacting axons. Direct aggregation of NGL on the dendritic surface induces postsynaptic protein clustering. The fact that both neuroligin and NGL associate with PSD-95 suggests that PSD-95 is one of the key postsynaptic scaffolds involved in adhesion-dependent postsynaptic differentiation. In addition, the dual association of PSD-95 with neuroligin and NGL suggests that these two adhesion molecules may have physical or functional interactions.

Extracellular factors capable of inducing aspects of postsynaptic differentiation at excitatory synapses include Narp, a secreted immediate early gene product upregulated by synaptic activity, and ephrin, a ligand of EphB receptor tyrosine kinases. Narp presented on nonneural cells induces the clustering of AMPA receptors, but not of NMDA receptors, in contacting dendrites. Narp interacts with the extracellular N-terminal domain of AMPA receptors. Narp induces AMPA receptor clustering at shaft synapses of aspiny neurons, and this leads to secondary NMDA receptor clustering, probably through stargazin and PSD-95. Ephrin activation of EphB receptor tyrosine kinases induces co-clustering of EphB and NMDA receptors. This interaction is mediated by their extracellular domains and does not require the kinase activity of EphB receptors.

Localization and Organization of Postsynaptic Scaffolds

If the clustering of postsynaptic adhesion molecules on dendrites is the beginning of postsynaptic differentiation, how might subsequent postsynaptic protein clustering occur? A possibility is that adhesion-induced primary clustering of neuroligin on dendrites may promote secondary clustering of PSD-95 though the C-terminal PDZ interaction, which would lead to additional recruitment of PSD-95-associated proteins. Against this, however, is the observation that while neuroligin-1 selectively binds to the third PDZ domain of PSD-95, synaptic localization of PSD-95 requires the first two PDZ domains but not the third. Notably, NGL, another adhesion molecule binding to both of the first two PDZ domains of PSD-95 but not to the third, enhances synaptic localization of PSD-95.

PSD-95 occurs in molar excess relative to other postsynaptic proteins. Therefore, instead of depending on its synaptic localization on the interaction with other proteins, PSD-95 might increase its cluster size at synapses by self-multimerization. In support of this notion, PSD-95 forms multimers through both N- and C-terminal domains. The expansion of PSD-95 multimers is more likely to be lateral than vertical because, ultrastructurally, PSD-95 mainly localizes to regions close to the postsynaptic membrane. The lateral expansion might be aided by PSD-95 interaction with membrane proteins and/or palmitoylation (a lipid modification promoting membrane attachment). Indeed, PSD-95 co-expressed with membrane proteins in heterologous cells forms large surface clusters in which both proteins are co-localized. In addition, mutations of PSD-95 that block palmitoylation eliminate membrane protein clustering by PSD-95.

PSD-95 is likely to recruit other postsynaptic scaffolds, including GKAP and Shank. The C-terminal GK domain of PSD-95 associates with GKAP, and the C-terminal PDZ-binding motif of GKAP further associates with Shank. GKAP and Shank are relatively abundant in deeper layers of the PSD and contain various domains for protein–protein interactions. Shank further associates with Homer, which is in turn linked to metabotropic glutamate receptors and IP3 receptors. Shank promotes spine maturation by mechanisms requiring synaptic Homer recruitment. In support of a possible role for PSD-95 in the recruitment of GKAP and Shank, a GKAP mutant lacking the ability to bind to PSD-95 induces the aggregation and degradation of Shank.

Synaptic Adhesion Molecules

Synaptically localized PSD-95 may reversely promote postsynaptic localization of adhesion molecules such as neuroligins or other postsynaptic adhesion molecules, further stabilizing synapse adhesion and promoting presynaptic differentiation. Indeed, overexpression of PSD-95 in cultured neurons concentrates neuroligin-1 and NGL at excitatory synapses. Importantly, PSD-95 induces the translocation of neuroligin-2 from inhibitory to excitatory synapses. Because neuroligin-2 induces presynaptic differentiation at both excitatory and inhibitory synapses, this translocation is likely to increase the number of excitatory synapses at the expense of inhibitory synapses. Therefore, the relative amounts of neuroligin-2 and PSD-95 in a single neuron may determine the ratio of excitatory and inhibitory synapses.

Although PSD-95 concentrates neuroligin at excitatory synapses, this does not seem to involve a direct interaction between the two proteins because a

neuroligin-1 mutant lacking the PSD-95-binding C-terminus is normally targeted to excitatory synapses. Instead, synaptic neuroligin-1 localization requires a membrane-proximal domain in the cytoplasmic domain. This suggests that neuroligin does not depend on its binding either to PSD-95 or to presynaptic neurexins for synaptic localization, and that there is a mechanism that precedes neuroligin localization for early postsynaptic differentiation.

Postsynaptic Receptors

Postsynaptic differentiation at excitatory synapses involves synaptic localization and local trafficking of NMDA and AMPA glutamate receptors. NMDA receptors are targeted to synapses at early stages of development, in contrast to AMPA receptors, thus forming NMDA receptor-only silent synapses. PSD-95 may contribute to synaptic localization of NMDA receptors by interaction with NR2 subunits. In support of this idea, C-terminal casein kinase II phosphorylation of NR2B on Ser1480 within the C-terminal PDZ-binding motif disrupts PSD-95 interaction with NR2B and decreases surface expression of NR2B. PSD-95 coexpression slows the internalization rate of chimeras of Tac (a surface membrane protein) containing the distal tail of NR2B. However, an NR2B mutant that lacks the ability to bind to both PSD-95 and AP2, a clathrin adaptor complex, is retained in the synapse, suggesting that PSD-95 binding may not be important for synaptic localization. In addition, mobile NMDA receptor transport packets in early stage neurons can be recruited to nascent synapses lacking PSD-95. In contrast to NR2B, NR2A does not depend on PSD-95 interaction for synaptic localization, suggesting subunit-specific rules for NMDA receptor trafficking.

Postsynaptic adhesion molecules may regulate synaptic NMDA receptor clustering. A mutant neuroligin-1 that lacks PSD-95 binding ability no longer induces PSD-95 clustering in cultured neurons but retains the ability to cluster NMDA receptors, although weaker than that afforded by wild-type neuroligin-1. This suggests that neuroligin is capable of recruiting NMDA receptors through PSD-95-independent mechanisms. SALM, a PSD-95-interacting family of synaptic adhesion-like molecules, exhibits NMDA receptor clustering activity. SALM1, a member of this family, directly associates with the NR1 subunit and promotes dendritic clustering of NMDA receptors through mechanisms requiring the PDZ-binding C-terminus. SALM2 forms a complex with both NMDA and AMPA receptors, and direct aggregation of SALM2 on dendrites induces co-clustering of NMDA and AMPA receptors.

Synaptic localization of AMPA receptors is regulated by stargazin/TARP (transmembrane AMPA receptor regulatory protein), which directly associates with both AMPA receptors and PSD-95. Stargazin traffics AMPA receptors to synapses via two distinct mechanisms. Stargazin induces surface expression of AMPA receptors and also facilitates synaptic docking of the stargazin–AMPA receptor complex. The latter mechanism depends on binding of the stargazin C-terminus to PSD-95. In support of a role for PSD-95 in synaptic localization of stargazin and AMPA receptors, a stargazin mutant that lacks PSD-95 binding rescues surface AMPA receptor responses, but not synaptic AMPA receptor responses, in cerebellar granule cells from stargazin-deficient stargazer mice.

Other postsynaptic proteins regulating synaptic localization and trafficking of AMPA receptors include GRIP/ABP, PICK1, and *N*-ethylmaleimide-sensitive factor (NSF). GRIP/ABP, a multi-PDZ protein, is implicated in the stabilization of AMPA receptors at the synaptic surface. Synaptic AMPA receptor localization is also regulated by various GRIP-associated proteins including liprin-α (a multidomain protein), GIT1 (a multidomain protein), and LAR (a receptor tyrosine phosphatase). PICK1, through its PDZ domain, associates with protein kinase Cα (PKCα) in addition to AMPA receptors, and it promotes synaptic delivery of PKCα. PKCα directly binds to GRIP, probably promoting the interaction between PICK1-bound PKCα and its substrate, GRIP-bound GluR2. PKC-dependent phosphorylation of GluR2 on Ser880 within the C-terminal PDZ-binding motif selectively disrupts GluR2 association with GRIP but not GluR2 association with PICK1, facilitating AMPA receptor endocytosis. NSF, an ATPase involved in membrane fusion, binds to a cytoplasmic region of AMPA receptors that is distinct from the GRIP/PICK1 binding site. NSF is implicated in maintaining synaptic AMPA receptors by disassembling the AMPA receptor–PICK1 complex and promoting AMPA receptor recycling/delivery. Interestingly, the NSF binding site in AMPA receptors overlaps with that of AP2, and the AP2–AMPA receptor interaction is required for regulated AMPA receptor endocytosis and LTD. In strong support of these *in vitro* results, cerebellar LTD is absent in GluR2 and PICK1 knockout mice and in two different strains of GluR2 mutant knockin mice (GluR2Δ7 and GluR2 K882A). GluR2Δ7 mice have a deletion of the last seven amino acid residues required for both GRIP and PICK1 binding, and GluR2 K882A mice carry a mutation to block PKC-dependent Ser880 phosphorylation. In addition to promotion of endocytosis, PICK1 and NSF regulate AMPA receptor exocytosis. PICK1 and NSF are required for activity-dependent

insertion of GluR2 (calcium-impermeable)-containing AMPA receptors in cerebellar granule–stellate cell synapses. In support of these *in vitro* observations, PICK1 knockout and GluR2Δ7 knockin mice lack this form of plasticity.

Other Membrane Proteins

Synaptic scaffolds concentrate and cluster interacting membrane proteins at the surface membrane. Stability of membrane proteins at the synaptic surface seems to be achieved through the inhibition of their endocytosis and promotion of their exit from intracellular pools and insertion into the plasma membrane. PSD-95 inhibits the endocytosis of NMDA receptors, Kv1.4 potassium channels, and β_1-adrenergic receptors. In addition, PSD-95 promotes the rate of membrane insertion of NMDA receptors. A C-terminal PDZ-binding motif in NR1-3, a splice variant of NR1, suppresses NR1-3 retention at the endoplasmic reticulum (ER), suggesting that a PDZ protein promotes the ER exit and surface expression of NMDA receptors. However, there are examples of the opposite situation, in which scaffolding proteins enhance endocytosis. S-SCAM/MAGI-2, a synaptic multi-PDZ protein, enhances the endocytosis of β_1-adrenergic receptors, and PICK1 is involved in AMPA receptor internalization, as described previously. Finally, functional properties of membrane proteins can be directly regulated by their interaction with scaffolds. PSD-95 suppresses single-channel conductance of the Kir2.3 potassium channel and increases the channel opening rate of NMDA receptors.

Signaling Pathways

Another key event in postsynaptic development is the establishment of signaling pathways in the PSD. A suggested role for synaptic scaffolds is to couple upstream receptor activations to downstream signaling pathways. PSD-95 associates with neuronal nitric oxide synthase, coupling NMDA receptor activation to nitric oxide generation. Similarly, PSD-95 associates with SynGAP, a neuronal GTPase activating protein (GAP) for Ras and Rap small GTPases. This interaction is not involved in synaptic localization of SynGAP but is implicated in functional coupling between NMDA receptors and the Ras-ERK signaling pathway, which regulates AMPA receptor trafficking and synaptic plasticity.

Synaptic scaffolds couple kinases and phosphatases with their specific substrates. PSD-95 and SAP97 associate with AKAP79/150, a neuronal A-kinase-anchoring protein interacting with protein kinase A (PKA), PKC, and protein phosphatase 2B (calcineurin). This interaction, in the context of SAP97 association with GluR1, promotes the PKA-dependent phosphorylation of GluR1 on Ser845, a modification implicated in AMPA receptor function and synaptic plasticity.

PSD-95 associates with Fyn, a nonreceptor tyrosine kinase, to promote Fyn-mediated tyrosine phosphorylation of NR2A. PSD-95 binds to another nonreceptor tyrosine kinase, Src, regulating NMDA receptor-dependent synaptic transmission and plasticity. Notably, this interaction is not involved in synaptic recruitment of Src but, rather, in the suppression of Src activity and Src-mediated NMDA receptor upregulation, reminiscent of the direct functional regulation of membrane proteins by scaffolding proteins.

F-Actin

F-actin is a key cytoskeletal component both in dendritic filopodia and in spines, and it is implicated in the regulation of spine morphogenesis and synaptic plasticity. F-actin is both physically and functionally associated with PSD components. For instance, stable maintenance of GKAP, Shank, and AMPA receptors at synapses requires F-actin integrity. Conversely, LTP- and LTD-inducing stimuli regulate F-actin polymerization. In this context, it is conceivable that PSD proteins may organize F-actin-regulatory signaling pathways.

F-actin polymerization in dendritic spines is regulated by small GTPases, including Rac, Cdc42, Rho, and Rap. Proteins acting upstream and downstream of these small GTPases associate with postsynaptic scaffolds, suggesting that these interactions may constitute related signaling pathways in the PSD. PSD-95 associates with and promotes synaptic localization of kalirin-7, a guanine nucleotide exchange factor (GEF) for Rac1. Shank binds βPIX, a GEF for Rac1 and Cdc42, and promotes synaptic localization of βPIX and βPIX-associated PAK, a kinase downstream of Rac1 and Cdc42 that regulates spine morphogenesis through LIMK-1 and MLC. Both PSD-95 and Shank associate with IRSp53, an abundant postsynaptic protein downstream of Rac1 that regulates spine morphogenesis. Shank associates with Abp1, α-fodrin, and cortactin, proteins that have F-actin binding, bundling, and nucleating activities, respectively. GRIP/ABP associates with EphB receptor tyrosine kinases, and ephrin activation of EphB receptors induces dendritic spine formation through the kalirin–Rac1–PAK pathway and the Cdc42 GEF intersection. Neurabin and spinophilin, which bind protein phosphatase 1 and F-actin and regulate dendritic spines, interact with Lfc, a Rho GEF. In

addition, NMDA receptors associate with and phosphorylate Tiam1, a Rac1 GEF that mediates NMDA receptor-dependent spine regulation.

Neuronal Transport

Synaptic proteins synthesized in the cell body must be transported to their target synapses. Kinesin is a microtubule (MT)-based motor protein implicated in this process. There are approximately 45 kinesin family proteins in the mouse and human genomes. Most kinesins move toward the plus end of MTs. MTs in axons are unidirectionally oriented, with their plus ends pointing toward nerve terminals, whereas dendritic MTs are bidirectionally arranged. Kinesin-dependent transport has been studied mainly in axons, although evidence supports kinesin involvement in dendritic transport.

An important question in neuron motor-dependent transport is how the limited number of kinesin proteins can transport a large number of cargoes. Studies raise the intriguing possibility that molecular scaffolds function as 'motor receptors,' linking motors to various cargoes through protein interaction domains. In accordance with this notion, synaptic scaffolds link kinesins to their specific cargoes. KIF1Bα, a kinesin motor, interacts with PSD-95 and S-SCAM, which are in turn linked to various synaptic proteins. KIF17 associates with the LIN2/7/10 PDZ protein complex that is coupled to NMDA receptors. KIF1A associates with liprin-α, a multidomain protein interacting with the GRIP–AMPA receptor complex. KIF5 interacts with GRIP/ABP, a binding partner of both AMPA receptors and EphB receptors, and disruption of the KIF5-GRIP interaction suppresses EphB trafficking and dendritic morphogenesis. Interestingly, GRIP drives KIF5 to dendrites, suggesting that a cargo regulates polarized transport of a motor.

Regulation of Postsynaptic Assembly

Synapses are dynamically formed and eliminated during development and plasticity. These processes are likely to involve rapid assembly and disassembly of the PSD. Indeed, neuronal activity regulates synaptic localization of PSD components, changing the overall molecular composition of the PSD. GluR1 and protein phosphatase 1 are delivered to synapses by LTP- and LTD-inducing stimuli, respectively. Phosphorylation of synaptic proteins regulates their synaptic localization by affecting, for example, protein–protein interactions. Phosphorylation of the N-terminal domain of PSD-95 by cyclin-dependent kinase 5 suppresses synaptic clustering of PSD-95, whereas SAP-97 phosphorylation in the L27 domain by CamKII enhances synaptic SAP97 localization. Phosphorylation of PDZ-binding ligands disrupts their binding to PDZ domains. Lipid modification also plays a role in postsynaptic assembly. Known examples include palmitoylation of PSD-95, PSD-93, GRIP, and AMPA receptors. The lipid addition regulates the trafficking and synaptic localization of these proteins. Synaptic activity depalmitoylates and disperses synaptic PSD-95 clusters. Enzymes that mediate protein palmitoylation (palmitoyl acyl transferases) of neuronal substrates have been identified. Lastly, protein degradation through the ubiquitin–proteasome pathway is involved in postsynaptic assembly. Neuronal activity regulates ubiquitination of key PSD proteins, including GKAP, Shank, and AKAP79/150. Mdm2, an E3 ubiquitin ligase, plays a role in ubiquitinating PSD-95. SNK, a polo-like kinase induced by synaptic activity, phosphorylates SPAR, a PSD-95-associated Rap GAP that regulates F-actin, and this in turn induces PSD-95 degradation and spine loss.

Introduction

Synapse are specialized contacts used by neurons to communicate with each other. Morphologically, they are cell junctions characterized by specialized membrane and submembrane regions, and their assembly takes place in various stages involving the accumulation of specific pre- and postsynaptic proteins at the contact site. Recent biochemical, genetic, and imaging studies have begun to elucidate the molecular mechanisms underlying their formation, growth, and maturation, and understanding the development and organization of neuron/neuron synapses is crucial to our understanding of the development of the nervous system, in which abnormalities contribute to most neurological and behavioral disorders. Moreover, it is now clear that the adult brain is constantly reorganizing itself in response to experience, and that at least some synaptic developmental mechanisms are used in mature brain during synaptic plasticity.

At the postsynaptic sites of excitatory synapses is localized a specific EM electron-dense organelle called the postsynaptic density (PSD) where the two main types of glutamate-receptor channels, *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, cluster in the postsynaptic membrane. The PSD has attracted the interest of a number of scientists because it is now clear that it regulates synapse function (Figure 1).

Inhibitory synapse in brain are mainly mediated by γ-aminobutyric acid (GABA) neurotransmitters, whose receptor channels are localized on the postsynaptic membrane and are not associated with a clear PSD because the molecular composition of the postsynaptic compartment is much simpler.

Excitatory and inhibitory synapses are therefore clearly distinguishable on the basis of the morphology and molecular composition of the postsynaptic compartment. Each neuron receives both excitatory and inhibitory synapses, which are located in cross-proximity to dendrites in strictly controlled numbers and ratios in order to allow the correct functioning of brain circuits.

Our knowledge of the neuron/neuron synaptogenesis of both types of synapses has recently increased as a result of improvements in time-lapse microscopy and the molecular identification of specific proteins in neuronal synapses. This article concentrates on the structure and development of the synapses between central neurons in mammals, paying particular attention to the postsynaptic compartment. Emphasis will be placed on their molecular and structural composition of the excitatory synapses, and the early steps of synapse formation that underlie their molecular mechanisms.

Excitatory Synapses: Postsynaptic Organization

The PSD is a protein complex that forms a specialized organelle and adheres to the postsynaptic membrane in opposition to the active zones located in the axonal presynaptic terminal. A number of functions have been proposed for this structure, including the regulation of adhesion, the control of receptor clustering, and the regulation of receptor functions.

The PSD contains neurotransmitter and transmembrane receptors, various scaffold proteins, cytoskeletal elements, and regulatory enzymes, all of which are assembled together in a disk-like structure that is 30–40 nm thick and a few hundred nanometers wide.

PSD molecular architecture is designed to specialize in signal transduction, and its protein composition is highly modifiable in order to allow for the strengthening and weakening of glutamatergic synapses. Neural activity dynamically regulates both the function and composition of the PSD, and involves mechanisms such as protein phosphorylation, local translation, ubiquitination and degradation, and subcellular redistribution. Because of the central role of the PSD in synaptic transmission and plasticity, the protein composition of the PSD has been extensively studied in an attempt to understand synaptic mechanisms.

The protein components of the PSD have been gradually discovered over the years using two-hybrid yeast and biochemical approaches. The PSD is typically purified by means of differential centrifugation, sucrose gradient sedimentation, and detergent extraction, because the PSD structure cannot be solubilized using mild nonionic detergents such as Triton X-100. Kennedy et al. first discovered several PSD proteins (e.g., PSD-95, densin-180) by sequencing protein bands from one-dimensional gels of PSD preparations, and many other PSD proteins were later identified using the two-hybrid yeast system as binding partners of known postsynaptic proteins, such as the PSD-95 family of PDZ-containing scaffolds that interact with the cytoplasmic tails of NMDA

[†]Deceased

Figure 1 Molecular organization of glutamatergic synapses. Only the major components and relative interactions are shown. receptors. More recently, modern proteomic and imaging techniques have probably identified all of the proteins of the PSD, and quantified the relative stoichiometry of some of them.

The components of PSD proteins can be divided into four subgroups on the basis of their functions: receptor transmembrane proteins, scaffold proteins, signaling proteins, and cytoskeletal proteins. We will here discuss the major PSD components in each subgroup.

The PSD-95 Family and Other Major PSD Scaffold Proteins

The first and still most widely studied PSD scaffold protein was PSD-95. The PSD-95 family is encoded by four genes: PSD-95/SAP90 (synapse-associated protein 90), PSD-93/chapsyn-110, SAP102, and SAP97. The structure of these proteins is characterized by the assembly of three PDZ (PSD-95, Dlg, ZO-1 homology) domains, an SRC homology (SH3) domain, and a guanylate kinase-like (GK) domain. SAP97 also has a LIN2/LIN7 (L27) domain at the N-terminal. The PSD-95 family belongs to a protein superfamily called membrane-associated guanylate kinase (MAGUK), which is characterized by the presence of at least one PDZ and one GK domain.

Immuno-EM and tomography studies have indicated that PSD-95 is localized very close to the postsynaptic membrane (a mean distance of 12 nm), a good position for interacting with postsynaptic membrane proteins such as receptors, ion channels, and cell-adhesion molecules, as well as with cytoplasmic proteins (Figure 1). It has been suggested that these interactions are important for PSD-95 clustering

and the targeting of postsynaptic membrane proteins, but there is still disagreement as to whether PSD-95 is essential for the synaptic clustering of NMDA receptors in mammals, which is certainly not eliminated by the genetic disruption of PSD-95.

It now seems clear that the most important biochemical function of PSD-95 is to organize the signaling complexes at the postsynaptic membrane. PSD-95 interacts with a wide variety of cytoplasmic signaling molecules and, by physically bringing together cytoplasmic signal-transducing enzymes and surface receptors, may therefore facilitate signal coupling in the PSD. For example, the overexpression of PSD-95 in hippocampal neurons increases the number of dendritic spines, the maturation of excitatory synapses, and the accumulation of AMPA receptors, whereas PSD-95 knockout by RNA interference in developing hippocampal neurons modifies the excitatory/inhibitory synapse ratio in favor of inhibitory synapses. PSD-95 directly binds to the proteins involved in actin remodeling: these include kalirin-7, a guanine nucleotide exchange factor (GEF) for RAC1 that promotes spine formation possibly as a downstream effector of the EphB receptor; SPAR, an inhibitory GTPase-activating protein (GAP) for RAP that promotes the growth of dendritic spines; and IRSp53, a downstream effector of Cdc42 small GTPase. The ability of PSD-95 to recruit AMPA receptors seems to be related to its binding to the tetra-spanning membrane proteins Stargazin and its relatives TARP, which are associated with AMPA receptors and essential for receptor surface expression, and synaptic accumulation and function.

Three other major scaffold components of the PSD that directly interact with each other are Shank, guanylate kinase-associated protein (GKAP), and Homer protein families. Shank, which is also known as proline-rich synapse-associated protein (ProSAP), is a large scaffold protein whose multidomain organization consists of an ankyrin repeat near the N-terminal, followed by an SH3 and a PDZ domain, a long proline-rich region, and a sterile alpha motif domain (SAM) at the C-terminus. Shank proteins (codified by the three genes *Shank1–3*) molecularly link two glutamate receptor subtypes: NMDA receptors and type-I metabotropic glutomate receptors (mGluRs). The Shank PDZ domain binds to the C-terminal of GKAP. Homer interaction with the proline-rich domain ensures the association of Shank with type-I mGluRs.

Shank interacts with a number of actin-binding proteins. It binds to cortactin, Abp1, fodrin, the Rac1 and Cdc42 exchange factor βPIX, and the Cdc42-binding protein IRSp53. Other important Shank interactors are proteins that regulate dendritic morphology and formation, such as Dasm1 and Densin-180, whose activity also seems to be regulated by Shank. Finally, Shank proteins can potentially be produced locally because of the presence of its mRNA in dendrites. The observation that the haploinsunficency of Shank3 in humans probably causes the neurological symptoms of individuals affected by the 22q13 deletion syndrome indicates that Shank proteins play a major role in synapse functions.

The GKAP/SAPAP family of proteins is less well characterized, but its four members were originally identified as proteins interacting with the GK domain of PSD-95. GKAP has five repeats of 14 amino acids involved in interacting with PSD-95 and, as it binds to *S*-SCAM, nArgBP2, Dynein light chain, and Shank, may therefore function as a scaffolding protein that links PSD protein complexes to motor proteins.

Homer proteins are encoded by three genes (*Homer 1–3*), and typically consist of an N-terminal Ena/VASP homology 1 (EVH1) domain followed by a coiled-coil domain that mediates dimerization with other Homer proteins. The EVH1 domain of Homer1 binds to a PPXXF or very similar sequence motif in Shank, mGluR1/5, inositol-1,4,5-trisphosphate (IP_3) receptor, ryanodine receptor, and to different members of the TRPC family of ion channels. Through their ability to self-associate, Homer isoforms containing the coiled-coil domain (called 'CC-Homer' or Homer1b in the case of the Homer1 gene) can physically and functionally link the proteins and receptors that bind to the EVH1 domain. Homer1a is a short-splice variant of Homer1 that contains the EVH1 domain, but lacks the coiled-coil domain; it functions as a natural dominant negative because it cannot dimerize. It is important to note that Homer1a expression is induced at mRNA level by synaptic activity.

AMPA receptors are linked to a different set of scaffolding proteins, which includes GRIP/ABP (encoded by the two distinct genes *GRIP1* and *ABP/GRIP2*), and the protein interacting with C kinase 1 (PICK1); these interactions may account for the dynamic cell biological behavior of AMPARs at synapses.

It is believed that GRIP is involved in the synaptic trafficking and/or stabilization of AMPARs and other interacting proteins. GRIP has up to seven PDZ domains by means of which it interacts with many proteins, including Eph receptors and their ephrin ligands, an RAS guanine nucleotide exchange factor (RasGEF), liprin-α, the transmembrane protein Fraser syndrome 1 (FRAS1), and the metabotropic and kainite-type glutamate receptors. It can therefore participate in synaptic function not only by interacting with AMPARs, but also by associating with Eph receptors and their ephrin ligands, which have been

found to be involved in dendrites and dendritic spine morphogenesis and hippocampal synaptic plasticity. The widespread cellular distribution of GRIP, and its interaction with motor proteins (directly with conventional kinesin KIF5 or indirectly with KIF1A via liprin-α), suggest that multiple motor proteins may contribute to the transport of AMPARs.

PICK1 is located at neuronal synaptic and nonsynaptic sites. Its PDZ domain has relatively promiscuous binding properties, and both pre- and postsynaptic partners have been found: PKCα, GluR2/3, the netrin receptor UNC5H, various metabotropic glutamate receptor subtypes, the dopamine plasma-membrane transporter, and the erythroblastic leukemia viral oncogene homolog 2 (ErbB2) receptor tyrosine kinase. In most of these cases, the subcellular localization and/or surface expression of these partners seems to be regulated by interactions with PICK1.

Receptor and Transmembrane Proteins

The major transmembrane and receptor proteins are of course the glutamate receptors which, in the PSD, are organized into supramolecular signaling complexes by interacting with specific PDZ domain-containing scaffold proteins, such as PSD-95/SAP90 and their associated proteins for the NMDA receptors, and GRIP/ABP for the AMPA receptors. The distribution of glutamate receptors and content of synapses vary during development: immature synapses preferentially contain NMDA receptors and gradually acquire AMPA receptors, an observation that has led to the identification of what have been called silent synapses because the absence of AMPA receptors makes them less responsive to glutamate. AMPA and NMDA receptors seem to be homogenously mixed and distributed inside the postsynaptic membrane, but the mGluRs are mainly distributed at the leading edge of the synapses.

Behind the receptors, an important role is played by the transmembrane adhesion molecules that regulate synapse formation and structures. Neuroligin is a synaptic adhesion molecule that probably plays an important role in synapse formation: it interacts with PSD-95 and transsynaptically with β-neurexins, which in turn bind to the PDZ domain of CASK/LIN2 (another scaffold of the MAGUK superfamily of proteins), which is enriched on both sides of the synapse and interacts with other synaptic membrane proteins such as syndecan and SynCAM. The transsynaptic neuroligin/β-neurexin interaction seems to be important for inducing pre- and postsynaptic synaptic differentiation, and the amount of PSDS-95 regulates the balance between the number of inhibitory and excitatory synapses (see below). When heterologous cells overexpressing neuroligin are co-cultured with neurons, they are able to induce morphological and functional presynaptic specializations in contacting axons.

Cadherins are found on both the pre- and postsynaptic sides of neuron synapses. Dominant-negative studies of neuronal(N)-cadherin function indicate that the cadherin cell-adhesion system is important for synapse integrity and the morphological maturation of dendritic spines; however, it is unclear whether cadherins play an initiating role in synapse formation or a supporting role in synapse growth. Through their cytoplasmic tails, cadherins bind α- and β-catenins, which in turn bind to the actin cytoskeleton and thus anchor and consolidate the cadherin cell-adhesion complex.

Integrins are heterodimeric glycoproteins that contain α- and β-subunits. Many of the 16 α- and eight β-subunits that have been identified so far are expressed in different spatial patterns in the brain. Integrins function as cell-to-matrix or cell-to-cell adhesion molecules by respectively binding to extracellular matrix proteins or immunoglobulin-superfamily receptors on other cells. They interact through their cytoplasmic domains with the actin-binding proteins, talin and α-actinin, and also activate nonreceptor protein tyrosine kinases, such as the focal-adhesion kinase that affects cytoskeletal organization and intracellular signal transduction. One immunoglobulin domain-containing protein that is found in synaptic membranes is the synaptic cell-adhesion molecule (SynCAM), which can also induce presynaptic differentiation in contacting axons when it is expressed in nonneuronal cells. SynCAM shows homophilic cell-adhesion activity through its extracellular domain, and can bind to PDZ proteins such as calcium/calmodulin-dependent serine protein kinase (CASK) through its cytoplasmic tail.

Finally, synapses contain the important tyrosine kinase EphB (ephrin B) family of RTKs and their cognate ephrinB ligands. These proteins play well-known roles in axon guidance and topographic map formation in the nervous system. The ephrinB/EphB receptor system is also involved in the development of excitatory synapses and dendritic spines by means of the phosphorylation of a cell-surface heparan/sulphate proteoglycan Syndecan and the recruitment of kalirin, a guanine-nucleotide exchange factor for the Rac GTPase. In addition, EphB2 seems to interact physically with NMDA receptors and enhance their channel activity, and ephrinB ligands can induce the clustering of NMDA receptors.

Signaling Proteins

A number of signaling proteins are associated with PSD-95. One of these is nitric oxide synthase (nNOS), a Ca^{2+}/calmodulin-activated enzyme that produces the

nitric oxide involved in regulating neurotransmission and excitotoxicity. Interestingly, the ternary NMDAR/PSD-95/nNOS complex may functionally couple NMDAR gating to nNOS activation, as is suggested by the fact that disrupting the NMDAR/PSD-95 interaction by means of a synthetic peptide mimicking the last nine residues of NR2B reduces NMDAR-induced excitotoxicity without affecting NMDAR function.

The most abundant signaling protein in the PSD is its predominant kinase CaMKII, whose multiple functions include regulating receptor targeting and function at synapses. The substrates for CaMKII have not yet been completely identified, but they include several PSD proteins.

Another abundant PSD signaling molecule that binds to PSD-95 is the synaptic Ras GTPase-activating protein (SynGAP), a GAP for the Ras small GTPase which, after activation by CaMKII, suppresses the ERK pathway regulating synaptic plasticity. PSD-95 also associates with the nonreceptor tyrosine kinases of the Src family and their upstream activator, proline-rich tyrosine kinase 2 (Pyk2), both of which are thought to be important for synaptic plasticity. It is therefore possible that it may localize the Pyk2–Src signaling cascade close to NMDARs, although the importance of PSD-95 scaffolds in synaptic regulation by tyrosine phosphorylation has not been directly investigated.

Smaller amounts of several other signaling proteins are associated with the PSD, including a number of kinases and phosphates whose functions have not been completely clarified.

Cytoskeletal Proteins

It has been demonstrated that a number of actin-binding proteins (usually Rho and Rac GTPase effectors regulated by Ca^{2+}) control the actin cytoskeleton in dendritic spines and excitatory synapses. Most of them are formed by the concatenation of different protein interaction domains and thus function as scaffolds assembled in multimolecular complexes that are enriched in the PSD.

One of the most abundant cytoskeletal proteins is drebrin, an F-actin-binding protein that is mainly expressed in neurons and highly concentrated in the PSD. In cortical neurons, drebrin overexpression increases the length of dendritic spines and, in hippocampal neurons, drebrin promotes actin assembly and the synaptic clustering of PSD-95 in the PSD. Importantly, drebrin (but also profilin II and αN-catenin) are redistributed to dendritic spines with an increased F-actin content after the induction of LTP in the dentate gyrus, or general synaptic activation and NMDA receptor activation, which suggests their importance in inducing F-actin polymerization and/or stabilization upon synaptic stimulation.

Profilin is a small actin-binding protein that promotes actin polymerization by positioning the actin monomers at the barbed end of the growing F-actin. Profilin II stabilizes spine morphology in a mature state, and suppresses dendritic spine motility by reducing actin dynamics.

αN-catenin is a cadherin-associated protein that, together with β-catenin, links adhesion molecules to the cytoskeleton and actin. In the absence of αN-catenin, dendritic spines are more motile and their filopodia rapidly protrude and retract from the spine heads, a sign of unstable synaptic contacts. Conversely, the overexpression of αN-catenin accelerates dendritic spine maturation and decreases spine motility, thus suggesting that it promotes spine morphogenesis and stabilization.

Spinophilin (or neurabin II) and neurabin I are two related F-actin-binding proteins with similar domain structures containing a PDZ and a coiled-coil domain that form homo- and heterodimers. Via its actin-binding domain, spinophilin is predominantly localized on the dendritic spines of pyramidal neurons (as its name suggests); it seems to be required for the correct maturation of dendritic spines because knockout mice have more filopodia and immature spines, and show altered glutamatergic transmission. On the contrary, neurabin I overexpression induces the formation of dendritic filopodia in immature cultured hippocampal neurons, and promotes the enlargement of dendritic spines in older neurons. It is not clear how spinophilin and neurabin I have opposite effect on spines, although they both bind a similar set of synaptic proteins.

Two other abundant actin-binding proteins localized at the PSD are α-actinin-2 and IRSp53. α-Actinin is a member of the spectrin/dystrophin family of actin-binding proteins, and binds to the NR1 and NR2B subunits of NMDA receptors, thus providing a cytoskeletal bridge between NMDA receptors and actin.

IRSp53 not only interacts with Shank, PSD-95 and PSD-93, and all of these interactions are required for its spine localization: its overexpression in cultured neurons increases the density of dendritic spines, while its siRNA-mediated knockdown reduces spine density, length, and width. IRSp53 plays a role in linking PSD-95 to activated Rac1/Cdc42 and downstream effectors of actin regulation in spines.

Inhibitory Synapses: Postsynaptic Organization

The composition of inhibitory postsynaptic components is much simpler. Fast GABAergic neurotransmission is mediated by ionotropic GABA receptors (principally

the $GABA_A$ receptor subtype), which are ligand-gated chloride channels that are segregated from glutamate receptors and concentrated in the postsynaptic membrane of inhibitory synapses. Unlike the subunits of ionotropic glutamate receptors, each subunit of a $GABA_A$ receptor has its carboxyl terminus on the extracellular side of the membrane. The only major cytoplasmic domain of $GABA_A$ receptors is the loop between the third and fourth transmembrane segments. Reasoning that this loop is likely to form the site of GABA receptor interactions with intracellular proteins, two-hybrid yeast screens have been used to search for interacting gene products using these loops, and two proteins associated with microtubules have been identified: GABARAP, which binds to the intracellular loop of the abundant $\gamma 2$ subunit of $GABA_A$ receptors, and the MAP1B heavy chain that specifically binds to the intracellular loop of the $\rho 1$ subunit of ionotropic $GABA_C$ receptors, almost exclusively in the retina. In addition to these proteins, gephyrin, neuroligin-2, and the dystroglycan/dystrophin complex are other identified components of some mature GABAergic postsynaptic sites. Gephyrin and neuroligin-2 have been respectively implicated in GABA receptor localization to synapses and the formation of inhibitory synapses, but the mechanisms underlying these activities remain elusive: for example, neuroligin-2 is mainly localized at inhibitory synapses, but a possible C-terminal interactor (like PSD-95 at excitatory synapses) has not yet been identified.

Synapse Development: A Morphological View

Over the last few years, a number of studies have described how synapses are formed morphologically: for example, the first rudimentary synapses in the rat hippocampus can be observed on postnatal day 1, after which the density of synapses in the CNS gradually increases during the following weeks with the number doubling in the second postnatal week and from day 15 to adulthood. A similar time course can be observed in neurons *in vitro*, although the maximum number is generally smaller in cultures.

As previously mentioned, adhesion molecules play an essential role in synapse development, but it is not known how many neuronal cell-surface molecules really participate in this interaction, or how they signal to effect downstream events in synapse differentiation.

Synapse assembly has been more directly visualized using cultured neurons transfected with synaptic proteins tagged with fluorescent proteins, and these time-lapse studies have shown that many components of the synaptic junction are rapidly assembled after the initial contact of axons and dendrites in a timescale of tens of minutes (Figure 2). Some studies have shown that presynaptic markers such as Bassoon (a scaffold protein of the presynaptic active zone) and synaptophysin (a synaptic-vesicle membrane protein) can accumulate at new synapses before postsynaptic NMDA receptors and PSD-95, which may indicate that presynaptic differentiation precedes postsynaptic development.

These findings support the hypothesis that presynaptic specialization is constructed from preassembled 'packets' of vesicles and/or proteins, and at least two types of precursor complexes have so far been identified, one including VAMP, synaptic-vesicle protein 2 (SV2), synapsin I, and voltage-gated calcium channels, the other containing Piccolo, Bassoon, Rab3-interacting molecule (RIM), syntaxin, and SNAP-25 and N-cadherin.

The mechanisms of assembling postsynaptic specialization are less well characterized than those on the presynaptic side. Postsynaptic assembly may depend either on the gradual recruitment of individual proteins, or on the delivery of prefabricated protein complexes to the PSD. For example, a study has identified in dendrites the presence of a class of vesicles that carry NMDA receptors associated to proteins including Veli/MALS, CASK, and the microtubule-dependent motor KIF17. In a more recent publication it has demonstrated that a complex of postsynaptic scaffold proteins consists of two populations with different content, mobility and involvement in synapse formation. One subpopulation is mobile and relies on actin transport for delivery to nascent and

Figure 2 Schematic representation of the temporal sequence accumulation of specific pre- and postsynapse compartments based on time-lapse imaging observations of developing neurons in culture. Synapse formation is initiated by contact between dendrites and axons. These studies suggest that both synaptic sides can differentiate before the other, and that there are probably contact-induced signals triggering synapse assembly on both the pre- and postsynaptic sides.

existing synapses: these mobile clusters contain the PSD-95, GKAP, and Shank scaffolding proteins, and a slow-moving and short-traveling proportion contain neuroligin-1. The second group consists of stationary nonsynaptic scaffold complexes that mainly contain neuroligin-1, and can recruit synaptophysin-containing axonal transport vesicles that are rapidly transformed to functional presynaptic contacts that recycle the vital dye FM 4-64. These results postulate a mechanism whereby preformed scaffold protein complexes serve as predetermined postsynaptic hot spots for the establishment of new functional excitatory synapses. Interestingly, it has been found that the assembly of the scaffold protein complex requires PSD-95, because interfering with PSD-95 expression by siRNA in young hippocampal neurons disrupts the clustering of GKAP and Shank, reduces the number of excitatory synapses, and increases the number of vesicular GABA transporter (VGAT) puncta that are positive for neuroligin-1, thus indicating a shift in neuroligin-1 localization from excitatory to inhibitory contacts. The main conclusion of this study indicates that this preformed complex plays a role in inducing presynaptic maturation.

Other time-lapse imaging studies performed in dissociated hippocampal cultures indicate that PSD proteins accumulate gradually at nascent synapses with kinetics that have time constants in the range of minutes. Although not well understood, the gradual clustering of these proteins indicates that PSD proteins are recruited to nascent synaptic sites from diffuse cytoplasmic or membranal pools or, in some cases, are recruited to extrasynaptic sites, from where could then move laterally and merge with nearby synaptic clusters. It is possible to postulate that during the early stages of synaptic formation, postsynaptic preassembled protein complexes play a major role in the PSD assembly by catalyzing the initial step of synapses formation, whereas in a later stage gradual recruitment from diffuse intracellular pools regulates synaptic grow and maintenance.

Overall, these studies suggest that there are probably contact-induced signals triggering synapse assembly on both the pre- and postsynaptic sides and that both synaptic sides can differentiate before the other.

Post-Tetanic Potentiation (PTP)

R S Zucker, University of California, Berkeley, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

The strength of synaptic transmission can increase or decrease during repetitive presynaptic activity. These changes, usually due to variations in amount of transmitter released by each action potential, dynamically shape the information transfer characteristics of synapses.

Components of Activity-Dependent Synaptic Plasticity

Phases of Enhanced Synaptic Transmission

Chemical synapses are rarely static transmitters of information between neurons. Their effectiveness waxes and wanes, depending upon frequency of stimulation and history of prior activity. At most synapses, repetitive high-frequency action potentials (often called a tetanus) result initially in a rapid growth of successive postsynaptic potential (PSP) amplitudes, called synaptic facilitation (or sometimes frequency facilitation). This process builds to a steady-state within about 1 s and decays equally rapidly when stimulation stops. Decay is measured by single test stimuli given at various intervals after a conditioning train. Facilitation can often be divided into two exponential phases, lasting tens and hundreds of milliseconds, respectively, and called the first and second components of facilitation. It may reach appreciable levels, as high as a doubling or more of the PSP amplitude in the second of two responses at short intervals, and as much as nearly 100-fold increase in PSP amplitude in a high-frequency train in some synapses. If presynaptic activity is sustained, facilitation is followed at most synapses by a slower phase of increased efficacy called augmentation, with a characteristic time constant of several seconds. Finally, prolonged activity results in a final phase of PSP growth, called potentiation and lasting several minutes. These processes can each increase transmission a further several-fold over initial baseline levels. The combination of all three processes, at least some of which (facilitation and potentiation in particular) appear to interact multiplicatively, could in principle elevate synaptic transmission several 100-fold, but in practice saturation of the release mechanisms usually limits the overall enhancement to less than 100-fold.

Synaptic Depression

Often superimposed on these phases of enhanced synaptic strength is a phase of diminishing transmission called synaptic depression. This process is characterized by a drop in PSP amplitude during repetitive presynaptic action potentials. Depression can be absent or undetectable, quite modest, or so severe that transmission drops to zero. Depression often tends to overlap and obscure the augmentation and potentiation phases. When repetitive activity ceases, recovery from the various components of short-term synaptic plasticity occurs in the same order in which they developed during the previous activity, with facilitation decaying first, then depression and augmentation, and finally potentiation (Figure 1). Thus, potentiation is often visible as a distinct phase only long after repetitive activity or a tetanus, and so is usually called posttetanic potentiation (PTP).

Short-Term Plasticity due to Changes in Transmitter Release

Presynaptic Locus Implicated by Quantal Analysis

There are many points at which synapses can be modulated to alter the strength of synaptic transmission. The possibilities may initially be divided into presynaptic and postsynaptic processes. A good way to distinguish these two classes is to make use of the fact that synaptic transmission is 'quantized,' in the sense that each PSP represents the summed effect of the fusion of a certain number of presynaptic vesicles, each of which causes a reasonably fixed 'unitary' postsynaptic response. The number of vesicles that contribute to synaptic transmission is not fixed, even in the complete absence of synaptic plasticity, but rather is a random variable that fluctuates about some average number or mean. By statistical analysis of these fluctuations, it is possible to determine the number of unitary components in a PSP. Furthermore, even in the absence of presynaptic action potentials, vesicles occasionally fuse spontaneously with the plasma membrane, and the secretion of the contents of a single vesicle can be observed as a spontaneously occurring unitary or miniature PSP (MPSP). Comparison of the size of MPSPs to full PSPs evoked by action potentials also allows estimation of the number of vesicles contributing to a synaptic response.

This kind of analysis, called quantal analysis, has been applied to a large number of instances of short-term synaptic plasticity, including facilitation, augmentation, potentiation, and depression in humans, lower mammals, birds, amphibians, crustaceans, mollusks, insects and annelids. In practically all cases, every kind of short-term plasticity is accompanied by changes in the number of quanta released, often called quantal

Figure 1 The red traces show the different kinetic components of short-term synaptic plasticity. On the left, transmission is shown as increasing early in a tetanus due to facilitation and then augmentation, and then as decreasing due to depression, and finally increasing again as potentiation is expressed after depression has reached a steady state. This curve represents the successive responses to action potentials during continuous stimulation. After the tetanus is stopped, recovery is measured by single action potentials at various times after the end of the tetanus, shown on the right. At very short intervals, facilitation is slightly higher than the last tetanic stimulus (because the inter-pulse interval is reduced from that during the tetanus), but facilitation decays rapidly, and augmentation more slowly. This is followed by recovery from depression, leaving only PTP. Different synapses have different mixes of facilitation, augmentation, depression, and PTP, and depression may develop and recover more or less rapidly than in this example.

content, with little or no change in the size or postsynaptic effectiveness of the unitary response to a quantum of transmitter. Thus, short-term synaptic plasticity is almost always a consequence of changes in one or more presynaptic process involved in determining the number of vesicles that action potentials cause to be secreted during neurotransmission.

Changes in Statistics of Transmitter Release

The statistics of transmitter release closely resemble those of a binomial process, in which an average of m quanta is released from a pool of n available quanta, each with a probability p of release by an action potential. The values of n obtained in such analyses are usually similar to or somewhat less than the number of anatomical synapses observed ultrastructurally. Each such synaptic contact, or active zone as it is sometimes called, consists of a cluster of presynaptic vesicles, some docked at the plasma membrane, opposed to a cluster of postsynaptic receptors across the synaptic cleft. The approximate correspondence between n and number of active zones suggests that each active zone can only release one docked vesicle in response to an action potential. If all the apparently docked vesicles could be released independently and simultaneously, n would greatly exceed the number of active zones, since it is usually clear that postsynaptic receptors are not saturated by a quantum, so that multiple quanta released at one site would summate in their effects and be readily detected. Studies of synapses consisting of a single active zone confirm that they are normally capable of releasing only a single vesicle.

Short-term synaptic plasticity is usually accompanied by parallel changes in both n and p. The likely explanation for this is that p is not uniform across all active zones (as assumed in the simple binomial model), and may be near zero for some sites that rarely release a vesicle. Synaptic enhancement increases the probability of release from active zones, and raises previously silent active zones to a level of activity in which they begin to participate in transmission. Depression has the opposite effect – fewer active zones participate effectively in the release process, and those still active have a reduced probability of releasing a vesicle.

Possible Presynaptic Mechanisms

Much experimental effort has gone into exploring presynaptic mechanisms that could underlie facilitation, augmentation, and potentiation. The first step in

synaptic transmission is the invasion of the action potential into presynaptic terminals. In a few preparations, facilitation has been found to be caused by action potential broadening, arising mainly from accumulating inactivation of K^+ channels involved in terminating action potentials. In these synapses, increases in Ca^{2+} influx in prolonged action potentials underlie facilitation of transmitter release.

At most synapses that have been studied, short-term synaptic plasticities occur in the absence of any changes in presynaptic action potential propagation or waveform in presynaptic terminals and can be elicited by trains of constant presynaptic depolarizing pulses. A second possible locus of modulation is the presynaptic Ca^{2+} channel. In a few instances, presynaptic Ca^{2+} channels have been found to show a form of facilitation, with increased duration or probability of opening to repeated depolarizations, but this process contributes little to enhanced synaptic transmission at neurons, although it appears to be involved in facilitation of hormonal secretion from adrenal chromaffin cells.

The Role of Ca^{2+} in Short-Term Synaptic Enhancement

That facilitation, augmentation, and potentiation depend upon presynaptic Ca^{2+} entry is now well established from experiments on several different preparations. The pioneering experiments of Bernard Katz and Ricardo Miledi demonstrated that an action potential that invades a nerve terminal in a Ca^{2+}-free medium not only evokes no transmitter release but also fails to facilitate release to closely following action potentials stimulated after the rapid reintroduction of Ca^{2+} to nerve terminals by local iontophoresis. Facilitation does not require that the first action potential trigger secretion, however, since action potentials that happen to cause no release (at low external $[Ca^{2+}]$ levels) are still effective in inducing facilitation. Experiments on augmentation and PTP also show that these longer-lasting forms of enhanced synaptic transmission depend on Ca^{2+} influx into nerve terminals during conditioning stimulation. Experimental elevation of presynaptic $[Ca^{2+}]_i$ levels has also been shown to substantially increase the number of quanta released by an action potential.

Much attention has focused on how Ca^{2+} ions induce these forms of plasticity. A number of possibilities exist.

The Single Site Summating Residual Ca^{2+} Hypothesis

The simplest possibility is that all forms of synaptic enhancement arise from the cooperative action of four or more Ca^{2+} ions in triggering secretion. This cooperativity is inferred from the finding that the magnitude of the phasic release of transmitter (i.e., the number of vesicles or quanta released) by an action potential depends on approximately the fourth power of external $[Ca^{2+}]$. Secretion can also be evoked by the rapid elevation of $[Ca^{2+}]_i$ liberated by intense flash irradiation of presynaptically injected photosensitive Ca^{2+} chelators; again, the maximal rate of secretion is related to the fourth power of the peak level of $[Ca^{2+}]_i$. This highly nonlinear dependence of secretory rate on $[Ca^{2+}]_i$ could naturally lead to increased transmitter release in the presence of a residual increase in $[Ca^{2+}]_i$ after action potentials. This is best seen by using a simple hypothetical calculation: suppose an increase of $[Ca^{2+}]_i$ by 1 μmol l^{-1} normally underlies an unfacilitated PSP consisting of 10 quanta, or the vesicle fusions occurring in 1 ms, and 20 ms later $[Ca^{2+}]_i$ is still elevated by 0.1 μmol l^{-1} above resting level (about 50 nmol l^{-1}). Then another action potential following the first by 20 ms might increase $[Ca^{2+}]_i$ to a peak level of 1.1 μmol l^{-1} above the resting level, which owing to the fourth-power dependence of secretion on $[Ca^{2+}]_i$ would facilitate release so that the second PSP is 46% larger (in quantal number) than the first ($1.1^4 - 1$). But the residual $[Ca^{2+}]_i$ itself would only cause secretion to occur at a rate of 1 quantum s^{-1} (10×0.1^4 ms^{-1}). Such modest increases in MPSP frequency are actually observed during facilitation, augmentation, and potentiation, and have been regarded as evidence for this hypothesis. The different phases of enhanced transmission could arise from different phases of calcium accumulation during nerve activity and its subsequent decay, with rapid phases limited by calcium diffusion away from docked vesicles near Ca^{2+} channels and slow phases representing effects of Ca^{2+} binding to intracellular buffers, Ca^{2+} being sequestered into Ca^{2+}-storing organelles such as endoplasmic reticulum and mitochondria, and Ca^{2+} extrusion from nerve terminals by pumps such as the Ca^{2+}-dependent ATPase and Na^+/Ca^{2+} exchanger at the plasma membrane.

The trouble with this simple and elegant hypothesis is that it should not be possible to obtain the very high levels of posttetanic facilitation/augmentation/potentiation sometimes observed (up to 100-fold increase) without a massive increase in MPSP frequency to levels substantially higher than the maximum rate of release to a single action potential (two times higher for an enhancement of 100: $100^{1/4} - 1$). Such predicted large increases in MPSP frequency are not observed.

The situation is even worse now that it is possible to estimate the peak $[Ca^{2+}]_i$ level needed to trigger phasic

secretion and the residual $[Ca^{2+}]_i$ present during periods of facilitation, augmentation, or potentiation. The former can be obtained from measurements of local $[Ca^{2+}]_i$ elevations using low-affinity indicators, calculations of the effects of presynaptically injected Ca^{2+} buffers on secretion, and the elevations of $[Ca^{2+}]_i$ released by photolysis of photosensitive chelators needed to mimic secretory rates triggered by action potentials. From all these methods, about 20 μmol l^{-1} $[Ca^{2+}]_i$ appears to be required to trigger a typical PSP. On the other hand, measurements of residual $[Ca^{2+}]_i$ during facilitation, augmentation, and PTP reveal levels of about 1 μmol l^{-1}, which would enhance release by only 22% maximally ($1.05^4 - 1$) – far less enhancement than any of these processes is capable of displaying at many synapses. However, at some synapses displaying only very modest facilitation, this nonlinear effect of residual $[Ca^{2+}]_i$ with the $[Ca^{2+}]_i$ transient during an action potential does appear to be responsible for the plasticity observed.

Independent Site Hypotheses

These considerations led to proposals that presynaptic Ca^{2+} acts in eliciting short-term synaptic enhancement at molecular targets different from the target involved in phasically triggering exocytosis. Two versions of this hypothesis may be distinguished. The first proposes that Ca^{2+} entering during action potentials binds to sites that enhance transmitter release to subsequent action potentials, and that the duration of each phase of enhancement reflects the binding time (dissociation rate) of Ca^{2+} from a different site. The second version proposes that synaptic enhancement is due to the continuing action of residual Ca^{2+} ions acting in equilibrium at one or more sites that enhance transmitter release to subsequent action potentials. The different phases of enhancement could reflect the kinetics of different processes removing residual Ca^{2+}. In support of the latter proposal is the finding in a number of synapses that facilitation, augmentation, and potentiation decay in parallel with phases of decay of residual Ca^{2+} in active zones.

The Residual Bound Ca^{2+} Hypothesis

One way to distinguish these possibilities is by use of exogenous Ca^{2+} buffers. Slowly binding buffers (e.g., ethylene glycol bis(*β*-aminoethyl ether)-*N*,*N* tetraacetic acid (EGTA)), or modest concentrations of fast-acting buffers (e.g., 1,2-bis(*o*-aminophenoxy) ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid (BAPTA)) ought to be able to hold residual rises in $[Ca^{2+}]_i$ to a minimum, while having little effect on the peak $[Ca^{2+}]_i$ concentrations at docked vesicles near Ca^{2+} channels that trigger exocytosis. Synaptic enhancement due to residual bound Ca^{2+} would be unaffected, while effects due to the continuing action of residual free Ca^{2+} would be blocked. However, experiments with these buffers loaded into presynaptic terminals have yielded variable results. Augmentation and PTP are usually (but not absolutely always) blocked, while facilitation is sometimes blocked and sometimes not. Such variable results may reflect different degrees of success in blocking residual $[Ca^{2+}]_i$ elevations, which have rarely been monitored in these experiments, and different degrees of saturation of the exogenous buffers by the $[Ca^{2+}]_i$ levels reached during action potentials in active zones in different preparations.

The Residual Free Ca^{2+} Hypothesis

In one study, the effect of exogenous BAPTA was monitored, and shown to eliminate the accumulation of residual Ca^{2+} in short trains causing facilitation. Facilitation was greatly reduced, and what was left had a much shorter time constant (40 ms). This was probably due to the effect of Ca^{2+} entering during the action potential on the facilitation site, suggesting that facilitation is a process which itself lasts less than 100 ms and is normally rate-limited by the decay of $[Ca^{2+}]_i$ within active zones, from which Ca^{2+} will diffuse with apparent time constants of tens and hundreds of milliseconds. It is still unclear whether the two components of facilitation are due to the multi-exponential time course of Ca^{2+} removal, or to actions on different molecular targets.

In another study, residual Ca^{2+} was rapidly reduced following conditioning stimulation by brief illumination of a photosensitive buffer that takes up Ca^{2+} on photolysis. Facilitation then disappeared within 10 ms after an action potential, while augmentation and PTP were both truncated to a process lasting less than a second. Since augmentation and PTP also show a similar dependence of magnitude of enhancement of transmitter release on submicromolar levels of residual $[Ca^{2+}]_i$, augmentation and potentiation appear to be due to residual Ca^{2+} acting at a high-affinity site distinct from the sites involved in either facilitation (intrinsically decaying more rapidly) or exocytosis (having a much lower Ca^{2+} affinity than either facilitation or augmentation/ PTP).

Saturation of Endogenous Ca^{2+} Buffers – A Special Form of the Second Site Hypothesis

Calcium is buffered in cytoplasm by a variety of proteins with different capacities and affinities for Ca^{2+} ions. At some synapses, an important part of the buffering is accomplished by high-affinity buffers such as calbindin-D28k that are easily saturated by

low levels of residual $[Ca^{2+}]_i$. Following one or more action potentials, less of this buffer is available to capture Ca^{2+} ions entering through Ca^{2+} channels, so that a higher local $[Ca^{2+}]_i$ triggers a facilitated release of vesicles docked near those channels. This process seems to occur at inhibitory synapses from mouse multipolar interneurons onto cortical pyramidal cells and at excitatory mossy fiber synapses onto CA3 hippocampal pyramidal cells. However, such a mechanism failed to account for facilitation at rat somatosensory cortical pyramidal synapses onto bitufted interneurons, or at Schaffer collateral afferents onto CA1 pyramidal neurons, where a different molecular Ca^{2+} target modulating transmitter release appears to be implicated.

Molecular Targets in Short-Term Synaptic Enhancement

The sites of Ca^{2+} action in facilitation, and in augmentation/ PTP, have generally not been identified. The rapid rise of facilitation after each action potential and the similarity of its kinetics to the expected diffusion of Ca^{2+} from active zones suggest that it is activated by Ca^{2+} acting at the level of one to a few micromolar on targets on or near docked vesicles. Neuronal Calcium Sensor-1 has been identified as a strong candidate for such a target at excitatory synapses between dissociated hippocampal neurons in culture, but it is not certain whether NCS-1 acts as a Ca^{2+} buffer or a regulator of synaptic transmission. Augmentation/PTP may result from Ca^{2+} acting at more distant sites, for example, on processes that mobilize vesicles to docking sites and ready them for release. Synapses formed between cultured hippocampal neurons seem to rely on Ca^{2+} binding to calmodulin and munc-13 to produce augmentation, which is therefore a strong candidate molecular target for generating augmentation at these synapses.

The Persistence of PTP

If augmentation and potentiation are due to Ca^{2+} acting at the same site with subsecond kinetics and high affinity, why does PTP last so much longer than augmentation? The answer is that both rise with the accumulation of Ca^{2+} in nerve terminals and last until residual Ca^{2+} is removed. Two processes slow down the removal of Ca^{2+} after prolonged activity. (1) Ca^{2+} gradually accumulates in mitochondria during sustained activity, and slowly leaks out afterwards into the cytoplasm. The gradual loading of mitochondria leads to a slow rise in cytoplasmic Ca^{2+} during activity, and the long time it takes to fully unload mitochondria results in the prolonged small posttetanic residual Ca^{2+} responsible for PTP. Blocking mitochondrial uptake of Ca^{2+} eliminates PTP. (2) Presynaptic $[Na^+]_i$ rises and reduces the rate of Ca^{2+} extrusion by Na^+/Ca^{2+} exchange. This exchanger uses the normally high external-to-internal sodium gradient as the energy source for removing Ca^{2+}, and reducing this gradient retards the pump. This is why procedures that increase the loading of presynaptic terminals with Na^+ ions magnify and prolong PTP.

Modulation of Short-Term Synaptic Enhancement

Facilitation, augmentation, and potentiation can be differently affected by divalent ion substitutions for Ca^{2+}, hormone treatments, neurotrophic factors, and mutations in genes for Ca^{2+}/calmodulin-dependent protein kinase, synapsins I and II, cyclic AMP phosphodiesterase, Ca^{2+}/calmodulin-dependent adenylyl cyclase, and the type 4 metabotrophic glutamate receptor. In one case, postsynaptic hyperpolarization and $[Ca^{2+}]_i$ chelation are also reported to affect PTP, perhaps owing to some sort of retrograde messenger. These manipulations may differentially affect the Ca^{2+} targets in activating short-term synaptic plasticity, or processes involved in the clearance of residual Ca^{2+} ions. Either way, they indicate a modifiability of synaptic plasticity that could have important effects on neural circuitry with plastic synapses (see below).

The Consequences of Short-Term Synaptic Plasticity

The dynamic reshaping of synaptic strength is an essential property of synapses, and is fundamental to the way they respond to inputs, selectively transmit signals, and shape the responses of nerve circuits and the activity of neural networks. Depression makes synapses respond adaptively, reporting mainly changes in signal strength, while facilitation and augmentation allow synapses to distinguish significant signals from noise when the former are represented as sustained or high-frequency activity. These properties can be used by neural circuits to distinguish different patterns of input. The shorter forms of synaptic enhancement, as well as PTP, can also effectively adjust the gain or sensitivity of neuronal circuits following prior activity and lead to alterations in neural circuit responsiveness that last for seconds or minutes. Neuroscientists trying to understand how neural circuits analyze sensory information or produce motor patterns are now paying a good deal of attention to the important consequences of short-term synaptic plasticity for the integrative functions of the nervous system.

Posttraumatic Stress Disorder as an Emotional Disorder

R K Pitman, Harvard Medical School, Charlestown, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Because psychopathologic phenomena often represent extreme forms of ordinarily adaptive human behavior, evolutionary neurobiologic mechanisms may be cast in higher relief in the mentally disordered. Darwin noted that the behavior of insane patients reveals the 'brute nature' within human beings. Behavior associated with mental disorders constitutes potentially useful data that are often overlooked by basic scientists. The rediscovered mental disorder known as posttraumatic stress disorder (PTSD) provides illustrations of human mechanisms of emotion, conditioning, and memory that can inform neuroscience. PTSD has also emerged as the model psychiatric disorder for studying the effect of psychological environmental events on the nervous system.

PTSD and Conditioned Fear

The current clinical definition of PTSD according to the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) appears in abbreviated form in Table 1. This article discusses the basic elements of classical (Pavlovian) conditioning that it incorporates. After a traumatic event (unconditioned stimulus, or UCS) has induced an intense emotional response of fear, helplessness, or horror (unconditioned response, or UCR), external and internal cues that were present at the time of the traumatic event (conditioned stimuli, or CSs) acquire the capacity, through their association with the traumatic experience, to evoke intense emotional conditioned responses (or CRs) on subsequent occasions. Avoidance of emotionally distressing and arousing trauma-related cues reflects secondary operant conditioning. In addition to the specific symptoms of PTSD (B.1–5, C.1–2 in Table 1) that are related to conditioning and uniquely define this disorder, there are several generic psychiatric symptoms (C.4–7, D.1–5) that PTSD shares with other anxiety and/or depressive disorders.

Conditioned Psychophysiologic Responses to Trauma-Related Cues

DSM-IV PTSD criterion B.5, "physiological reactivity upon exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event," has been amply supported in the laboratory. Several studies have shown that audiovisual cues of battle situations, such as pictures of ground troops unloading from helicopters or sounds of machine gun fire, produce larger peripheral physiologic, including heart rate (HR), skin conductance (SC), blood pressure (BP), and facial electromyogram (EMG), increases in veterans with PTSD. When individuals with PTSD recall past traumatic events via internal, script-driven imagery, they also produce larger physiologic responses compared with individuals who experienced similarly stressful events but did not develop the disorder. This finding has held for various types of traumatic events including combat in Vietnam, Korea, and World War II; terrorist attacks; automobile accidents; and childhood sexual abuse. Results of a large multisite study of 1328 Vietnam veterans that combined audiovisual cues and script-driven imagery confirmed heightened physiologic reactivity to trauma-related cues in the veterans with PTSD.

Trauma-Related Brain Activation Studies

Neuroimaging studies of PTSD have directly examined changes in brain activity that presumably underlie emotional re-experiencing in PTSD. A seminal study using positron emission tomography (PET) employed personal script-driven imagery to study individuals with PTSD stemming from a variety of traumatic events. During traumatic imagery compared to neutral imagery, there were significant increases in regional cerebral blood flow (rCBF) in anterior paralimbic structures, including posterior medial orbitofrontal, insular, anterior temporal, medial temporal, and anterior cingulate cortices, as well as amygdala. However, because this study did not include a non-PTSD comparison group, it was not possible to determine the specificity of the findings to PTSD. A follow-up study examined rCBF during script-driven imagery in women with histories of childhood sexual abuse with and without PTSD. PTSD subjects showed significantly greater activation than non-PTSD subjects during personal sexual abuse imagery compared to neutral imagery in orbitofrontal cortex and anterior temporal pole. Anterior cingulate cortex (ACC), which is a component of ventromedial prefrontal cortex, however, was activated in the non-PTSD group but not in the PTSD group. In a study that employed single photon emission computed

Table 1 Abridged DSM-IV diagnostic criteria for PTSD

A. Traumatic event/response (both required)
   1. An event that threatens or inflicts serious injury to self or others
   2. A response of intense fear, helplessness, or horror
B. Re-experiencing criteria (one required)
   1. Recurrent, intrusive, distressing recollections of the traumatic event
   2. Recurrent, distressing dreams of the traumatic event
   3. Flashbacks to the traumatic event
   4/5. Intense psychological distress/physiological reactivity on exposure to traumatic event-related cues
C. Avoidance/numbing criteria (three required)
   1. Of thoughts and feelings associated with the trauma
   2. Of activities, places, or people associated with the trauma
   3. Inability to recall an important aspect of the trauma
   4. Markedly diminished interest in significant activities
   5. Feelings of detachment or estrangement from others
   6. Restricted range of affect (numbing)
   7. Sense of a foreshortened future
D. Arousal criteria (two required)
   1. Insomnia
   2. Irritability or outbursts of anger
   3. Difficulty concentrating
   4. Hypervigilance
   5. Exaggerated startle response
E. Duration at least one month (required)
F. Distress/Impairment, for example, social, occupational (required)

tomography (SPECT) in Vietnam veterans with and without PTSD and normal control subjects, the PTSD group exhibited greater activation in the left amygdaloid region in response to combat sounds.

More recently, again using PET and script-driven imagery, it was found that male and female Vietnam veterans with PTSD exhibited rCBF decreases in medial frontal gyrus in a traumatic versus neutral mental imagery comparison. Moreover, male combat veterans also exhibited rCBF increases in the left amygdala. In both males and females, rCBF changes in medial frontal gyrus were inversely correlated with rCBF changes in the left amygdala and the right amygdala/periamygdaloid cortex. Furthermore, in the traumatic condition, for both subgroups with PTSD, symptom severity was positively related to rCBF in the right amygdala and negatively related to rCBF in medial frontal gyrus. These results suggest a reciprocal relationship between medial prefrontal cortex and amygdala function in PTSD. The script-driven imagery procedure has also been adapted to functional magnetic resonance imaging (fMRI), which has revealed deficient ACC activation, as measured by blood oxygenation level-dependent (BOLD) signal, in persons with PTSD. Another fMRI study found the absence of BOLD signal increases in rostral ACC in response to the presentation of combat-related words in the context of the emotional Stroop task in combat veterans with PTSD compared to combat-exposed, non-PTSD veterans.

Conditionability

Conditioning theory provides an explanation as to how trauma-related cues might acquire the capacity to generate heightened physiologic responses in individuals with PTSD, but it does not explain why, upon exposure to comparably stressful events (i.e., comparable UCSs), some individuals develop PTSD whereas others do not. To investigate this, researchers performed a *de novo* differential conditioning study. CSs were colored circles, and the UCS was a 'highly annoying' electrical stimulus. The PTSD group showed larger differential HR, SC, and EMG responses to the reinforced versus nonreinforced stimuli (CS+ vs. CS−) compared with the non-PTSD group. Fearfulness increased for the PTSD group as the CS+ acquired signal value for predicting the UCS, whereas for individuals without PTSD, fearfulness decreased as the UCS became more predictable. Only PTSD participants continued to show differential SC responses to CS+ versus CS− during extinction trials. Results suggest that individuals with PTSD form new conditioned fear responses more strongly and extinguish them more poorly than do trauma-exposed individuals without PTSD.

Whereas the amygdala is critically involved in the acquisition of conditioned fear, a critical structure for the extinction of conditioned fear response in rodents is the infralimbic cortex, which inhibits the expression of conditioned fear by the amygdala. A homolog

of the infralimbic cortex, at least in part, is the ACC, especially its pregenual and subcallosal components. In a recent PET study of women with PTSD from childhood sexual abuse, rCBF was measured during acquisition and extinction in another *de novo* conditioning study. Compared to non-trauma-exposed controls, PTSD patients had increased left amygdala activation with fear acquisition, and decreased ACC activation during extinction. These findings implicate amygdala and ACC in the acquisition and extinction of fear responses, respectively, in PTSD.

Unconditioned Physiologic Responses

Sometimes it is difficult to identify a role for a conditioned stimulus in PTSD patients' reactions. Indeed, a problem faced by many of them is that their emotional responses are not conditional enough. Unable to confine their fear and other emotional responses to reminders of the traumatic situation, they find them spilling over into excessive, inappropriate reactions to ordinary events. A probe that has proved useful in the study of unconditioned responding in PTSD is the startle response. Indeed, 'exaggerated startle' is one of the diagnostic criteria for PTSD (Table 1, criterion D.5). In studies of the startle response in PTSD, the evocative stimulus is usually a sudden, loud pure tone or white noise that does not have any plausible associative connection to the traumatic event. Baseline measures of the muscular, for example, eyeblink, EMG response in PTSD have not consistently confirmed the presence of exaggerated startle in PTSD. More consistent EMG results have been obtained when PTSD subjects have been studied under stressful experimental conditions, suggesting an enhanced sensitivity to generally stressful contexts. Greater evidence of increased baseline startle has been provided by autonomic measures. Several studies have confirmed increased heart rate responses to sudden, loud tones in PTSD, which may indirectly reflect increased amygdala reactivity.

Two longitudinal studies have suggested disparate origins of increased autonomic startle responses in PTSD. One evaluated responses to sudden, loud tones in individuals who arrived at a hospital emergency room after psychologically traumatic events. Although those who went on to develop PTSD at 4 months posttrauma showed comparable physiologic startle responses to those who did not develop PTSD when startale was measured 1 week posttrauma, at 1 and 4 months posttrauma, the subjects with PTSD showed a greater heart rate response and required more stimulus trials to reach the criteria of skin conductance and orbicularis oculi electromyogram nonresponse. These results suggest that differences in physiologic response to startling tones incubate after the occurrence of the traumatic event. However, in a prospective study of the auditory startle response in firefighters before and after trauma exposure, pretrauma skin conductance response to startling stimuli was found to be predictive of posttrauma PTSD severity. These latter results support elevated startle response's being a vulnerability factor for PTSD. Clearly further studies are necessary. (The issue of the origin of biologic abnormalities in PTSD is also addressed below.)

Direct Studies of Amygdala Reactivity in PTSD

The 'masked faces' task has been used to measure amygdala reactivity in combat veterans with PTSD. During fMRI, investigators presented fearful and happy faces temporally masked by neutral faces. Normal subjects are typically aware of seeing only the neutral faces, although their amygdalae are activated by the fearful faces. Veterans with PTSD exhibited greater amygdala activation, as indexed by BOLD signal changes, compared to combat-exposed, non-PTSD veterans. Moreover, the magnitude of amygdala activation significantly correlated with PTSD severity. Another 'overt faces' fMRI experiment administered the same fearful and happy faces to trauma-exposed male Vietnam veterans or firefighters with and without PTSD, although the facial stimuli were not masked. The PTSD group again exhibited exaggerated amygdala responses, as well as diminished medial prefrontal cortical responses, to the fearful versus happy facial expressions. In addition, in the PTSD group, activation in the amygdala was negatively correlated with activation in the medial prefrontal cortex, and symptom severity was also negatively related to medial prefrontal cortical activation. These results provide further evidence for exaggerated amygdala responsivity, diminished medial prefrontal cortical responsivity, and a reciprocal relationship between these two regions, similar to that reported during script-driven imagery.

Event-Related Potentials

The most widely studied event-related potential component in normal and clinical populations is the parietal P300 component, or P3b. In the 'auditory oddball' procedure, the P3b response to target tones presumably reflects increased neural activity associated with effortful attention to the processing of salient information. Reduced P3b is typically interpreted as indicative of a generalized, attention-related cognitive deficit. Several studies of PTSD from various kinds of traumatic events in men and women have

reported smaller P3b responses to target stimuli. These findings have been interpreted as electrophysiologic evidence for difficulty concentrating, one of the diagnostic symptoms of PTSD (Table 1, criterion D.3).

Neurologic Soft Signs

Neurologic soft signs (NSSs) are various subtle indices of central nervous system dysfunction. It has been found that male combat veterans, as well as adult females sexually abused as children, with chronic PTSD are more neurologically compromised than their counterparts without PTSD, as evidenced by more NSSs. Even though NSSs by definition are difficult to localize to specific brain areas, their increase in PTSD suggests the presence of underlying neuroanatomic abnormalities. Structural magnetic resonance imaging (sMRI) provides an opportunity to calculate volumes of brain structures or areas by manually delimiting the boundaries of the structure on a series of slices and then integrating the areas into a volume, as well as by the use of other semi-automated and automated techniques.

Hippocampus

Volumetric studies of persons with PTSD that have employed sMRI have focused heavily on the hippocampus, a structure that has been implicated in declarative memory as well as spatial and contextual learning. Indeed, several studies have found declarative memory impairments in PTSD. The research focus on hippocampus has also been driven by animal research indicating that chronic stress can damage this brain structure. There have by now been more than a dozen studies that have reported decreased volume of the hippocampus in persons with PTSD. In some of these studies, the volumetric diminution has been accompanied by reduced declarative memory capacity, in others not. Although nearly as many other studies have failed to find smaller hippocampi, few if any have reported larger hippocampal volume in PTSD. A recent meta-analysis of hippocampal volumetric studies revealed significantly smaller volume in both right and left hippocampi in adult subjects with chronic PTSD, in comparison with both healthy controls and traumatized controls, establishing beyond doubt that diminished hippocampal volume is a bona fide feature of PTSD, albeit not a highly sensitive one. Another neuroimaging technique, magnetic resonance spectroscopy (MRS), has identified diminution of *N*-acetylaspartate (NAA), a neuronal viability marker, even in the hippocampi of persons with posttraumatic stress disorder who do not show volumetric diminution. This finding implies that there are structural hippocampal abnormalities in PTSD that may not rise to the level of gross anatomic differences. Ultimately, metabolite changes may become more sensitive indicators of PTSD neuropathology than volume losses.

Although the presence of smaller hippocampi in at least a substantial portion of persons with PTSD is no longer a matter for debate, the origin of this phenomenon is. With regard to the hippocampus, it is tempting to accept the explanation offered by findings from the animal literature, namely, that stress has damaged this brain structure in persons with PTSD. However, there are at least five possible explanations of the association between an abnormality such as diminished hippocampal volume and PTSD:

1. Preexisting hippocampal diminution may increase the risk of exposure to a traumatic event capable of causing PTSD. As noted above, the hippocampus is critically involved in declarative memory. Those with a smaller hippocampus (e.g., from inheritance, perinatal trauma, or adverse development during childhood) may have less ability to learn from experience and therefore be less able to avoid dangerous situations. Exposure to traumatic events may thus be increased, with the consequent risk of PTSD.
2. Preexisting hippocampal diminution may increase the individual's vulnerability to developing PTSD after exposure to a traumatic event. The hippocampus is critical for the encoding of context. Failure to register the context in which the traumatic event took place may lead to failure to restrict the fear response to a specific context, with resulting generalization to a variety of contexts. For example, veterans who narrowly escaped death in combat may continue to show hypervigilance and exaggerated startle in a variety of situations after redeployment, failing to recognize that they are home and no longer in a dangerous situation.
3. Traumatic exposure may damage the hippocampus, and the damaged hippocampus may lead PTSD, for example, according to the foregoing mechanism.
4. Traumatic exposure may cause the PTSD, and the PTSD may lead to the abnormality. For example, the chronic stress of having PTSD may damage the hippocampus.
5. Traumatic exposure may produce the PTSD, and the PTSD may in turn lead to sequelae or complications that produce the abnormality. For example, alcoholism is a frequent comorbid condition in PTSD, and there is evidence that ethanol damages hippocampal tissue. However, studies have found reduced hippocampal volume in subgroups of PTSD veterans with a history of lifetime alcohol abuse or dependence, in comparison to non-PTSD veterans.

Functional studies of hippocampus lag far behind structural studies. PET has revealed a failure of hippocampal activation during a verbal declarative memory task in women with sexual abuse-related PTSD compared to women with abuse but without PTSD. Another PET study used a word-stem completion task to study firefighters with and without PTSD. Relative to the non-PTSD group, the PTSD group exhibited significantly smaller rCBF increases in the left hippocampus in a high versus low recall comparison. However, this finding reflected relatively elevated rCBF in the low recall condition in the PTSD group, making the results difficult to interpret.

Anterior Cingulate Cortex

Given that decreased ACC activation, especially in its pregenual or rostral division, during exposure to trauma-related stimuli is a prominent functional neuroimaging finding in PTSD, volumetric studies of this structure are of high interest, but they are also rare. Researchers performed semi-automated cortical parcellation of sRMI data in Vietnam veteran nurses with and without PTSD. Three subdivisions of ACC were examined separately: dorsal ('cognitive'), pregenual or rostral ('affective'), and subgenual or subcallosal ('visceral'). The PTSD group exhibited substantially smaller pregenual and subcallosal, but not dorsal, ACC volumes. These reductions were relatively anatomically specific, given that a survey of all 46 other cortical parcellation units found only three that differed significantly between groups, which was consistent with chance.

The technique of voxel-based morphometry (VBM) allows an automated examination of structural brain differences throughout the brain by applying automated statistical parametric mapping to high-resolution sMRI. Researchers studied victims of the Tokyo subway sarin gas attack with and without PTSD. Results showed significant reduced gray matter density, presumably indicative of volumetric reduction, in the ACC in trauma survivors with PTSD compared with those without PTSD, although the location was fairly dorsal. PTSD severity was negatively correlated with gray matter density in the left ACC in PTSD subjects. There were no significant differences in other gray matter regions, or any white matter regions, between the two groups. Also using VBM, researchers compared the ACCs of individuals with acute PTSD with matched healthy control subjects. Results revealed significantly less gray matter density in the right pregenual ACC of the PTSD group, despite the fact that volumetric analyses of the ACC using manual tracing revealed no group differences. Probabilistic maps indicated that the difference between groups in gray matter density was due to difference in shape but not size.

Study of Identical Twins

Trauma does not occur in a vacuum. For example, abused children may also suffer from such potentially deleterious factors as neglect, socioeconomic deprivation, and malnutrition. They may also be more likely to inherit abnormalities from behaviorally disordered parents who abuse them. Soldiers with deprived backgrounds, including child abuse, may be more likely to be assigned to combat roles, and less well equipped to handle the consequent stress. Dissecting the specific pathogenic influences on the brains of persons with PTSD from a complex web of pre-, peri-, and posttraumatic factors requires scientific ingenuity and persistence.

Although successful in demonstrating the presence of brain and other biologic abnormalities in PTSD, the cross-sectional designs of the vast majority of neuroimaging and other biologic studies to date limit their ability to resolve the origin of such abnormalities. Ultimately, prospective studies will be needed that evaluate PTSD biologic markers of interest prior to and following a traumatic event. For obvious ethical and moral reasons, however, studies of the neurologic and psychiatric response to trauma must be naturalistic. Trauma cannot be scheduled in advance. This poses a challenge to prospective studies, which must screen a great many subjects in order to reap enough who will be exposed to a traumatic event during the study period, develop PTSD, and participate in follow-up evaluations.

An alternate approach to the study of the origin of abnormalities in PTSD is to study persons who serve as surrogates for what a trauma-exposed person would have been like but for the traumatic event. The best such surrogates are the identical twins of trauma-exposed persons who were not themselves exposed to the trauma. If an abnormality is genetic or due to environmental influences shared by twins during their rearing, that is, if the abnormality is a 'familial' pretrauma vulnerability factor, then it should also be found in the non-trauma-exposed co-twins of trauma-exposed twins with PTSD. On the other hand, if the abnormality results from an environmental factor unique to exposed twins, for example, a traumatic event, then their co-twins should not share the abnormality. Unfortunately, this approach is unsuitable for the study of abnormal responses to trauma-related stimuli, because such stimuli would not be salient for non-trauma-exposed co-twins.

Over the past several years, researchers have performed a series of studies of identical twins discordant for combat exposure in Vietnam, which have informed the origin of several of the neuroscientific abnormalities that have been found in PTSD discussed above, with the following results. Replicating previous findings, heart rate responses to loud tones were found to be larger in Vietnam combat veteran twins with PTSD. These larger responses were not shared by their non-combat-exposed co-twins, whose responses were similar to those of the non-PTSD combat veterans and their non-combat-exposed co-twins. These results suggest that larger heart rate responses to sudden, loud tones represent an acquired sign of PTSD, rather than a familial vulnerability factor. A similar pattern of results has emerged for diminished P3b amplitude, suggesting it too is an acquired PTSD sign.

In contrast, smaller hippocampi were found both in the Vietnam combat veteran twins with PTSD and their non-combat-exposed, 'high-risk' co-twins. PTSD severity in trauma-exposed PTSD twins was negatively correlated with both their own hippocampal volumes, as well as the hippocampal volumes of their trauma-unexposed identical twin brothers. This pattern of results suggests that diminished hippocampal volume is a pretrauma vulnerability factor for PTSD, rather than an acquired PTSD. A similar pattern of results has recently been reported for NSSs. These results do not support the suggestion that the stress of the traumatic event and/or the PTSD that may follow it cause damage to the hippocampus or other central nervous system components in this disorder.

PTSD, Hormones, and Memory

A substantial body of animal research has demonstrated that stress hormones, especially epinephrine, strengthen emotional memory or conditioned responses. This effect is eliminated by beta-adrenergic blockers such as propranolol, either given systemically or injected into the amygdala. Drawing from this line of research, it has been theorized that stress hormones and neuromodulators, especially epinephrine and norepinephrine, released in response to a traumatic event may over-consolidate memories of the event. These memories subsequently may manifest themselves as intrusive recollections and re-experiencing symptoms. Recalling the event may release additional stress hormones that further enhance the strength of the traumatic memory, creating a positive feedback loop that may eventuate in PTSD. There are several points of opportunity in this loop for secondary preventive psychopharmacological interventions (Figure 1). Based upon the frequently reported (but not consistently replicated) finding of low cortisol levels in PTSD, including

Figure 1 Conceptual model of the pathogenesis of posttraumatic stress disorder with points of opportunity for secondary preventive psychopharmacological agents.

in the immediate aftermath of the traumatic event, as well as upon work that suggests that exogenous cortisol administration has a preventive effect on PTSD, an integrative model posits that deficient cortisol activation at the time of the traumatic event fails to contain the acute catecholamine response putatively implicated in the PTSD's pathogenesis.

An implication of this theory is that pharmacologic intervention, for example, administration of a beta-blocker such as propranolol, soon after a traumatic event might interrupt this cycle of events and prevent the development of PTSD. This hypothesis was tested in a pilot study of patients presenting to a hospital emergency department (ED) after an acute psychologically traumatic event. Patients were randomized to begin, within 6 h of the event's occurrence, a 10-day course of propranolol. When tested 3 months later, the placebo subjects showed higher physiologic responding during script-driven imagery of the event that had brought them to the hospital. These pilot results suggest that acute, posttrauma propranolol has a preventive effect on the physiologic manifestations of subsequent PTSD, possibly by diminishing consolidation of the memory of the traumatic event (or associated conditioned fear response). Subsequently, researchers studied patients shortly after a motor vehicle accident or physical assault. These investigators compared patients who received a course of propranolol with those refused propranolol but agreed to participate in the study. At 2 months post-event, levels of PTSD symptoms were lower in the subjects treated with propranolol. The results of these preliminary studies offer support for the secondary prevention of PTSD with propranol, but more research is needed.

Posttraumatic Stress Disorder: Neurobiology

P Runnels, A S New, and D S Charney, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

The physiologic response to threatening and stressful situations serves as an important mechanism for increasing survival and fitness. However, when stressful cues overwhelm the body's natural homeostatic ability to terminate this response once the stressor has resolved, the results can produce long-term psychological and physiological distress. One way to conceptualize posttraumatic stress disorder (PTSD) is as the persistence of heightened fear despite the cessation of a threatening stimulus, resulting in persistent, vivid recall of traumatic events, autonomic hyperarousal, avoidance of nontraumatic stimuli, and emotional numbing.

While trauma is necessary for the development of PTSD, recent evidence from twin studies suggests that neurobiologic characteristics present before the onset of trauma may play an equally important role. One such study showed a significant decrease in IQ, verbal memory, attention, and executive function in combat veterans who developed PTSD compared to those who did not develop PTSD. However, the novel finding in this study was that these findings were also present in the non-combat-exposed identical twins of those veterans who developed PTSD, while the non-combat-exposed twins of those who did not develop PTSD resembled their combat-exposed twins who did not develop PTSD. Thus, these cognitive abnormalities appeared to track with the genetic factors predisposing to PTSD, rather than arising from trauma exposure. Two other studies showed that combat-exposed Vietnam veterans who developed PTSD had significant reductions in hippocampal volume, increased prevalence of a cavum septum pellucidum, and significantly increased neurologic soft signs when compared with combat veterans who did not develop PTSD. Again, the non-combat-exposed twins of the PTSD veterans more closely resembled their combat-exposed twin with PTSD and were markedly different from the non-combat-exposed twins of the veterans who did not develop symptoms. This suggests that there are genetic factors in individuals which may predispose them to the development of PTSD when they are exposed to traumatic experiences. As new evidence arises, our understanding of stress and PTSD continues to expand. This article explores the neural pathways involved in the fear response, the neurotransmitters that modulate this response, and the most recent evidence for the physiologic processes that are disordered both before and after the onset of PTSD.

Neural Mechanisms of Fear

Classic fear conditioning can be conceptualized as the development of a physiologic reaction to a previously neutral environmental cue (conditioned stimulus) which has become associated with a traumatic event (unconditioned stimulus), such that repeated exposure to this cue consistently elicits anxiety and fear. Physiologically, the conditioned stimulus is perceived by external and visceral pathways and is transferred to the thalamus, from which the signal is transmitted to the basolateral nucleus of the amygdala by means of two circuits: a rapid, direct, subcortical pathway from the dorsal (sensory) thalamus and a slower, regulatory cortical pathway that passes through the primary somatosensory cortices, the insula, and the anterior cingulate/prefrontal cortex. Through this indirect pathway, the stimulus eventually reaches the hippocampus and from there is projected to the lateral amygdala. In passing through this long pathway, the stimulus is exposed to centers of cognition, which interpret the significance of the stimulus and provide a cognitive mechanism for modulating the fear response based on past exposure to similar stimuli. While the basolateral amygdala is primarily responsible for voluntary emotional behavior based upon aversive emotional events, the central nucleus of the amygdala is more involved in conditioned responses to fear-inducing stimuli. Once signals reach the lateral amygdala, they proceed to the central amygdala, which then projects to areas of the hypothalamus and brain stem that mediate the conditioned autonomic, endocrine, and behavioral responses associated with fear.

Emotional Memories and Fear

Brain imaging studies have consistently demonstrated that the amygdala plays a central role in fear conditioning and associated emotional responses to environmental cues. Specifically, the basolateral amygdala has been shown to be integral to the storage of emotionally salient memories. When a traumatic event occurs, memory for emotionally salient aspects of this event remain vivid and intact, while memory for other, less salient information is often impaired. Beta-adrenergic

activity in the amygdala is thought to play a central role in this process. Numerous studies involving propranolol (a centrally acting beta-adrenergic blocker) demonstrate that beta-blockade impairs the explicit memory of emotionally traumatic events while having no effect on emotionally neutral events. This suggests that beta-adrenergic hyperactivity in the amygdala might be an underlying mechanism for the exaggerated and prolonged intrusive memories characteristic of PTSD.

Of course, the exact nature of amygdala involvement in PTSD is still being characterized. Multiple studies have demonstrated amygdala hyperactivity in patients with PTSD when they are exposed to traumatic imagery, and one functional magnetic resonance imaging (fMRI) study of patients with PTSD, compared with controls, showed increased amygdala activity when patients were presented with subliminal, fearful stimuli (in particular, fearful faces). However, other studies using similar paradigms have failed to demonstrate a clear difference. This remains an active area of investigation.

The role of the amygdala in processing emotional memories is further modulated by other agencies. Located in the medial prefrontal cortex (mPFC), the subgenual anterior cingulate gyrus (ACG) appears to play a central role in cognitively processing the significance of emotional stimuli. Multiple reciprocal neuronal pathways have been defined between the amygdala and the PFC, particularly in the ACG. Specifically, studies have demonstrated that lesions of the PFC produce longer extinction times for conditioned aversive stimuli, that the degree of cerebral blood flow predicts subjective experience of negative emotion, and that glucose metabolism in the PFC and amygdala are inversely related.

Such findings suggest a central role for the mPFC and specifically the ACG in controlling consolidation of emotional memories, prompting studies of the ACG in patients with PTSD. Volumetric studies of the ACG in PTSD have been mixed. Two separate studies showed decreased ACG volume in patients with PTSD compared with controls who have experienced similar traumas, but a more recent study using more robust imaging techniques failed to confirm these findings.

Other studies have examined overall activity of the ACG using imaging techniques. Several studies using both positron emission tomography (PET) and fMRI showed that activation of the ACG in response to stressful or negative images and sounds is decreased in subjects with PTSD compared with controls, and that, conversely, symptoms of PTSD are reduced in patients with greater mPFC activation. Another study using PET to measure blood flow demonstrated that patients with PTSD deactivated the ACG while controls deactivated the mPFC instead.

Finally, the role of the hippocampus in emotional memories and PTSD symptoms has also been explored. A meta-analysis of nine studies representing a total of 133 patients compared with 148 controls confirms that hippocampal volume is decreased in patients with chronic PTSD. One specific study of a population of police officers diagnosed with PTSD demonstrated these findings as well. That same study also showed that increased reexperience symptoms are negatively correlated with hippocampal volume. While some have hypothesized that cortisol damages hippocampal cells slowly over time, as an explanation for decreased hippocampal volume in patients with PTSD, the patients in this study had only experienced symptoms for a mean of 1.7 years, hardly long enough for chronic brain damage. This suggests that decreased hippocampal volume is a predisposing factor for, rather than a consequence of, PTSD.

The Hypothalamic–Pituitary Axis in the Normal Stress Response

The normal stress response involves a wide range of neurotransmitters. In response to acute and chronic stress, the paraventricular nucleus (PVN) of the hypothalamus secretes corticotropin-releasing factor (CRH), which, in turn, stimulates both the anterior pituitary gland to synthesize and release adrenocorticotropin (ACTH) and the locus coeruleus to release norepinephrine in the PVN, hippocampus, and prefrontal cortex. ACTH then stimulates the synthesis and release of adrenal glucocorticoids, principally cortisol. Cortisol mobilizes and replenishes energy stores, inhibits growth and reproductive systems, contains the immune response, and affects behavior through actions on multiple neurotransmitter systems and brain regions. Cortisol has important regulatory effects on the hippocampus, amygdala, and prefrontal cortex, including overall enhancement of amygdala activity, increased CRH mRNA concentrations in the central amygdala, an enhanced effect of CRH on conditioned fear, and improved encoding of emotion-related memory.

Recently, the role of cortisol in memory consolidation has been more closely examined. In one set of patients, increased exogenous cortisol doses did not affect alertness and attention, but did impair long-term memory consolidation. Subsequently, another study demonstrated that patients with PTSD are more sensitive to working/declarative memory impairment in the setting of increased cortisol levels. The suspected

target for the effects of cortisol on memory is the hippocampus, where specific glucocorticoid receptors are thought to downregulate working memory when activated. Interestingly, a study of patients with PTSD demonstrated a smaller reduction in working memory compared with controls when dexamethasone was administered, suggesting that the chronic elevation of cortisol in PTSD results in downregulation of hippocampal glucocorticoid receptors.

Abnormalities in the Hypothalamic–Pituitary Axis

Hypothalamic–pituitary axis (HPA) abnormalities in PTSD have been explored in numerous studies. Elevated CRH has been demonstrated in chronic PTSD, suggesting hyperactivity of hypothalamic stress response. Other studies have shown a decreased peripheral stress-response, suggesting an adrenocortical insufficiency in PTSD, a finding which has been further supported by multiple studies showing increased glucocorticoid receptor binding in peripheral mononuclear cells in combat PTSD and hypersuppression of cortisol in response to low-dose dexamethasone administration. These findings, taken together, suggest that patients with PTSD have increased feedback inhibition of cortisol release secondary to enhanced secretion of CRH. Recent work examining the possibility that specific glucocorticoid receptor gene polymorphisms might be responsible for enhanced response to cortisol, and, therefore, a greater risk for developing PTSD, have failed to identify any clear candidate genes at this point.

CRH is among the most important mediators of the stress response. The CRH-containing neurons are located throughout the brain beyond the PVN of the hypothalamus, including the prefrontal and cingulate cortices, the central nucleus of the amygdala, the bed nucleus of the stria terminalis, the nucleus accumbens, the periaqueductal gray matter, the locus coeruleus, and even the dorsal and median raphe nuclei, normally associated with serotonin. Fear-related behaviors are increased when CRH neurons in the amygdala are activated, while reward expectation is reduced when similar CRH neurons in the cortex are excited. Like cortisol, CRH inhibits multiple neurovegetative functions, including food intake, sexual activity, growth, and reproduction. CRH levels are also negatively correlated with percentage of time spent in delta wave sleep.

Increased levels of CRH in cerebrospinal fluid (CSF) and saliva have been linked to PTSD. CRH hyperfunction might be influenced by early-life stress, a negative social environment, past trauma history, and behavioral dominance. Conversely, the biologic propensity to restrain the initial CRH response to an acute stressor may be related to psychobiological resilience to developing PTSD. Furthermore, two subtypes of CRH receptors, CRH-1 and CRH-2, have been found distributed widely throughout the neocortex, amygdala, and hippocampus of the primate brain and appear to have contrasting roles in mediating the stress response. CRH-1-deficient mice display decreased anxiety-like behavior and an impaired stress response, while CRH-2-deficient mice display increased anxiety-like behavior and are hypersensitive to stress. This evidence suggests that regulation of the relative contribution of the two CRH receptor subtypes may be essential to coordinating psychological and physiological responses to stressors. To date, no studies have been able to successfully evaluate CRH-1 and CRH-2 receptors in living humans, though avenues using CRH ligands in PET scans are being explored. This represents an avenue of research targeting pharmacologic interventions that might enhance stress resilience in at-risk or even symptomatic PTSD patients.

Dehydroepiandrosterone

Along with cortisol, dehydroepiandrosterone (DHEA) is another adrenal steroid that is released under stress, and its actions appear to be antagonistic to those of cortisol. Like cortisol, in response to fluctuating levels of ACTH, DHEA is also released synchronously and episodically from the adrenal glands. In the brain, DHEA has antiglucocorticoid and antiglutaminergic activity; however, regionally specific metabolism of DHEA appears to be the primary control mechanism by which DHEA's effects on cognition and behavior are mediated. For instance, 7-hydroxylated metabolites of DHEA in the hippocampus interfere with the normal uptake of activated glucocorticoid receptors. This action may be an intrinsic neuroprotective mechanism aimed at curbing the development of physiological and psychological changes that persistently interfere with function in the absence of trauma or stress. Data supporting this include a negative correlation between DHEA reactivity (in response to ACTH administration) and severity of PTSD symptoms, and a negative correlation between DHEA/cortisol ratios and stress-induced levels of dissociation among elite special forces soldiers undergoing intense survival training. DHEA also restores cortisol-induced suppression of long-term potentiation in hippocampal neurons, thereby enhancing the consolidation of nonemotionally salient memories which are inhibited by the amygdala. Aside from the antiglucocorticoid actions

of DHEA, effects γ-aminobutyric acid (GABA)-A receptors and *N*-methyl-D-aspartic acid (NMDA)-based neurotransmission may be involved in the behavioral effects of DHEA.

Locus Coeruleus and Norepinephrine

The locus coeruleus is a major focus of norepinephrine production and release in the brain, particularly during times of stress. Stressors (physical or emotional, extrinsic or intrinsic) activate the locus coeruleus to release norepinephrine to certain projection sites, including the amygdala, the hippocampus, and the prefrontal cortex, while activating other sites through different neurotransmitters, most notably the sympathetic nervous system (SNS) and the HPA axis. While activating these systems, the locus coeruleus concomitantly inhibits the parasympathetic system, magnifying the decreased need for sleep and food, and, at high levels of activation, even the prefrontal cortex, predisposing an organism to instinctual responses over more complex cognition – to react before thinking.

Encoding of traumatic or emotionally charged memories at the level of the amygdala is heightened by activation of the HPA and locus coeruleus–norepinephrine systems. Once activated, the amygdala activates a feedback loop that further inhibits the prefrontal cortex and stimulates both hypothalamic CRH release and brain stem autonomic centers, further increasing HPA and locus coeruleus activity. Unchecked, such feedback loops presumably lead to persistent hyperresponsiveness of the locus coeruleus–norepinephrine system, thereby contributing to the chronic anxiety, fear, and intrusive memories seen in patients suffering from PTSD.

The relative magnitude of this stress response by the sympathetic system varies from person to person, such that some individuals are prone to 'over-react' and develop PTSD, while others have a more tightly controlled reaction and are less likely to develop PTSD. In fact, in support of this concept, some studies have demonstrated heightened locus coeruleus–norepinephrine activity in patients with panic disorder and PTSD, while other studies suggest that elevated noradrenergic function resulting in total body elevations of norepinephrine increases overall levels of anxiety in response to stress.

Neuropeptide Y

Neurons containing the amino acid neuropeptide Y (NPY) are densely concentrated in five brain areas: the locus coeruleus, the PVN of the hypothalamus, septohippocampal neurons, the nucleus of the solitary tract, and the ventral lateral medulla. Significant levels are also found in the amygdala, hippocampus, cerebral cortex, basal ganglia, and thalamus. NPY is released with norepinephrine when the sympathetic nervous system is activated and appears to have strongly anxiolytic effects. Along with preventing sympathetic overactivation, NPY administration has also been shown to result in a decrease of HPA activation. Microinjection of NPY into the central nucleus of the amygdala reduced anxious behaviors, while NPY mRNA levels were upregulated in the amygdala after chronic stress.

A series of studies on humans confirm that acute stress results in increased levels of cortisol, norepinephrine (NE), and plasma NPY. US Army soldiers as well as US Navy personnel who have participated in survival school training that included capture and interrogation demonstrate an increased level of plasma NPY positively correlated with elevation in plasma cortisol and NE; specifically, stress-induced increases of NPY were significantly and negatively correlated with subjective reports of distress. In another study involving military personnel, soldiers undergoing special operations training consistently produce significantly higher levels of NPY secretion in response to acute stress and had higher baseline levels of NPY in the absence of stress than did soldiers who did not undergo special forces training. These data suggest that military personnel with decreased capacity for stress-induced NPY release and increased dissociation are at a greater risk for the development of stress-related illnesses such as PTSD. The anxiolytic effects of NPY also involve the locus coeruleus, possibly by means of the neuropeptide Y-Y2 receptor. NPY reduces the firing of neurons in the locus coeruleus, thereby reducing the overall levels of norepinephrine, which is anxiogenic. Furthermore, brain regions that express CRH and CRH receptors also contain NPY and NPY receptors, and the functional effects are often opposing, particularly in the locus coeruleus, amygdala, and periaqueductal gray matter. NPY has been shown to counteract the anxiogenic effects of CRH, while CRH antagonists have been shown to block the anxiogenic effects of a neuropeptide Y-Y1 antagonist, leading to the hypothesis that the balance between NPY and CRH neurotransmission is important to a balanced emotional response to stress.

Finally, NPY has been shown to be involved in the consolidation of fear memories. Robust evidence suggests NPY exerts action on the amygdala, probably by means of the neuropeptide Y-Y1 receptor. In rats, injection of NPY into the amygdala impairs memory retention in a foot-shock avoidance paradigm. NPY also has behaviorally relevant effects on memory in the hippocampus. Transgenic rats with hippocampal

NPY overexpression adapt more slowly to the behavioral consequences of stress.

Serotonin

Serotonin (hydroxytryptamine; HT) induces both anxiogenic and anxiolytic effects, depending on the brain region and receptor subtype involved. While the 5-HT_{2A} receptor may induce anxiety, the 5-HT_{1A} receptors are anxiolytic and may even be involved in adaptive responses to stress. The role of the 5-HT_{1A} receptor in the genesis and modulation of anxiety and stress has been most clearly defined. The 5-HT_{1A} receptors are found in the superficial cortical layers, the hippocampus, the amygdala, and the raphe nucleus (primarily presynaptic). 5-HT_{1A} knockout mice show increases in anxiety-like behaviors mediated by postsynaptic 5-HT_{1A} receptors in the hippocampus, amygdala, and cortex.

An interesting recent finding shows that embryonic and early postnatal knockout of 5-HT_{1A} receptors produces an anxiety phenotype that cannot be restored with replacement of 5-HT_{1A} receptors once individuals reach adulthood. By contrast, the same knockout and replacement models conducted in mice entirely during adulthood show a clear ability to regain appropriate anxiety modulation, demonstrating a necessary but poorly understood contribution to anxiety regulation in early development. Postsynaptic 5-HT_{1A} receptor gene expression can also be inhibited by adrenal steroids, demonstrated by the reduction of 5-HT_{1A} receptor density and mRNA levels in response to stress, a reduction which was then prevented by adrenalectomy. These results taken together suggest that early-life increases in CRH and cortisol levels secondary to stress may in turn downregulate 5-HT_{1A} receptors, resulting in a persistently lowered threshold for stressful life events to produce anxiety. Alternatively, genetic decreases in 5-HT_{1A} receptors might be expected to produce a similar phenotype. The density of 5-HT_{1A} receptors is reduced in depressed patients when they are depressed as well as when in remission.

Galanin

Galanin, a peptide containing 30 amino acids, is involved in a number of physiological and behavioral functions, including learning and memory, pain control, food intake, neuroendocrine control, cardiovascular regulation, and anxiety. Galanin is found in high concentrations in the locus coeruleus, where approximately 80% of noradrenergic cells co-express galanin. Furthermore, a dense galanin fiber system originates in the locus coeruleus and innervates forebrain and midbrain structures, including the hippocampus, hypothalamus, amygdala, and prefrontal cortex. Galanin-1 receptor mRNA levels are high in the amygdala, hypothalamus, and bed nucleus of the stria terminalis, and galanin-1 receptor-deficient mice show increased anxiety-like behavior. Studies have shown that galanin reduces the firing rate of the locus coeruleus, possibly by stimulating a galanin-1 autoreceptor. In separate studies, mice that overexpress galanin are unresponsive to the anxiogenic effects of the α-2 receptor antagonist yohimbine. Yohimbine itself increases galanin release in the central nucleus of the amygdala in normal mice. Consistent with these observations, galanin administered directly into the central nucleus of the amygdala of normal mice blocked the anxiogenic effects of stress. Separately, galanin administration or galanin overexpression in the hippocampus results in deficits in fear conditioning.

These results suggest that the noradrenergic response to stress includes induction of galanin release to the central nucleus of the amygdala and prefrontal cortex, and along with NPY, galanin acts as a buffer to the anxiogenic effects of norepinephrine. Interestingly, a recent study examining galanin receptor subtypes demonstrated that treatment with orally administered galanin-3 receptor specific antagonists also reduced anxious behavior in rats, suggesting that galanin activity varies based on receptor subtype. To this point, galanin has not been a focus of studies in patients exposed to traumatic stress or patients with PTSD.

Testosterone

Testosterone levels are reduced in the setting of psychological stress. The mechanism by which physical and psychological stress reduce plasma testosterone remains unclear. The involvement of luteinizing hormone-releasing hormone (LH-RH) synthesis at the hypothalamus level or luteinizing hormone (LH) secretion in the pituitary also remains unclear and has, until now, not been well defined. One possible mechanism involves a recently characterized hypothalamic-testicular pathway, independent of the pituitary, that travels through the spinal cord – this pathway appears to reduce testosterone levels secondary to being acted upon directly by CRH. There is a recent report of reduced CSF testosterone levels in PTSD patients; the finding was negatively correlated with CSF CRH concentrations, but, in the same study, no correlation between plasma and CSF testosterone levels was found. The data from studies measuring plasma testosterone levels in PTSD patients are mixed.

Estrogen

The role of estrogen in anxiety and in the development of PTSD is even less clear. A survey found that

31% of women, compared with 19% of men, develop PTSD when exposed to major trauma; the role of estrogen in the development of PTSD, however, has not been directly investigated in humans. Several studies in female rats lacking endogenous sources of estrogen suggest that estradiol enhances the stress response in female rats and that this effect was dose related. However, a more recent investigation in female rats with intact ovaries found that estradiol reduced the ability of female rats to restrain stress. Taken together, these results indicate that short-term exposure to low doses of estrogen can suppress HPA axis responses to stress, but higher doses and more prolonged treatment potentiate HPA axis responses. The mechanism underlying these effects remains to be elucidated. Greater increases in corticosterone and ACTH levels in female rats in response to both acute and chronic stressors is thought to result from the role of gonadal steroids in activating elements of the HPA axis in females. The effects on the noradrenergic and serotonergic systems are less well understood.

In humans, estrogen has been shown to blunt HPA axis responses to psychological stress in postmenopausal women and to blunt the ACTH response to CRH in postmenopausal women with high levels of body fat. In addition, 8 weeks of estrogen supplementation to perimenopausal women blunted systolic and diastolic blood pressure, cortisol, ACTH, plasma epinephrine and norepinephrine, and norepinephrine responses of the entire body to stress.

Posttraumatic Stress Disorder: Overview

R Yehuda, Mount Sinai School of Medicine and Bronx Veterans Affairs, New York, NY, USA

Published by Elsevier Ltd.

Posttraumatic stress disorder (PTSD) is an anxiety disorder that can develop in persons who experience exposure to life-threatening traumatic experiences. Approximately 15–25% of those exposed to such events develop this disorder, but the prevalence rates may be higher or lower depending on the nature and severity of the event. Trauma survivors are also at increased risk for the development of other mental disorders, such as major depression, panic disorder, generalized anxiety disorder, and substance abuse, as well as persistent anxiety and distress that does not meet criteria for a specific psychological disorder. They are also at risk for developing more somatic symptoms and physical illnesses, particularly hypertension, asthma, chronic pain syndromes, and other psychosomatic illnesses which can occur separately or in tandem with PTSD. However, it is far more common for persons who undergo traumatic stress exposure to not develop any mental illness, including PTSD.

In the immediate aftermath of trauma exposure, it is natural for persons to experience symptoms such as depression, anxiety, nightmares, or repeated, distressing images of the event. However, in the vast majority of cases, these symptoms abate over time, and the presence of such symptoms does not constitute psychiatric impairment. It is only in a minority of persons that the PTSD symptoms that develop in the immediate aftermath of a trauma do not abate. If symptoms progress for several months (or years), chronic PTSD may be diagnosed. Some develop PTSD weeks, months, or even years after an event occurs even if they did not have PTSD immediately after the event. For such persons, PTSD can be a chronic, disabling illness that results in substantial costs to individuals and to society. Longer term consequences of PTSD include absenteeism, reduced productivity, loss of employment, and increased utilization of health care systems due to both mental and physical disability. This article provides relevant information about the conception, phenomenology, psychology, and biology of PTSD, as well as about the therapeutic options for this disorder, which will likely become increasingly relevant in medical settings.

Epidemiology

Studies of the incidence of PTSD in the United States demonstrate that approximately 10% of men and 18% of women had developed PTSD at some time in their lives, making PTSD the fourth most common psychiatric disorder. Events that give rise to PTSD typically involve interpersonal violence, (e.g., rape, assault, violent crime, and torture) or exposure to life-threatening accidents or disaster (e.g., fires and earthquake). These events can result in severe physical injury; however, the defining characteristic of a traumatic event, as described in the context of PTSD, is its capacity to provoke a psychological response of fear, helplessness, or horror owing to the threat of injury or death. Indeed, PTSD can also occur in individuals who witness or learn about traumatic events. This aspect of traumatic stress has become particularly relevant because many people report becoming symptomic to coverage of horrific events in the media. This was particularly true in the aftermath of the September 11, 2001 terrorist attacks. Even those who did not directly witness the collapse of the World Trade Center watched the attacks and their aftermath on television and became extremely anxious and symptomatic as a result. True PTSD is far more likely to occur following direct than indirect exposure to trauma; nonetheless, observing a violent injury or unnatural death of another person, or even learning about such an event occurring to a loved one, can result in the development of PTSD, provided there is a sufficient associated terror or shock.

Different types of traumatic experiences are associated with different probabilities for the development of PTSD. Generally, events that involve interpersonal violence more often given rise to PTSD than those that do not. For example, the prevalence of rape trauma is 0.7% in men and 9.2% in women. Correspondingly, the prevalence of PTSD to rape is 65% in men and 45.9% in women. By comparison, the prevalence of accidents is 35.0% for men and 13.8% for women, with a rate of PTSD of 3.2% for men and 8.8% for women. The witnessing of traumatic events is also associated with relatively low prevalence of PTSD. Thus, events that are more common are associated with lower prevalence rates. Regarding the gender differences in prevalence, this may reflect that women are more vulnerable to the development of PTSD, or it may reflect an increased incidence of violence toward women that might preferentially affect them compared to men.

Most of those who experience a traumatic event – even those who experience it directly – will not meet the criteria for PTSD even if they experience symptoms for several days or weeks following exposure to an event. PTSD is a condition that is only first diagnosed at least 1 month after exposure to a traumatic

event. This time delay between the event and declaration of disorder suggests that symptoms observed in the earlier aftermath should not be conceptualized as mental illness but, rather, as part of universal responses that are expected to abate. Additionally, many of those initially diagnosed with PTSD will recover, either spontaneously or with treatment.

However, the diagnosis of PTSD implies that it is certainly possible to have a prolonged recovery process. This recognition has constituted a major conceptual shift in how stress responses are viewed. Prior to the establishment of the diagnosis of PTSD, stress-related symptoms were generally viewed as transient and not requiring intensive treatment. This notion reflected a still-held view that persons should be able, with time, to 'get over' the effects of a traumatic experience and move on without noticeable impairment. One of the tensions inherent in educating both patients and the public about the effects of trauma is managing the dialectic that requires an emphasis on recovery and resilience as the most common outcomes of trauma while simultaneously validating the potency of its detrimental consequences.

The experience of trauma survivors in the immediate aftermath of a trauma may be quite intense, but it should be interpreted to the survivor as reflecting a normal stage of recovery. It is the failure of PTSD symptoms to abate with time which culminates in multiple mental and physical consequences. Yet, it is often difficult to determine the timeline for recovery, and substantial differences among individuals are present in the time it takes to recover from trauma, even for those demonstrating a normal course of symptom resolution.

An important question is whether the survivor's immediate distress and symptoms in response to trauma are a condition that requires mental health treatment. Treatment should be sought if there is distress and functional impairment since it is currently difficult to predict whether any individual's symptoms will resolve over time. Immediate treatment may forestall a more chronic and debilitating disease. Often, the survivor communicates treatment preference by seeking or not seeking medical or mental health treatment in the immediate weeks following trauma. Typically, trauma survivors rely on natural supports such as family members, clergy, and community during this time. As time goes on and symptoms do not resolve, trauma survivors can become more reluctant to seek treatment. In cases of public disasters, the passage of time results in the fading of interest in the survivor's ordeal or aftermath, creating a shortage of treatment options, embarrassment for not having recovered, and doubts in the survivor's mind about whether ongoing symptoms are in fact related to trauma exposure. It is therefore critically important to emphasize that for those who develop PTSD, the course of illness can be extremely chronic.

Definition and Description of PTSD

In the immediate aftermath of a traumatic event, the biological and psychological components of the response serve to modify one another, creating a dynamic network. The initial fear response to a traumatic event is inherently biological, but it can be modified by the body's interpretation of this biologic state. Moreover, the initial biological and psychological responses to trauma are influenced by prior history and other individual characteristics that together influence whether the initial responses to trauma are transformed on a pathway to recovery or transduced into a chronic disorder. Because PTSD is an evolving dynamic of biological, physiological, psychological, and cognitive connections, it is also highly amenable to therapeutic intervention of both a psychological and a biological nature.

PTSD defines a syndrome with multiple symptoms, most of which reflect ways in which the experience of trauma dominates a person's life and adversely affects mood, cognitive functioning, interpersonal relationships, and quality of life. The three symptom clusters are (1) re-experiencing symptoms, which refer to the ways in which the traumatic events repeatedly intrude into consciousness in the form of distressing images, unwanted memories, nightmares, or flashbacks; these are typically associated with emotional distress and attendant physical symptoms such as palpitations, shortness of breath, and other panic-like symptoms; (2) avoiding reminders of the event, including persons, places, or things associated with the trauma, and becoming emotionally numb and constricted; and (3) physiologic symptoms reflecting hyperarousal, such as insomnia, irritability, impaired concentration, hypervigilance, and increased startle responses.

The symptoms are readily identifiable by a primary care physician. However, the diagnosis of PTSD cannot be made unless one asks about the occurrence of a traumatic event. Often, practitioners are reluctant to ask their patients to talk about events that might be distressing or that might involve shame or secrecy. By providing the opportunity for disclose about the presence of trauma, the practitioner breaks down an important barrier to treatment by legitimizing trauma exposure as a valid explanation for symptoms. The survivor's concern of being misunderstood and pathologized is further allayed when his or her experience of PTSD is clearly understood by the provider.

The Psychological Experience of PTSD

The experience of trauma profoundly alters the survivors' thoughts and beliefs about the world and the self by challenging the illusion of personal safety and causing feelings of vulnerability and powerlessness. If one had previously felt that the world was a safe place, or at least that the United States was a safe place, and that it was possible to protect oneself from adversity, being exposed to a situation in which there was no ability to protect oneself challenged that belief. Recovering from trauma involves accepting or accommodating a new reality about the world in a way that allows for learning, mastery, and empowerment. However, such accommodations are difficult to achieve in the immediate aftermath of a trauma because the body's biologic response perpetuates a physical state of fear that is more conducive to exaggerating a negative supposition about one's own safety. When people feel afraid in response to having experienced an uncontrollable threat to their lives, they may be more compelled to conclude that they can never be safe. Such inaccurate or extreme views perpetuate fear. Many theorists believe that PTSD emerges because of the development of a fear network in memory that compels individuals to avoid thoughts and feelings associated with the traumatic experience. Avoidance prevents exposure to information that can disconfirm inaccurate cognitions about the world.

Other responses, such as horror, anger, sadness, humiliation, or guilt, also occur following trauma. Failure to recover from traumatic experiences is typically due not to emotions that are direct outcomes of traumatic exposure (e.g., horror) but, rather, to those that result from faulty interpretations made by the survivor. For example, many people blame themselves for how they respond during trauma, and such reactions promote shame or embarrassment. Traumatic grief is also typically associated with feelings of blame and guilt. These reactions are not necessarily part of the biologic fear response to the traumatic event but, rather, appear to represent thoughts and interpretations which lead to faulty beliefs.

The process of recovering from trauma requires active engagement with the traumatic experience. To heal from trauma, a person must allow him- or herself to think about what has happened and not run away from the distressing emotions that invariably result from thinking about the event. If one can confront one's feelings in the early aftermath of an event, this will promote a process of habituation. Over time, thoughts about the event and emotional responses will become less distressing. Once a survivor can feel that he or she has achieved some control over the emotional distress of the memory, it will be possible to challenge and correct cognitive misinformation that is erroneous and has led to overgeneralization and further distress.

Biological Aspects

The biologic component of PTSD has become increasingly important as findings delineate that this essentially psychological condition is associated with distinct, often circumscribed physical alterations in the same hormonal, immune, neurochemical, and physiological systems involved in other medical illnesses. In tandem with observations of the phenomenology and psychology of PTSD, neurobiological examinations of trauma survivors have also supported the possibility that the development of PTSD is facilitated by a failure to contain the normal stress response at the time of the trauma, resulting in a cascade of biological alterations that lead to intrusive, avoidance, and hyperarousal symptoms. This failure represents an alternative trajectory to the normal process of adaptation and recovery observed in most people who undergo traumatic experiences.

The normal fear response is characterized by a series of biological reactions that help the body cope with, and gradually recover from, stress. Activation of the sympathetic nervous system (SNS) and the release of adrenaline allow the organism to increase its physiological capacity for 'fight-or-flight' in response to threat and facilitate consolidation of the threat memory. The simultaneous activation of the hypothalamic–pituitary–adrenal (HPA) axis, culminating in the release of cortisol, helps contain the neural, defensive stress reactions. As stress-activated biological reactions are restricted, elevated cortisol levels also suppress the further release of cortisol through negative feedback inhibition on the pituitary, hypothalamus, hippocampus, and amygdala.

Prospective biologic studies have demonstrated that individuals who develop PTSD or PTSD symptoms appear to have attenuated cortisol increases in the acute aftermath of a trauma compared to those who do not develop this disorder. Moreover, persons who develop PTSD show higher heart rates in the emergency room and at 1 week posttrauma compared to those who ultimately recover, suggesting a greater degree of SNS activation. These findings imply that the actual biologic response to acute trauma may be altered in persons who develop PTSD, some of which are typical of and others atypical of the 'normal' stress response.

Low cortisol levels have also been observed in chronic PTSD, even decades after trauma exposure, and therefore appear to be sustained throughout the course of the illness. However, corticotropin-releasing

factor (CRF) levels, measured in cerebrospinal fluid, appear to be increased in this disorder. The pattern of lower cortisol and higher CRF is in contrast to the findings of acute and chronic stress, and of major depressive disorder, which are typically associated with both increased cortisol and increased CRF. That the HPA axis alterations in PTSD are distinct from these conditions has also been shown in studies that have demonstrated an increased negative feedback sensitivity. This enhanced sensitivity of the HPA axis is reflected by an exaggerated suppression of cortisol in response to DEX administration and an increased concentration and sensitivity of lymphocyte glucocorticoid receptors. These findings contrast with the well-demonstrated phenomenon of reduced cortisol suppression in response to DEX, which has been routinely observed in approximately 50% of depressed patients, as well as findings of reductions in glucocorticoid receptor number and sensitivity in major depressive disorder.

The origin and onset of the HPA axis alterations in PTSD have not been elucidated. Low cortisol levels may represent a risk factor for the disorder rather than either a consequence of trauma exposure or a reflection of the pathophysiologic expression of the disorder. Persons who have a parent with PTSD have lower cortisol levels than those who do not. Lower cortisol levels are also associated with childhood emotional abuse, which is itself a risk factor for PTSD. In a study examining the cortisol response in the hours following the trauma of rape, the strongest predictor of low cortisol levels was the risk factor of prior rape or assault.

Since cortisol inhibits its own release through negative feedback at the level of the pituitary and the hypothalamus, lower levels may disrupt the process of stress recovery by failing to inhibit the activation of the pituitary, resulting in increased CRF stimulation in synergy with other neuropeptides, such as arginine vasopressin. This would result in a higher magnitude ACTH response, which might further stimulate the SNS. Moreover, since glucocorticoid release inhibits norepinephrine secretion from the sympathetic nerve terminals, lower cortisol levels may have the consequence of prolonging norepinephrine availability to synapses both in the periphery and in the brain. Ultimately, low cortisol levels might result in an upregulation or increased sensitivity of glucocorticoid receptors in response to the detection of a greater internal demand by the pituitary, and this would further strengthen negative feedback inhibition. Alternatively, an enhanced negative feedback inhibition may be present at the time of the trauma, and it may contribute to the premature suppression of ACTH and cortisol.

There may be consequences of increased catecholamine levels in the acute aftermath of the trauma for promoting the consolidation of the traumatic memory. Under such conditions, the memory of the event would not only be strongly encoded but also be associated with extreme subjective distress. The distress, in turn, would likely facilitate the development of altered cognitions in the aftermath of the event, particularly those associated with one's own perception of danger or ability to cope with threat. These altered cognitions would serve to further delay recovery by leading to a failure to quell fearful responses, which would further serve to strengthen, rather than reduce, both maladaptive cognitions in response to trauma and fear responses, thus perpetuating the intrusive, avoidance, and hyperarousal symptoms as described previously.

The previously mentioned cascade can lead to substantial impairments in brain function. It is well established that persons with PTSD do not show the normal circuitry between the amygdala and the anterior cingulate cortex, which is generally one in which the latter region exerts an inhibition on the amygdala, particularly during exposure to fear-producing triggers. Alterations in hippocampal volume have also been noted in PTSD, although it has been more rare to observe changes in hippocampus brain metabolism in response to traumatic triggers; alterations in this region have been observed in persons with PTSD in association with cognitive deficits. There is evidence that, like lower cortisol levels, smaller hippocampal volumes may constitute early risk factors for PTSD rather than occur as a result of trauma exposure. Thus, the biology of PTSD appears to be one in which there may be a set of pretraumatic biological risk factors that serve to impede the individual's ability to contain the stress response and facilitate a biological sensitization to subsequent traumatic events by allowing for a heightened level of physiologic arousal and consequently distress at the time of the traumatic event. PTSD has been associated with numerous other biologic alterations, including immune, catecholaminergic, psychophysiologic, and in sleep physiology, and these are likely also relevant to the expression of the disorder. The biologic findings in PTSD have contributed to our knowledge substantially by providing an important framework for understanding how similar events could result in biologically heterogeneous outcomes related to individual differences in the presence and severity of PTSD.

Treatment Options for Chronic PTSD

Counseling

An important component of treating trauma survivors is the provision of education, safety, and support,

which can be done in primary care. Education helps the survivor understand the nature of his or her condition and what is involved in the process of recovery. An important element of education involves explaining posttraumatic symptoms in the context of a normal biologic reaction to overwhelming stressors so as to help the survivor understand that such reactions do not represent flaws in character or personal weakness. It is essential to listen noncritically and to provide the frequent message to the survivor that he or she is not alone.

Such intervention can serve the critical role of engaging the trauma survivor and highlighting the need for therapy. Trauma survivors are notoriously reluctant to seek help for their symptoms, particularly from mental health practitioners. Sometimes this may result from a lack of awareness on the part of the survivors that their symptoms are linked to a traumatic event. Often, however, survivors do have an awareness of the relationship between trauma and their symptoms but are concerned about the stigma associated with being portrayed as 'damaged' or emotionally unstable. For many survivors, there may be consequences of disclosure of trauma or treatment (e.g., a police officer may lose the right to carry a weapon and a politician may be affected by disclosure of past trauma or psychiatric treatment). Supportive counseling in primary care can help address many of these barriers to care and reassure patients of confidential treatment options.

Alleviating the core symptoms of PTSD, however, sometimes requires the use of specialized techniques that help the survivor confront fears and emotional responses to the traumatic event in a more structured format, without running away or being overwhelmed. PTSD treatment fundamentally involves reducing the distress associated with traumatic memories and quelling the resultant physiological reactions. Research has demonstrated the effectiveness of a variety of cognitive behavioral techniques, such as exposure therapy, cognitive processing therapy, and eye movement desensitization, which help the person confront painful memories and feelings. Cognitive therapy, in particular, helps the individual modify his or her thoughts and beliefs about safety after a traumatic event, anxiety management, and interpersonal therapies (which focus on how the impact of the traumatic event on relationships and current problems). Group therapy may also be helpful since persons with similar experiences can often support each other in a particularly effective way. Although there are less empirical studies to support treatments such as massage therapy, acupuncture, and other alternative body-focused approaches, many persons seek these avenues of treatment in the aftermath of trauma and report feeling benefited by them.

Pharmacology

Medications can also benefit trauma survivors and can be prescribed by a primary care physician. Results of randomized clinical trials demonstrate that medications such as selective serotonin uptake inhibitors (SSRIs), tricyclic antidepressants, and MAOIs appear to alleviate PTSD symptoms and are also associated with improvements in global functioning quality of life. SSRIs are considered a superior first-line medication because they are safer and better tolerated. Two SSRIs, sertraline, and paroxetine, have been approved by the Food and Drug Administration for the treatment of PTSD. Prasozin, an α_1 agonist, has been demonstrated to reduce nightmares in PTSD patients, and if doses are carefully monitored by a physician, it can achieve very good effects, particularly in improving sleep. There is consensus that benzodiazepines should be avoided or used very judiciously in PTSD. This is based not only on clinical anecdotal wisdom but also on a randomized, double-blind controlled trial that failed to show improvement of alprazolam over placebo in chronic PTSD, as did a study using either alprazolam or clonazepam in the acute aftermath of trauma.

Most experts agree that prescribing medication may not provide a complete treatment response for PTSD, and it is best done as an adjunct to psychotherapy. The partial response to medication may be due to the fact that pharmacologic agents targeting the specific constellation of biologic alterations in PTSD have not been developed. Rather, pharmacotherapy for PTSD has involved administering agents with proven efficacy in other mood and anxiety disorders. In contrast, there has been a focused attempt to develop specialized psychological treatments for PTSD.

There is great interest in medications that may prevent the development of PTSD if administered early enough in the aftermath of a traumatic event. Approaches that focus on reducing distress and the consolidation of traumatic memories are currently being investigated. These include direct reduction of SNS activity (e.g., with medications such as propranolol) or indirect reduction of SNS activity by augmenting HPA axis functioning (e.g., administration of cortisol). Both of these treatments may be somewhat efficacious in preventing the formation of PTSD or traumatic memories.

Summary

PTSD is a serious condition that results from exposure to traumatic stress and appears to represent a failure to recover from what is almost a universal set of emotions and reactions. PTSD typically manifests in distressing memories or nightmares that replay the traumatic event, attempts to avoid reminders of the trauma, and

a heightened state of physiological arousal. The disorder is very common, and it has been shown to occur in 8–10% of the general population at some point in their lives. Studies of the biology of PTSD have delineated circumscribed alterations in brain regions such as the amygdala and hippocampus that are associated with fear and memory, as well as changes in hormonal, immune, neurochemical, and physiological systems involved in coordinating the body's response to stress. The treatment of PTSD involves educating the patient about the nature of the disorder, providing a safe and supportive environment for discussing traumatic events and their impact, and attending to the distress associated with experiencing and avoiding traumatic memories and reminders. A variety of modalities, such as exposure therapy, cognitive therapy, and pharmacotherapy, have been found effective in the treatment of PTSD.

Potassium Channel Regulation

Introduction

Voltage-Gated Potassium Channels

Voltage-dependent potassium channels (Kv) play essential roles in establishing membrane excitability and belong to a large, diverse family of membrane proteins. The nomenclature for voltage-gated potassium channels consists of 'K' (potassium), 'v' (voltage gated), 'number' (subfamily), and '.number' (subfamily member). Each Kv gene encodes a channel subunit containing a signature set of motifs, many of which are targets for developmental or activity-dependent regulation.

In the nervous system, neurons display cell-type-specific expression patterns for Kv genes. Although neurons express multiple Kv genes, many Kv genes are detected in only discrete, restricted populations of neurons. Thus, the repertoire of Kv genes expressed within a neuron limits and defines, in a cell-specific manner, the mechanisms available for modulation of potassium current function and membrane excitability. Here, we will focus on recent progress regarding two of the more thoroughly understood subfamilies of potassium channels, Kv1 (Shaker) and Kv2 (Shab). We compare structural motifs predicted by primary sequence and review evidence implicating subunit-specific domains in developmental or activity-dependent regulation.

The Kv1 and Kv2 Families of K^+ Channels

Kv1 subfamily members have been the focus of numerous studies investigating *in vivo* mechanisms of channel regulation. In contrast, much less is known about the regulation of Kv2 subfamily members, especially Kv2.2. Recent work regarding Kv2.1 channels, however, has provided novel insights. The emerging view indicates that substantially different mechanisms regulate Kv1 and Kv2 channels.

Structural comparisons of Kv1 and Kv2 channels Although the primary sequences of Kv1 and Kv2 genes predict proteins that share many structural features, important subfamily and subunit-specific motifs exist (Figure 1). Overall transmembrane topologies include similar features, such as six transmembrane-spanning (S) domains, a P-loop between the fifth (S5) and sixth (S6) transmembrane domains (pore, ion selectivity filter), and an S4 domain with positively charged residues at every third position (voltage sensor). Each Kv1 or Kv2 gene codes for a single pore-forming (α) subunit of a potassium channel that contains four α-subunits and additional auxiliary subunits. In both Kv1 and Kv2 subunits, the amino (N)- and carboxy (C)-termini are thought to be cytoplasmic (Figure 1). However, closer examination of structural domains highlights important differences.

N-terminal domains Each Kv1 and Kv2 subunit contains a cytoplasmic N-terminal tetramerization domain (T1; Figure 1). However, the T1 domains of Kv1 and Kv2 differ significantly and mediate subfamily-specific co-assembly of subunits. The Kv1 T1 domain also contains the interaction site for accessory (Kvβ) subunits. Kvβ subunits influence surface expression, localization, and kinetic properties of Kv1 complexes.

Heterologous expression studies indicate that Kv1 and Kv2 heteromultimers function as channels with novel properties, indicating that the molecular diversity produced by subunit heteromultimerization has functional consequences. Kv1 heteromultimers form *in vitro* as well as *in vivo*. In contrast, evidence for Kv2 heteromultimerization exists for channels formed *in vitro* but not in neurons.

A distinguishing feature of some Kv1 subunits is an inactivation 'ball' motif contained within the N-terminus (Figure 2). The inactivation ball mediates fast (N-type) inactivation and converts sustained outward currents (I_{Kv}) into transient potassium currents (I_{KA}). The two current types have dramatically different consequences on neuronal excitability. In some Kv1 channel complexes, the inactivation ball resides not within the Kv1 α-subunit but instead on the auxiliary Kvβ subunit, which interacts with the T1 domain (Figure 1). Kvβ1 and Kvβ3, but not Kvβ2, subunits contain inactivation balls. Thus Kv1 channel complexes can carry either sustained or transient currents, depending on the identity of their pore-forming and/or accessory subunits.

There also exist auxiliary proteins that modify the effects of Kvβ subunits. Co-assembly of Kv1.1 and Kvβ1.1 results in formation of a channel that carries inactivating current. An additional protein, leucine-rich glioma inactivating gene 1 (Lgi1), exists in Kv1.1 channel complexes identified *in vivo*. Lgi1 alters channel function by removing fast inactivation. Some forms of temporal lobe epilepsy are due to mutations in Lgi1, highlighting the functional significance of regulation of channel inactivation properties.

Figure 1 The primary sequences of Kv1 and Kv2 genes predict pore-forming subunits with similar transmembrane topologies. The channel will contain four α-subunits plus additional β-subunits. The β-subunits interact with the T1 domain of Kv1 α-subunits and exist in channel complexes detected *in vivo*. Subunits interacting *in vivo* with Kv2 subunits have yet to be identified. N, amino-terminus; C, carboxy-terminus; S, transmembrane domain; NIP, N-type inactivation prevention domain; T1, tetramerization domain; PDZ BD, PDZ-binding domain; ProxC, proximal carboxy-tail regulatory region; PRC, proximal restriction and clustering signal.

Figure 2 Kv1 channel complexes can carry sustained noninactivating or inactivating currents. Channel complexes containing inactivation balls underlie currents that inactivate rapidly. The inactivation ball can reside on either the pore-forming α-subunit or the auxiliary β-subunit.

In heterologous systems, Kv2 isotypes co-assemble with KChAP (a putative chaperone protein), Kv6, Kv8, or Kv9 subunits (Table 1). Co-expression of KChAP with Kv2 subunits increases the densities of surface membrane Kv2 protein and Kv current. In contrast, Kv6, Kv8, and Kv9 subunits share high amino acid identity with pore-forming Kv2 subunits. However, they do not generate current when expressed on their own. When co-expressed with Kv2 subunits, Kv6, Kv8, or Kv9 subunits decrease current amplitudes. While it is tempting to speculate that Kv6, Kv8, or Kv9 subunits may function as endogenous dominant-negative subunits, direct evidence demonstrating co-assembly with Kv2 subunits *in vivo* is lacking.

C-terminal domains The cytoplasmic C-terminal regions of Kv1 and Kv2 subunits differ substantially. Most obviously, the regions have different amino acid lengths, being much longer in Kv2 subunits (Figure 1). In addition, the C-termini of Kv1 and Kv2 channels mediate different interactions and functions. For example, the C-terminal amino acids of Kv1 subunits bind to modules in neuronal scaffold proteins, known as postsynaptic density/disc/zonula

Table 1 Known Kv1 and Kv2 auxiliary proteins and the effect of interaction

Auxiliary protein	*Associates with*	*Effect of association*[a]
Cytoplasmic		
Kvβ1.1	Kv1.1	Induces inactivated state
	Kv1.3	–
Lgi1	Kv1.1 and Kvβ1.1	Removes fast N-type inactivation, producing sustained currents
Kvβ1.2	Kv1.1	–
	Kv1.2	Increases channel density in surface membrane
	Kv1.4	Increases the rate of inactivation
	Kv1.5	Increases the rate of inactivation, decreases current amplitude
Kvβ1.3	Kv1.5	Binds to the N-terminus of Kv1.5 to induce N-type inactivation, change voltage dependence; alters kinetics of activation and slows the rate of inactivation
	Kv1.6	Immune to Kv1.6 NIP domain, results in fast inactivation
Kvβ2.1	Kv1.1	–
	Kv1.5	Increases the rate of inactivation
	Kv1.4	Increases the rate of inactivation
Kvβ2.2	–	–
Kvβ3.1	Kv1.1	–
Kvβ3.2	Kv2.2	Chaperones channel integration into membrane
KChAP	Kv1.5	–
	Kv2.1	Binds to N-terminus and increases surface expression
	Kv2.2	Binds to N-terminus and increases surface expression
Transmembrane		
Kv5.1	Kv2.1 or Kv2.2	Decreases current amplitude, slows inactivation
Kv6.1	Kv2.1	Decreases current amplitude, slows inactivation
Kv8.1	Kv2.1 or Kv2.2	Modifier or suppressor of activity, depending on concentration; modifies properties of inactivation process
Kv9.1	Kv2.1 or Kv2.2	Modifies kinetics and expression: shifts one-half activation potential to more hyperpolarized values
Kv9.2	Kv2.1 or Kv2.2	Modifies kinetics and expression: shifts activation $V_{1/2}$ to more hyperpolarized values

[a]The designation '–' in some columns indicates that this information is unknown.

occludens (PDZ) proteins (e.g., PSD-95). Scaffold proteins play multiple roles in neurons, including organization of signaling complexes and subcellular localization of membrane proteins. Evidence exists implicating a clustering function for the PDZ-binding domain (PDZ BD) of Kv1 subunits.

Kv2 subunits do not contain any standard PDZ-binding domains or other recognized sites for interactions with scaffold proteins. However, Kv2.1-containing potassium channels form discrete clusters in the soma and dendrites. For Kv2.1 subunits, a novel domain, the proximal restriction and clustering (PRC) signal, directs the characteristic clustering of the channel in the neuronal soma and proximal dendrites. The region corresponding to the PRC in Kv2.2 subunits is poorly conserved, consistent with no clusters of Kv2.2 channels in the somatodendritic region. The carboxy-tail region of Kv2.2 does possess its own signature sequence, called ProxC, because it resides within the proximal portion of the large cytoplasmic carboxy-tail region. The analogous region in Kv2.1 subunits shows little sequence similarity with the Kv2.2 ProxC, suggesting a subunit-specific function. In Kv2.2 subunits, the presence of the ProxC sequence limits potassium current density in mature neurons, ensuring that current density does not exceed a limit referred to as the set point, even when overexpression is attempted empirically by loading neurons with excess Kv2.2 mRNA. In contrast, Kv2.1 subunits can be functionally overexpressed in mature neurons. In addition to subunit specificity, ProxC displays developmental specificity. In neurons that have recently left the postmitotic cycle and are initiating postmitotic differentiation, the ProxC does not limit functional overexpression of Kv2.2 channels.

Additional structural motifs In addition to the structural motifs just described, Kv1 and Kv2 sequences contain several different consensus sites for posttranslational modification. For example, both Kv1 and Kv2 subunits contain an N-linked glycosylation site in an extracellular loop. Glycosylation occurs co-translationally and influences protein folding and stability, often by preventing premature degradation. In Kv1 subunits, the N-glycosylation site resides in an extracellular loop between S1 and S2. Glycosylation at this site contributes to surface expression and membrane stability of channels. In Kv2 subunits, the extracellular loop between S3 and S4 contains a potential N-glycosylation site, but the role of this

posttranslational modification for Kv2 subunits has not yet been tested.

Sites regulating intracellular trafficking have been identified in several different Kv1 subunits. Endoplasmic reticulum (ER) retention sites ensure that, unless appropriately modified, proteins are retained in the ER after translation. Kv1.1 and Kv1.2 subunits, which are abundantly expressed in neurons and heteromultimerize with each other, have ER retention sites flanking the P-loop. Kv1.4 subunits, in contrast, lack ER retention signals in the P-loop but instead have a sequence, VKESL, which promotes surface insertion of channels.

Consensus sites for protein phosphorylation abound in Kv1 and Kv2 subunits. Further, the majority of sites are subfamily, if not subunit, specific. For Kv1 and Kv2 subunits, evidence exists implicating phosphorylation in trafficking of channels through intracellular membrane compartments, control of surface channel density via endocytosis, and modulation of channel functional properties such as voltage dependence. The *in vivo* roles of these mechanisms are discussed in more detail in the following sections.

Regulation of Kv1 and Kv2 Channels

In the mature central nervous system, a majority of changes that occur in response to activity arise through regulation of existing cells rather than by replacement of cell populations. During development, changes in cell number and identity specification also occur, suggesting that nonoverlapping sets of mechanisms may regulate a neuron's electrical phenotype in the developing versus mature nervous systems. For example, on the basis of *in situ* hybridization studies, developmental regulation of ion channel gene transcription is inferred. However, the molecular mechanisms directing expression of specific channel genes in coordinated temporal sequences have yet to be identified.

Mechanisms regulating Kv1 and Kv2 channel function have been identified at the molecular level. The majority of the mechanisms target posttranslational events, although translational control also has emerged as a powerful way to regulate electrical membrane properties in discrete compartments of a neuron in an activity-dependent manner.

Activity-Dependent Translational Regulation of Kv1.1

mTOR mediated Activity-dependent changes in dendrites result in structural remodeling and changes in synaptic strength of synapses. Recent evidence indicates that synaptic activity can also regulate the density of Kv1.1-containing channels at postsynpatic sites. Specifically, *N*-methyl-D-aspartate (NMDA) receptor activation triggers a dendritic signaling pathway that uses the mTOR serine/threonine kinase to specifically block local translation of Kv1.1. If Kv1.1 current density were to decrease, excitatory synaptic stimulation would produce larger dendritic depolarizations, thereby functionally and selectively tagging recent sites of NMDA receptor by an increase in membrane excitability. The mTOR pathway regulates synthesis of Kv1.1 but not Kv1.4 protein, even though dendrites contain mRNAs coding for both.

Posttranslational Regulation

Trafficking and localization Regulation of channel density and location in the surface membrane will dramatically affect the consequences of channel activity on neuronal function. Both pore-forming and auxiliary subunits of a channel complex influence the trafficking of a channel from point of synthesis in the ER to the surface. Surface dwell time reflects the balance between surface membrane insertion and removal, the latter typically achieved by endocytosis.

Studies in heterologous systems have revealed an ER retention sequence near the pore domain of Kv1.1 subunits. Heterotetramerization of Kv1.1 with different Kv1 subunits or binding of dendrotoxin K to the pore region masks the ER retention sequence, resulting in increased trafficking of Kv1.1 channel complexes to the surface membrane. The effect of dendrotoxin K raises the possibility of an endogenous protein that similarly masks the ER retention site, regulating surface insertion of Kv1.1 channels.

Co-assembly of Kv1 with Kvβ2 subunits also promotes increased surface insertion of complexes. However, whether the effect involves masking of ER retention motifs or another mechanism is not yet known. Removal of channels from the surface membrane, known as retrograde trafficking, regulates Kv1.5 channel density in the surface membrane. The mechanism involves dynein, a motor protein that associates channel-containing in-membrane vesicles with microtubules, and results in molecule transport toward the minus, or inward, direction.

Axonal targeting of Kv1.2 channel complexes relies upon Kvβ2 subunits. In addition to the T1 domains of Kv1 subunits, Kvβ2 binds to two different microtubule (MT)-associating proteins called EB1 and kinesin II (Figure 3). EB1, an MT plus-end tracking protein, associates with the MT developing end and promotes addition of tubulin. Kinesin II is a plus-end-directed motor protein. Similar to EB1, the plus-end-directed motor protein kinesin II moves toward the cell surface. However, unlike EB1, kinesin

Figure 3 Kvβ2 subunits mediate axonal targeting of potassium channels. The microtubule proteins EB1 and kinesin II direct transport of Kv1.2-containing membrane vesicles via interactions with the auxiliary Kvβ2 subunits. These interactions result in targeted delivery of Kv1.2–Kvβ2 channel complexes to the axon.

II does not necessarily remain associated with the MT end. Interactions of Kvβ2 with EB1 and kinesin II direct trafficking of vesicles containing intracellular pools of Kv1 channel complexes down the MT cytoskeleton of the axon.

As mentioned, Kv2.1 channels localize to the soma and dendrites of neurons in discrete clusters. Interestingly, channels are inserted into the surface membrane at cluster sites. Thus, random insertion of Kv2.1 channels followed by redistribution into clusters does not seem to occur. Further, although channels are restricted to clusters, they move freely within a cluster. The underlying mechanism has been suggested to resemble a fence rather than a scaffold. Channel clustering is not universally observed. For example, Kv1.3 and Kv1.4 channels are highly mobile and evenly distributed throughout the surface membrane. Further, when Kv1.3, Kv1.4, and Kv2.1 channels are present in the same cell, the three subunits exist in separate compartments.

Phosphorylation Ion channel phosphorylation reversibly and dynamically modulates channel function and, consequently, membrane excitability. Phosphorylation often regulates channel density, but the underlying mechanism can differ significantly. For example, phosphorylation can trigger endocytosis of potassium channels from the surface membrane and thereby reduce potassium current density. Alternatively, phosphorylation can alter biophysical properties of the channel and regulate current density elicited by physiological levels of membrane depolarization.

Three Kv1 family channels, Kv1.2, Kv1.3, and Kv1.5, contain consensus sites for tyrosine phosphorylation. Phosphorylation of Kv1.3 subunits by the tyrosine kinase v-src leads to a dramatic reduction in current density. Similarly, Kv1.5 contains an SH3 consensus site for tyrosine phosphorylation that plays a role in mechanisms that reduce current density and/or change biophysical properties of the channel. As expected, modulation of the channel occurs upon phosphorylation of the targeted tyrosine. However, modulation also occurs in the absence of phosphorylation, upon binding of the tyrosine kinase to the SH3 consensus site. Channel removal involves endocytosis via motifs that are regulated by phosphorylation of tyrosine residues. This type of phosphorylation-dependent endocytosis occurs for Kv1.2 and a distantly related potassium channel, the inward rectifier potassium channel, Kir1.1. Thus, tyrosine phosphorylation-dependent endocytosis has been conserved as mechanism for regulation of surface membrane density for potassium channels with significantly different functions.

Phosphorylation of serines in the N- and C-terminal tail regions of Kv2.1 underlies an activity-dependent regulation of channel function. Further, similar to the positive-feedback activity-dependent regulation of Kv1.1, synaptic activity leads to a positive-feedback regulation of Kv2.1 that in turn mediates negative-feedback regulation of activity. Activity promotes release of calcium from the ER that, in turn, activates the phosphatase calcineurin. Upon dephosphorylation of serines by calcineurin, Kv2.1 clusters disperse. Further, the voltage-sensitivity of Kv2.1 channels changes so that the $V_{1/2}$ for activation becomes more negative, allowing a larger percentage of the channels to be activated by physiological levels of membrane depolarization. Thus, neuronal activity leads to generation of larger potassium currents in response to

physiological levels of membrane depolarization; this is positive-feedback regulation of the current. However, increases in potassium conductance will lead to a decrease in membrane excitability and reduction in calcium influx, and thus to negative-feedback regulation of neuronal activity. These findings implicate Kv2.1 in homeostatic mechanisms that are important for maintaining appropriate responses to inputs during periods of plasticity.

Sumoylation Sumoylation, the covalent attachment of small ubiquitin-like modifier (SUMO) to lysine residues of a protein, is known to affect the function of transcription factors and other developmental genes. However, recent results indicate that ion channels also serve as targets for this form of posttranslational modification. The first channel to be recognized as a target for sumoylation was K2P1, a leak 2-pore-type potassium channel. When K2P1 is sumoylated, the conductance of the channel drops essentially to zero. Recently, sumoylation of Kv1.5 subunits was detected *in vivo*. In Kv1.5, SUMO groups attach to lysines in two regions flanking the six transmembrane-spanning domains and shift the voltage-dependence of steady-state inactivation to more negative membrane potentials. Thus, fewer channels are available for activation when the membrane potential is at rest. Interestingly, KChAP, a protein previously identified to interact with Kv1.5, shows up in a Basic Local Alignment Search Tool (BLAST) search as E3 SUMO-protein ligase/PIAS3. Moreover, KChAP also interacts with other Kv1 subunits as well as with both Kv2 subunits, raising the possibility that sumoylation regulates the function of several Kv1 and Kv2 channels.

Conclusions

Studies of Kv1 and Kv2 channels have provided insights into how potassium channel regulation allows neurons to adjust appropriately and dynamically to changes in inputs and activity. During development, these challenges can be extreme because the intrinsic excitable membrane properties change rapidly, from the time when neuronal cells first emerge to maturity. In addition, the number of inputs (e.g., synapses) also changes dramatically, from zero to sometimes hundreds of thousands. In the mature nervous system, such changes are thought to underlie learning and memory. Both the pore-forming components and the auxiliary subunits are targets for regulatory mechanisms. Modification of channel inactivation properties has profound effects on neuronal excitability. Inactivation kinetics are determined in large part by the subunit composition of the channel. The channel density in the surface membrane will affect many critical properties of neuronal excitability, such as the threshold for action potential generation. Regulation of forward or reverse trafficking of Kv1 and Kv2 channel complexes plays a major role in setting surface membrane channel density levels. Moreover, and of particular relevance to the mature nervous system, highly dynamic regulation of channel function also occurs. Signature motifs within each subunit, such as ones for phosphorylation in addition to newly discovered functional modules, determine the set of available regulatory mechanisms and allow an impressive degree of fine-tuning of neuronal excitability. Control of neuronal excitability can occur in temporally and spatially specific manners, depending upon expression pattern. However, little is known about transcriptional mechanisms that control ion channel gene expression, either during development or in the mature nervous system. Thus, identification of transcription factors and RNA-binding proteins that regulate channel expression will provide important new information about potassium channel regulation.

Potassium in the Extracellular Environment of the Central Nervous System

Potassium concentration in the extracellular environment of the central nervous system (CNS) is kept at relatively low levels (2.5–5 mM) compared to inside neurons (100–130 mM). The transmembrane concentration gradient for Na^+ ions is reversed, with higher Na^+ outside. These transmembrane gradients for K^+ and Na^+ ions are exploited by neurons for fast electrical signaling and synaptic communication. During the repolarizing phase of action potentials and during excitatory synaptic potentials, K^+ ions exit neurons via voltage-dependent K^+ channels and various ionotropic receptors. Even modest neuronal K^+ efflux generates considerable changes in the extracellular K^+ concentration ($[K^+]_o$), given the low initial K^+ concentration and the tortuosity and relatively small volume of extracellular space in the CNS. Small increases in $[K^+]_o$ bring about neuronal depolarization and raised excitability. Larger increases in $[K^+]_o$, on the other hand, inactivate voltage-gated channels and therefore suppress excitability. Thus, it is not surprising that diverse cellular mechanisms are present in the CNS of vertebrates and invertebrates for tightly controlling $[K^+]_o$.

Glial Cells

Numerous functions have been attributed to glial cells in the CNS, including neurotransmitter clearance from synapses, guidance during neuronal migration and, more recently, active control of neuronal synaptic transmission. Additionally, it has long been accepted that glial cells help to maintain the optimal extracellular ionic environment required for communication between neurons. Direct experimental evidence indicates that glial cells, most notably astrocytes, can effectively minimize fast (timescale of seconds) changes in $[K^+]_o$. Astrocytes are well suited for this task because they have processes that are in close association to neuronal synapses and blood vessels (Figure 1) and are abundant in the CNS.

Astrocytes have plasma membranes that are almost exclusively and highly permeable to K^+. The high membrane permeability to K^+ in astrocytes accounts for their relatively hyperpolarized membrane potentials, which are in the range of −70 to −90 mV, close to the predicted K^+ equilibrium potential (E_K). Astrocytes are also connected to each other by gap junctions, which are composed of connexins. Connexins of two adjacent cells can dock with each other to form the gap junction channel, allowing the exchange of small molecules and ions. Astrocytes are extensively coupled to each other, forming a functional electrical syncytium.

Overview of Extracellular K^+ Regulatory Mechanisms

Potassium buffering mechanisms work efficiently in the CNS; increases in $[K^+]_o$ do not surpass a plateau or ceiling level of approximately 10–12 mM, even during intense and prolonged neuronal activity. When these clearance mechanisms are weakened in instances such as spreading depression or ischemia, $[K^+]_o$ can reach values as high as 60 mM. Neuronal function is then severely suppressed.

Glial cells play a key role in regulating extracellular K^+ in the CNS. Glial mechanisms of $[K^+]_o$ buffering are broadly categorized as either net K^+ uptake or K^+ spatial buffering (Figure 1). In net K^+ uptake, excess extracellular K^+ released from active neurons is temporarily sequestered in neighboring glial cells by the activity of K^+ transporters and pumps. To preserve electroneutrality, K^+ influx into glial cells is accompanied by either influx of anions such as Cl^- or efflux of cations such as Na^+ (Figure 1). With net K^+ uptake there is an initial gain of K^+ in glial cells which is usually followed by water influx and swelling. Eventually, the K^+ accumulated in glia is released back into the extracellular space and the overall distribution of K^+ across different cellular compartments in the CNS is restored.

The K^+ spatial buffering mechanism was first proposed by Orkand and colleagues in their landmark experiments on the optic nerve of amphibians. They stated, "If a glial cell becomes depolarized by K^+ that has accumulated in the clefts, the resulting current carries K^+ inward in the high $[K^+]_o$ region and out again, through electrically coupled glial cells in low $[K^+]_o$ regions." Localized increases in $[K^+]_o$ in the CNS are dissipated through transfer of K^+ through glial cells from areas of elevated $[K^+]_o$ to areas in which $[K^+]_o$ is low.

Net K^+ Uptake by Glial Cells

Net K^+ uptake is mediated mainly by glial Na, K-ATPase pumps and Na–K–Cl cotransporters. The

Figure 1 Diagram depicting the role of glial cells in $[K^+]_o$ homeostasis. (Top) Glial cells are electrically coupled via gap junctions forming a functional syncytium. With $[K^+]_o$ equaling 3 mM, the glial syncytium has a membrane potential of approximately −90 mV. (A) Net K^+ uptake mechanism. When $[K^+]_o$ is increased, glial cells accumulate K^+ either by the activity of an Na,K-ATPase or by a pathway in which K^+ is cotranported with Cl^-. In this mechanism of $[K^+]_o$ regulation, the membrane potential in the glial syncytium is spatially uniform at −56 mV. (B) K^+ spatial buffering mechanism. Local increases of $[K^+]_o$ produce a glial depolarization that spreads through the glial syncytium. The local difference in glial syncytium membrane potential (V_m) and the K^+ equilibrium potential (E_K) drives the K^+ uptake in regions of elevated $[K^+]_o$ and K^+ outflow at distant regions. The intracellular currents are carried by K^+ and extracellular currents are mediated by other ions such as Na^+. Reproduced from Orkand RK (1986) Glial–interstitial fluid exchange. *Annals of the New York Academy of Sciences* 481: 269–272, with permission from Blackwell Publishing Ltd.

Na, K-ATPase pump is an integral membrane protein that utilizes the energy from ATP hydrolysis to transport Na^+ out of cells and K^+ into cells, against their concentration gradients. The Na, K-ATPase is a member of the P-type family of ATPases and is closely related to Ca^{2+}-ATPases and H^+–K^+-ATPases. Upon local $[K^+]_o$ increases, the activity of the Na, K-ATPase rises and K^+ is transported into cells, in exchange for Na^+ ions.

Several lines of evidence demonstrate that Na, K-ATPase pumps contribute to $[K^+]_o$ buffering in the CNS. For instance, a transient accumulation of K^+ ions and a simultaneous depletion of Na^+ ions are detected in glial cells of the guinea pig cortex following intense electrical stimulation. A substantial fraction of this K^+ accumulation is prevented by pharmacological blockade of Na, K-ATPase pumps. Likewise, in rat hippocampal slices, blockade of Na, K-ATPase pumps increases baseline $[K^+]_o$ and prevents the rapid clearance of extracellular K^+ ions following neuronal stimulation. In the rat optic nerve, clearance of K^+ accumulation following axonal stimulation is highly temperature dependent, as expected for a carrier-mediated process, and is largely blocked by Na, K-ATPase pump inhibitors.

Transient accumulation of K^+ in cultured astrocytes has also been linked to the activity of Na–K–Cl cotransporters. To date, two Na–K–Cl cotransporter isoforms have been identified: NKCC1, which is present in a wide variety of secretory epithelia and nonepithelial cells, and NKCC2, which is present exclusively in the kidney. Both NKCC isoforms are members of a diverse family of cation–chloride cotransporter proteins that share a common predicted membrane topology and are sensitive to loop diuretics such as bumetanide and furosemide. In cultured astrocytes, intracellular K^+ accumulation following increased $[K^+]_o$ can be partially prevented by furosemide or bumetanide or by removal of external Na^+ and Cl^-. The role of Na–K–Cl cotransporters in $[K^+]_o$ homeostasis has also been demonstrated by optical methods. In the rat optic nerve, intrinsic optical signals reveal that increased $[K^+]_o$ induces astrocyte swelling. This swelling is reversibly depressed by furosemide and bumetanide. Monoclonal antibody labeling of the NKCC1 form of the Na–K–Cl cotransporter shows that NKCC1 is expressed in astrocytes from optic nerves, suggesting the involvement of this particular Na–K–Cl cotransporter isoform in $[K^+]_o$ buffering.

Net K^+ accumulation could, in theory, also occur by K^+ influx through Kir channels accompanied by Cl^- influx through Cl^- channels. However, the Cl^- permeability of nonreactive astrocytes is low, and little K^+ accumulation is believed to occur by this mechanism.

K^+ Spatial Buffering

During K^+ spatial buffering, K^+ enters and exits glial cells via Ba^{2+}-sensitive inwardly rectifying K^+ (Kir) channels. Kir channels have a high open probability at the normal glial resting membrane potential and their slope conductance increases with elevations in $[K^+]_o$. This unique property of Kir channels allows K^+ conductance to increase in glial cells when $[K^+]_o$ is raised, enhancing K^+ clearance rates. Transcellular movement of K^+ ions in the glial syncytium is mediated by various connexins. Gap junctions in astrocytes are primarily composed of Cx43. Astrocytes also express Cx30, Cx47, Cx40, Cx45, Cx46, and Cx26.

During K^+ spatial buffering, the transcellular transfer of K^+ ions from areas of elevated $[K^+]_o$ to areas of lower $[K^+]_o$ generates return current loops in the extracellular space, giving rise to extracellular field potentials. These activity-induced slow extracellular field potentials are generated in various CNS regions, including the neocortex and retina. In the retina, slow field potentials (slow PIII and M waves) are generated upon light stimulation. Current source density analysis indicates that these waves originate from K^+ spatial buffering by retinal glial cells. The transfer of K^+ ions by retinal glial cells, which generates the slow PIII wave, buffers the photoreceptor-based light-evoked decrease in $[K^+]_o$ in the outer retina. As expected, these K^+ spatial buffering fluxes are abolished by blocking retinal glial cell K^+ channels with Ba^{2+}.

Measurements of activity-dependent $[K^+]_o$ changes in the neocortex and cerebellum show that $[K^+]_o$ varies with depth and time in a manner consistent with transcellular transfer of K^+ ions. These $[K^+]_o$ changes are not abolished by sodium pump inhibitors, indicating that they are likely due to a passive K^+ transport mechanism such as K^+ spatial buffering. Similar results are obtained in the drone bee retina, in which it is estimated that approximately 10 times more K^+ ions move as a result of spatial buffering than by simple diffusion through the extracellular space.

Potassium Siphoning in the Retina

In the retina, the Müller cell is the principal type of glial cell. Müller cells display morphological polarization with an end foot process in close apposition to the vitreous humor and apical microvilli projecting into the subretinal space. Like many other glial cells, Müller cells are distinguished from their neuronal counterparts by a resting membrane potential that closely follows the E_K with changes in $[K^+]_o$. This behavior demonstrates a high selectivity of Müller cell membranes to K^+. High membrane permeability is due to the high density and localized expression of Kir channels. Potassium channels are highly concentrated in the end foot process, with more than 90% of the total K^+ conductance localized to this relatively small subcellular domain in amphibian Müller cells.

The highly nonuniform distribution of Kir channels in Müller cells and the lack of extensive gap junctional coupling led to the hypothesis by Newman of a specialized form of the spatial buffering mechanism in the retina called K^+ siphoning. In this hypothesis, excess K^+ from the inner plexiform layer of retina, where most retinal synapses are located, is 'siphoned' by Müller cells to the vitreous humor (Figure 2). The asymmetric subcellular distribution of Kir channels in Müller cells directs clearance of K^+ into large reservoirs such as the vitreous humor.

Figure 2 K^+ siphoning in the retina. K^+ released in the inner plexiform layer (IPL) upon neuronal stimulation enters the principal glial cell of the retina, the Müller cell. K^+ leaves the glial cell preferentially from the end foot processes enveloping blood vessels and the vitreal end foot since K^+ conductance is maximal in these membrane regions. Light-evoked $[K^+]_o$ decreases in the subretinal space (SRS) lead to K^+ efflux from apical processes. Reproduced from Newman EA (1996) Regulation of extracellular K^+ and pH by polarized ion fluxes in glial cells: The retinal Muller cell. *Neuroscientist* 2: 109–117, with permission.

Potassium siphoning has been observed in the amphibian retina, in which light flashes evoke increases in $[K^+]_o$ in the vitreous humor. This light-evoked K^+ increase is mediated by Kir channels expressed in Müller cells, as shown by the observation that vitreal increases are blocked by superfusion of retinas with Ba^{2+}, a Kir channel blocker. Similarly, in cat retinas, light-evoked $[K^+]_o$ increases in the inner plexiform layer are threefold larger following blockade of Kir channels, confirming that glial-mediated K^+ spatial buffering currents play an important role in curtailing large changes in $[K^+]_o$.

Glial Cells and K^+ Channels

The Kir channels have recently been cloned, and more than 20 genes are currently known to encode different Kir channel subunits. The basic Kir channel design is of two transmembrane domains and a reentry loop (P-loop), with intracellular N- and C-termini. The Kir channel subunits are usually categorized into seven major subfamilies (Kir1–Kir7) that are diversely regulated by intracellular and extracellular factors.

Of these Kir family members, immunocytochemical and *in situ* hybridization studies demonstrate that the Kir4.1 subtype is broadly expressed in glial cells in the CNS. Kir4.1 immunoreactivity can be demonstrated in cultured and *in situ* astrocytes. Immunogold microscopic examination reveals that Kir4.1 channels are enriched in the processes of astrocytes enveloping synapses and blood vessels. In the retina, highly concentrated expression of Kir4.1 channels is found in Müller cell end feet and on the processes enveloping blood vessels (Figure 3), a distribution that correlates well with electrophysiological studies. Genetic ablation of Kir4.1 channels in mice decreases the membrane conductance of Müller cells by more than tenfold, indicating that the Kir4.1 channel accounts for more than 90% of the cell membrane conductance.

Kir Channel Accessory Proteins in Müller Cells: Localization and Function

The water channel aquaporin 4 (AQP4) is also highly enriched in the end feet and perivascular processes of Müller cells. Transfer of K^+ by K^+ siphoning in the retina will generate osmotic imbalances. Parallel water fluxes are needed to dissipate such imbalances. The highly asymmetric distribution of AQP4 channels allows funneling of water to the appropriate intracellular and extracellular compartments in the retina.

Although the Kir4.1 and AQP4 channels are highly divergent in their primary sequences, they share a key-S-X-V-COOH motif in their C-termini. This sequence binds to PDZ domains, which are modular amino acid motifs implicated in many protein–protein interactions. Proteins possessing these domains are abundantly expressed in the nervous system and include postsynaptic density protein-95 (PSD-95), Chapsyn-110/PSD-93, SAP-102, and hDlg/SAP97.

The PDZ domain-containing adapter protein, α-syntrophin, is crucial for the clustering and subcellular localization of AQP4 and Kir4.1 channels in Müller cells. α-Syntrophin is localized to the cell membrane by its association with the multiprotein dystrophin glycoprotein complex (DGC). DGC spans the cell membrane, forming a molecular bridge between basal lamina proteins in the extracellular space and an array of signaling molecules in the intracellular domain. Immunolocalization studies in retina reveal that the DGC components α-dystroglycan and the short dystrophin isoform, Dp71, are localized in a manner very similar to that of Kir4.1 in Müller cells. The role of Dp71 in the localization of Kir4.1 has been investigated in the dystrophin null mutant mouse, mdx^{3Cv}. The polarized subcellular distribution of Kir4.1 is altered in Müller glial cells from mdx^{3Cv} mice, displaying a more homogeneous distribution pattern (Figure 3). Immunoblotting and whole cell patch clamp experiments demonstrate that the channel is expressed at normal levels at the plasma membrane and its electrophysiological properties are unchanged. Only the cellular distribution of Kir4.1 is changed in the transgenic animals.

In astrocytes, the direct participation of DGC proteins in the targeting of Kir4.1 and AQP4 channels has been demonstrated in an α-syntrophin knockout mouse line. In astrocytes of wild-type animals, as in Müller cells, AQP4 and Kir4.1 are strongly expressed in glial membranes (end feet) that are in direct contact with capillaries and the pia. Quantitative immunoelectromicroscopy shows that in the hippocampus of α-syntrophin knockout mice, the expression of AQP4 in astrocyte end feet is greatly diminished, although the expression of Kir4.1 channels is less affected. These results indicate that α-syntrophin is critical for the targeting and clustering of AQP4 channels to astrocytic end feet but is perhaps not as vital for targeting of Kir4.1 channels.

Despite the apparent lack of major rearrangements in Kir4.1 channel localization and expression in hippocampus astrocytes of α-syntrophin knockout mice, the clearance of extracellular K^+ following neuronal stimulation is significantly impaired in hippocampus slices. Such studies provide the first evidence for a direct functional coupling between AQP4 and Kir4.1 channels in the regulation of $[K^+]_o$.

Figure 3 Kir4.1 channel localization in wild-type and mdx3Cv (dystrophin knockout) mouse retinal sections. (a) Kir4.1 is concentrated at the inner limiting membrane (arrow) and to processes around blood vessels (arrowheads) in wild-type retina. (b) In the mdx3Cv mouse, Kir4.1 is more evenly distributed throughout the retina, with a reduction in staining at the inner limiting membrane (arrow) and no apparent enrichment of Kir4.1 around blood vessels (arrowheads). The Müller-specific marker glutamine synthetase (c and d) and merged images (e and f) suggest that Kir4.1 is localized to Müller cells. Scale bar = 25 μm. Reproduced from Connors NC and Kofuji P (2002) Dystrophin Dp71 is critical for the clustered localization of potassium channels in retinal glial cells. *Journal of Neuroscience* 22: 4321–4327. Potassium Buffering and Pathology

In conditions of increased neuronal activity such as epilepsy there is an elevation of $[K^+]_o$ in the CNS which may further contribute to seizure generation and spread. In the hippocampus of patients with temporal lobe epilepsy, there is substantial reduction in Kir channel expression in astrocytes. Similar findings are reported in animal models of epilepsy. Such reductions of Kir conductance in astrocytes will impair K^+ spatial buffering and contribute to focal hyperexcitabilty and seizure spread.

In animal models of ischemia and diabetes in the retina, there is downregulation of Kir4.1 channel expression in Müller cells as assessed with immunocytochemical and electrophysiological assays. Such decreases in Kir4.1 conductances will impair retinal K^+ siphoning and perhaps contribute to neuronal insult observed in these pathological conditions.

Prader–Willi Syndrome

D C Bittel and M G Butler, University of Missouri–Kansas City School of Medicine and Children's Mercy Hospitals and Clinics, Kansas City, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

Clinical Description and Natural History

Prader–Willi syndrome (PWS) is a neurodevelopmental disorder characterized by infantile hypotonia with reduced muscle tone, feeding difficulties, hypogonadism and hypogenitalism, hyperphagia and obesity, small hands and feet, mild mental deficiency, behavioral problems, and a characteristic face (small upturned nose, narrow bifrontal diameter, dolichocephaly, downturned mouth, and almond-shaped eyes) (Figure 1). Hyperphagia in early childhood leads to life-threatening obesity, if uncontrolled. Short stature, scoliosis, and dental and endocrine problems are common (Table 1). In addition, diabetes mellitus, sleep apnea, and other comorbidities associated with obesity may be present. Approximately 50% of children with PWS develop temper tantrums and stubbornness between 3 and 5 years of age and depression during adolescence and adulthood; behavioral problems may be precipitated by withholding food. Intolerance to changes in routine can be a severe problem for many adolescents and adults with PWS, as well as poor peer interaction, immaturity, and inappropriate social behavior. PWS can be divided into two clinical stages: stage 1 is recognized in early infancy with hypotonia, feeding difficulties, and failure to thrive; stage 2 begins in early childhood with onset of hyperphagia and obesity.

PWS arises from lack of expression of paternally inherited genes known to be imprinted in the chromosome 15q11–q13 region. Genomic imprinting is an epigenetic phenomenon whereby gene expression is modified depending on the sex of the parent contributing the allele. It arises from epigenetic changes (e.g., methylation) of genes during gametogenesis which is reversible and parent-specific monoallelic expression of either the maternal or the paternal allele of a particular imprinted gene locus. Approximately 70% of PWS cases are caused by a deletion of the paternal chromosome 15q11–q13 region; approximately 25% have maternal disomy 15 (i.e., two maternal chromosome 15s and no paternal chromosome 15); and the remaining cases arise either from defects of the imprinting center (IC) located in the 15q11–q13 region or from chromosome 15 translocations. The IC is a *cis*-acting sequence involved in establishing and maintaining epigenetic modifications which determine gene expression patterns based on parental origin of the chromosome (Figure 2).

PWS occurs in approximately 1 in 20 000 individuals, with all ethnic groups involved but a reportedly higher occurrence in Caucasians. Most cases are sporadic, with recurrence less than 1%; however, in rare cases the father carries an imprinting defect on his maternal chromosome 15 resulting in a risk of 50%. This occurs due to an inability to replace the female imprint pattern with a male pattern, thus interfering with gene expression in the 15q11–q13 region in the offspring.

As a result of better awareness and advances in genetic testing, the diagnosis of PWS is made earlier than in the past. Early diagnosis is important since nutritional intervention and growth hormone (GH) therapy is frequently prescribed, which improves stature, body composition, energy level, and metabolism. Specific serotonin reuptake inhibitors have been helpful in treating skin picking and depression. If weight is adequately controlled, life expectancy is similar to that of mildly retarded individuals, with an approximate death rate of 3% per year. Obesity and related complications are the most common causes of death in PWS. Caloric diet restriction (approximately 60% of normal) and increased physical activity are important to control the obesity and comorbidities.

Imprinting Center: Characteristics, Function, and Regulation

PWS critical region (PWSCR) is a 2 Mb region within 15q11–q13 containing the IC. It is a bipartite structure composed of five domains which impart maternal- and paternal-specific epigenetic patterns of gene expression, and it spans 35 kilobases (kbs) containing a 4.3 kb sequence (PWS–IC), implicated in PWS, including the *SNRPN* promoter/exon 1 and an 880 bp sequence (AS–IC) located just upstream of the *SNRPN* transcription start site. Deletions of the AS–IC sequence is implicated in Angelman syndrome (AS), an entirely different clinical syndrome generally due to loss of maternally expressed genes in the 15q11–q13. These modules are short sequences which bind different protein complexes depending on gametogenic origin. The modules interact and constitute the *cis*-regulatory elements of the imprinting center that control imprinting of the entire 2 Mb AS/PWS domain (Figure 3). These elements include two copies of a *de novo* methylation sequence (DMS1 and -2) that establish the maternal imprint during oogenesis, an allele discrimination sequence (ADS) that establishes the paternal imprint, and two

elements that maintain the paternal imprint (MPI1 and -2). All five elements bind specific proteins that are presumably the factors acting in *trans* in the imprinting process. The DMS binds a homodimer protein (DMSP) which induces methylation during oogenesis in the CpG island of the promoter, exon 1, and enhancer of *SNRPN*. The ADS binds an allele discrimination protein complex (ADP) which prevents methylation of the CpG islands during spermatogenesis. The MPI elements bind proteins (MPIP1 and MPIP2) together with the ADP complex maintain the unmethylated state of the paternal sequences after fertilization. The *SNRPN* enhancer (SE), which is necessary for *SNRPN* transcription, remains unmethylated on the paternal allele and allows binding of an enhancer protein complex (SEP) which promotes transcription.

Methylation status is apparently constant in somatic tissues throughout life. In addition to *SNRPN*, three other genes (*NDN*, *MAGEL3*, and *MKRN3*) are also maternally imprinted and paternally expressed. The *SNRPN* transcript contains a second protein coding sequence, *SNURF*, as well as multiple copies of small nucleolar RNAs (snoRNAs) thought to participate in RNA processing, all of which are under the IC control. Furthermore, two genes (*UBE3A* and *ATP10A)* are paternally methylated and maternally expressed at least in some tissues. Interestingly, *UBE3A* causes AS but is monoallelically (maternally) expressed in the brain and biallelic in other tissues.

Figure 1 An 8-year-old male with Prader–Willi syndrome showing the facial appearance, obesity, and small hands typically seen in this condition.

Molecular Biology: Candidate Genes for Prader–Willi Syndrome

Imprinted Genes

Candidate genes causing PWS should be paternally expressed and maternally silenced, located within the chromosome 15q11–q13 region and involved directly or indirectly in brain development and function. Genes that meet these criteria include the *SNURF–SNRPN*–snoRNA complex, *NDN*, *MKRN3*, and *MAGEL2*. The most extensively studied paternally expressed gene that is active in brain tissue is the bicistronic gene *SNURF–SNRPN*. Exons 4–10 (termed *SNRPN* for small nuclear ribonucleoprotein N) encode a core spliceosomal protein (SmN) involved in messenger RNA (mRNA) splicing in the brain, whereas exons 1–3 (termed *SNURF* for '*SNRPN* upstream reading frame') encode a 71-amino-acid protein enriched in arginine residues without known function. The promoter and first exon of *SNURF–SNRPN* contain integral sequences of the IC that controls the regulation of imprinting or gene activity throughout the chromosome 15q11–q13 region. A disruption (i.e., paternal deletion, maternal disomy 15, imprinting defects, or chromosome translocations) of this complex locus

Table 1 Clinical characteristics of Prader–Willi syndrome

Stage 1 (0–3 years)	
Pregnancy	Reduced fetal activity, breech delivery, pre- or postterm delivery
Neonatal period and infancy	Narrow forehead, undescended testicles, small genitals and testicles, poor muscle tone (hypotonia), feeding problems, poor suck, sticky saliva, weak cry, temperature instability, developmental delay
Stage 2 (>3 years)	
Childhood	Short stature, small hands and feet, light skin and eye color (in deletion subjects), almond-shaped eyes, strabismus, myopia, skin picking, dental caries, excessive appetite/food foraging, obesity, cognitive impairment, behavioral problems, obsessive–compulsive behavior
Adolescence and adulthood	Short stature, excessive appetite, obesity, cognitive impairment, small hands and feet, scoliosis, osteoporosis, delayed puberty, diabetes mellitus, depression, excessive sleepiness

Figure 2 Chromosome 15 ideogram showing the deletion breakpoints (BP1–BP3) and the order of genes within the 15q11–q13 region. Adapted from Bittel DC and Butler MG (2005) Prader–Willi syndrome: Clinical genetics, cytogenetics and molecular biology. *Expert Reviews in Molecular Medicine* 7: 1–20, by permission of Cambridge University Press.

will cause loss of function of paternally expressed genes leading to PWS.

Necdin (*NDN*), a member of the melanoma-associated antigen gene (MAGE) family of proteins, is expressed only from the paternal allele in the 15q11–q13 region. The function of the MAGE family of proteins remains unclear, but they may play a role in cell cycle regulation and apoptosis. Necdin is detected in all developing neurons of the embryonic mouse, in both the central and peripheral nervous system, with the highest expression levels in the diencephalon and hindbrain. After embryonic day 13, necdin has been shown to be essential for axonal outgrowth and is expressed in specific brain structures (hypothalamus, thalamus, and pons), suggesting a developmental role. Mice deficient for necdin have shown hypothalamic deficiency, neonatal lethality, and respiratory and behavioral problems similarly seen in PWS.

The three breakpoint sites (BP1–BP3) within the 15q11–q13 region are 450–500 kb sequences containing a large transcribed gene (*HERC2*) with many partially duplicated copies, some of which are transcribed. The functional *HERC2* gene located at BP3 encodes a highly conserved large protein distantly related to HERC1, a guanine nucleotide exchange factor (GEF) implicated in vesicular trafficking. The mouse genome contains a single *Herc2* locus, located in the juvenile development and fertility-2 (jdf2) interval of chromosome 7C. Mutations in *Herc2* lead to defects in neuromuscular secretory vesicles and sperm acrosomes, other developmental abnormalities, and juvenile lethality of jdf2 mice. These findings suggest that *HERC2* is an important gene encoding a GEF involved in protein trafficking and degradation pathways in the cell. *HERC2* repeated sequences have also been implicated in unequal crossing over in meiosis and may participate in the typical 15q11–q13

Figure 3 Imprinting elements within the SNRPN promotor. The *de novo* methylation protein (DMP) binds the maternal (Mat) allele at the *de novo* methylation sequence (DMS1 and -2) and induces methylation (M) at the CpG islands, including at the SNRPN enhancer (SE) during oogenesis. The unmethylated state is established on the paternal (Pat) allele when the allele discrimination protein (ADP) displaces DMP during spermatogenesis. The unmethylated state is protected by the maintenance of paternal imprint protein (MPIP1 and -2) binding to the maintenance of paternal imprint sequence (MPI1 and -2), protecting the paternal allele from methylation and allowing transcription to proceed. Adapted from Kantor B, Makedonski K, Green-Finberg Y, Shemer R, and Razin A (2004) Control elements within the PWS/AS imprinting box and their function in the imprinting process. *Human Molecular Genetics* 13: 751–762, by permission of Oxford University Press.

deletion of two sizes (type I and type II; Figure 2). In addition, a PWS female with the typical deletion has been reported with a duplication of the proximal end of the 15q11–q13 region inherited from her father.

Other genes implicated in PWS include *IPW* ('imprinted in Prader–Willi'), *MAGEL2*, and a series of highly repeated sequences encoding snoRNAs. *IPW* is a component of the large *SNURF–SNRPN* transcript and is spliced and polyadenylated but apparently does not encode a protein. However, it may be a functional RNA, similar to *H19* and *XIST*. Also encoded within the *SNURF–SNRPN* transcript are multiple snoRNAs. Two snoRNAs – HBII-52 and HBII-85 – are encoded in a tandemly repeated array of 47 and 24 units, respectively. These snoRNAs were absent from the brain cortex of an individual studied with PWS and from a PWS mouse model, demonstrating paternal expression and a possible causal role in PWS. Importantly, the snoRNA, HBII-52, has been shown to exhibit sequence complementarity to an alternatively spliced exon of the serotonin receptor 5-HT(2C)R, thus regulating alternative splice forms of the receptor. PWS individuals lacking HBII-52 have different 5-HT(2C)R mRNA isoforms than healthy individuals, suggesting that the chromosome 15 defect contributes to misregulation within the serotonin response pathway. Finally, the orthologous mouse gene (*Magel2*) is paternally expressed predominantly in late developmental stages and in adult brain. In humans, the loss of expression of *MAGEL2* might contribute to brain abnormalities and possibly other dysmorphic features seen in PWS.

Comparing overlapping deletion regions among cases of PWS has allowed the identification of a minimal critical region for PWS. This critical region includes an approximately 121 kb segment within the >460 kb *SNRPN* locus which contains only the PWCR1/HBII-85 cluster of snoRNAs and a single HBII-438A snoRNA, further implicating snoRNAs in PWS.

Paternal Bias (GABA Receptor Subunit Genes)

Little consideration has been given to the potential contribution to the PWS phenotype by altered gene expression of nonimprinted genes. Gene expression analysis by microarray technology suggested that several genes/transcripts thought to be biallelically expressed within or proximal to the PWSCR had expression but it was reduced by more than 50% in lymphoblasts from PWS subjects with 15q11–q13 deletions compared to controls. Furthermore, cells from maternal disomy subjects had reduced expression of these genes compared to controls, even though two alleles were present. Most notable of these genes

with paternal bias (i.e., greater expression from the paternal allele) were receptor subunit genes (*GABRA5* and *GABRB3*) for the inhibitory neurotransmitter gamma aminobutyric acid (GABA) located in the 15q11–q13 region. Loss of the paternal allele results in reduction of expression greater than 50% since the paternal allele accounts for a larger percentage of gene expression. GABAergic mechanisms have been implicated in a number of symptoms associated with PWS, including hunger, obsessive–compulsive disorder, and altered visual perception and memory.

Maternally Expressed Genes (*UBE3A* and *ATP10A*)

UBE3A and *ATP10A* are both expressed from maternal alleles in the brain. *UBE3A*, a ubiquitin ligase required for long-term synaptic potentiation, has been identified as the gene causing AS. Studies of the molecular neurophysiology of AS subjects suggest aberrant electroencephalographic patterns resulting from dysregulation of synaptic GABAergic neurotransmission by deficient recruitment of functional $GABA_A$ receptors related to reduced *UBE3A* gene expression. Furthermore, AS subjects with deletions may have decreased amounts of the β_3 subunit for $GABA_A$ receptors due to reduced *GABRB3* gene expression. In addition, the mouse *Atp10a* gene shows tissue-specific maternal expression in the hippocampus and olfactory bulbs overlapping the region of expression of *Ube3a*, suggesting an association with neurological disorders, including AS and autism. Both of these genes have been shown to be overexpressed in PWS subjects with maternal disomy relative to controls. Although the effect of overexpression of these genes has not been studied, it is possible that one or both may contribute to unique features associated with PWS due to maternal disomy (e.g., increased psychosis). Other genes from chromosome 15 may also be differentially expressed depending on parental origin.

Physiology of Eating Behavior and Obesity

Abnormal levels of multiple neuropeptides and hormones involved in eating and neurological function, such as ghrelin, growth and sex hormones, and GABA, have been reported in PWS but the molecular mechanisms are not understood. The peptide ghrelin is produced by the stomach and stimulates eating. Conversely, peptide YY released by the intestine inhibits eating. PWS subjects have higher ghrelin levels compared to lean or obese controls, but expression studies for both genes have shown activity throughout the brain in both PWS and control subjects. A third peptide, obestatin, cleaved from preproghrelin, is thought to inhibit eating.

A 30% reduction in the number of GH-releasing hormone (GHRH) neurons was found in the arcuate nucleus in the brain of PWS subjects, which may explain why GH responsiveness to GHRH is impaired in PWS. Furthermore, PWS has been suggested as a genetic model of starvation due to abnormal hypothalamic function that results in the body interpreting the absence of satiation as a state of starvation. In addition, 7B2 peptide (secretory granule, neuroendocrine protein 1, also known as SGNE1), a neuroendocrine chaperone protein that interacts with prohormone convertase 2 (PC2), is involved in the regulation of secretory pathways in the brain including the release of hormones. SGNE1 is detected in the supraoptic and paraventricular nucleus of the hypothalamus in control subjects but not in the majority of PWS individuals.

GABA is widely distributed throughout the central nervous system and an estimated 40% of the brain and spinal cord neurons utilize GABA as their neurotransmitter, making it the most important inhibitory brain neurotransmitter. Plasma GABA levels are increased three- or fourfold in individuals with PWS compared to control subjects. Furthermore, three genes encoding subunits for $GABA_A$ receptors (*GABRA5*, *GABRB3*, and *GABRG3*) are located in the 15q11–q13 region. The results of a study in which positron emission tomography was used suggested a reduction in GABA receptors in the cingulate, frontal, and temporal neocortices and insula in six adult PWS patients as measured by reduced benzodiazepine binding. An increase in GABA level may be a direct response to the reduction of subunit expression in PWS subjects. Abnormal function of the genetic material on chromosome 15 might alter synthesis, release, metabolism, binding, intrinsic activity, or reuptake of specific neurotransmitters or alter the receptor numbers and/or distribution involved in modulating appetite. Evidence strongly implicates a significant role of altered GABAergic pathways in PWS.

As mentioned previously, most PWS subjects have reduced GH secretory capacity and hypogonadotropic hypogonadism, suggesting hypothalamic–pituitary dysfunction. Replacement of GH and/or sex hormones has been shown to be beneficial in children with PWS. Characteristics such as decreased growth velocity despite the onset of obesity, reduced lean body mass in the presence of adiposity, small hands and feet, relatively low insulin-like growth factor-1 (IGF-1), and relatively low insulin levels are probably the direct result of the hypothalamic GH deficiency in PWS.

Leptin, a peptide produced by adipose tissue, is involved in regulation of appetite and fat storage.

An association has been found between genetic variants of the human obesity gene (*OB*) or leptin and body mass index (BMI) or weight in PWS and age- and gender-matched lean and obese subjects. However, there is no evidence for reduced leptin in PWS. Furthermore, the functional leptin receptor gene (*OBRb*) was reported to be active in lymphoblasts; however, no *OBRb* gene activity was found in human hypothalamus. Reduction of leptin levels after GH treatment and associated reduction of body fat in PWS patients further suggest that leptin is not misregulated in PWS. There is no evidence of abnormalities of leptin receptors, neuropeptide Y, or agouti-related protein in PWS subjects.

Adiponectin is another peptide produced by adipose tissue that plays a role in regulating adiposity. Serum adiponectin levels are significantly lower in PWS subjects compared to lean controls but significantly higher than in obese controls. In addition, no differences in adiponectin levels were found between PWS subjects with 15q deletions compared to those with maternal disomy. No correlation was found between adiponectin and anthropometric parameters or measures of insulin sensitivity or between adiponectin and IGF-binding protein 1 or IGF-1 levels in PWS. Furthermore, adiponectin levels did not change during GH treatment in PWS. Evidence suggests that PWS individuals are less likely to develop diabetes than comparison subjects without PWS but with comparable BMI. However, this may be a consequence of altered fat distribution in PWS resulting in greater adiponectin levels than in obese controls.

Oxytocin, another important neuropeptide produced by the hypothalamus and involved with behavior, has been reported to have significantly higher levels in the cerebral spinal fluid of PWS individuals compared to controls. However, circulating oxytocin levels were abnormally low in relationship to obesity after GH treatment of PWS. A decrease of oxytocin neurons and leptin resistance in PWS might also induce hyperphagia and obesity. However, diabetes mellitus is not a diagnostic criterion for PWS but is often present. The etiology for diabetes mellitus in PWS might be related to the morbid obesity and consequent insulin resistance.

Genetic Subclass Comparison in Prader–Willi Syndrome and Relationship to Imprinting

Gene Expression and Behavior Correlates

The typical deletion, consisting of two classes (type I and type II) of the 15q11–q13 region, is the most common cause of PWS presumably due to unequal crossing over in meiosis at repeated transcribed DNA sequences (i.e., *HERC2* genes) located at the proximal and distal ends of the 15q11–q13 region. The typical deletion is of two sizes and involves a distal breakpoint (BP3) at the end of the 15q11–q13 region and either of two proximally positioned breakpoints (BP1 or BP2) resulting in two different-sized deletions – type I or type II. The type I deletion is larger and involves breakpoints BP1 and BP3; it is approximately 6 Mb in size. The type II deletion involves breakpoints BP2 and BP3 and is approximately 1 Mb smaller based on array comparative genomic hybridization (aCGH). Maternal disomy 15 is found in about 25% of PWS subjects and may occur from nondisjunction during maternal meiosis resulting in a trisomy 15 embryo. Through trisomy rescue of the fetus and loss of the father's chromosome 15, the pregnancy is salvaged and not spontaneously aborted. The fetus is delivered at term having PWS with normal chromosomes but with maternal disomy 15.

Maternal disomy 15 is of two types – heterodisomy or isodisomy. Maternal heterodisomy occurs when the infant inherits each of the mother's chromosome 15s but no chromosome 15 from the father. Maternal isodisomy results when two identical chromosome 15s are inherited from the mother as a result of nondisjunction in meiosis II or from nondisjunction in meiosis I with crossing over occurring in the proximal long arm of chromosome 15. Maternal isodisomy presents the possibility of additional genetic disorders in the PWS subject if the mother is a carrier of an autosomal recessive gene mutation on chromosome 15 (e.g., Bloom syndrome at 15q26.1).

PWS individuals with the typical chromosome 15 deletion are more homogeneous in their clinical presentation and have hypopigmentation due to the deletion of the *OCA2* gene involved with pigment formation. PWS subjects with maternal disomy have fewer typical facial features and are less likely to have certain behavioral findings such as skin picking, unusual skill with jigsaw puzzles, a high pain threshold, and articulation problems. The diagnosis of PWS is often delayed in those with maternal disomy 15 compared to the 15q deletion, reflecting a milder phenotype in the maternal disomy subjects.

Behavioral problems including obsessive–compulsive and self-injurious behavior are frequently reported in PWS. The incidence of self-injurious behavior in individuals with intellectual impairment, autism, and developmental disabilities without PWS ranges from 5% to 60%. However, self-injurious behavior is reported in approximately 70% of PWS adolescents. Self-injurious behavior has been analyzed in a cohort of PWS individuals and skin picking was found to be the most common form of self-injury, particularly in those

PWS individuals with the typical 15q11–q13 deletion. Additionally, PWS individuals hoard and arrange items excessively. Compulsive symptoms have been found in approximately 60% of PWS patients. Those with the deletion recorded higher scores on the Compulsive Behavior Checklist, indicating a greater number of compulsive symptoms and more symptom-related distress than for those with maternal disomy 15. In addition, acute psychosis has been reported in PWS, particularly adults with maternal disomy 15, with possibly more seizures in PWS deletion subjects. PWS children with the deletion showed relative strengths in standardized visual–spatial tasks such as object assembly compared with age- and IQ-matched controls with mixed mental retardation. Interestingly, the PWS group outperformed normal peers in proficiency at jigsaw puzzle placement.

Measures of intelligence and academic achievement in PWS have shown that those with maternal disomy had significantly higher verbal IQ scores than those with the typical deletion. However, PWS deletion subjects also scored higher than the maternal disomy subjects on object-assembly subtests, supporting specific visual perceptual skills as being relative strengths for the deletion group. Additionally, discrimination of shape and motion testing showed that the kinetic form visual performance of the maternal disomy group was significantly worse than that of the comparison or typical deletion PWS groups. Poorer performance in the maternal disomy group could be due to retinal function and visual processing differences related to excessive GABA levels and abnormal GABA subunit receptors. However, PWS individuals with maternal disomy performed better than either typical deletion or comparison subjects in visual recognition and memory tasks. Superior visual recognition memory in the maternal disomy subjects further supports the possible role of two active alleles of maternally expressed genes from chromosome 15 (Table 2).

Although PWS individuals share common characteristics, deletion subjects have poorer outcomes compared to maternal disomy individuals. Although paternally expressed genes are inactive in both subtypes, the increased severity associated with the deletion must be due to reduced expression of hemizygous genes and compensated when two maternal copies are present or there is disruption of interactive genes outside chromosome 15 by altered expression of chromosome 15 genes. In addition, some of the differences might be due to changes in expression of genes distal to the PWSCR that could be affected by the deletion process, repositioning of the genes on chromosome 15, or maternal disomy.

Clinical Findings Associated with Type I versus Type II Typical Deletions

Clinical findings associated with longer (type I) versus shorter (type II) typical deletions have been compared (Table 3). Clinical, anthropometric, and behavioral data were analyzed in PWS individuals with type I or type II deletions. PWS individuals with type I deletions scored significantly worse in self-injurious and maladaptive behavior assessments compared to PWS

Table 2 Differences among subjects with Prader–Willi syndrome due to typical deletion or uniparental maternal disomy (UPD)

15q11–q13 deletion	*Maternal disomy 15 (UPD)*
Hypopigmentation	Shorter course of gavage feeding (in females)
Homogeneous clinical findings and more typical facial appearance	Delayed diagnosis
Lower birth weight	Higher verbal IQ scores
Greater birth length (in males)	Greater numeric calculation skills, attention, word meanings, factual knowledge, and social reasoning
More self-injurious behavior (skin picking)	Superior visual memory
Higher pain threshold	Poorer object assembly and visual perceptual skills
Greater jigsaw puzzle (spatial) skills	Poorer random element stereopsis
	Increased psychosis and autistic behaviors

Table 3 Comparison of genetic subtypes in Prader–Willi syndrome

Genetic subtype	*Behavioral differences*
Type I deletion	Increased maladaptive and compulsive behavior relative to type II and maternal disomy; poorer academic performance relative to type II and maternal disomy
Type II deletion	Better adaptive behavior relative to type I; better social skills relative to type I or maternal disomy
Maternal disomy	Higher verbal IQ scores, greater numeric calculation skills, superior visual memory, poorer object assembly and visual perceptual skills, and increased psychosis relative to typical deletion

subjects with shorter (type II) deletions. Obsessive–compulsive behavior was also more evident in PWS subjects with type I deletions, along with more impairment of visual perception.

Interestingly, individuals with shorter deletions exhibited significantly more self-injury than those with maternal disomy but less than those with longer deletions. The disassociation of compulsivity and skin picking is consistent with our previous factor analytic study revealing that skin picking does not factor with compulsivity using the Compulsive Behavior Checklist. Psychobehavioral characteristics of PWS individuals with type I deletions involving BP1 were similar in several aspects to those of individuals with uncharacterized typical deletions but differed from those with type II deletions involving BP2, the latter group resembling PWS individuals with maternal disomy.

Several academic achievement scores differed between those with shorter and those with longer typical deletions, reflecting a difference in intellectual functioning and visual perceptional skills affecting reading. Therefore, loss of genetic material between BP1 and BP2 apparently increases the severity of behavioral and psychological problems seen in PWS.

Four genes identified in the chromosomal region between BP1 and BP2 (*NIPA1*, *NIPA2*, *CYFIP1*, and *GCP5*) are implicated in compulsive behavior and lower cognition in PWS individuals with type I versus type II deletions. mRNA of these four genes have been compared between subjects with type I and type II deletions and correlated with psychological and behavioral outcomes. mRNA from the four genes was reduced in PWS subjects with the type I deletion, supporting biallelic expression. Generally, mRNA levels were positively correlated with assessment parameters, indicating a direct relationship between mRNA levels and better assessment scores, with the highest correlation for *NIPA2*. Covariate analysis indicated that the quantity of mRNA of the four genes explained a considerable amount (e.g., >50%) of the variation in behavioral and academic parameters measured. More research is needed to illuminate the subtle interactions between the genes on chromosome 15 and interactive networks to clarify the role of these genes in regulating brain development and function.

Genetic Research in Progress in Prader–Willi Syndrome

Microarrays: Pathways and Systems Analysis

The loss of function of genes from the 15q11–q13 region does not directly explain the phenotype of PWS. Genes in *cis* (located on chromosome 15) are affected by the disturbance of chromosome 15, but with the exception of *NDN*, none have been demonstrated to have a phenotype observed in PWS. Therefore, *trans* effects, caused by disturbance of genes not located on chromosome 15 may be responsible for many of the phenotypic consequences associated with the disruption of 15q11–q13 gene expression. Using custom-made microarrays to examine expression of genes/transcripts from 15q11–q13, a higher level of regulatory mechanisms were perturbed in PWS. For example, several genes/transcripts acting in *cis* (e.g., *GABRA5* and *GABRB3*) showed increased expression in PWS lymphoblastoid cell lines established from individuals with maternal disomy compared with those with the typical deletion. However, these genes showed less expression in PWS individuals with maternal disomy than in controls, whereas two maternal copies of the genes produced less RNA than one maternal and one paternal copy of the same gene. This indicated paternal bias of expression. In addition, several transcripts outside the PWSCR had increased expression in individuals with typical deletions relative to controls or PWS individuals with maternal disomy. These observations were confirmed using similar methodology in AS. This expression pattern is presumably a consequence of repositioning of these genes on the proximal long arm region of the deleted chromosome 15. These results warrant further investigations since they indicate that interconnected mechanisms can produce subtle and unexpected changes in gene expression that may relate to phenotypic differences observed among the genetic subtypes of PWS.

Microarray analysis of a transgenic mouse model of PWS equivalent to the deletion genetic subtype demonstrated that genes located in a single chromosomal domain on mouse chromosome 18 are modestly upregulated by the loss of gene expression from the PWSCR (mouse chromosome 7), suggesting a transacting regulatory mechanism. It appears that a gene(s) from the PWSCR interacts with a regulatory element within this domain to reduce expression from this group of genes under normal conditions. We reported transcriptome studies of an IC knockout PWS mouse model and found that out of more than 45 000 probes examined, only 69 had a significant change in expression of at least 1.5-fold between PWS and control mice, 8 of which were from the PWS critical region. Two genes with increased expression in the PWS IC deletion mice were *Pomc* and *Mc5r*; both were validated by quantitative reverse-transcriptase polymerase chain reaction (RT-PCR). *Pomc* gene products are known to be anorexigenic, whereas *Mc5r* directly responds to upregulation of *Pomc* and is involved with thermoregulation, which

is abnormal in PWS infants. PWS model mice generally do not survive more than a few days presumably as a consequence of neonatal failure to thrive reminiscent of the human condition. Imbalances in the Pomc/melanocortin pathway may be an important genetic factor in the survival of these mice because this may negatively affect energy homeostasis.

Whole genome microarrays have been used to analyze mRNA levels in lymphoblastoid cells from PWS subjects and matched controls. Significant differences of at least 1.5 times were seen in 323 genes in PWS lymphoblastoid cells relative to comparison cells, 14 of which were related to neurodevelopment and function. Alterations in expression of serotonin receptor genes (e.g., *HTR2B*) and genes involved in eating behavior and energy homoeostasis (*ADIPOR2*, *MC2R*, *HCRT*, and *OXTR*) were noted. Other genes of interest with reduced expression in PWS subjects included *STAR* (a key regulator of steroid synthesis) and *SAG* (an arrestin family member which desensitizes G-protein-coupled receptors). Quantitative RT-PCR validated differences were seen in microarrays using RNA from both lymphoblastoid cells and brain (frontal cortex) from separate PWS individuals and controls. Our analysis further identified previously unappreciated changes in gene expression which may contribute to the clinical manifestations seen in PWS.

Microarray analyses suggested a cumulative effect of modest changes in expression of many genes, especially those involved in energy metabolism which may contribute to failure to thrive in PWS infants. Subtle transactivational control of gene activity by genes within the PWSCR suggests that changes in the transcriptome and/or proteome remain to be discovered to explain dramatic phenotypic effects of loss of expression of 15q11–q13 genes.

Behavior and Brain Imaging

Brain imaging studies using functional magnetic resonance imaging from a cohort of PWS individuals and controls revealed postprandial hyperfunction in the limbic and paralimbic regions of the brain in PWS. Conversely, brain imaging of healthy weight individuals indicated increased activity of the limbic and paralimbic regions prior to consumption of a meal. After eating, these regions of the brain were normalized and neuronal activity decreased substantially. In contrast to healthy weight individuals, PWS subjects failed to normalize these regions of the brain after meal consumption and instead developed a dramatic increase in neurological activity (Figure 4). Thus, the failure of satiation following a meal appears to have a neurological basis in PWS.

Future Directions

PWS individuals exhibit reduced selectivity in choosing food items for consumption (i.e., they may consume inappropriate food items). There is a known correlation between smell and taste and/or selection

Figure 4 Functional magnetic resonance imaging (fMRI) of the limbic region (arrows indicate the amygdala) in Prader–Willi syndrome (PWS) and control subjects while viewing food stimuli pictures before and after a meal. of food for consumption. Interestingly, two olfactory receptor genes (*OR4M2* and *OR4N4*) are located proximally at the boundary of the PWSCR on chromosome 15 (UCSC Genome Browser). If these genes are misregulated or perturbed in PWS due to genetic rearrangements, they might contribute to reduced olfactory sensitivity or normal olfaction. This disturbance could lead to failure to discriminate between appropriate and inappropriate food items for consumption. Therefore, the expression of the olfactory receptor genes might be affected more in the larger type I deletion. One could propose to investigate olfactory receptor gene expression patterns in PWS and identify differences that correlate with food-seeking and food-preference behavior. In addition, proteomic technology in brain and peripheral tissues may help in elucidating the role of deleted or perturbed genes in neurobehavioral outcomes in PWS.

There is increasing evidence that the loss of expression of *SNRPN* and snoRNAs causes some or all features recognized in PWS, although these genes do not appear to be directly causal. As described previously, these genes are involved in processing/splicing of other genes, particularly in the hypothalamus, where they are known to be paternally expressed. There are a number of nonimprinted genes acting in the hypothalamus that are involved in appetite and behavior regulation with complex processing and splicing required prior to translation (e.g., ghrelin, ghrelin receptor, and vasopressin receptor). It is possible that faulty production of mature mRNA of these and/or other downstream genes as a result of the loss of *SNRPN* function and/or snoRNAs could produce PWS (Figure 5). Genomic and proteomic tools and bioinformatics will undoubtedly identify more interactive genes outside the 15q11–q13 region that are affected by incorrect posttranscriptional or post-translational processing in PWS, possibly leading to treatment modalities.

Prediction Errors in Neural Processing: Imaging in Humans

Introduction

In the mid-1990s several studies strongly suggested that recordings from single midbrain dopamine neurons in monkeys engaged in conditioning tasks could be explained by a computational model. This model, temporal difference (TD) learning, imported from the machine learning community, was used to model the phasic firing of single midbrain dopamine neurons in alert monkeys harvesting rewards in a Pavlovian conditioning task. In this task there were several salient features (Figure 1). Before training, the receipt of unpredicted reward – the unconditioned stimulus (UCS) – caused dopamine neuron firing. Also before training, the conditioned stimulus (CS) caused no firing in the dopamine neurons, while the receipt of reward still did. After training, the CS caused dopamine firing, but the receipt of the UCS no longer did, while if the predicted reward was omitted, the firing rate fell. How does TD learning capture these features of the data?

Brief Review of the TD Algorithm

TD learning is a solution method for a class of statistical learning models called Markov decision problems (MDPs). More formally, the basic setup for a Markov decision problem is given by a set of states S, a set of actions A, transition functions $P^a_{ss'}$ giving the probability of moving from state s to state s' given action a, and the expected return $R^a_{ss'}$ from taking action a and transitioning from s to s'. A policy π is a function from states to actions (or more generally a probability distribution on actions). The value of a given state s under a certain policy π is given by the expected discounted reward to be obtained from starting at state s and following policy π:

$$V^\pi(s) = E_\pi\left[\sum_{i=1}^{\infty}\gamma^{i-1}r_i\right] \qquad [1]$$

The goal is to learn the function V^π. TD learning is a way to learn the value function while executing the policy π. Suppose in state s the action is given by $a = \pi(s)$ and we transition from $s \to s'$. Then if V denotes our approximation to the value function V^π, an improved approximate value function at state s is then given by

$$V(s) \leftarrow V(s) + \alpha[r + \gamma V(s') - V(s)] \qquad [2]$$

The expression inside the brackets is the TD error term, δ. Two parameters appear here: α, the learning rate, and γ, the discount factor ($0 < \gamma < 1$).

Under assumptions on α this process will converge to V^π. Once one has a value function V^π one can improve the policy π, since the real aim is to find the best policy π and its value function V^*. A convenient change in point of view is to look at the value of a state action pair rather than just the state value. The letter Q is usually reserved for this function and is defined by

$$Q^\pi(s,a) = E_\pi\left[\sum_{i=1}^{\infty}\gamma^{i-1}r_i \,\middle|\, s_0 = s, a_1 = a\right] \qquad [3]$$

In words, $Q(s,a)$ is the value of taking action a in state s and then following policy π.

This formulation leads directly to the method of policy improvement. If we have in some state that for some action a, $Q^\pi(s,a) > V^\pi(s)$, then we can modify the policy π to a policy π' so that $\pi'(s) = a$ (and equals π for all other states) and in fact $V^{\pi'}(s) \geq V^\pi(s)$ for all s. A general method to find an optimal value function is generalized policy iteration: start with an arbitrary policy π, and approximation to $\hat{V}^\pi(s)$. Take the action under policy π, receive the reward r, and make the state transition $s \to s'$. Compute the TD error as given previously, update the value function, and then make the policy improvement step to get an improved policy π'. Now repeat. This process will converge to the optimal policy π^* and value function V^*.

There are a few variations on this idea that are important to consider. The first uses the Q values directly to find an optimal policy. This algorithm is called SARSA (state, action, reward, state, action) and goes as follows. Start with an arbitrary Q. Decide on a way to go from Qs to an action. (There are two popular ways to pick an action: (1) ε-greedy, in which the action a with largest $Q(s,a)$ is chosen with probability $1 - \varepsilon$, and the rest of the actions are chosen with probability $\varepsilon/n - 1$ if there is a total of n possible actions; and (2) softmax, or Boltzmann, in which the probability of choosing an action a in state s is given by

$$P(a,s) = \frac{e^{\beta Q(s,a)}}{\sum_{\tilde{a}} e^{\beta Q(s,\tilde{a})}} \qquad [4]$$

Figure 1 Raster plots of recordings from monkey dopamine neurons during a Pavlovian conditioning task. Top: Before training, no increase in spiking at cue (conditioned stimulus; CS), but increase at delivery of juice reward (R; unconditioned stimulus). Middle: After training, increased spiking at presentation of CS, and no increase at reward. Bottom: After training, decreased spiking at unpredicted omission of unconditioned stimulus (no R). From Schultz W, Dayan P, and Montague PR (1997) A neural substrate of prediction and reward. *Science* 275: 1593–1599.

where β is a parameter (the inverse temperature) that determines how sensitive the probability is to difference in the Qs. As $\beta \to 0$, the distribution becomes uniform; as $\beta \to \infty$, the distribution localizes on the action with the biggest Q.) Pick the action, receive the reward r, make the transition to the new state s', and update Q using the TD algorithm:

$$\begin{aligned} Q(s,a) &\leftarrow Q(s,a) + \alpha\delta \\ \delta &= r + \gamma Q(s',a') - Q(s,a) \end{aligned} \qquad [5]$$

where the action a' is the action that is determined by the policy determined by Q. SARSA is an on-policy algorithm because the Qs are updated using the current policy.

An off-policy algorithm using the Q functions is called Q-learning. In this algorithm, the policy used to explore the state space is divorced from the policy determined by the Qs. All that matters is that the sampling policy samples the state-action space 'well enough.' The actual algorithm is given as follows: choose action a according to sampling policy, receive reward r, transition to state s', and update Q according to

$$\begin{aligned} Q(s,a) &\leftarrow Q(s,a) + \alpha\delta \\ \delta &= r + \gamma \max_{\tilde{a}} Q(s',\tilde{a}) - Q(s,a) \end{aligned} \qquad [6]$$

Another reinforcement learning algorithm worth mentioning at this point is the 'actor–critic' architecture. In this architecture, the value function is maintained by the critic, while the policy is maintained by a separate actor. The standard TD error signal is used both to update the value function estimate and to criticize the policy. For example, if the policy is encoded by a preference function $p(s,a)$, the preference for action a while in state s, and the probability of taking in action a while in state s is given by the softmax formula, then after an action a is taken and a reward r is received we have the updates:

$$\begin{aligned} \text{critic}: \quad & V(s) \leftarrow V(s) + \alpha_1\delta \\ & \delta = r + \gamma V(s') - V(s) \\ \text{actor}: \quad & p(s,a) \leftarrow p(s,a) + \alpha_2\delta \end{aligned}$$

One final algorithm which has been used in functional magnetic resonance imaging (fMRI) work is advantage learning. In advantage learning, the advantage of an action a in a state s is the key quantity:

$$A(s,a) = Q(s,a) - V(s) \qquad [7]$$

After taking an action a, $V(s)$ is updated as in the basic TD algorithm, while the advantage is updated by the error signal:

$$\begin{aligned} \delta_A &= r + \gamma V(s') - Q(s,a) \\ &= r + \gamma V(s') - V(s) - [Q(s,a) - V(s)] \\ &= \delta_{TD} - A(s,a) \end{aligned} \qquad [8]$$

One can see that this is the correct update by observing that $r + \gamma V(s')$ is the new estimate of $Q(s,a)$ after taking action a and then receiving reward r. δ_A is the change in the advantage coming from the update to $Q(s,a)$, while the rest of the update is handled by updating V. In the simple Pavlovian task described earlier, the model is given as follows. States are represented by the vector $\vec{x}(t)$, the components of which represent the presentation of the CS in time. For example, if the CS is presented at $t = 0$,

$$\begin{aligned} \vec{x}(0) &= (1,0,0,0,0,0) \\ \vec{x}(1) &= (0,1,0,0,0,0) \\ \vec{x}(2) &= (0,0,1,0,0,0)\ldots \end{aligned} \qquad [9]$$

The value function is given by a linear representation in weights: $\vec{w}\,(t) = (w_1, w_2, \ldots, w_n)$,

$$V(t) = V(\vec{x}(t)) = \vec{w}(t) \cdot \vec{x}(t) \qquad [10]$$

The TD error is given by

$$\delta_t = r_t + \gamma V(\vec{x}(t+1)) - V(\vec{x}(t)) \qquad [11]$$

and the value function update is given by updating the linear weights:

$$\vec{w} \leftarrow \vec{w} + \alpha \cdot \vec{x}(t) \cdot \delta_t \qquad [12]$$

The following example illustrates two important points of TD learning: (1) The TD error response moves backward to the CS, and (2) the (TD error) response at the delivery of the UCS decreases as it becomes predicted. We leave it as an exercise for the reader to continue these calculations until the response occurs at the CS, and is predicted away at the delivery of the UCS.

Suppose that each trial lasts 6 time units, and that the UCS is delivered at $t = 5$. Set the weights initially at $\vec{w} = 0$. The CS appears at $t = 0$, so that the states are

$$[1] \quad \begin{aligned} \vec{x}(0) &= (1,0,0,0,0,0) \\ \vec{x}(1) &= (0,1,0,0,0,0) \\ \vec{x}(2) &= (0,0,1,0,0,0) \\ \vec{x}(3) &= (0,0,0,1,0,0) \\ \vec{x}(4) &= (0,0,0,0,1,0) \\ \vec{x}(5) &= (0,0,0,0,0,1), \end{aligned}$$

and since $\vec{w} = 0$, and no reward is obtained until $t = 5$, $V(\vec{x}(t)) = 0$, $t = 0, 1, 2, 3, 4, 5$.

On the first trial the only interesting thing happens at $t = 5$. Here $r = 1$, so that

$$[2] \quad \begin{aligned} \delta_5 &= r + \gamma V(\vec{x}(6)) - V(\vec{x}(5)) \\ &= 1 + \gamma \vec{w} \cdot \vec{x}(6) - \vec{w} \cdot \vec{x}(5) \\ &= 1, \end{aligned}$$

and thus

$$[3] \quad \begin{aligned} \vec{w}_{new} &= w_{old} + \alpha \cdot \vec{x}(5) \cdot \delta_5 \\ &= \vec{0} + \alpha \cdot (0,0,0,0,0,1) \cdot 1 \\ &= (0,0,0,0,0,\alpha). \end{aligned}$$

On the second trial, something interesting happens at $t = 4$: the signal 'moves back' toward the CS. At $t = 4$, no reward occurs, but the TD update is given by

$$[4] \quad \begin{aligned} \delta_4 &= r + \gamma V(\vec{x}(5)) - V(\vec{x}(4)) \\ &= 0 + \gamma \cdot (0,0,0,0,0,1) \cdot (0,0,0,0,0,\alpha) \\ &\quad - (0,0,0,0,1,0) \cdot (0,0,0,0,0,\alpha) \\ &= \gamma \cdot \alpha. \end{aligned}$$

The weights are updated accordingly:

$$[5] \quad \begin{aligned} \vec{w}_{new} &= \vec{w}_{old} + \alpha \cdot \vec{x}(4) \cdot \delta_4 \\ &= (0,0,0,0,0,\alpha) + \alpha \cdot (0,0,0,0,1,0) \cdot \gamma \cdot \alpha \\ &= (0,0,0,0,\gamma \cdot \alpha^2, \alpha). \end{aligned}$$

At $t = 5$, a reward is again received, and we get the TD error:

$$[6] \quad \begin{aligned} \delta_5 &= 1 + \gamma V(\vec{x}(6)) - V(\vec{x}(5)) \\ &= 1 - (0,0,0,0,\gamma \cdot \alpha^2, \alpha) \cdot (0,0,0,0,0,1) \\ &= 1 - \alpha. \end{aligned}$$

TD Error Signals in Humans: fMRI Evidence

While the original impetus for the TD error theory came from single-unit recordings in nonhuman primates, the advent of sophisticated fMRI paradigms has allowed researchers to hunt for TD error signals in the human brain. In this section we review the results some of these experiments.

Early Developments

A relatively early study that captured an aspect of the TD error signal in the human brain was undertaken by Berns and colleagues in 2001. The TD error algorithm is able to distinguish errors in both timing and type or amount of reward. Hence, rewards that are unpredictable in both timing and type should generate a larger reward signal than that generated by predictable rewards. Berns et al. used a 2×2 design to test this hypothesis. More precisely, study participants received squirts of either juice or water (and were queried afterward as to which they preferred), and received the squirts either in a regular sequence or in an unpredictable fashion (randomized over both type and time). The main finding of this study supported the hypothesis: the contrast of unpredictable–predictable showed significant activity in the bilateral nucleus accumbens/ventral striatum, areas known to be direct projections of dopamine neurons in the substantia nigra pars compacta (SNc) and the ventral tegmentum area (VTA). It should be stressed at this point that none of these experiments (save one discussed in the last section) will provide any direct evidence that these activations are the result of the phasic firing of dopamine neurons in the SNc or VTA. The nonhuman primate evidence suggests that the midbrain dopamine (DA) signals encode TD error signals (and we will examine some recent results from single-unit recordings in monkeys later), and the dopamine neurons in these regions project into the striatum, but it is conceivable that TD error signals found in the striatum (or elsewhere) could be the result of the combination of signals from the DA system (e.g., for positive errors) and, for example, the serotonin system (for negative errors), as has been suggested (and see later).

Another early result was that of Pagnoni and co-workers in 2002. In an instrumental design,

study participants were shown a visual cue, then pushed a button, and then 4 s later, juice was delivered. In a small percentage of the trials the juice squirt was omitted until 8 s later, thus setting up the conditions for a prediction error at the time of the omitted juice squirt. In the fMRI analysis, the authors examined a region of interest (ROI) centered on the nucleus accumbens (NAcc). Indeed, they found a significant difference between the activations in the delivered and undelivered conditions at the time of the juice delivery (more precisely, 6–8 s after the juice delivery time, the approximate peak hemodynamic response time for an event at the delivery time).

The experiments of Berns et al. and Pagnoni et al., while suggestive, had shortcomings. The Berns et al. design changed two things at one time: both the type of reward and the reward time were changed from predictable to unpredictable. In the Pagnoni study, the instrumental nature of the design (the button press) makes the interpretation less clear as compared to a passive task. McClure and colleagues, in 2003, attempted to address these issues in a passive design that incorporated only unpredictability in time. In their design a light cue came to predict a squirt of juice (see Figure 2). After a series of normal training trials in which juice was delivered 6 s after the cue, six catch events were inserted randomly among normal trials. In these catch trials, the juice expected 6 s after the light cue was omitted, and then was delivered 4 s later. In this design, two hypotheses are generated from a prediction-error model: (1) activity in the striatum at unexpected delivery of juice 4 s after the omission of juice at the expected time should be significantly higher than the activity at the expected delivery of juice (evidence of positive prediction error); (2) activity in the striatum at the time of omission of expected juice should be greater than that 4 s after the expected delivery of juice (evidence of negative prediction error). This is exactly what the authors found.

While the preceding studies give convincing evidence that the signal in the ventral striatum is consistent with a prediction error signal, they do not explicitly model the TD error signal during the conditioning process, and regress this signal with the neural activity. In 2003, O'Doherty et al. addressed these issues in a Pavlovian conditioning task (see Figure 3). Their paradigm trials consisted of the presentation of one of three visual stimuli followed 3 s later by a squirt of liquid that was either sweet (positive), saliva-like (neutral), or of no taste (negative). After a number of pairings of the positive cue with reward, subsequent positive cues were sometimes followed by the omission of the reward. Additionally, sometimes after the negative cue, a reward was delivered. A TD model of the each participant's experience using a model is almost identical to that described at the end of the introductory modeling section (see previous section, 'Brief review of the TD algorithm'). Two learning rates (previously denoted α) were chosen as 'biologically plausible, $\alpha = 0.2, 0.7$ (since no decisions were made, there are no behavioral data to fit and optimize α; this will not be true in the following discussion), and the discount factor was set at $\gamma = 0.99$ (the future really matters a lot). The principal finding of this study is that the TD signal obtained from a computational model correlated significantly with the actual blood oxygen level-dependent (BOLD) signal in the ventral striatum and the orbitofrontal cortex. In particular, the authors tested both a signed prediction error model and a model using the absolute value of the prediction error. The signed version produced the results already reported, while

the absolute value produced significant activation only in the inferior prefrontal gyrus. The different learning rates produced qualitatively similar results. It should be noted that the results of this study seem to contradict those of Pagnoni et al. In particular, this study (as well as that of McClure et al.) shows that an undelivered expected reward produces a negative prediction error in the ventral striatum. As the authors of the study under consideration have noted, the Pagnoni study focused solely on the NAcc, an area with no reported activations. However, Knutson and colleagues, in 2001, did report a deactivation on omitted monetary reward.

Refinements and Questions

Aside from the Pagnoni study, none of the above paradigms involves an actual decision. Even in the Pagnoni task the choice was only about when the participant was ready for the juice delivery. Presumably the DA system is not just about reward prediction, but is also about making choices. In the aforementioned computational models, discussed in the review of the TD algorithm, the analysis split between the value of a state under a certain policy V^{π} and the policy π itself. Indeed, one architecture discussed, the actor–critic, explicitly splits the functions of state value estimation (critic) and policy (actor). Previous evidence (by O'Doherty, in 2004) had suggested a division along these lines in the striatum – dopaminergic projections to the ventral striatum corresponding to the critic, and dopaminergic projections to the dorsal striatum corresponding to the actor (or error signals to the actor). O'Doherty and co-workers performed a study to explicitly test this hypothesis (see Figure 4). In their study, a Pavlovian conditioning task was intermixed with an instrumental task. In the instrumental task, participants had to choose between two fractal images: in the reward condition, one image represented a high probability of a juice reward (60%) while the other represented a low probability of reward (30%). The unrewarded case was similar except that the stimuli were different, and the reward was no longer a sweet juice but was instead a neutral liquid. The Pavlovian trials were randomly distributed throughout the experiment and were identical except that the computer, rather than the participant, made the choice between the two stimuli.

For the Pavlovian condition, a TD model similar to the one discussed earlier was constructed. For the instrumental condition, an advantage-learning model was fit. The result was that the ventral striatum was activated in both the Pavlovian and the instrumental conditions, while the dorsal striatum was active only in the instrumental condition. Interestingly, the authors selected the advantage-learning algorithm versus the actor–critic architecture on the basis of behavioral fits: the advantage-learning model fit actual behavior better on the basis of the log-likelihood of the various fits.

An important question is to what extent these previous results hinge on the fact that the rewards were

Figure 4 Functional magnetic resonance image, showing activation in ventral and dorsal striatum in an instrumental task. all in fact appetitive. Does TD learning (or a variant) work for aversive stimuli? Additionally, the previous studies were first-order conditioning paradigms. Does TD learning work for higher order conditioning? Seymour and colleagues address this question, in 2004, in a higher order Pavlovian design with pain as the unconditioned stimulus. The design was higher order because there were two sequential visual cues, followed by a high- or low-intensity shock. If the first two possible cues are denoted A and C, and the second two are denoted B and D, then the sequences led to $A, B \rightarrow$ high pain, $A, D \rightarrow$ low pain, $C, B \rightarrow$ high pain, $C, D \rightarrow$ low pain. A basic (i.e., value function) TD learning algorithm was used to model the brain responses. Six states for three time points were used: s_1 for cue A at time 1, s_2 for cue C at time 1, s_3 for cue B at time 2, s_4 for cue D at time 2, s_5 for high pain ($r = 1$) at time 3, and s_6 for low pain ($r = 0$) at time 3. The prediction error signal (taken at the three time points) was used as a regressor in the fMRI analysis, and showed activation in the bilateral ventral putamen, right head of caudate, left substantia nigra, right insula, and bilateral cerebellum, areas broadly consistent with the findings from the appetitive cause. Notably, the predicted prediction error signal included both positive and negative activations, and these (suitably normalized) predictions were borne out in ROI analysis.

A related question is whether avoiding an aversive UCS carries a reward signal similar to an actual appetitive reward. Avoidance learning poses a puzzle for reinforcement learning, since, on the face of it, successfully avoiding an aversive experience means the absence of a UCS to reinforce behavior. Kim and colleagues tackled this issue in 2006, using an advantage learning model for analysis of the fMRI and behavioral data. In their paradigm, study participants are presented with two visual stimuli patterns which represent choices. In the reward condition, one pattern represents a 60% reward probability (60% chance of earning \$1, 40% no-change outcome) and the other represents a 30% chance. In the avoidance condition, one pattern represents a 60% chance of a neutral outcome (60% chance of no-change, 40% chance of losing \$1) and the other represents a 30% chance of a neutral outcome. There were also two control conditions in which participants made a choice to get either neutral feedback or no feedback at all. The first finding was that medial orbitofrontal complex/ventral medial prefrontal cortex (OFC/VMPFC) showed activity that correlated with reward receipt and loss

avoidance (i.e., activity was positive for received rewards and avoided losses, and activity was decreased for missed rewards or losses received). This finding is in line with other studies of the outcome phase of reward paradigms. The second finding concerns the prediction error signal. Separate advantage learning models were estimated from the behavioral data by subject and for the rewarding, aversive, and neutral conditions, and were entered as regressors at the time of outcome. The reward prediction error signal correlated significantly with activity in the ventral striatum, whereas the aversive prediction error signal (for the case when the receipt of an unexpected loss gave a positive signal) correlated strongly with activity in the insula. The authors found no significant activity correlating with a prediction error signal such that an unexpected aversive signal predicted decreased activity. The OFC/VMPFC result is positive, in the sense that previously identified valuation areas treat an avoided loss as a reward. On the other hand, the prediction error result (as the authors noted) is in contradiction to other results, including the work by Seymour et al. in 2004, as discussed previously. Also, since the authors used an advantage learning model in an instrumental task, one would expect to see, as in the work of O'Doherty et al., activity in the dorsal striatum associated with the 'actor' in the actor–critic architecture. Why this activity is not present in this experiment is not readily apparent.

Yacubian did an fMRI study in 2006, investigating the differences between gain and loss conditions (see Figure 5). In this work, individuals were essentially presented with high- and low-probability conditions of making either 1 or 5 euros, with the conjugate probabilities of losing the same amount. For example, in the high-probability (5 euros) condition, the probability of winning 5 euros was 0.66, while the probability of losing 5 euros was $1 - 0.66 = 0.33$. In any

Figure 5 Dissociable functional magnetic resonance image activation from positive and negative parts of expected value and prediction errors during a guessing task. Top: Activation from the positive part of expected value during the anticipation phase (a) and the positive part of prediction error during the outcome phase (b). Bottom: Activation from the negative part of expected value during the outcome phase (a) and the negative part of prediction error during the outcome phase (b). (2006) Dissociable systems for gain- and loss-related value predictions and errors of prediction in the human brain. *Journal of Neuroscience* 26: 9530–9537.

trial, the expected value can be expressed as the sum of a positive part and a negative part:

$$EV = p_{\text{win}} \cdot V - (1 - p_{\text{win}}) \cdot V \equiv EV_+ + EV_-$$

where V is the amount at stake (1 or 5 euros). Yacubian also defined positive and negative prediction errors:

$$\delta_+ = R - EV_+$$
$$\delta_- = R - EV_-$$

where R is the actual outcome of the trial. The main result is that EV_+ (during an anticipation phase) and δ_+ (during the outcome phase) are localized in the ventral striatum, while EV_- and δ_- are localized in the amygdala.

The TD algorithm hypothesis of reinforcement learning makes a strong qualitative prediction about the presentation of a second stimulus after a first conditioned stimulus has been strongly associated with reward. Since the appearance of the reward is already fully predicted by the first stimulus, the second stimulus acquires no meaning, since no prediction error is generated. This prediction, blocking, has previously been investigated in single-unit recordings of dopamine neurons in monkeys. In particular, the firing patterns of the individual dopamine neurons supported the predictions of the TD learning algorithm. Tobler et al. investigated this prediction of TD learning theory, in 2006, in an fMRI experiment in humans. In this paradigm, individuals were trained to expect reward after a visual stimulus A, and to expect nothing after B. Next they paired a new stimulus X with A, still predicting reward, and another new stimulus Y with B, now followed by reward. Test trials were then introduced, whereby X and Y were presented by themselves and were not followed by reward. Blocking predicts that the response to X will basically be flat (it is blocked), while Y will show a response at the presentation of the stimulus, and a decrease (negative prediction error) at the expected time of the reward (which is omitted). This is the main finding of Tobler's work, and provides strong evidence in favor of TD learning which does not rely on the details of a particular model.

Discussion

While the preceding discussions paint a picture that is supportive of the TD learning hypothesis, we have seen some ambiguities and contradictions. There are competing models (value learning, actor–critic, Q-learning, advantage learning), the Pagnoni result for prediction error is the wrong sign (perhaps the NAcc carries a different signal), and the Kim study contradicts the Seymour study, while not reproducing the result of O'Doherty. These difficulties we see getting worked out as more refined experiments are conducted and repeated. However, on the modeling front there are two particular issues that seem worth discussing. The first is incorporating a model of the task into the reinforcement learning (RL) algorithm. Hampton et al. took a step in this direction in a 2006 study of choice in a reversal learning task (see Figure 6). In this work, they compare a variant of the Q-learning model with a Bayesian hidden Markov model (BHMM). The BHMM incorporates a hidden state variable with Bayesian updating to model an individual's choices. One key prediction of this model is that value signals of both alternatives are updated at the same time (to capture the constraint of the model, which is that, if one alternative has x probability of being 'good,' then the other choice has $1 - x\%$ chance of being good). Thus if your current choice is 'bad,' and you decide to switch, the value goes up, which is not the same as RL, since the value of a choice not recently selected has not been updated. In this model, the posterior, prior difference becomes the error signal.

Figure 6 Top: Error signal. Bottom: Activation in the medial prefrontal cortex is greater in the state-based model, compared to standard reinforcement learning (RL). See text for discussion. From Hampton AN, Bossaerts P, and O'Doherty JP (2006) The role of the ventromedial prefrontal cortex in abstract state-based inference during decision-making in animals. *The Journal of Neuroscience* 26: 8360–8367.

Another source of information that could easily be incorporated in to the RL framework is what could be called fictive errors: the difference between what could have been obtained and what was actually received, rather than the difference between what was received and what was expected. In many of the tasks that have been considered experimentally, only the outcome of the choice actually made is revealed, but in reality this is often not the case: we often have access to outcome that we could have received if we had made a different choice. Indeed, regret is an emotion we often associate with this putative error signal. Several experiments have touched upon this topic. In 2005, Kuhnen and Knutson used a form of fictive error as an fMRI regressor to analyze choice behavior in a gambling task in which more than one outcome is revealed. In the same year, Coricelli et al. also considered a regret or fictive error term in their fMRI analysis of a choice task in which multiple outcomes were revealed. In the behavioral realm, in 1999, Camerer and Ho used foregone alternatives to update the value of choices in their experiential weighted attraction model.

Exciting possibilities remain for the study of RL, and in particular TD models, in human choice behavior. Incorporating more detailed task structure into the models, as well as information from foregone choices, in a coherent model that matches both choice and fMRI data remains a challenge. Furthermore, the issue of how gains and losses are encoded still remains to be settled.

Prefrontal Contributions to Reward Encoding

E T Rolls, University of Oxford, Oxford, UK

© 2009 Elsevier Ltd. All rights reserved.

The (primate and human) orbitofrontal cortex receives taste, olfactory, visual, somatosensory, and auditory inputs from cortical regions which are toward the end of the unimodal cortical processing streams that build representations of what stimulus is present in each of these sensory modalities. In this article, I review evidence from human functional neuroimaging and neuropsychology showing that the orbitofrontal cortex and a region to which it projects, the anterior cingulate cortex (ACC), are involved not only in rewards produced by olfactory and taste stimuli but also in much more abstract types of reward, such as monetary reward, and in altering behavior when rewards change. This indicates that the orbitofrontal and cingulate cortices are involved in emotion, and this is confirmed by many changes in emotion described here that can result from damage to the human orbitofrontal or ACC.

Functional Neuroimaging of the Human Orbitofrontal Cortex: Reward and Nonreward

Investigations with functional magnetic resonance imaging (fMRI) show that taste and olfactory stimuli can activate the orbitofrontal cortex and that the activation is related to the pleasantness or unpleasantness of the stimuli, that is, to their reward value. For example, activation of a part of the human orbitofrontal cortex is related to the pleasantness of food odor, in that the activation measured with fMRI produced by one food odor, banana, decreased after banana was eaten for lunch to satiety but remained strong to another food odor, vanilla, not eaten in the meal. Further evidence that pleasant odors are represented in the orbitofrontal cortex is that three pleasant odors (linalyl acetate (floral, sweet), geranyl acetate (floral), and alpha-ionone (woody, slightly food-related)) had overlapping activations in the medial orbitofrontal cortex in a region not activated by three unpleasant odors (hexanoic acid, octanol, and isovaleric acid). Moreover, activation of the medial orbitofrontal cortex was correlated with the subjective pleasantness ratings of the odors, and activation of the lateral orbitofrontal cortex was correlated with the subjective unpleasantness of the odors. Pleasant touch has also been shown to activate the medial orbitofrontal cortex, and pain has been shown to activate the lateral orbitofrontal cortex.

Visual stimuli that activate the human orbitofrontal cortex include those associated with pleasant taste. But it has been possible to extend the types of visual conditioned reinforcers to quite abstract reinforcers, such as monetary reward. In an fMRI study, we used a visual discrimination task in which one stimulus was associated with monetary reward and a different visual stimulus with monetary loss (punishment). The actual amounts of money won on reward trials and lost on punishment trials were probabilistic. This part of the design, and the fact that unexpected visual discrimination reversals occurred so that there were trials on which money was lost, enabled us to show that the magnitude of the activation of the medial orbitofrontal cortex was correlated with the amount of money won on each trial and that the magnitude of the activation of the lateral orbitofrontal cortex was correlated with the amount of money lost on each trial. Activation of the medial orbitofrontal cortex is also correlated with face attractiveness. Auditory stimuli may have similar representations in the orbitofrontal cortex related to their affective value. For example, a correlation has been found between subjective ratings of dissonance and consonance of musical chords and the activations produced in the orbitofrontal cortex. Another type of reward, the administration of amphetamine to naive human subjects, also activates the medial prefrontal cortex.

Cognition can reach down into the orbitofrontal cortex to influence affect, as shown by the effects that word descriptors (such as cheese vs. body odor) have on the activations produced by olfactory stimuli in the medial orbitofrontal cortex. Related to the orbitofrontal cortex error neurons, we have also been able to obtain evidence that nonreward used as a signal to reverse behavioral choice is represented in the human orbitofrontal cortex. Kringelbach and Rolls used the faces of two different people; if one face was selected, then that face smiled, and if the other was selected, the face showed an angry expression. After good performance was acquired, there were repeated reversals of the visual discrimination task. It was found that activation of a lateral part of the orbitofrontal cortex in the fMRI study was produced on the error trials, that is, when the human chose a face and did not obtain the expected reward. Control tasks showed that the response was related to the error and the mismatch between what was expected and what was obtained, in that just showing an angry

face expression did not selectively activate this part of the lateral orbitofrontal cortex. An interesting aspect of this study that makes it relevant to human social behavior is that the conditioned stimuli were faces of particular individuals and the unconditioned stimuli were face expressions. Moreover, the study reveals that the human orbitofrontal cortex is very sensitive to social feedback when it must be used to change behavior.

The activations found in functional neuroimaging studies by many types of reward appear to involve relatively medial parts of the human orbitofrontal cortex and unpleasant stimuli or nonreward appear to involve more lateral parts of the human orbitofrontal cortex. Single-neuron recording studies in macaques show that neurons can be exquisitely tuned differently not only to reinforcers in different sensory modalities (taste, smell, touch, etc.) but also to combinations of these, and even within any one modality (e.g., with neurons tuned to different tastes). Nevertheless, what account might we give for why so many different types of reward are represented in the human medial orbitofrontal cortex? I suggested in *Emotion Explained* that part of the functional utility of this is that there can be a comparison of the magnitudes of what may be quite different types of reward, implemented by the local lateral inhibition mediated via inhibitory interneurons. The result of the mutual inhibition is that the relative magnitude of the different rewards available can be compared and that the most strongly firing neurons after the competition reflect the strongest reward.

Neuropsychology of the Human Orbitofrontal Cortex

Having considered evidence from neuroimaging on the functions of the human orbitofrontal cortex in emotion and motivation, we now consider complementary evidence from the effects of damage to the human orbitofrontal cortex.

Reward Reversal and Its Relation to Other Changes in Behavior

It is of interest that a number of the symptoms of frontal lobe damage in humans appear to be related to the functions of representing primary (unlearned) reinforcers and of altering behavior when stimulus–reinforcement associations alter. Thus, humans with frontal lobe damage can show impairments in a number of tasks in which an alteration of behavioral strategy is required in response to a change in environmental reinforcement contingencies. It is of interest that frontal patients may be able to verbalize the correct rules yet be unable to correct their behavioral sets or strategies appropriately.

Some of the personality changes that can follow frontal lobe damage may be related to a similar type of dysfunction in processing rewards and punishers. For example, the euphoria, irresponsibility, lack of affect, and lack of concern for the present or future that can follow frontal lobe damage may be related to a dysfunction in altering behavior appropriately in response to a change in reinforcement contingencies. Indeed, in so far as the orbitofrontal cortex is involved in the disconnection of stimulus–reinforcer associations, and such associations are important in learned emotional responses, it follows that the orbitofrontal cortex is involved in emotional responses by correcting stimulus–reinforcer associations when they become inappropriate.

The hypotheses about the role of the orbitofrontal cortex in the rapid alteration of stimulus–reinforcer associations and the functions more generally of the orbitofrontal cortex in human behavior have been investigated in recent studies in humans with damage to the ventral parts of the frontal lobe. (The description ventral is given to indicate that there was pathology in the orbitofrontal or related parts of the frontal lobe, and not in the more dorsolateral parts of the frontal lobe.) A task that was directed at assessing the rapid alteration of stimulus–reinforcer associations was used because the findings indicated that the orbitofrontal cortex is involved in this type of learning. The task used was visual discrimination reversal, in which patients could learn to obtain points by touching one stimulus when it appeared on a video monitor but had to withhold a response when a different visual stimulus appeared, otherwise a point was lost. After the subjects had acquired the visual discrimination, the reinforcement contingencies unexpectedly reversed. The patients with ventral frontal lesions made more errors in the reversal (or in a similar extinction) task, and completed fewer reversals, than control patients with damage elsewhere in the frontal lobes or in other brain regions (see **Figure 1**).

An important aspect of the findings was that the reversal learning impairment correlated highly with the socially inappropriate or disinhibited behavior of the patients (see **Figure 1**), and also with their subjective evaluation of the changes in their emotional state since the brain damage. The patients were not impaired at other types of memory task, such as paired associate learning. It is of interest that the patients can often verbalize the correct response yet commit the incorrect action. This is consistent with the hypothesis that the orbitofrontal cortex is normally involved in executing behavior when the behavior is performed by evaluating the

Figure 1 Visual discrimination reversal performance in humans with damage to the ventral part of the frontal lobe. The task was to touch the screen when one image, the S+, was shown in order to obtain a point and to refrain from touching the screen when a different visual stimulus, the S−, was shown in order to obtain a point. The scattergraph shows that during the reversal the group with ventral damage were more likely to touch the previously rewarded stimulus (Old S+) and that this was related to the score on a behavior questionnaire. Each point represents one patient in the ventral-frontal group or in a control group. The behavior questionnaire rating reflected high ratings on at least some of the following: disinhibited or socially inappropriate behavior, misinterpretation of other people's moods. impulsiveness. unconcern about or underestimation of the seriousness of the individual's condition. and lack of initiative. Reproduced from Rolls ET, Hornak J, Wade D, and McGrath J (1994) Emotion-related learning in patients with social and emotional changes associated with frontal lobe damage. *Journal of Neurology, Neurosurgery and Psychiatry* 57: 1518–1524.

reinforcement associations of environmental stimuli. The orbitofrontal cortex seems to be involved in this in both humans and nonhuman primates when the learning must be performed rapidly, for example, in acquisition and during reversal.

To seek positive confirmation that effects on stimulus–reinforcer association learning and reversal were related to orbitofrontal cortex damage rather than to any other associated pathology, a new reversal-learning task was used with a group of patients with discrete, surgically produced lesions of the orbitofrontal cortex. In the new visual discrimination task (the same as that used in the O' Doherty et al. in 2001 monetary-reward functional neuroimaging task, two stimuli are always present on the video monitor and the patient obtains monetary reward by touching the correct stimulus and loses money by touching the incorrect stimulus. This design controls for an effect of the lesion in simply increasing the probability that any response will be made. The new task also uses probabilistic amounts of reward and punishment on each trial to make it harder to use a verbal strategy with an explicit rule. The task also had the advantage that it was the same as that used in our human functional neuroimaging study that showed the activation of the orbitofrontal cortex by monetary gain or loss. It was found that a group of patients with bilateral orbitofrontal cortex lesions were severely impaired at the reversal task, in that they accumulated less money. The investigation showed that the impairment was only obtained with bilateral orbitofrontal cortex damage, in that patients with unilateral orbitofrontal cortex (or medial prefrontal cortex) lesions were not impaired in the reversal task. These patients often failed to switch their choice of stimulus after a large loss; and often did switch their choice even though they had just received a reward; this was quantified in a more recent study.

It is of interest that the patients with bilateral orbitofrontal cortex damage who were impaired at the visual discrimination reversal task had high scores on parts of a social behavior questionnaire in which the patients were rated on behaviors such as emotion recognition in others (e.g., their sad, angry, or disgusted mood), in interpersonal relationships (e.g., not caring what others think and not being close to the family), emotional empathy (e.g., when others are happy, they are not happy for them), interpersonal relationships (e.g., does not care what others think and are not close to the family), public behavior (is uncooperative), antisocial behavior (is critical of and impatient with others), impulsivity (does things without thinking), and sociability (is not sociable, and has difficulty making or maintaining close relationships) – all of which could reflect less behavioral sensitivity to different types of punishment and reward. Further, in a subjective emotional change questionnaire, in which the patients reported on any changes in the intensity and/or frequency of their own experience of emotions, patients with bilateral orbitofrontal cortex lesions with deficits in the visual discrimination reversal task reported a number of changes, including changes in sadness, anger, fear, and happiness.

These results on the effects of brain damage to the orbitofrontal cortex and the complementary neuroimaging results already described provide evidence that at least part of the function of the orbitofrontal cortex in emotion, social behavior, and decision making is related to representing reinforcers, detecting changes in the reinforcers being received, using these changes to rapidly reset stimulus–reinforcer associations, and rapidly changing behavior as a result.

An idea of how such stimulus–reinforcer learning may play an important role in normal human behavior, and may be related to the behavioral changes seen clinically in patients with ventral-frontal lobe damage, can be provided by summarizing the behavioral ratings given by the carers of these patients. The patients were rated high on at least some of the following: disinhibition or socially inappropriate behavior, violence, verbal abusiveness, lack of initiative, misinterpretation of other people's behavior, anger or irritability, and lack of concern for their own condition. Such behavioral changes correlated with the stimulus–reinforcer reversal and extinction learning impairment. The suggestion, thus, is that the insensitivity to reinforcement changes in the learning task may be at least part of what produces the changes in behavior found in these patients with ventral-frontal lobe damage.

The more general impact on the behavior of these patients is that their irresponsibility tended to affect their everyday lives. For example, if such patients had received their brain damage in a road traffic accident and compensation had been awarded, the patients often tended to spend their money without appropriate concern for the future, sometimes, for example, buying a very expensive car. Such patients often find it difficult to invest in relationships, too, and are sometimes described by their family as having changed personalities, in that they care less about a wide range of factors than before the brain damage. The suggestion that follows from this is that the orbitofrontal cortex may normally be involved in much social behavior and the ability to respond rapidly and appropriately to social reinforcers which is, of course, an important aspect of primate social behavior.

Bechara and colleagues also have findings in patients with frontal lobe damage when they performed a gambling task that are consistent with those already described. In the Iowa gambling task, subjects were asked to select cards from four decks of cards and maximize their winnings. During the task, the electrodermal activity (skin conductance responses (SCR)) of the subject was measured as an index of somatic activation. After each selection of a card, facsimile money was lost or won. Two of the four decks produced large payouts with larger penalties (and can thus be considered high risk), whereas the other two decks produced small payouts but smaller penalties (low risk). The most profitable strategy was, therefore, to consistently select cards from the two low-risk decks, which is the strategy adopted by normal control subjects. Patients with damage to the ventromedial part of the orbitofrontal cortex, but not the dorsolateral prefrontal cortex, persistently drew cards from the high-risk packs and lacked anticipatory SCRs while they pondered risky choices. The task was designed to mimic aspects of real-life decision making that patients with orbitofrontal cortex lesions find difficult. Such decisions typically involve choices between actions associated with differing magnitudes of reward and punishment in which the underlying contingencies relating actions to relevant outcomes remain hidden.

Most known cases of human orbitofrontal damage occurred in adulthood, but two cases of damage acquired in early life have been reported. The two patients showed life-long behavioral problems, which were resistant to corrective influences. But more importantly, the patients appeared completely to lack knowledge about moral and societal conventions. Interestingly, other patients with late acquired orbitofrontal lesions retained knowledge of such matters, even if they did not always act in accordance with this explicit knowledge. The lack of this moral knowledge and subsequent reckless behavior in the two patients with early life damage to the orbitofrontal cortex is consistent with the hypothesis that the orbitofrontal cortex is crucial for stimulus–reinforcer association learning. The implication seems to be that the orbitofrontal cortex is necessary for the development of personal moral-based knowledge based on the processing of rewards and punishers.

Face and Voice Expression

To investigate the possible significance of face-related inputs to the orbitofrontal visual neurons, we also tested the responses of these patients to faces. We included tests of face (and also voice) expression decoding because these are ways in which the reinforcing quality of individuals is often indicated. Impairments in the identification of facial and vocal emotional expression were demonstrated in a group of patients with ventral-frontal lobe damage who had socially inappropriate behavior. The expression identification impairments occurred independently of perceptual impairments in facial recognition, voice discrimination, or environmental sound recognition. The face and voice expression problems did not necessarily occur together in the same patients, providing an indication of separate processing. Poor performance on both expression tests was correlated with the degree of alteration of emotional experience reported by the patients. There was also a strong positive correlation between the degree of altered emotional experience and the severity of the behavioral problems (e.g., disinhibition) found in these patients. A comparison group of patients with brain damage outside the ventral-frontal lobe region, and without these behavioral problems, was unimpaired on the face expression identification test, was significantly less impaired at vocal expression

identification, and reported little subjective emotional change.

These findings were extended, and it was found that patients with face expression-decoding problems do not necessarily have impairments of visual discrimination reversal, and vice versa. This is consistent with some topography in the orbitofrontal cortex.

To obtain clear evidence that the changes in face and voice expression identification, emotional behavior, and subjective emotional state were related to orbitofrontal cortex damage itself, and not to damage to surrounding areas which is present in many closed-head injury patients, we performed these assessments in patients with circumscribed lesions made surgically in the course of treatment. This study also enabled us to determine whether there was functional specialization within the orbitofrontal cortex and whether damage to nearby and connected areas (such as the ACC), in which some of the patients had lesions, could produce similar effects. We found that some patients with bilateral lesions of the orbitofrontal cortex had deficits in voice and face expression identification and that the group had impairments in social behavior and significant changes in their subjective emotional state. The same group of patients had deficits on the probabilistic monetary reward task. Some patients with unilateral damage restricted to the orbitofrontal cortex also had deficits in voice expression identification, and the group did not have significant changes in social behavior or in their subjective emotional state. Patients with unilateral lesions of the anteroventral part of the ACC and/or medial prefrontal cortex area BA9 were in some cases impaired on voice and face expression identification, had some change in social behavior, and had significant changes in their subjective emotional state. Patients with dorsolateral prefrontal cortex lesions or with medial lesions outside the ACC and medial prefrontal BA9 areas were unimpaired on any of these measures of emotion. In all cases in which voice expression identification was impaired, there were no deficits in the control tests of the discrimination of unfamiliar voices and the recognition of environmental sounds.

Relation to Psychiatric Symptoms

It is also becoming possible to relate the functions of the orbitofrontal cortex to some psychiatric symptoms. Berlin et al. compared the symptoms of patients with a personality disorder syndrome, borderline personality disorder (BPD), with those of patients with lesions of the orbitofrontal cortex. The symptoms of the self-harming BPD patients include high impulsivity, high affective instability, high emotionality, and low extraversion. It was found that orbitofrontal cortex and BPD patients performed similarly in that they were more impulsive; reported more inappropriate behaviors in the frontal behavior questionnaire; and had more BPD characteristics, more anger, and less happiness than control groups (either normals or patients with lesions outside the orbitofrontal cortex).

Both the orbitofrontal and BPD groups also had a faster perception of time (i.e., they underproduced time) than normal controls. This may be one factor underlying their increased impulsiveness; they feel that sufficient time has elapsed to initiate action. It was of considerable interest that the BPD group, as well as the orbitofrontal group, scored highly on the frontal behavior questionnaire, which assessed inappropriate behaviors typical of orbitofrontal cortex patients including disinhibition, social inappropriateness, perseveration, and uncooperativeness. Both groups were also less open to experience (i.e., less open-minded), a personality characteristic.

The orbitofrontal and BPD patients performed differently on other tasks. BPD patients were less extraverted and conscientious, and were more neurotic and emotional, than all other groups. Patients with orbitofrontal cortex lesions had more severe deficits in reversing stimulus–reinforcer associations than all other groups and had a faster perception of time (overestimated time) than normal controls. These deficits were not related to spatial working-memory functions, which are impaired by dorsolateral prefrontal cortex damage.

Thus, some but not other symptoms of self-harming BPD patients are similar to those of patients with orbitofrontal cortex damage. The symptoms the groups have in common include impulsiveness and the inappropriate behaviors typical of frontal patients. This could imply that in BPD patients some aspects of the operation of the orbitofrontal cortex are occurring (whatever their etiology, which could include innate or acquired changes and might involve different expression or operation of neurotransmitters) differently from the way they operate in normal control subjects. Part of our interest in this is that it may help to point toward new concepts that may be useful in the treatment of some of the symptoms of patients with BPD. On the other hand, other aspects of BPD do not appear to be related to orbitofrontal cortex functions, including the more neurotic and more emotional personality characteristics of the BPD group, together with their lower extraversion and conscientious.

Frontotemporal Dementia

Another case in which it is possible to relate psychiatric types of symptom to orbitofrontal cortex function

is frontotemporal dementia, which is a progressive neurodegenerative disorder attacking the frontal lobes and producing major and pervasive behavioral changes in personality and social conduct resembling those produced by orbitofrontal lesions. Patients appear either socially disinhibited, with facetiousness and inappropriate jocularity, or apathetic and withdrawn. Many patients show mental rigidity and an inability to appreciate irony or other subtle aspects of language. They tend to engage in ritualistic and stereotypical behavior, and their planning skills are invariably impaired. The dementia is accompanied by gradual withdrawal from all social interactions. Memory is usually intact but patients have difficulties with working memory and concentration. Interestingly, given the anatomy and physiology of the orbitofrontal cortex, frontotemporal dementia causes profound changes in eating habits, with escalating desire for sweet food coupled with reduced satiety, which is often followed by enormous weight gain.

The ACC and Affect

The perigenual cingulate area occupies approximately the anterior one-third of the cingulate cortex (see Figure 2) and is involved in emotion; it may be distinguished from a midcingulate area (i.e., further back than the perigenual cingulate region and occupying approximately the middle third of the cingulate cortex), which has been termed the cingulate motor area and may be involved in response selection. Both the perigenual and midcingulate areas are part of what anatomically is frequently termed the ACC; but, for convenience, when using the term anterior cingulate cortex I refer here to the perigenual cingulate cortex and distinguish this from the midcingulate cortex described elsewhere.

Vogt and colleagues showed that pain produced an increase in regional cerebral blood flow (rCBF, measured with positron emission tomography (PET)) in an area of perigenual cingulate cortex which included parts of areas 25, 32, 24a, 24b, and/or 24c. Vogt et al. suggested that the activation of the anterior part of the cingulate area is related to the affective aspect of pain. There are direct projections to the cingulate cortex from medial thalamic areas that relay pain inputs, including the parafascicular nucleus. In terms of other connections, the ACC is connected to the medial orbitofrontal areas, parts of lateral orbitofrontal area 12, the amygdala (which projects strongly to cingulate subgenual area 25), and the temporal pole cortex; it also receives somatosensory inputs from the insula and other somatosensory cortical areas (see Figure 2). The ACC has output projections to the periaqueductal gray in the midbrain (which is implicated in pain processing), to the nucleus of the solitary tract and dorsal motor nucleus of the vagus (through which autonomic effects can be elicited), and to the ventral striatum and caudate nucleus (through which behavioral responses could be produced).

Consistent with the anterior cingulate region being involved in affect, it is close to (just above) the area activated by the induction of a sad mood in studies made by Mayberg and colleagues. Also consistent with this region being involved in affect, Lane and colleagues found increased regional blood flow in a 1997 PET study in a far anterior part of the cingulate cortex, where it adjoins the prefrontal cortex, when humans paid attention to the affective aspects of pictures they were being shown which contained pleasant images (e.g., flowers) and unpleasant pictures (e.g., a mangled face and a snake). The perigenual ACC (approximately the anterior one-third of the cingulate cortex and including parts of areas 32, 24, and 25) is thus related to affect.

The perigenual cingulate cortex may be part of an executive output response-selection system for some emotional states, in which the responses can include autonomic responses. Part of the basis for this suggestion is its inputs from somatosensory cortical areas, including the insula, the orbitofrontal cortex, and the amygdala (see Figure 2), and its outputs to brain stem areas such as the periaqueductal (or central) gray in the midbrain, the ventral striatum, and the autonomic brain stem nuclei. Anterior cingulate lesions in humans can produce apathy, autonomic dysregulation, and emotional instability. We have shown that patients with circumscribed, even unilateral, surgical lesions of the ACC/perigenual cingulate cortex may be impaired for voice and face expression identification; have impaired subjective emotional states; and have some changes in social behavior, including being less likely to notice when other people were angry, not being close to his or her family, and doing things without thinking.

Functional neuroimaging studies showed that there appear to be separate representations of aversive and positively affective stimuli in the ACC/perigenual cingulate cortex. The area activated by pain is typically 10–30 mm behind and above the most anterior (i.e., pre- or perigenual) part of the ACC. Pleasant touch was found to activate the most anterior part of the ACC, just in front of the (genu, or knee, of the) corpus callosum (i.e., the pregenual cingulate cortex). Oral somatosensory stimuli such as viscosity and fat texture also activate this most anterior part of the ACC. More than just somatosensory stimuli are represented, however, in that (pleasant) sweet taste also activates the most anterior part of the

Figure 2 Connections of the perigenual and midcingulate cortical areas (shown on views of the primate brain). The cingulate sulcus (cgs) has been opened to reveal the cortex in the sulcus, with the dashed line indicating the depths (fundus) of the sulcus. The cingulate cortex is in the lower bank of this sulcus and in the cingulate gyrus, which hooks above the corpus callosum and around the corpus callosum at the front and the back. The perigenual cingulate cortex extends from cingulate areas 32, 24a, and 24b to subgenual cingulate area 25. (The cortex is called subgenual because it is below the genu (knee) formed by the anterior end of the corpus callosum (cc).) The perigenual cingulate cortex tends to have connections with the amygdala and orbitofrontal cortex, whereas area 24c tends to have connections with the somatosensory insula (INS), the auditory association cortex (22, TA), and the temporal pole cortex (38). The midcingulate areas include area 24d, which is part of the cingulate motor area. 12, 13, 11, orbitofrontal cortex; 38, TG, temporal pole cortex; 51, olfactory (prepyriform and periamygdaloid) cortex; A, amygdala; as, arcuate sulcus; cc, corpus callosum; cf, calcarine fissure; cgs, cingulate sulcus; cs, central sulcus; fros, fronto-orbital sulcus; ios, inferior occpital sulcas; ips, intraparietal sulcus; mts, middle temporal sulcus; INS, insula; ios, inferior occipital sulcus; lf, lateral (or Sylvian) fissure (which has been opened to reveal the insula); ls, lunate sulcus; mos, medial orbital sulcus; NTS, autonomic areas in the medulla, including the nucleus of the solitary tract and the dorsal motor nucleus of the vagus; os, orbital sulcus; ps, principal sulcus; sts, superior temporal sulcus; S2, somatosensory cortical area S2; TG, temporal pole cytoarchitectomic area; TA (22), superior temporal auditory association cortex; TE (21), inferior temporal visual cortex; TF and TH, parahippocampal cortex; TPO, multimodal cortical area in the superior temporal sulcus.

ACC, as do pleasant odors and cognitive inputs that influence the pleasantness of odors. Unpleasant odors activate further back in the ACC. Activations in the anterior/perigenual cingulate cortex are also produced by the taste of water when it is rewarding because of thirst, by the flavor of food, and by monetary reward. The locations of some of these activations are shown in Figure 3, from which it is clear that many positively affective stimuli are represented in the most anterior part of the perigenual cingulate cortex, with some less positively affective or negatively affective stimuli activating a region of the cingulate cortex which is just posterior to this, above the corpus callosum.

In addition to the pregenual cingulate sites which are activated in many of our studies of affective stimuli, it was also frequently found that activation in a region at the intersection of the medial prefrontal cortex, the subgenual cingulate cortex, and the orbitofrontal cortex is activated by positively affective

Figure 3 Activations of the most anterior part of the perigenual cingulate cortex by different positively affective stimuli, with less positively affective or negatively affective stimuli producing activations centered just behind this area. Touch: 3 pleasant, 14 unpleasant/pain, 5 unpleasant/pain; Odor: 7 pleasant, 2 correlation with pleasantness ratings, 9 unpleasant; monetary loss: 8; Water: 6 correlation with pleasantness, 15 correlation with pleasantness; Taste: 10 glucose, 11 salt, 4 salt; sucrose and fat: 1; nonreward in a social reversal task: 13, 12. Reproduced from Rolls ET (2005) *Emotion Explained*, figure 4.61, p. 183. Oxford: Oxford University Press by permission of Oxford University Press.

stimuli. The facts that this anterior cingulate region is activated by many rewarding stimuli (as just summarized), affects emotion if lesioned, and is connected with the orbitofrontal cortex indicate that it is important in emotion, perhaps as a region linking the orbitofrontal cortex to outputs. It is in this context very interesting that chronic electrical stimulation in or close to this region (in the subgenual cingulate cortex) relieved symptoms of treatment-resistant depression in some patients. This provides a close link between evidence from neuroscience about the functions of this medial region and the therapeutic potential of these concepts for helping to understand and treat depression.

Overall, it is thus notable that what can be termed an affective part of the ACC, the perigenual cingulate cortex, appears to have a most anterior part where activations are produced by a number of different pleasant stimuli. But further back toward the junction with the midcingulate area and perhaps sometimes including parts of the midcingulate area several affectively negative stimuli produce activations.

An investigation in patients with selective surgical lesions showed that patients with unilateral lesions of the anteroventral part of the ACC and/or medial BA9 were in some cases impaired for voice and face expression identification; had some change in social behavior, such as inappropriateness; and had significant changes in their subjective emotional state. Unilateral lesions were sufficient to produce these effects, and there were no strong laterality effects. Consistent with the effects of the anterior cingulate lesions in humans on recognizing vocal (and, in some cases, facial) emotional expression, neuroimaging studies concerned with vocal expression identification have reported orbital and medial activation. For example nonverbal sounds expressing fear, sadness, and happiness, when compared to a neutral condition, activated BA11 (orbital cortex) bilaterally and the medial BA9 on the left. Fear-related increases in activity were also found on the right only in BA11. In another study, it was found that fearful sounds activated the medial BA32 and BA24 (the anterior cingulate at/below the level of the genu of the corpus callosum), again on the right side only.

There is also neuroimaging evidence that complements the effects of lesions in suggesting a role for certain medial regions in the subjective experience of emotion. In neuroimaging studies by Lane and colleagues with normal human subjects, bilateral activations in the medial BA9 were found as subjects viewed emotion-laden stimuli, and in both the medial BA9 and ventral ACC during self-generated emotional experience (i.e., in the absence of a stimulus) as subjects recalled emotions of sadness or happiness. On the basis of a review of imaging studies which consistently emphasize the importance of anterior and ventral regions of the ACC for emotion, Bush et al. argued that the ACC can be divided into a ventral affective division (which includes the subcallosal region and the part anterior to the corpus callosum) and a dorsal cognitive division, a view strengthened by the demonstration of reciprocally inhibitory interactions between these two regions.

The subgenual part (area 25) of the anterior cingulate cortex is, via its outputs to the hypothalamus and brain stem autonomic regions, involved in the autonomic component of emotion. The ACC is also activated in relation to autonomic events, and Critchley and colleagues showed that there is a correlation with skin conductance, a measure of autonomic activity related to sympathetic activation, in the ACC and related areas.

A current working hypothesis is that the affective part of the ACC receives inputs about expected rewards and punishers, and about the rewards and punishers received, from the orbitofrontal cortex and amygdala. There is some segregation of the areas that receive these inputs. The ACC may compare these signals, and use them in functions such as affective decision making and in producing autonomic

responses. As such, the perigenual cingulate cortex may act as an output system for emotional responses and actions.

Prefrontal Cortex

J M Fuster, University of California, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

The cortex of the anterior pole of the brain can be subdivided, histologically and physiologically, into three major parts. They have been most clearly identified and extensively investigated in the frontal lobe of the primate: (1) the primary motor cortex, a strip of agranular cortex rostral and adjacent to the central sulcus; (2) the premotor cortex, a conglomerate of cytoarchitectonically transitional areas, including the supplementary motor area (SMA); and (3) the prefrontal cortex, which constitutes the largest and most anterior of the three components and which in the primate has a prominent internal granular layer (IV) and for this reason is designated as the granular frontal cortex. The three components can be well distinguished in the external convexity of the frontal lobe; in the cingulate and inferior (orbital) aspects of the lobe, the first two components are absent and the granular cytoarchitecture of the prefrontal cortex blends more or less gradually into that of limbic cortex behind it.

All three parts of the frontal cortex are functionally involved in behavior. The premotor and motor areas participate in the preparation and execution of specific movements, whereas the prefrontal cortex participates in cognitive aspects of behavior. Although its functions have not been completely elucidated, current knowledge strongly indicates that the prefrontal cortex is essentially engaged in the organization of goal-directed behavioral sequences. Furthermore, the prefrontal cortex seems essential for goal-directed rational thinking. Thus, the functional integrity of this cortex is necessary for the temporal organization of behavioral actions as well as of the 'internal actions' that constitute logical reasoning.

Development

Phylogenetically, the prefrontal cortex is the most rostral portion of the neocortex. It is one of the cortical regions to undergo the latest and most expansive development in the course of evolution (Figure 1); this is especially true for the cortex of the external prefrontal convexity, which is the part of frontal cortex most heavily involved in cognitive functions. Such development reaches a maximum in the human brain, where the prefrontal cortex constitutes nearly one-third of the neocortex. Ontogenetically, the prefrontal cortex also develops relatively late. In the human, its myelinization is not complete until the second decade of life.

Connections

The prefrontal cortex is connected with many other cerebral structures. Its extrinsic connectivity has certain peculiarities that distinguish it from other neocortical regions. They are as follows:

1. Reciprocal connections with anterior and dorsal nuclei of the thalamus; the prominent links of the prefrontal cortex with the nucleus medialis dorsalis are conventionally used as the criterion for the definition of this cortex in all species.
2. Reciprocal connections with several sensory processing areas of posterior association cortex; afferent inputs from various sensory systems (somatic, visual, auditory, and olfactory) arrive in the prefrontal cortex, which therefore may be considered cortex of polymodal sensory convergence and association.
3. Reciprocal connections with limbic formations, especially the hypothalamus, the amygdala, and the hippocampus, which are known to be involved in certain aspects of emotion, motivation, and memory.
4. Efferent connections to subcortical structures involved in motor control, such as the basal ganglia; further, through the basal ganglia, the cerebellum, and the thalamus, the prefrontal cortex has indirect connective access to the neighboring motor areas of the frontal lobe.

In addition, the prefrontal cortex, as in other associative regions of the neocortex, is reciprocally connected with diencephalic and mesencephalic nuclei and reticular formations with diffuse cortical projection. As in other regions, some afferent (corticocortical) connections in the prefrontal cortex have been noted to terminate in columnar transcortical patterns of distribution.

Neurotransmitters

All major types of neurotransmitter terminals and receptors are represented in the prefrontal cortex. The principal monoaminergic afferent systems from the brain stem and limbic structures innervate the prefrontal cortex. Conversely, the prefrontal cortex sends descending monoaminergic efferents to the thalamus, hypothalamus, subthalamus, and the core of the lower brain stem. Norepinephrine and dopamine seem to be synthesized and concentrated in

Figure 1 Lateral and medial views of the brains of several species. The prefrontal cortex is indicated by dark shading.

Figure 2 Monkey facing a panel with stimulus–response buttons for performance of delay tasks (mouth spigot for delivery of liquid reward). Below, the sequence of events in three such tasks: delayed response (DR), delayed alternation (DA), and delayed matching-to-sample (DMS). A DR trial begins with brief illumination of a button (right or left, randomly changing); after a delay of a few seconds, two buttons are simultaneously lit, and the animal must press the one lit at the start of the trial. In DA, the animal must alternately press the right and the left of a pair of buttons that are simultaneously lighted between delays. In DMS, the trial begins with brief presentation of a sample color, red or green (upper button); after the delay, both colors appear in the lower buttons, and the animal must press the one matching the sample color; both that color and the positions of the two colors in the lower buttons are changed randomly between trials. (White triangles mark the site of correct response).

higher quantities in the prefrontal cortex than in posterior sensory and associative cortex. The reverse is true for serotonin. The prefrontal region is the recipient of abundant cholinergic fibers from the basal nucleus of Meynert (or its equivalent in the rat and the cat). This nucleus is a relay in a cholinergic system of ascending connections that originates in the brain stem reticular core and diffusely projects to the cerebral cortex. Both catecholamine and acetylcholine systems have been postulated to mediate, in a yet unspecified manner, the participation of the prefrontal cortex in cognitive processes, memory in particular.

Neuropsychology

Lesions of the prefrontal cortex cause changes in various aspects and forms of behavior. The magnitude of the changes depends on the location and extent of the lesion. This has been most systematically studied in primates, but the general characteristics of the behavioral changes observed are the same in all species in which they have been investigated.

The best known alterations resulting from lesions of the dorsolateral prefrontal convexity are deficits in learning and performance of various structured behavioral tasks that have one common feature: the necessity to execute motor acts in accord with sensory information no longer present in the environment. The temporal discontinuity between information and action (cross-temporal contingency) is an essential element of these tasks (Figure 2). Thus, the deficit is neither sensory nor motor but has to do with the ability of the animal to integrate, across a span of time, sensory input with appropriate action. However, the degree of deficit depends not only on the length of that time but also on the novelty and complexity of the sensory stimulus or stimuli before it.

It also depends on whether the stimulus–response coupling required for the task is merely one of two or more similar and alternative couplings in the behavioral repertoire of the animal. If only one specific signal calls for one specific act, without the competing possibility of similar signals and acts, no deficit can be seen after prefrontal lesion, however long the time between the signal and the action.

Most typical and documented are the deleterious effects of prefrontal lesions, especially if they involve the lateral convexity, on the performance of delay tasks (e.g., delayed response, delayed alternation, delayed matching to sample) and discrimination reversal tasks. All such tasks impose the need to bridge a cross-temporal contingency between information and action, as well as the need to reject similar alternatives.

Lesions of inferior (orbital) or medial prefrontal cortex may also disrupt to some extent the performance of behavioral tasks, especially if they require the inhibition or suppression of a prepotent and well-established tendency or response alternative. Inferior lesions severely disrupt such tasks as conditioned inhibition and successive discrimination, where that requirement is critical for successful performance but the bridging of cross-temporal contingencies is not.

Summing up, cortical lesion experiments show that the prefrontal cortex, unlike other parts of the cerebral cortex, is essential for the formation of goal-directed structures of behavior that demand cross-temporal integration and the rejection of inappropriate alternatives. The behavioral effects of selective cortical ablations and reversible lesions (by cooling) in the monkey suggest that this is accomplished by the joint action of a temporally retrospective function of short-term memory – also called 'working memory' – and a function of control of internal interference. The former seems mainly based in dorsolateral, the latter in inferior (orbital) prefrontal cortex.

Although clinical observations of the effects of frontal lobe pathology were made long before the relevant animal lesion studies had been carried out, the data from prefrontal lesions in the human have been less systematically investigated and are more difficult to evaluate than those from nonhuman primates. Nevertheless, in recent years, rigorous neuropsychological studies of patients with frontal lobe lesions have shed new light on the nature of symptoms that are commonly encountered in such patients (e.g., difficulties in attention, recent memory, planning). These studies also reveal a remarkable degree of similarity between the prefrontal syndromes of humans and animals. It has now been shown that humans with lesions of the prefrontal convexity, like monkeys with such lesions, exhibit deficits in performance of short-term memory tasks (e.g., delayed matching) and tasks that require the ordering of items in time. In the human, as in the monkey, lesions of orbital prefrontal cortex disrupt the ability to perform tasks demanding the inhibition of strong response tendencies (e.g., discrimination reversal, go/no go). Thus, also in humans, prefrontal lesions result in deficits of short-term memory and control of interference.

As might be expected from these observations, the human subject with a prefrontal lesion is likely to be deficient in the temporal organization of sequential behaviors, such as the spoken language, that rely heavily on cognitive operations. The most dramatic language difficulty resulting from prefrontal pathology is Broca's aphasia, a severe deficit in the construction and articulation of speech resulting from lesions of a small area of the left inferolateral prefrontal cortex. Lesions of more anterior and superior cortex induce more subtle deficits, characterized by a general impoverishment of language and trouble in the construction of elaborate propositions; there is a diminution of spontaneous speech production and of the use of dependent clauses.

In humans, as in animals, extensive bilateral lesions involving most or all areas of the prefrontal cortex result in a generalized blunting of affect and emotions. Apathy and neglect characterize the subject's attitude toward others and the environment. Circumscribed lesions of dorsolateral prefrontal cortex induce cognitive deficits but only rarely changes in emotional behavior. On the other hand, in the monkey, orbital lesions result in fear and loss of normal aggressiveness; in the human, the effects are more variable and frequently include disinhibition, abnormal excitability, irritability, and poor ethical judgment. It is worth noting that the high incidence of emotional abnormalities deriving from ventromedial (in contrast to dorsolateral) prefrontal lesions is probably related to the anatomical and functional relationships between the ventromedial prefrontal cortex and the limbic structures of the hypothalamus and the temporal lobe.

Electrophysiology

Slow electrical potentials and sustained changes of neuronal discharge can be recorded from the prefrontal cortex in the time elapsing between a stimulus and a consequent delayed response to it. A surface-negative potential occurring between these two mutually contingent events is commonly known as the contingent negative variation (CNV) or expectancy wave. It may be observed in both humans and animals. Cellular

discharge shows important correlations with this field potential. By microelectrode recording in the monkey, large numbers of prefrontal cells can be seen to undergo altered discharge throughout the delay (seconds or minutes) that separates cue from choice in a delay task. The sustained activation of some prefrontal cells during that delay depends on the behavioral significance and the physical attributes of the cue. That of others depends on the characteristics of the impending motor response. Cells of the first type appear to participate in the short-term memory process; those of the second appear to do it in the preparation for movement. The two types of cells are found interspersed in certain areas of dorsolateral prefrontal cortex.

The posterior fringe of the dorsolateral prefrontal cortex bordering the premotor cortex contains the so-called frontal eye fields. Electrical stimulation of sites in these cortical fields elicits conjugate eye movements. The cells within them show increases of discharge in temporal relation to ocular movements. In an animal conditioned to move its eyes in response to a visual stimulus, some cells are activated right after the stimulus, some right before the movement, and still others through the time that separates the two. Thus, like the neurons in the dorsolateral prefrontal cortex at large, but on a shorter timescale, eye field neurons seem to be involved in the temporal integration of sensory stimuli with their consequent motor responses.

Metabolism and Blood Flow

Modern methods yielding images of the working human brain by the use of computer tomography and radioactive tracers reveal that blood flow and metabolic activity increase in prefrontal areas of the cortex during the ideation and programming of speech and motor sequences. Premotor and motor areas mainly show activation during the performance of speech and skeletal movements. In the past few years, neuroimaging has revealed the activation of the human dorsolateral prefrontal cortex during performance of short-term memory tasks. Increased prefrontal metabolism has been demonstrated during memorization of verbal or visual material. The activation of dorsolateral prefrontal and premotor cortices has also been found related to the preparation of movements that are dependent on the material memorized. Therefore, the metabolic studies in the human confirm the basic inferences from neuropsychological and neurophysiological studies in nonhuman primates, namely, that the neuronal populations of dorsolateral prefrontal cortex are involved in the retention of sensory information for prospective action, as well as in the preparation of motor systems for that action. Both are essential for organizing behavior in the time domain.

General Conclusions

In conclusion, the functions of the prefrontal cortex are not yet fully understood, but the evidence from human and animal studies points to a critical role of this cortex in the temporal organization of behavior. The prefrontal cortex may play that role by the coordinated works of at least three subordinate functions, each with a somewhat different topographic representation within the prefrontal region: (1) short-term memory, (2) short-term set for action, and (3) control of interference. Thus, the various sectors of prefrontal cortex, heterogeneous as to connectivity and apparent behavioral function, may cooperate with one another and with other parts of the brain in providing the cognitive support that the organism needs to bridge cross-temporal contingencies and to form goal-directed and temporally extended structures of behavior.

Overview

The prefrontal cortex has been associated with central executive functions, involved in selecting relevant information and ignoring irrelevant information for the task at hand. To accomplish these functions the prefrontal cortex must have access to information from structures associated with sensory perception, memory, and emotions. Indeed, the prefrontal cortex receives a wealth of information from a large variety of cortical and subcortical structures. In turn, the prefrontal cortex issues projections to the same structures, targeting both excitatory and inhibitory neurons, a pattern that likely underlies the selection of relevant signals and the suppression of irrelevant signals. Within the prefrontal cortex there is division of labor and specialization, so that distinct areas receive and issue topographically organized projections. The participation of different prefrontal sectors in complex behavioral settings appears to be complementary. A key distinction of prefrontal cortex among high-order association areas is its orientation for action, facilitated by its rich and diverse connections with motor control systems.

The prefrontal areas commonly associated with central executive functions are the lateral areas (**Figure 1(b)**), particularly the areas around the posterior principal sulcus and prearcuate region. These areas have a role in cognitive tasks, requiring the selection, retrieval, and temporary holding of information long enough to accomplish a task at hand. The prefrontal cortex, however, has additional components on the medial and orbitofrontal surfaces, which have a key role in the function of the prefrontal cortex (**Figures 1(a) and 1(c)**). The posterior parts of medial and orbitofrontal cortices belong to the cortical component of the limbic system by virtue of their architecture and connections (**Figure 1**, dark blue). Damage to prefrontal limbic areas in primates has detrimental consequences on emotional behavior and social interactions. The limbic components of the prefrontal cortex have strong connections with the rest of the prefrontal cortex, providing the anatomic basis for the merging of pathways associated with cognitive and emotional processes.

Location of the Prefrontal Cortex in Primates

The frontal lobe extends from the central sulcus to the frontal pole. This large cortical expanse includes about half of the entire cortex in primates. The prefrontal cortex occupies roughly the anterior half of the frontal lobe in macaque monkeys, and about two-thirds in humans. The primary motor cortex, also known as M1 (or area 4 of Brodmann), marks the posterior extent of the frontal lobe, and the premotor cortex (also known as area 6) is interposed between the primary motor and prefrontal cortices (**Figures 1 and 2**). Species other than primates have a prefrontal cortex, and at least in mammals it is found in front of the premotor cortex. In birds, a region thought to be analogous to the prefrontal cortex, on the basis of physiological properties and connections, occupies the posterior pole of the telencephalon.

The prefrontal cortex is greatly expanded and specialized in primates, and its architectonic organization and connections have been studied most widely in nonhuman primates, and more specifically, in macaque monkeys. In this species, the lateral aspect of the prefrontal cortex extends from the arcuate sulcus to the frontal pole (**Figure 1(b)**, light blue). The medial prefrontal cortex lies in front of the medial parts of the premotor cortex –the supplementary motor area (SMA), or MII – and the cingulate motor areas, and extends from the anterior part of the corpus callosum in the anterior cingulate to the medial part of the frontal pole (**Figure 1(a)**). The orbitofrontal cortex occupies the basal aspect of the brain. In macaque monkeys it is located behind the eye socket, and forms a concave shape around the orbit (**Figure 1(c)**). This large cortical region extends from the olfactory areas and the anterior insula to the basal surface of the frontal pole.

Global and Local Architecture

The prefrontal cortex is composed of 13 principal architectonic areas in the human in the classic map of Brodmann (**Figure 2**), and 12 in the nonhuman primate rhesus monkey, as depicted in the map of Walker (**Figure 3**). These classic maps have been modified by several investigators, and nearly all architectonic areas in the macaque monkey prefrontal cortex have been further subdivided into two or more subdivisions, now numbering over 20 in this species. The

Figure 1 The principal architectonic areas of the prefrontal cortex of the rhesus monkey brain (shaded areas), depicting the (a) medial, (b) lateral, and (c) orbital surfaces. Light blue shading indicates eulaminate areas, with six cortical layers and a distinct granular layer IV. Dark blue shading indicates areas with fewer than six layers (noneulaminate) and which have a poorly developed layer IV (dysgranular) or no granular layer IV (agranular). The prefrontal cortex is bounded posteriorly by the premotor cortices (supplementary motor area MII; SMA) on the medial surface (a), and area 6 on the lateral surface (b). A, arcuate sulcus; Cg, cingulate sulcus; MII SMA, supplementary motor area; OLF, olfactory area; OPAII, orbital periallo cortex; OPro, orbital proisocortex; P, principal sulcus.

classic maps were largely based on brain sections stained for Nissl substance, which labels the cell bodies of neurons and glia. More recent maps have relied on an increasing number of specific neurochemical and molecular markers that aid in delineating architectonic borders by labeling distinct classes of neurons. Nevertheless, the Nissl stain has provided the most reliable information about the organization of the cortex (because architectonic areas vary reliably in overall density) and the relative distribution of neurons in different cortical layers.

The popular name 'frontal granular cortex' is based on the presence of a well-delineated granular layer IV, which is particularly prominent in lateral prefrontal cortex. Most prefrontal areas, including the entire lateral surface, the anterior medial surface, and the anterior orbitofrontal region, have six layers, including a granular layer IV, and thus are called eulaminate (**Figure 1**, light blue). However, the width and density of neurons in layer IV vary widely among prefrontal areas. Layer IV is densest and widest in lateral prefrontal area 8 and posterior area 46 (prearcuate region) of macaque monkeys (**Figure 4**), and least developed in anterior medial and anterior orbitofrontal areas (**Figures 1(a) and 1(c)**, light blue). But not all prefrontal cortex has a granular layer IV. The most posterior parts of the medial and orbitofrontal cortex have fewer than six layers and are either agranular, meaning that they lack granular layer IV, or dysgranular, meaning that they have a poorly developed layer IV (**Figures 1(a) and 1(c)**, dark blue). In the posterior orbitofrontal and anterior cingulate areas the deep layers (V and VI) predominate in cell density in comparison with the upper layers (II–III) (**Figure 5**). In contrast, all eulaminate prefrontal areas, and particularly the lateral areas, have a well-developed granular layer IV and a broad layer III, which is densely populated with neurons. The geographically and structurally distinct sectors of the prefrontal cortex have some common connections as well as some specific connections that underlie their specialization.

Common and Specialized Thalamic Connections of Prefrontal Cortices

All prefrontal cortices have bidirectional connections with the mediodorsal (MD) thalamic nucleus. In fact, the prefrontal cortex has often been defined as the cortical region that is connected with the MD thalamic nucleus. This definition is only approximate, because the prefrontal cortex is also connected with thalamic nuclei other than the MD nucleus, and conversely, the MD thalamic nucleus projects to areas outside the classic geographic extent of the prefrontal cortex, albeit more sparsely. Nevertheless, the MD thalamic nucleus is robustly connected with all prefrontal cortices in a topographic manner. Lateral prefrontal cortices are connected with the lateral

Figure 2 The architectonic map of the human cortex by Brodmann. Prefrontal areas are shown by numbers in red. The medial surface is shown on the top, and the lateral surface is shown on the bottom. IF, inferior frontal sulcus; SF, superior frontal sulcus.

parts of the MD thalamic nucleus, including its most lateral or multiform sector, and with the adjacent parvicellular sector. 'Multiform' refers to the various shapes of neurons, and 'parvicellular' refers to the small size of neurons. Medial and orbitofrontal cortices are connected mainly with the medial, or magnocellular (large cell), sector of the MD thalamic nucleus.

In addition to their connections with the MD thalamic nucleus, the prefrontal cortex is connected with other thalamic nuclei, including the ventral anterior, the medial pulvinar, intralaminar, medial, and anterior nuclei. Lateral prefrontal areas are connected primarily with the MD thalamic nucleus, and have only sparse connections with midline nuclei, but they have connections with some intralaminar nuclei and the medial pulvinar. On the other hand, orbitofrontal and posterior medial prefrontal areas have significant connections with midline and intralaminar nuclei, anterior nuclei, and the medial pulvinar, but still have substantial thalamic connections with the MD thalamic nucleus.

Figure 3 Architectonic areas of the rhesus monkey prefrontal cortex according to the map of Walker. The lateral surface is on the left, the orbital surface (inferior) is on the right; the medial surface is not shown.

Figure 4 Example of granular prefrontal cortices. (a) Cross section (coronal) through the posterior part of prefrontal cortex of a macaque monkey (*Macaca nemestrina*), showing granular prefrontal cortex within the lateral bank of the arcuate sulcus (A) and adjacent cortex (to the right), and within the banks of the principal sulcus (P). The section was stained with cresyl violet to show the cell bodies and glia. Roman numerals indicate cortical layers. (b) A section at about the same level through the prefrontal cortex of a rhesus monkey brain stained with an antibody to neurofilament protein (SMI-32), which labels neurons in layers II–III and V–VI but not in layer IV. The empty zone in this frame shows clearly the position of granular layer IV. Medial is to the left. Scale bar = 3 mm.

Specialized Connections of Prefrontal Cortices with Other Cortical Systems

Projections from Sensory Association Areas to Prefrontal Cortices

One of the key sources of information to the prefrontal cortex comes from most cortical sensory and

polymodal association areas. The primary koniocortices ('dustlike'), which include visual area V1, somatosensory area 3b, and auditory area A1, do not project directly to the prefrontal cortex. On the lateral surface of the prefrontal cortex, projections from visual association cortices reach several areas in the prearcuate region, targeting robustly area 8, which includes the frontal eye fields, and the posterior extent of the principal sulcus (area 46) and lateral area 12. Auditory association cortices project to several sites within the lateral prefrontal cortex, targeting robustly the frontal polar cortex (area 10), several sites of the dorsal bank of the principal sulcus (area 46), and the anterior tips of the limbs of the arcuate sulcus, including the anterior part of dorsal area 8, and area 9. Projections from somatosensory cortices reach the central portion of the principal sulcus (ventral area 46) and the subadjacent area 12. Cortices which are not unimodal, identified as those with neurons that respond to stimuli from two or more modalities, project to prefrontal cortices as well. On the lateral surface these projections originate mostly from the depths of the upper bank of the superior temporal sulcus, and to a lesser extent from the inferior parietal lobule.

Medial prefrontal areas receive projections from auditory association cortices, from polymodal areas in the depths of the upper bank of the superior temporal sulcus and perirhinal region, and only sparse projections from either visual or somatosensory association cortices. The orbitofrontal cortex, on the other hand, receives projections from all unimodal sensory cortices, including the primary olfactory cortices, and visual, auditory, somatosensory, and gustatory association cortices, as well as from polymodal association areas in the superior temporal and perirhinal regions.

There is a big difference in the topography of sensory projections to prefrontal cortices. The prearcuate cortex receives projections from posterior visual association areas, which represent relatively early stages of visual processing. The frontal eye fields seem to be specialized for processing signals from a large variety of visual association cortices, extending from as far back as V2 in the occipital region, up to the anterior parts of the inferior temporal visual association cortices. In contrast, orbitofrontal cortices receive projections from anterior inferior temporal cortices, where the visual receptive fields are global.

There is a comparable organization in the projections from auditory association areas to prefrontal cortices. The prearcuate cortex (area 8; at the tip of the upper limb of the arcuate sulcus) and posterior area 46 receive projections from posterior auditory association cortices in the superior temporal gyrus; these cortices are comparatively close to the primary auditory cortex. In contrast, orbitofrontal and medial prefrontal areas receive projections from the anterior superior temporal gyrus, from areas that process signals associated with species-specific vocalizations in nonhuman primates. Similarly, projections from other sensory association areas to the posterior orbitofrontal cortex originate in late-processing sensory association cortices. Visual input to orbitofrontal cortex, for example, originates in the anterior inferior temporal cortex, where neurons have large visual receptive fields and have a role in visual memory. The only exception is the input from primary olfactory areas to posterior orbitofrontal cortices.

Interface of Prefrontal Projections with Excitatory and Inhibitory Systems

One of the fundamental functional attributes of the prefrontal cortex is the selection of relevant signals and the suppression of irrelevant signals in behavior. This function can be illustrated by the interaction of prefrontal cortices with temporal auditory association cortices. Damage to the lateral prefrontal cortex after a stroke, or in pathological aging, impairs the ability of humans to ignore irrelevant auditory stimuli and thus to follow a conversation in a noisy environment. This function is likely mediated through robust projections from prefrontal cortices to auditory association cortices. Long-distance prefrontal pathways to sensory cortices are excitatory in nature, but they interface with both excitatory and inhibitory systems in auditory association areas. These pathways may form the anatomic substrate for choosing relevant signals and ignoring irrelevant signals. Similar interactions occur between medial prefrontal areas and auditory association areas. Interestingly, medial prefrontal areas in the anterior cingulate are hypoactive in schizophrenia, which likely affects medial prefrontal to temporal cortical communication. The same types of interactions with both excitatory and inhibitory systems occur between prefrontal and parietal cortices, as well as with other sensory and high-order association cortices.

Pathways Related to Specific Aspects of Memory Processing in the Prefrontal Cortex

Lateral Prefrontal Areas and Working Memory

Posterior lateral prefrontal areas are robustly and bidirectionally connected with lateral intraparietal areas, a region associated with visuomotor functions. Connections with the visuomotor parts of the lateral intraparietal cortex are restricted to the prearcuate region, including the cortex within the anterior bank

of the arcuate sulcus and the adjacent cortex (area 8), and to the posterior quarter of the principal sulcus (caudal area 46) in macaque monkeys. The prearcuate and lateral intraparietal cortices have in common a role in selective attention, required in cognitive operations. The strong and bidirectional connections that link these distant cortices suggest that they may function in concert in cognitive operations. The posterior cingulate cortex, which has a role in oculomotor responses and attentional processes, is also connected with the prearcuate cortex.

Posterior Medial and Orbitofrontal Areas and Long-Term Memory

Medial and orbitofrontal cortices are robustly connected with structures associated with long-term memory. These areas include the perirhinal region (areas 35 and 36), the entorhinal cortex (area 28), and the parahippocampal cortex (areas TF and TH). In addition, posterior orbitofrontal areas, and especially medial prefrontal cortices in the anterior cingulate, receive projections from the hippocampal formation, originating from the subiculum, presubiculum, and CA1 fields. Posterior medial prefrontal areas share long-term memory functions with the hippocampus, and their damage in humans results in memory deficits.

Pathways for Emotional Processing

Among prefrontal cortices, the posterior orbitofrontal and posterior medial cortices have the heaviest connections with the amygdala, a group of nuclei in the temporal lobe associated with emotional processing. Most of these connections involve the basal complex of the amygdala, especially the basolateral nucleus, and to a lesser extent the cortical and lateral nuclei. The projections of the posterior orbitofrontal cortex with the amygdala are particularly specialized, as they terminate heavily onto a group of nuclei known as the intercalated masses, which are composed of inhibitory neurons and have a role in the internal processing of the amygdala. The connections of posterior orbitofrontal areas are with the posterior half of the amygdala, which, in turn, receives projections from all sensory association cortices (Figure 6). One hypothesis is that the rich direct and indirect sensory inputs to posterior orbitofrontal cortices underlie the process through which events acquire emotional significance.

Posterior medial prefrontal cortices also have substantial connections with the amygdala. Projections from posterior medial prefrontal cortices reach heavily the output nuclei of the amygdala to hypothalamic and brain stem autonomic centers, and also terminate onto hypothalamic autonomic centers (Figure 7). In monkeys, posterior medial prefrontal cortices in the

Figure 6 Multiple sources of projections to orbitofrontal cortices. Projections from sensory association cortices reach orbitofrontal cortex as well as the amygdala, which has bidirectional connections with orbitofrontal cortex (pathway a). The amygdala also projects to the medial (magnocellular) part of the mediodorsal thalamic nucleus (MDmc, pathway a1), which has bidirectional connections with the orbitofrontal cortex (pathway a2). Connections of sensory association cortices with orbitofrontal cortex, or with the amygdala, are also bidirectional (not shown). Architectonic areas indicated by letters are: OLF, olfactory area; OPAll, orbital periallo cortex; OPro, orbital prosiocortex.

Figure 7 Summary of the connections of orbitofrontal and medial prefrontal cortices associated with perception and expression of emotions. The orbitofrontal cortex and the amygdala receive projections from every sensory modality through the cortex (pathways so, s), and are robustly connected with each other, providing the structural basis for direct (so) and indirect (s′) sensory information to the orbitofrontal cortex. Orbitofrontal axons terminate heavily in the intercalated masses (IMs) of the amygdala (pathway a), which then project to the central nucleus of the amygdala (pathway a′). The central nucleus projects to hypothalamic autonomic nuclei (pathway b). A direct pathway (c) from posterior medial prefrontal cortex reaches hypothalamic autonomic nuclei, which project to brain stem autonomic nuclei (pathway c′) and to spinal autonomic nuclei (pathway o′). Medial prefrontal cortices also project to the parvicellular basolateral nucleus of the amygdala (BLpc, pathway d), and to the magnocellular basolateral nucleus of the amygdala (BLmc, pathway d1), which project to hypothalamic autonomic nuclei (pathway d′), providing sequential pathways through which posterior medial prefrontal areas may influence hypothalamic autonomic nuclei (dotted pathways). A lighter pathway from orbitofrontal cortex terminates directly on the central nucleus of the amygdala (pathway i). Thickness of the lines represents the density of the projections. Red, inhibitory pathways; green, excitatory pathways. Reproduced from Barbas H, Saha S, Rempel-Clower N, and Ghashghaei HT (2003) Serial pathways from primate prefrontal cortex to autonomic areas may influence emotional expression. *BMC Neuroscience* 4:25, copyright 2003 Barbas H et al; licensee BioMed Central Ltd.

anterior cingulate region have a direct role in vocalization associated with emotional communication, emitted in fear or distress, such as at the sight of a predator.

Connections of Prefrontal Cortices with Neurotransmitter-Specific Systems

Like other cortical systems, the prefrontal cortex receives projections from modulatory neurotransmitter systems, including cholinergic projections from the basal forebrain, noradrenergic projections from the locus coeruleus, dopaminergic projections from the substantia nigra/ventral tegmental area, and serotonergic projections from the raphe nuclei. These systems have a role in the attentional and cognitive functions of the prefrontal cortex. In macaque monkeys and rats, the strongest interactions of the basal forebrain are with orbitofrontal and posterior medial prefrontal cortices and are distinct for being bidirectional, in contrast with other prefrontal cortices, which receive, but do not send, projections to the basal forebrain.

In the lateral prefrontal cortex a delicate balance in the availability of dopamine and noradrenaline appears to be crucial in optimal performance on working memory tasks in nonhuman primates. These functions are thought to be mediated through projections from neurotransmitter-specific systems, which target dopamine receptors of the D1 type, and adrenergic receptors of the α-2A type. Disruption of the optimal levels of these neurotransmitters in stress impairs performance on working memory tasks. Imbalance in the neurotransmitter equilibrium in prefrontal cortex may underlie attention-deficit/hyperactivity disorder in humans.

Another system with widespread connections to all sectors of the prefrontal cortex is the hypothalamus, which projects widely to all prefrontal cortices, but has bidirectional connections only with posterior orbitofrontal and posterior medial prefrontal cortices (Figures 1(a) and 1(c), dark blue). Some of these projections from the hypothalamus to the cortex may be histaminergic, constituting yet another neurochemically distinct pathway.

Common Connections of Prefrontal Cortices with Motor Control Systems

Linkage of Prefrontal Cortices with the Basal Ganglia

The prefrontal cortex is in an ideal position to exercise executive control through its multiple links with motor control systems. All prefrontal cortices project to the neostriatum (caudate and putamen), the input center of the basal ganglia. The neostriatum receives projections from all cortical areas, but the output of the basal ganglia (the globus pallidus and substantia nigra reticulata) reaches selectively the frontal cortex, including the motor/premotor and prefrontal cortices. Information from the basal ganglia reaches the frontal cortex indirectly, through specific thalamic nuclei. The principal nuclei involved in this system, as it pertains to the prefrontal cortex, are the mediodorsal nucleus and the ventral anterior nucleus, and to a lesser extent the anterior medial nucleus, all of which have bidirectional connections with the prefrontal cortex. Distinct prefrontal areas are influenced by the basal ganglia through parallel pathways, suggesting that they have specific roles in behavior. However, the segregation of pathways through the basal ganglia is relative rather than absolute, so that the pathway from lateral prefrontal cortices to the basal ganglia through the thalamus reaches not only lateral prefrontal cortices, but the adjacent premotor cortex as well. These connections suggest that lateral prefrontal cortices have multiple interactions with premotor cortices for action.

The projections of the prefrontal cortex are directed to the anterior part of the neostriatum, terminating mostly in the caudate nucleus. These projections have a certain degree of topographic organization, so that lateral prefrontal areas reach mostly the dorsal part of the caudate nucleus, medial areas project to a more medial position within the caudate, and posterior orbitofrontal cortices project to the ventral striatum. The latter is also known as the limbic striatum, and is also connected with the amygdala and the hippocampus. The limbic striatum projects through a relay in the ventral pallidum to the medial (magnocellular) part of the mediodorsal thalamic nucleus, which has strong bidirectional connections with the posterior orbitofrontal cortex (Figure 6) and the anterior cingulate.

Specialized Connections of Prefrontal Areas with Motor Control Systems

Lateral Prefrontal Cortices Are Linked with Brain Stem and Cortical Premotor Systems

Prearcuate prefrontal cortices are connected with neighboring premotor areas, which, in turn, are connected with the motor cortex, suggesting that the prefrontal cortex has close access to cortical motor control systems. Another specialized motor circuit is the projection of the frontal eye fields to the superior colliculus and brain stem oculomotor control systems, which are involved in eye movements. The frontal eye fields, situated within cortical area 8, were so named after the observation that damage to the area in humans or monkeys temporarily shifted the eyes toward the side of the lesion. It subsequently became clear that the frontal eye fields are not necessary for the execution of eye movements. It is now known that the involvement of the frontal eye fields in eye movement is related to attentional processes and to orienting the eyes to relevant stimuli in the environment.

Posterior Parts of Medial and Orbitofrontal Cortices Have Access to Central Efferent Autonomic Structures

The medial and orbitofrontal cortices have a different role in motor control. The posterior orbitofrontal cortex and, especially, the anterior cingulate cortex are connected with hypothalamic and brain stem autonomic structures (Figure 7), which innervate peripheral organs, such as the heart, the lungs, and the gut, the activities of which are markedly changed in emotional arousal. These prefrontal areas, therefore, have a role in motor control associated with emotional expression. These circuits are consistent with evidence that damage to orbitofrontal cortex in humans impairs the ability to respond appropriately in emotional situations. Conversely, overactivity of the orbitofrontal cortex is seen in patients with anxiety disorder and obsessive–compulsive disease.

Medial prefrontal cortices have an additional specialization within the motor domain, namely emotional vocalization, effected through a projection to brain stem structures that innervate laryngeal muscles necessary for phonation. This pathway has a role in emotional communication, such as the characteristic cries emitted by monkeys in emotional distress.

There are also other projections from orbitofrontal and, especially, anterior cingulate cortices to central autonomic structures targeting noncholinergic parts of the basal forebrain. One of these basal forebrain regions is the ventral striatopallidum, found in the dorsal half of the basal forebrain, and another is the extended amygdala, which is made up of groups of neurons scattered from the central nucleus of the amygdala through the basal forebrain to the bed nucleus of the stria terminalis. These specialized pathways provide parallel avenues from anterior cingulate and posterior orbitofrontal cortex to central autonomic structures.

Functional Relatedness of Cortical and Subcortical Connections of Prefrontal Cortices

Structures that are anatomically connected collaborate in distinct functions. For example, lateral prefrontal cortices in the posterior part of the principal sulcus and the adjacent prearcuate cortex have a role in working memory, as do the parts of the MD thalamic nucleus with which they are bidirectionally linked. Experimental inactivation of the lateral prefrontal cortex disrupts neuronal responses in the MD thalamic nucleus, observed during working memory tasks, suggesting the interdependence of these structures in behavior. The frontal eye fields have additional thalamic connections with intralaminar neurons, and in both structures neurons have visual and visuomotor properties. The prearcuate and lateral intraparietal regions are also strongly connected bidirectionally, and both have a role in oculomotor responses related to cognitive operations.

Posterior orbitofrontal and anterior cingulate areas are connected with the magnocellular part of the MD thalamic nucleus and with midline and anterior thalamic nuclei, and all of these structures have a common role in long-term memory and emotional memory. Similarly, the polymodal nature of projections to the posterior orbitofrontal region is matched by an equally polymodal input from the same high-order sensory association cortices to the amygdala (Figure 6). In turn, the amygdala and the orbitofrontal cortices have strong bidirectional connections, involving the same parts of the amygdala that receive input from sensory and polymodal cortices (Figure 7). Finally, medial prefrontal cortices have the strongest connections with central autonomic structures in several distinct brain regions. These pathways include hypothalamic and brain stem autonomic centers, basal forebrain structures, and nuclei of the amygdala that are preferentially connected with central autonomic structures.

Summary

Specialized sectors of the prefrontal cortex have a distinct set of connections and complementary roles in cognition, memory, and emotion. Cortical input to each prefrontal sector is complemented by connections with functionally related subcortical structures. The connections of the prefrontal cortex with the MD thalamic nucleus appear to unify them as one cortical region, though they occur with topographically and functionally distinct sectors of the MD thalamic nucleus, consistent with the specialization of each region in cognitive, mnemonic, and emotional operations.

Notwithstanding the distinctiveness of the set of connections of each prefrontal sector, there are connections between prefrontal sectors, suggesting that they function synergistically in behavior. Moreover, the different sectors of the prefrontal cortex target specific layers of each other, in an intricate but highly ordered communication system. The posterior orbitofrontal and anterior cingulate areas, for example, issue projections through their deep layers, and their axons terminate in the upper layers of eulaminate prefrontal cortices, especially layer I, suggesting 'feedback' communication. Conversely, eulaminate prefrontal areas communicate with anterior cingulate and orbitofrontal cortices through their supragranular layers (layers II–III), and their axons reach the middle–deep layers of noneulaminate cingulate and posterior orbitofrontal cortices. Reciprocity of connections is a common feature in cortical systems and appears to be fundamental to normal function. In their participation in bidirectional circuits, posterior orbitofrontal and the anterior cingulate cortices may function as feedback systems to the neuraxis. The frequent involvement of posterior medial and orbitofrontal cortices in neurologic and psychiatric diseases may be related to disconnection of feedback systems necessary for the synthesis of cognition, memory, and emotions, as these areas are linked with other parts of the prefrontal cortex.

Premenstrual Dysphoric Disorder and Postpartum Major Depression: Chronobiology

B L Parry, C J Meliska, A M López, L F Martínez, D L Sorenson, S Nowakowski, and R T Loving, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Women have at least twice the risk of developing a major depressive episode (MDE) compared with men. They are prone to develop depressive episodes during times of reproductive hormonal change during the menstrual cycle, the postpartum period, and the menopause transition. This chapter focuses on depressive mood changes that occur during the menstrual cycle, termed premenstrual dysphoric disorder (PMDD) in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), and during the postpartum period. Some 3–5% of menstruating women experience PMDD, characterized by moderate to severe changes in mood (depression, anxiety, irritability, affective lability, anhedonia), cognition (difficulty concentrating, sense of being overwhelmed), and physical functioning (sleep, energy, appetite, pain). These disturbances interfere with work, school, or usual social activities and relationships with others. The PMDD diagnosis must be confirmed by prospective daily ratings which document that at least five of the symptoms are present most of the time during the last week of the luteal (premenstrual) phase, and begin to remit within a few days after the onset of the follicular phase (menses). Premenstrual mood symptoms usually begin during the teens to late 20s; women often seek treatment in their 30s. Selective serotonin reuptake inhibitor (SSRI) antidepressants, fluoxetine and sertraline, are approved by the Food and Drug Administration (FDA) for treatment of PMDD.

Postpartum depression is categorized as an onset specifier for mood disorders in the DSM-IV. Postpartum psychiatric syndromes have three types of presentation. (1) The maternity or 'baby blues,' occurring in 50–80% of postpartum women, is not considered a disorder. It is characterized by crying and rapid mood shifts after the third postpartum day, often remitting 7–10 days postpartum. (2) An MDE postpartum, occurring in 10–15% of mothers, 25% of whom may require hospitalization, generally has an insidious onset characterized by anxious, agitated features with sleep disturbance (even when the child is sleeping) within 4–6 weeks postpartum and sometimes progressing to symptoms of melancholia that peak 3–5 months postpartum. (3) Postpartum psychosis occurs in 1/500–1/1000 primiparous women; with subsequent deliveries, the risk increases to 1/3 to 1/5. Onset is typically acute, occurring within the first 2 weeks postpartum. It is characterized by hallucinations and delusions and represents a medical emergency that may require hospitalization to prevent infanticide, which occurs in 1% of women with postpartum psychosis. When treated early and aggressively with antipsychotic (but not atypical) medication for at least 6–8 weeks, with close follow-up for 6–12 months postpartum, prognosis is relatively good. Untreated, postpartum depression and psychosis become more severe with time, more likely to recur (one-third of episodes outside of the postpartum period), and more refractory to intervention, causing extensive disability to the woman and her family, and potentially impairing neurocognitive development of the child.

Alterations in reproductive hormones may exert pathogenic effects in predisposed individuals by influencing the circadian system. When estrogen and progesterone decline postpartum, or during the luteal phase of the menstrual cycle, they may destabilize the normal temporal relationship between the circadian rhythms of melatonin, cortisol, thyroid hormones, prolactin (PRL), and sleep. To elucidate the role of these hormones in depressive disorders linked to the reproductive cycle in women, it is important to examine the diurnal secretion of these hormones in relation to the light/dark cycle of the environment, to sleep, and to each other, as each of these factors influences the expression of biological rhythms.

Studies of the amplitude, phase, and temporal organization of the circadian rhythms of these hormones during reproductive epochs reveal differences between depressed patients (DPs) and matched healthy normal control (NC) women. Women with PMDD have decreased morning secretion of melatonin in the symptomatic luteal, compared with the asymptomatic follicular, menstrual cycle phase. In postpartum major depressive disorder (MDD), subjective and objective measures of sleep disturbance distinguish DP from NC women. Further study of circadian measures in well-defined diagnostic groups is needed to identify common versus distinctive neuroendocrine profiles for DP during each reproductive epoch. This information could serve as a basis for developing more specific treatment modalities.

Menstrual Cycle Circadian Neuroendocrine Studies

Menstrual Cycle Sleep Studies

Healthy women. Subjective sleep reports in six healthy women show sleep duration was an hour longer and most disturbed premenstrually (5 days preceding the onset of menses), and shortest at ovulation. In case histories, two adolescent females reported hypersomnia associated with menstruation. Small sample sizes and lack of objective measures of sleep, mood, or reproductive hormones to define menstrual cycle phase limit interpretations of these studies.

Objective sleep recordings in 13 healthy women showed that rapid-eye-movement (REM) sleep latency was shorter during the luteal, compared with the follicular, menstrual phase. Three study subjects, however, used oral contraceptives, and the follicular and luteal phase measures were not randomized or sequential.

In a careful study of objective and electroencephalogram (EEG) power density throughout one menstrual cycle (phase determined by temperature and hormonal measures), nine healthy women without symptoms of premenstrual syndrome (PMS) showed no significant variations across the menstrual cycle in subjective mood and sleep quality, or in objective measures of total sleep time, sleep efficiency, sleep latency, REM, or slow-wave sleep. Spectral analysis of non-REM (NREM) sleep, however, showed a large variation in power density (14.25–15.0 Hz band of sleep spindles) across the menstrual cycle, with a maximum in the luteal phase that paralleled core body temperature activity. In contrast, the time course of EEG slow-wave activity (reflecting homeostatic sleep regulatory mechanisms) did not vary across the menstrual cycle.

To investigate diurnal fluctuations of sleep propensity in the follicular and luteal phases, excluding masking effects of light and behavior, investigators conducted multiple nap tests using an ultrashort sleep–wake cycle in eight healthy women (20–23 years of age) without sleep disorders. Although there were no nighttime sleep differences between the two menstrual cycles, daytime (09:00–16:30 h) subjective sleepiness and napping increased from the follicular to the luteal phase, suggesting a relation to mechanisms controlling slow-wave sleep.

Depressed women. In one study, increased REM sleep premenstrually was correlated with severity of 'premenstrual tension' in four normal individuals and three inpatients with diagnoses that included depression and schizophrenia. Total sleep time and number of awakenings were unchanged; however, the fact that the subjects were taking medications, including oral contraceptives and stimulants, compromises the interpretation of these findings. While collecting sleep EEG data from four female students for eight nights over a single menstrual cycle, investigators found an increase in stage 2 and a decrease in delta (deep) sleep at the time of menses in the one subject who reported dysphoric mood premenstrually. Similarly, researchers compared sleep EEG, temperature, and activity two nights per week over the course of a menstrual cycle in eight women with moderate to severe premenstrual depression, with that of eight age-matched controls, after adaptation to the sleep laboratory. Depressed women had more stage 2 sleep and less REM sleep than healthy controls. Stage 3 sleep and the frequency of intermittent awakenings, but not temperature or motor activity, varied with menstrual cycle phase. Other investigators showed that women with premenstrual negative effect had less delta sleep than asymptomatic women during both follicular and luteal menstrual cycle phases. In contrast, another group of scientists observed no significant polysomnographic (PSG) changes related to the menstrual cycle in nine sleep parameters or differences between three patients with PMS (diagnosed by interview and a visual linear analog scale) and six control subjects.

Menstrual Cycle Melatonin Studies

Healthy women. One study showed a phase delay of the nocturnal peak of melatonin secretion during the mid-menstrual period (mid-cycle), although melatonin was sampled only every 2–4 h at two points in the cycle and without documentation of estradiol or progesterone levels. Other investigators found melatonin circadian rhythms were relatively stable and resistant to hormonal influences during the menstrual cycle in NC women. As noted above, eight healthy women who underwent an ultrashort sleep–wake cycle schedule had decreased serum melatonin secretion in the luteal, compared with the follicular, menstrual cycle phase.

Depressed women. In one study, melatonin secretion had an earlier (phase-advanced) offset, shorter secretion duration and a decreased area under the curve (AUC) in eight women with PMDD. In contrast, melatonin rhythms in eight NC women remained unchanged during four phases of the menstrual cycle. In a larger follow-up study of 21 PMDD and 11 NC subjects, melatonin onset time was delayed, duration was compressed, and AUC, amplitude, and mean levels were decreased in PMDD subjects, during the symptomatic luteal compared with the asymptomatic follicular menstrual cycle phase. Melatonin rhythms remained unchanged with the menstrual cycle in NC subjects.

Menstrual Cycle Cortisol Studies

Healthy women. Using ultrashort sleep–wake cycles in eight healthy women, scientists observed that the amplitude of cortisol rhythms was decreased in the luteal, compared with the follicular menstrual cycle phase.

Depressed women. In eight women with PMDD who had multiple samplings for cortisol during mid-cycle (late follicular) and the late luteal (LL) menstrual cycle phase, investigators reported that serum cortisol levels were increased during the mid-cycle phase. In 20 women with LL phase dysphoric disorder (LLPDD) and 11 NC subjects, in whom cortisol levels were measured every 30 min from 18:00 to 09:00 h, during the mid-follicular (MF) and LL menstrual cycle phases, in NC, but not in LLPDD, subjects, the cortisol peak was significantly delayed in the LL compared with the MF menstrual cycle phase. In a study of 15 women with PMDD and 15 NC subjects, timing but not quantitative measures of cortisol secretion were altered in PMDD versus NC: in the LL versus MF phase, the cortisol acrophase occurred 1 h earlier, on average, in NC, but not in PMDD subjects.

Menstrual Cycle TSH Studies

Healthy women. In the study of eight healthy women undergoing ultrashort sleep–wake cycle schedules, thyroid-stimulating hormone (TSH) rhythm amplitude decreased in the luteal, compared with the follicular menstrual cycle phase.

Depressed women. In a study of the circadian rhythms of TSH in 23 PMDD and 18 NC subjects in which samples for TSH were measured every 30 min from 18:00 to 09:00 h, TSH acrophase (time of the highest point of a fitted cosine curve) and peak time (based on absolute values) occurred earlier in PMDD than in NC subjects during MF and LL menstrual cycle phases.

Menstrual Cycle PRL Studies

In a study of 20 LLPDD and 11 NC women, investigators measured PRL every 30 min from 18:00 to 09:00 h during MF and LL menstrual cycle phases. PRL peak and amplitude were higher, and acrophase earlier, in LLPDD patients, than in NC subjects. In a related study of 23 PMDD and 18 NC subjects, PRL during MF and LL menstrual cycle phases was higher in PMDD than in NC subjects, consistent with previous findings.

Postpartum Circadian Neuroendocrine Studies

Postpartum Sleep Studies

Healthy women. Using subjective ratings, 30 primiparous women reported more evening awakenings, more time awake after retiring, and more naps than 28 nonpostpartum mothers, but sleep times were similar. Controlling for time awake at night indicated dysphoric mood in the first week in postpartum women was due to sleep disruption. Other investigators compared 12 primigravidae with 19 multigravidae. Primigravidae experienced more fatigue and disturbed sleep, third trimester sleep efficiency falling from 90% to 77% postpartum, while multigravidae had only a minor reduction in sleep efficiency. In a study of seven Japanese women, based on subjective sleep logs, wake time at night gradually decreased from the 5th to the 12th week postpartum. Hormonal measures were not specified in these studies.

Most PSG assessments suggest REM sleep decreases after delivery. Researchers noted only a slight increase in REM sleep in seven women in the postpartum, compared with the prepartum period. Sleep efficiency increased, and wake after sleep onset decreased by 3–5 months postpartum. A study of 31 women showed REM latency was shorter at 1 month postpartum, when mood state was most negative compared with the third trimester of pregnancy. In a cross-sectional study, other investigators compared 12 nonpregnant Japanese women with 10 primipara women at home from 9–12 weeks postpartum. Postpartum women had more interrupted sleep, lower sleep efficiency, decreased total sleep time, decreased stage 2 and increased stage 4 sleep. Another group found that 12 postpartum women who breast-fed babies (from 4 to 30 weeks) had increased slow-wave sleep, and a compensatory reduction in light NREM sleep compared with seven women who bottle-fed infants, or with 12 age-matched control subjects studied during the follicular menstrual cycle phase. Other investigators found total sleep time and sleep efficiency deteriorated in 10 women from the 5th prepartum to the 15th postpartum week, compared with late pregnancy, for 12 weeks after delivery. Increased wake after sleep onset persisted for 10 weeks postpartum. Studying arousal to auditory stimulation in six women showed that compared with pregnancy, there was a significant lowering of awakening threshold postpartum during stage 2, REM, and slow-wave sleep.

Depressed women. Compared with 28 women without pregnancy-related depressive episodes, 24 women with postpartum episodes that began during pregnancy had significantly longer REM time and more REM activity, suggesting a greater biological vulnerability to depression. Studies comparing women with ($n = 14$) and without ($n = 20$) a history of mood disorder show childbearing was associated with greater changes in total sleep time, and with REM reduction, apparently earlier in the childbearing course, that persisted throughout the 8th postpartum month in

women with prior history, supporting the association between sleep abnormalities and a vulnerability to mood disorders. Sleep disturbances diagnostic for MDE are strongly associated with the risk of future depression. As demonstrated for MDE, sleep disturbance may antedate subsequent postpartum depression. In a PSG study of 15 postpartum DP and eight NC subjects, DP had a longer sleep latency, later sleep onset time, lower sleep efficiency, and less total sleep time than NC subjects.

Postpartum Melatonin Studies

A study of 11 women with an MDE postpartum and five matched NC women showed DP had a trend toward higher mean melatonin peak and AUC compared with NC subjects. When age, weeks postpartum, and body mass index (BMI) were applied as covariates in the analysis, melatonin offset was significantly later in DP than in NC (09:23 vs. 07:52 h). Other timing measures (onset, duration) were not significantly different between groups.

Although not systematically studied in postpartum women, melatonin levels were reported lower in most studies comparing DP with NC subjects, consistent with replicated studies demonstrating lower melatonin circadian rhythms in patients with PMDD and in combined pregnant and postpartum DP compared with NC.

Postpartum Cortisol Studies

Investigators measured cortisol and progesterone from 2 weeks before delivery to day 35 postpartum in 120 primiparous women. Seven women developed major depression postpartum. Lower levels of evening cortisol (but not progesterone) in the immediate peripartum period were associated with postnatal depression. Another study, however, reported no significant differences in serum cortisol between 11 DP and five NC postpartum subjects.

Postpartum PRL Studies

PRL concentrations obtained at 20 min intervals for 12–24 h remained elevated in eight nonlactating healthy postpartum women, 20–26 days postpartum, with the diurnal pattern of secretion conserved. Serum PRL concentrations declined with each successive postpartum week. Another examination of plasma PRL between 08:00 and 09:00 h just prior to delivery and 3 days postpartum in 25 NC women showed the rise in PRL plasma levels postpartum had a negative and significant correlation with scores on the Hamilton Anxiety Scale, suggesting that high PRL plasma levels associated with milk production reduced anxiety in lactating women. When a group of 43 lactating women was randomly assigned to either breast-feed or merely hold their infants, both conditions decreased anxiety, as well as lowering adrenocorticotropin (ACTH) and plasma cortisol. Breast-feeding (but not holding) reduced cortisol responses to a brief psychological stressor.

In postpartum DP, researchers observed that of 147 postpartum mothers, 14.9% of whom were depressed, plasma PRL levels were inappropriately low in depressed women who breast-fed. In other studies, however, hyperprolactinemia has been associated with depressive symptoms. In a study of 11 postpartum DP and five NC subjects, in which serum PRL was sampled at 30 min intervals from breast-feeding mothers, PRL was elevated from 04:00 to 11:00 h in DP relative to NC, when weeks postpartum and BMI were applied as covariates in the analyses. In contrast, other investigators found lower plasma PRL levels in postpartum depressed women when only a single morning sample was obtained.

Reproductive Hormones

Estradiol. In 15 DP and eight NC postpartum women, estradiol was significantly lower in DP than NC when age, weeks postpartum, BMI, and breast-feeding status were applied as covariates in the analyses. DP and NC groups did not differ in progesterone, luteinizing harmone (LH), and follice stimulating harmone (FSH) levels. When applied as covariates, levels of reproductive hormones did not affect the outcomes of statistical analyses of other neuroendocrine measures.

Comparisons of Sleep and Circadian Neuroendocrine Hormones across Reproductive Events

Sleep in Menstrual Cycle versus Postpartum Women

Longer sleep latencies, later sleep onset times, and reduced stage 3 percentage sleep distinguish PMDD versus postpartum DP, while menstrual NC women show less stage 3 percentage and delta percentage sleep compared to postpartum NC women.

Neuroendocrine Hormones in Menstrual Cycle versus Postpartum Women

As expected, postpartum NC and DP women who breast-fed had higher PRL levels than nonlactating menstrual cycle women. In contrast, TSH levels were reduced in postpartum breast-feeding women compared with menstrual cycle women, when controlling for age and weeks postpartum. Nonbreast-feeding postpartum women did not differ from

menstrual cycle women in any of these neuroendocrine measures. A comparison across reproductive events showed that serum TSH levels of menstrual cycle women were marginally higher than postpartum women in NC and DP combined; DP and NC women did not differ reliably.

Summary

Menstrual Cycle Studies

While some studies suggest lighter, more disturbed sleep premenstrually and increased REM sleep and decreased REM latency in DPs, we must consider the marked inconsistency in the results, which can be attributed to variability of methods, small sample sizes, subjects on different medications, or lack of hormonal measures to define menstrual cycle phase and no standardized criteria to diagnose depression.

For menstrual cycle studies of serum or plasma melatonin, those that sampled more frequently, for example, at 30 min intervals, suggest that melatonin circadian rhythms are relatively stable and resistant to hormonal influences during the menstrual cycle in NC subjects. In contrast, women with well-defined mood symptoms during the menstrual cycle have decreased amplitude (quantitative) measures of melatonin, which are associated with changes in phase markers, in the symptomatic luteal phase. The findings suggest DPs have decreased amplitudes of the circadian pacemaker that impairs their ability to regulate biological rhythms.

With regard to cortisol, TSH, and PRL circadian rhythms during the menstrual cycle, the data suggest greater differences between healthy and depressed women in the timing, rather than in the quantitative measures of cortisol secretion. TSH levels are marginally higher in menstruating than in postpartum women, but do not differentiate DP and NC women. In contrast, increased PRL amplitude measures differentiate DP versus NC during the menstrual cycle. Sleep architecture studies in DP versus NC women generally have inconsistent findings, although most women with PMDD report more disturbed sleep premenstrually.

Postpartum Studies

In postpartum sleep studies, the general findings suggest that postpartum sleep is disrupted and does not return to baseline levels until at least 12 weeks postpartum (at which time the infant's sleep and melatonin rhythms tend to establish diurnal patterns).

Postpartum studies of melatonin, cortisol, TSH, and PRL circadian rhythms suggest melatonin and PRL are elevated in postpartum compared with healthy women. In contrast, in healthy postpartum women, higher PRL levels were associated with decreased anxiety in lactating women. Estradiol levels were lower in DP compared with NC postpartum women when age, weeks postpartum, BMI, and breast-feeding status were applied as covariates in the analyses. Impaired sleep, as measured primarily by objective (i.e., PSG) quality of sleep indices (e.g., decreased total sleep time and sleep efficiency, increased sleep latency, and delayed sleep onset) characterize postpartum DP compared with NC women.

Conclusions

Certain circadian neuroendocrine features distinguish DPs from healthy controls across reproductive epochs. Elevated PRL levels characterize menstruating and postpartum depressed women. Melatonin levels are lower in menstruating depressed women and higher in postpartum depressed women compared with healthy women. In future work, neuroendocrine variables should be examined for the influence of modulating factors such as age, season of the year studied, BMI, menstrual cycle phase, week postpartum, breast-feeding status, and estradiol and progesterone levels in well-defined diagnostic groups. With more precise measurements and larger sample sizes, further work in each of these reproductively related depressive disorders would serve as the basis for developing treatment modalities targeted to each specific population. These endeavors also have the potential to yield valuable information on how changes in reproductive endocrine function affect the brain's regulation of circadian rhythms and mood.

Premotor Areas: Medial

J Tanji and E Hoshi, Tamagawa University Research Institute, Tokyo, Japan

© 2009 Elsevier Ltd. All rights reserved.

Overview

At least five premotor areas are present in the medial part of the frontal cortex (see Figure 1). The supplementary motor area (SMA) is located immediately anterior to the hindlimb representation area of the primary motor cortex (M1). The SMA occupies the medial wall of the cortical hemisphere above the cingulate sulcus, extending several millimeters into the dorsal surface. The pre-SMA is located rostral to the SMA. Although both of these areas correspond to the medial agranular cortex (area 6), the anatomical connectivity of these two areas is strikingly different, suggesting different functional roles. Cingulate motor areas (CMAs) are located in the banks of the cingulate sulcus and should be distinguished from the cingulate gyrus (occupying the medial wall below the cingulate sulcus), which belongs to the limbic cortex. The rostral part, CMAr, corresponds to area 24 occupying the upper and lower banks of the cingulate sulcus. The caudal part, CMAc, is often subdivided into two parts corresponding to the upper and lower banks of the sulcus. The supplementary eye field (SEF) is an oculomotor area located anterolateral to the pre-SMA. The organizational principles of these medial motor areas are similar in humans and nonhuman primates.

Clinical investigations in human patients have discovered that unlike the primary motor cortex, lesions in the medial premotor areas cause little if any motor paralysis. Instead, the clinical signs include impairment in the initiation of voluntary movements or the release of reflexive hand movements (forced grasping in response to sensory stimuli). Moreover, the release of certain voluntary motions takes mysterious forms, including the alien hand sign, forced tool use, or the release of well-learned, routine motions. Furthermore, impairments in the temporal organization of sequential movements, the correct sequencing of multiple movements, the coordination of bilateral limb movements, or the rhythmic organization of motor routines have been the focus of attention in the literature describing the effects of lesions in the medial motor areas. Corresponding to these intriguing clinical findings, basic studies in system neuroscience have made discoveries that characterize each of the medial motor areas. Above all, the analysis of cellular activity in monkeys performing motor tasks has revealed the preferential use of individual areas for various aspects of motor behavior.

SMA

The SMA was first described by Penfield and Welch as the secondary motor area in humans. The term 'supplementary' was selected because of subtle lesion effects and the less striking effects of electrical stimulation than those observed in the M1. However, subsequent studies revealed that this area is involved in important aspects of motor control in a way very different from the M1. For many years since its discovery, the SMA was viewed as a single motor area. Based on anatomical and physiological studies, it is now established that the traditionally defined SMA should be divided into two different areas: the caudal area, now redefined as the SMA, and the rostral area, called the pre-SMA. These two areas, which have different anatomical connections with other brain areas, are now viewed as separate areas with distinct functional properties. In addition, a separate area involved in oculomotor control (the SEF) has also been identified at a cortical site situated rostrolateral to the pre-SMA.

Basic Organization and Anatomical Connectivity

In both humans and monkeys, the SMA is organized somatotopically. Its subareas representing the face, forelimb, trunk, and hindlimb are arranged in essentially an anterior-to-posterior order in such a way that the face area is immediately posterior to the pre-SMA and the hindlimb area is rostral to the hindlimb area of the M1. The distal and proximal parts of the limb are represented in the SMA, indicating that this area is not merely the area for postural control. The SMA sends its output to other motor areas in the cortex, the M1 and premotor cortex, and to the striatum, brain stem, and spinal cord. It receives afferent inputs from the primary and secondary somatosensory areas, as well as from the M1, premotor cortex, and CMAs. Through afferents coming from the thalamus, the SMA receives more information from the basal ganglia than from the cerebellum.

Effects of Lesions or Inactivation

In humans, the clinical consequences of ablation of the medial frontal cortex, including the SMA, have been reported as deficits in initiating movements or speech, the release of pathological reflexive movements (forced grasping), and at later stages, the involuntary release of learned movements. It is important

Figure 1 Schematic drawing of the cortical areas in the macaque frontal cortex. The lateral view is illustrated in the bottom panel. The top panel shows the medial view in an inverted manner. The cingulate sulcus is opened; its lips are depicted with solid lines, and its fundus is depicted with a broken line. CMAd, dorsal cingulate motor area; CMAr, rostral CMA; CMAv, ventral CMA; FEF, frontal eye field; M1, the primary motor cortex; PFC, prefrontal cortex; PMC, premotor cortex; pre-SMA, presupplementary motor area; SEF, supplementary eye field; SMA, supplementary motor area.

to note that as long as the lesions do not include the M1, the limbs are not paralyzed. Instead, patients are reported to be impaired in organizing sequential movements temporally, exerting rhythm control, or coordinating the limbs bilaterally. In nonhuman primates, the effects of ablation of the SMA have been reported to be subtle, unlike the effects of M1 lesions. No gross changes in general motor behavior are apparent, and effort is required to specify the nature of the deficits in motor behavior after ablation. The lesion effects include the inappropriate use of both hands in retrieving food and impairment in selecting between movements or changing between movements without external instructions. Transient inactivation of the SMA by the local injection of an inhibitory substance also demonstrated that the effects are subtle. If movements are triggered by visual signals, the reaction time is not altered. In contrast, SMA inactivation leads to impairment in arranging multiple movements in the correct order on the basis of memorized information.

Functional Brain Imaging Studies in Humans

Functional imaging of the human brain has provided evidence that the medial frontal cortex is involved in multiple aspects of motor control. Early cerebral blood flow studies emphasized differences in the participation of the medial frontal cortex and M1 in various aspects of motor control. Subsequent studies revealed the need to delineate separate areas in the medial wall. The level of the anterior commissure (the VCA line) is used as the border between the SMA and pre-SMA. The SMA, located caudally, has been found to be active in association with relatively simple motor tasks, such as key pressing, joystick manipulation, tracking, and fixed-direction finger movements, as well as in sequential finger movements. Imaging studies have also hinted at somatotopy in the SMA. In contrast, the pre-SMA is active during the performance of relatively complex motor tasks, such as sequential key pressing, conditional pointing movements, and playing a musical score. During speech tasks, the pre-SMA is activated more often during demanding verbal tasks, whereas the SMA is active during the simple repetition of words. The acquisition of new motor skills leads to more activation of either the SMA or the pre-SMA.

Functional Role of the SMA Suggested from the Analysis of Cell Activity

Cells in the SMA are often active when one is initiating or planning to initiate limb movements, regardless of whether the movements are triggered or self-initiated. Activity is observed when an individual is initiating either simple or complex organized movements. These observations led to the view that the SMA is similarly involved in the initiation or preparation of limb movements. However, just because cells in both the SMA and M1 fire on initiation of limb movements, it does not necessarily follow that the functional meaning of the cellular activity is similar. To address this issue, researchers trained monkeys to select three different distal movements: to press a key with the digits of the right or left hand alone or both together. Cells in the M1 are typically active in association with contralateral hand movements. Therefore, the activity accompanying a right-hand key press or bilateral (simultaneous) key press was similar. However, a majority of SMA cells behaved differently. SMA cells were typically active before the initiation of the right-hand key press only (and not before the bilateral key press), or the left-hand key press only, or exclusively when both hands pressed the key together (Figure 2). This implies that the SMA cells are involved in selecting which hand to use rather than selecting muscles in the contralateral

Figure 2 Three examples of activity in supplementary motor area neurons exhibiting specific relationships to the use of digits in the right, left, or both hands. In the raster displays, dots represent individual discharges of a single cell. The discharges are aligned at the onset of the key press movement (↓). In the histograms below, the discharges are summed across trials. The neuron shown in (a) was active only when the animal pressed the key with digits in the right hand, but not with the left hand or both hands together. The neurons in (b) and (c) were exclusively active when the animals used the left hand and both hands together, respectively. From Tanji J, Okano K, and Sato KC (1988) Neuronal activity in cortical motor areas related to ipsilateral, contralateral, and bilateral digit movements of the monkey. *Journal of Neurophysiology* 60: 325–343.

limb (as is applicable for M1 cells). It is important to note that an observation of this sort is possible only when experiments are designed rigorously to pursue the aim of the investigation. The proposal that the SMA plays a role in selecting body parts to be used in intended actions was substantiated in a recent report. A separate report proposed a role of the SMA in the temporal organization of multiple movements; SMA cells were found to take part in retrieving the sequences of multiple movements and in temporally connecting one movement to another.

Pre-SMA

It is now established that the pre-SMA, which corresponds to cytoarchitectonic area 6aβ of Vogt, is a distinct entity separate from the SMA, which corresponds to area 6aα. Although these two adjacent areas were originally treated as a single area named the SMA in the old terminology, an anatomical and physiological basis exists for regarding these areas as separate. The pre-SMA, but not the SMA, receives substantial input from the prefrontal cortex. The SMA, but not the pre-SMA, sends output to the M1. In addition, the input–output relationships with other cortical areas, the thalamus, and the basal ganglia differ. Intracortical microstimulation of the pre-SMA gives rise to limb movements. However, the stimulation effects are more complex and variable than those observed in the SMA. Positive stimulus effects require stronger currents or a long pulse duration.

Brain Imaging Studies in Humans

Although considerable doubts remain whether the pre-SMA and SMA have been delineated convincingly using brain imaging techniques that have limited spatial resolution, some indications that the pre-SMA participates in aspects of behavioral control have emerged from numerous reports. First, concerning the control of motor behavior, this region seems to be effector-independent because similar regions are activated in manual motor and oculomotor tasks. Second, the pre-SMA is often active under conditions that activate the lateral prefrontal cortex, such as during working memory tasks, attentional shift tasks, and conditional association tasks. These reports indicate that the pre-SMA is under powerful control of inputs from the lateral prefrontal cortex. More recent studies using functional magnetic resonance imaging (fMRI) revealed activity focused in the pre-SMA that was attributable to task switching or attention to intention.

Pre-SMA Studied by Analyzing Single-Cell Activity

The first attempt to analyze pre-SMA cells found that the activity was much less strongly associated with movement initiation than that of SMA cells. This means that the pre-SMA is not very involved in specifying movements themselves. Instead, responses to visual signals and delay-period activity reflecting visual instructions were dominant. Subsequent studies revealed the role of the pre-SMA in regulating the

temporal sequences of multiple actions. In a behavioral task requiring control of the temporal sequence of multiple arm movements, pre-SMA cells were found to reflect the ordinal number in the task sequence (i.e., the first, second, or third movement; see Figure 3), as well as the order of different movements (e.g., push, pull, and turn a handle, in that order). It is interesting that the activity of pre-SMA cells also reflects the temporal structure of the oculomotor sequence during planning. This finding is consistent with the view that the pre-SMA is involved in organizing the temporal structure of forthcoming actions irrespective of the effectors (body parts) to be used. A recent study also found that the pre-SMA is not very involved in selecting the limb to be used. Instead, pre-SMA cells were found to participate in specifying a motor target in space, in a manner commonly found in cells in the lateral prefrontal cortex. Another dominant factor characterizing the activity of SMA cells is the transitional process involved in changing from one behavioral routine to another. In the first study of this, pre-SMA cells were found to be particularly active when a change occurred in the plan to reach toward a target. In a subsequent study, monkeys were trained to perform three different movements sequentially in a temporal order. The correct order was planned based on visual information before it was executed. A population of pre-SMA cells was active during the process when monkeys were required to discard the current motor plan and develop a plan appropriate for the next sequential movements. Such activity was not common in the SMA and not found in the primary motor cortex. This suggests a role of pre-SMA cells in updating motor plans for subsequent temporally ordered movements. These findings, together with the aforementioned fMRI reports, indicate a role of the pre-SMA in selecting motor behavior to conform to alterations in behavioral demands.

CMAs

In the dorsal and ventral banks of the cingulate sulcus, three distinct motor areas have been identified: the rostral CMA (CMAr) in the banks of the rostral part of the cingulate sulcus (corresponding to area 24c), the dorsal CMA (CMAd) in the dorsal bank (area 6c) caudal to the CMAr, and the ventral CMA (CMAv) in the ventral bank (area 23c) facing the CMAd. These areas all project to brain structures involved in the control of movements, such as the primary motor cortex and motor centers in the brain stem and spinal cord. This section deals with the CMAs in the human brain separately because they are often named in a manner different from traditional nomenclature.

CMAr of Nonhuman Primates

The CMAr has interconnections with limbic areas in the brain, such as the rostral and caudal parts of the cingulate gyrus, parahippocampal gyrus, and perirhinal cortex. It is also interconnected with the prefrontal cortex, premotor cortex in the lateral surface of the frontal cortex, and primary motor cortex. These wide-ranging connections suggest that the CMAr both integrates diverse sets of limbic and cognitive information and sends its output signals to motor areas. In line with the anatomical connectivity placing the CMAr at a pivotal position between the limbic and motor centers, a variety of behavioral roles have been inferred, on the basis primarily of the analysis of neuronal activity in this area. Main aspects of such behavioral factors are summarized below.

Motor control The CMAr is viewed as a motor area because this area projects to the M1, intracortical microstimulation evokes body movements, and neurons exhibit changes in activity during the execution and preparation of limb movements. It is important to note, however, that the premovement or preparatory activity, although profound, does not reflect motor parameters such as the location of motor targets or body parts to use. Therefore, the participation of the CMAr in motor control should differ in nature from that of the M1. It is conjectured that the long-lasting and prominent preparatory activity represents a general intention for action.

Processing of reward information CMAr neurons change their activity in response to reward delivery or the omission of an expected reward, consistent with the anatomical connectivity of this area with limbic structures. Furthermore, activities of the CMAr neurons reflect the expectancy of, or proximity to, a forthcoming reward. These findings suggest that the CMAr is involved in information processing relevant to a reward in the context of behavioral planning or the motivational modulation of behavior.

Performance monitoring Neurons in the CMAr are active in close temporal relation to the occurrence of a variety of behavioral events, including sensory signals, instruction cues, motor performance, and the outcomes of motor responses (correct or error). Neurons are also active in differentiating exploratory or

Figure 3 Two examples of neuronal activity during the execution of sequential arm movements, exhibiting rank order selectivity. (a) Discharges of a presupplementary motor area (pre-SMA) neuron that was most prominently active during the preparatory period before initiating the first movement. repetitive selection tasks, or behavioral sequences. These reports suggest that the CMAr is involved in monitoring the performance of ongoing behavior.

Reward-based selection of action To investigate the role of the CMAr in aspects of behavioral control based on reward information, Shima and Tanji trained monkeys to select and perform two different arm movements triggered by a visual signal. The monkeys selected the motor task themselves, based on the amount of reward. During a series of constant-reward trials, monkeys had to keep selecting a particular movement. If they detected a reduction in the reward, they chose to perform the alternate movement because if they did, the reward returned to its full amount. Muscimol injection revealed that CMAr inactivation led to the impairment of proper selection based on the reward amount. Furthermore, CMAr cells were found to exhibit changes in activity during the interval between the detection of the reduced reward and the initiation of a new movement (Figure 4). A group of cells responded shortly after the occurrence of the reduced reward, and others were active progressively before selecting the alternate movement. These findings support the view that CMAr cells take part in selecting an action based on the reward obtained as a result of the action. A subsequent study examined the effect of ablation of the CMAr and its adjacent region in monkeys performing a reward-conditional response selection task. The results of this study led the authors to conclude that the CMAr is concerned with action–reward associations and is not limited to just detecting when actions lead to errors, and that the role of the CMAr is in action–reinforcer associations but not stimulus–reward associations.

Caudal CMAs of Nonhuman Primates

The CMAd and CMAv have dense connections with the primary motor cortex and spinal cord. Intracortical microstimulation of these areas evokes limb movements with less current than required for activating the CMAr. Neurons in these areas show distinct activity changes in association with the execution of movements, with apparent selectivity for such motor parameters as the direction of arm movements. Neuronal activity specifying the precision grip by the fingers has also been reported. These findings suggest that the caudal CMAs are much more involved in movement control than the CMAr is. However, more studies are necessary to determine the specific functional roles of these areas. Although the differences in the cytoarchitecture and anatomical connectivity of the CMAd and CMAv suggest the functional specificity of these two areas, no reports have validated this contention.

CMAs in the Human Brain

In the human brain, the complexity of the cingulate sulcus precludes straightforward delineation of the CMAs. A currently prevailing view holds that the CMAs contain two major regions: the rostral cingulate zone (RCZ) and the caudal cingulate zone (CCZ). The RCZ is further divided into anterior (RCZa) and posterior (RCZp) subdivisions. Functional brain imaging studies found that the CCZ is activated primarily in relation to movement execution and that the RCZ is involved more in willed control of action, suppressing unwanted and facilitating wanted actions. The RCZ occupies a portion of an area often called the anterior cingulate cortex, which refers to a broad, ill-defined area in the anterior, inferior part of the mesial cortex. One current hypothesis emphasizes the role of RCZa in conflict monitoring and the role of RCZp in action selection.

Supplementary Eye Field

The dorsomedial frontal cortex rostral and lateral to the pre-SMA contains an area in which intracortical microstimulation evokes eye movements. This area, located inside Brodmann's area 6, is called the supplementary eye field (SEF). The SEF is interconnected with structures controlling eye movements, such as the superior colliculus in the brain stem and the frontal eye field in the frontal cortex, providing the basis for its involvement in oculomotor control. Moreover, the SEF is interconnected with the lateral prefrontal cortex and pre-SMA, suggesting the participation of this area in cognitive aspects of oculomotor behavior. Aspects of the functional roles played by this area, listed below, have been revealed primarily by studies in nonhuman primates. However, clinical studies and functional brain imaging studies in humans have confirmed that the basic principles of its morphological organization and functional properties are similar in humans and nonhuman primates.

Oculomotor Control

As commonly found in oculomotor areas, electrical stimulation of the SEF with low currents evokes eye movements. Detailed analyses have revealed that the properties of the evoked saccades are complex and vary greatly depending on the behavioral conditions. Evoked saccades could have either constant-vector or converging properties, in which the eyes tend to converge toward a certain goal in space or in the orbit.

Figure 4 Left panels: The activity of four types of rostral cingulate motor area cells (a–d) showing increased discharges after the reward (Rew) was reduced and before a newly selected movement was initiated. Each raster corresponds to a single trial when the animal switched from Turn to Push (a, b) or Push to Turn (c, d), with 5 to 12 trials in between. (a) Short-lasting activity after the reward. (b) Long-lasting, but decaying, activity. (c) Continuous activity. (d) Activity that increases progressively before the next movement. Right panels: The same four cells were not as active under the constant reward condition when the animals did not select an alternative movement. In the raster displays, small crosses denote the onset of movement. In the histograms, discharges over 11 trials are aligned with the onset of the reward and summed, except for (d), which is aligned with the onset of the next movement. The horizontal bar in the top right of a raster display indicates the time range of occurrences of the movement. From Shima K and Tanji J (1998) Role for cingulate motor area cells in voluntary movement selection based on reward. *Science* 282: 1335–1338.

It is interesting that if a stimulus is applied during an oculomotor task, the properties of the evoked saccades vary in a task-dependent manner. For example, during the period of saccade preparation, electrical stimulation can trigger saccades in the direction of a target that an animal is intending to capture in advance. An analysis of neuronal activity has also reflected the complexity of the manner in which this

area is involved in a variety of oculomotor tasks. SEF neurons typically discharge before or after the initiation of saccades, or in repose to the appearance of visual signals. Some neurons also show a buildup of activity before a spontaneous/self-paced saccade. Usually, these neurons have a preferential response field in space. It is important to note that the properties of presaccade activity could vary depending on such behavioral factors as attention, reward condition, and task training. Furthermore, an interesting hypothesis has been proposed concerning the reference frame controlling saccade direction. Some SEF neurons were selectively active preceding saccades capturing the right (or left) end of an object, suggesting that the SEF tunes saccade direction using an object-centered, spatial frame of reference.

Monitoring Oculomotor Behavior

As stated above, the activity of SEF neurons is modulated in relation to diverse aspects of oculomotor behavior. A possible interpretation of the SEF neuronal activity is monitoring, rather than generating, oculomotor behavior. For example, when monkeys are engaged in an eye movement-countermanding task that requires withholding a saccade immediately before its prepared initiation, distinct groups of neurons were active after errors, after successful withholding, and in association with reinforcement. These results suggest that the SEF plays a role in monitoring the performance of oculomotor behavior.

Control of Sequential Oculomotor Performance

Electrical stimulation of the SEF affects the performance of successive saccades that are made in conforming to two successive target flashes. The activity of SEF neurons reflects either the sequence or rank order of multiple saccades performed in predetermined sequences. These findings suggest that the SEF is involved in the executive control of sequential saccades, as well as in the cognitive control of sequential oculomotor behavior.

Summary and Conclusions

The motor areas in the medial frontal cortex are key structures constituting either a somatomotor or an oculomotor network in the cortex. With the interconnections depicted in Figure 5, each of the medial premotor areas plays a crucial role in processing information provided by perceptual or memory systems, providing a basis for generating output signals that are sent primarily from the M1 or frontal eye field. Obviously, broader anatomical networks including other cortical and subcortical areas, such as the parietal cortex, basal ganglia, and cerebellum, enable the medial premotor areas to play their part in each aspect of organizing motor behavior.

Figure 5 Diagrams representing the cortico-cortical networks involving the medial premotor areas in the frontal cortex. The top panel illustrates a network processing information necessary for generating output signals controlling body movements (somatomotor network). The bottom panel illustrates a network for oculomotor behavioral control before generating eye movements (oculomotor network). Premotor Cortex in Primates: Dorsal and Ventral

G Rizzolatti and M Fabbri-Destro, Universitá di Parma, Parma, Italy

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In primates, the motor cortex occupies the caudal part of the frontal lobe. Histologically, it is characterized by a complete, or almost complete, lack of granular cells ('agranular frontal cortex'). According to Brodmann, the motor cortex consists of two main cytoarchitectonic areas: area 4, or primary motor cortex, and area 6, or premotor cortex. Modern anatomical techniques and functional data have shown that this subdivision is inadequate. Today, there is general agreement that the agranular frontal cortex of primates is composed of seven functionally distinct motor areas. Their locations are shown in Figure 1.

Of the seven areas forming the motor cortex, two are located on the mesial surface (area F3, or supplementary motor area, and area F6, or presupplementary motor area) and four (F2, F4, F5, and F7) on the lateral convexity. F4 and F5 are often collectively indicated as the ventral premotor cortex, whereas F2 and F7 are referred to as the dorsal premotor cortex. In this article, we review the properties of the four areas located on the lateral cortical surface.

Area F5 (Rostral Ventral Premotor Cortex)

General Properties

Area F5 forms the rostral part of the ventral premotor cortex. Electrical stimulation studies reveal that area F5 contains a movement representation of the hand and the mouth. The two representations overlap to a considerable extent.

Single neuron recordings showed that most F5 neurons code specific motor acts – that is, movements with a specific goal (e.g., grasping) – rather than the individual movements forming the acts (e.g., finger movements) (Figure 2). Using the effective motor act as the classification criterion, F5 neurons have been subdivided into various classes, such as grasping (the most represented), holding, tearing, and manipulating. In each class, many neurons code specific types of hand shaping, such as precision grip, whole hand prehension, and finger prehension. Finally, whereas some neurons discharge during the whole action (e.g., opening and closing of the hand), others fire only during a certain part of the action (e.g., the last part of the grasping).

It therefore appears that F5 contains a storage ('vocabulary') of motor acts. This motor vocabulary is composed of 'words,' each of which is represented by a population of F5 neurons. Some words code the general goal of a motor act (e.g., grasping and holding). Others code how, within a general goal, a specific motor act must be executed (e.g., precision grip). Finally, other words specify the temporal aspects of the action to be executed (e.g., opening of the hand, closing it, and holding).

Approximately 20% of F5 neurons respond to visual stimuli. F5 visuomotor neurons are grouped into two classes: 'canonical' neurons and 'mirror' neurons. Canonical neurons discharge to the presentation of three-dimensional (3-D) objects. Mirror neurons discharge when the monkey observes another individual performing an action similar to that encoded by those neurons.

Canonical Neurons

The functional properties of canonical neurons have been studied using a behavioral paradigm that separates activity elicited by object presentation from that related to action execution (Figure 3). The results showed that the majority of canonical neurons respond selectively to the presentation of objects of a certain size, shape, and orientation. Typically, congruence was found between the object's physical characteristics that activate a given neuron and its motor properties.

On the basis of these results and control experiments, which ruled out the possibility that the object-triggered neuron discharges were due to motor preparation, attention, or intention to act, it was concluded that the discharge of canonical neurons, in the absence of movement, represents a potential motor act. This potential motor act may be executed or not, according to the external contingencies and intentions.

Canonical circuit Area F5 receives its main parietal input from the rostral part of the inferior parietal lobule (IPL) and in particular from the anterior intraparietal area (AIP; Figure 1). AIP neurons have been subdivided into three main classes: motor-dominant neurons, visual-dominant neurons, and visual-and-motor neurons. Motor-dominant neurons discharge during grasping in both light and dark. They are silent during object fixation. Visual-dominant neurons discharge during grasping in light and during object fixation but not during grasping in dark. Visual-and-motor neurons discharge both during grasping in light and grasping in dark. They also discharge during object fixation. Most

Figure 1 Mesial and lateral views of the macaque brain showing the cytoarchitectonic parcellation of the frontal motor cortex (areas indicated with 'F' and numbers) and of the parietal lobe (areas indicated with 'P' and progressive letters). Areas buried within the intraparietal sulcus are shown in an unfolded view of the sulcus. AI, inferior arcuate sulcus; AIP, anterior intraparietal area; AS, superior arcuate sulcus; C, central sulcus; Ca, calcarine fissure; CG, cingulate cortex; FEF, frontal eye field; IP, intraparietal sulcus; L, lateral sulcus; LIP, lateral intraparietal area; Lu, lunate sulcus; MIP, medial intraparietal area; P, principal sulcus; POS, parieto-occipital sulcus; STS, superior temporal sulcus.

AIP neurons, regardless of the class, respond preferentially or even selectively to the presentation of 3-D objects of a certain size and shape.

The neural properties of AIP and F5 neurons suggest that these two areas, which are richly connected with each other, play an important role in visuomotor transformations for object grasping. Strong evidence supporting this hypothesis derives from inactivation studies of AIP and F5 with a GABA agonist. Inactivation of each of these areas produces a dramatic deficit in the hand-shaping necessary to grasp objects.

The grasping circuit: Functional interpretations How do AIP and F5 interact? The properties of parietal and premotor grasping neurons, previously summarized, enable the proposal of a theoretical model of how visual object representations are transformed into hand movements appropriate for grasping those objects. As previously discussed, a fundamental property of AIP visual-dominant and visual-and-motor neurons is that they respond to the presentation of 3-D objects. The functional meaning of these responses can be easily accounted for if one considers the notion of affordance introduced by James Gibson. According to Gibson, the observation of an object entails an immediate selection of those of its properties that allow one to interact with it. These properties are not the figural properties of the object but, rather, the pragmatic opportunities that it offers to the observer.

It is well known that the visual stimuli features necessary for acting on objects are extracted in the dorsal visual stream. AIP visual-dominant neurons and visual-and-motor neurons represent the stage in object processing in which, following dorsal stream elaboration, object affordances become neuron triggering features. Information on affordances is then sent to F5 neurons, which code potential motor acts. Because of the congruence between F5 neuron responses elicited by a specific object affordance and the motor act they code, a given object affordance

Figure 2 Example of a 'grasping' F5 neuron. (a) Neurons discharge during grasping with mouth. (b) Neurons discharge during grasping with the right hand. Bin width = 10 ms.

is transformed into the appropriate potential motor act. Object becomes action.

The model discussed up to now takes into consideration a very simple situation, namely that each object has only one affordance. In real life, however, objects, especially those that humans use, have typically more than one affordance and may be grasped in several ways. How can this problem be solved?

Behavioral analysis of prehension showed that when objects possess several affordances, other nonvisual factors determine the selection of the affordances and ultimately how an object will be grasped. These factors are the object semantics (what is that object) and what the individual, who acts on the object, wants to do with it at that specific moment. A simple example will clarify these points. Imagine a cup. The cup has three major affordances: the handle, the top, and the body. If the cup is recognized as a cup, and the agent wants to use it in the way cups are commonly used, he or she will grasp it by the handle. However, if one wants to move the cup, the cup will be taken not by the handle but by its body or its top (Figure 4).

Thus, a more complete model of the F5–AIP grasping circuit should assume that this circuit automatically extracts not one but all the affordances of a given object and that only one of them is then selected, according to the object semantics and the agent's intention on how to use the object.

The neural substrate for selection on the basis of object semantics is most likely represented by the connections between the inferotemporal lobe (i.e., the final stage of ventral visual stream – the 'what' circuit) and AIP, whereas the neural substrate for affordance selection related to the current goal of the agent is represented by the connections between AIP and the prefrontal lobe, the cortical region in which long-term action plans are elaborated. When necessary, the pre-

Figure 3 Example of an F5 canonical neuron. Panels show neural activity recorded during three different experimental conditions: grasping in light (object grasping), object fixation, and LED fixation. Note the neuron's response selectivity for the ring. Note also that the neuron has two response peaks, one at stimulus presentation and the second during grasping. Rasters and histograms are aligned (vertical bar) with key press (onset of object presentation). Horizontal scale = 1 s. Vertical scale = spikes/bin. Bin width = 20 ms.

frontal lobe input can override the selection of affordances based on the object standard use and can select those affordances that are congruent with the agent's intention at that moment.

Mirror Neurons

Mirror neurons are a particular class of visuomotor neurons that discharge both when the monkey does

Figure 4 Schematic illustration of the steps involved in the transformation of an object (a cup) into its grasping. The neural centers involved in the process are indicated at the top of the figure, whereas the operations carried out by them are summarized at the bottom.

a particular action and when it observes another individual doing a similar action (Figure 5).

In order to be triggered by visual stimuli, mirror neurons require an interaction between an effector and an object. The sight of an object alone is ineffective. Mirror neurons show a large degree of visual generalization. Different visual stimuli representing the same action are equally effective. For example, the same grasping mirror neuron responding to a human hand grasping an object also responds when the grasping hand is that of a monkey. Similarly, the response is typically not affected if the action is done near or far from the monkey, despite the fact that the size of the observed hand is obviously different in the two conditions.

An important functional aspect of mirror neurons is the relation between their visual and motor properties. Virtually all mirror neurons show congruence between the motor responses they code and the observed action, done by another, to which they respond. Mirror neurons for which the effective observed and the effective executed actions correspond in terms of goal and means for reaching the goal have been termed 'strictly congruent.' Mirror neurons that do not require the observation of exactly the same action that they code motorically to be triggered have been termed 'broadly congruent.' They represent the majority of F5 mirror neurons.

Besides area F5, mirror neurons have also been described in the rostral part of the IPL (Figure 1). This region receives input from the cortex of the superior temporal sulcus (STS) and sends output to ventral premotor cortex including area F5. STS neurons respond to the observation of actions done by others but are not endowed with motor properties. Thus, the cortical mirror neuron circuit is formed by two main regions: the ventral premotor cortex and the rostral part of the inferior parietal lobule.

Functional role of the mirror neurons It is generally accepted that the basic functional role of mirror neurons is that of understanding actions done by others. How do mirror neurons mediate this function? The proposed mechanism is that each time an individual sees an action done by another individual, neurons which represent that action are activated in the observer's premotor cortex. This automatically induced motor representation corresponds to the one that is spontaneously generated during active action and the outcome of which is known to the acting individual. Thus, the mirror neuron system transforms visual information into knowledge.

This hypothesis was tested by experiments in which the monkey could not see the action done by another individual but had clues for understanding it. The rationale of the experiments was the following: If mirror neurons mediate action understanding, they should discharge even in the absence of action visual features.

On the basis of these considerations, two series of experiments were carried out. In the first, it was tested whether F5 mirror neurons were able to recognize actions from their sound. The results showed that mirror neurons that respond to the vision of a noisy action, such as ripping a piece of paper, also respond to its sound, without the vision of it. In the second experiment, grasping neurons were tested in two conditions. In one condition, the monkey saw a complete reaching-to-grasp action, and in the other a screen was placed between the monkey and the object to be grasped and the monkey saw only the reaching phase of it. The results showed that grasping mirror neurons started to discharge during the reaching and continued firing during the grasping, although the monkey could not see the hand–object interaction. This suggests that the observing monkey generated a mental representation of the action done behind the screen.

Correlation between Anatomical and Functional Organization of F5

F5 is not a homogeneous area, but cytoarchitectonically it consists of three sectors: area F5 convexity (F5c), the posterior part of the posterior bank of

Figure 5 Example of an F5 mirror neuron selectively discharging during monkey grasping movements and during observation of a grasping movement done by the experimenter. (a) Lateral view of the brain with the location of F5 indicated.

the arcuate sulcus (F5p), and the anterior part of the same bank (F5a) (Figure 6).

Although no differences in the motor properties of the neurons of the different F5 sectors have been described, differences have been observed in the visual properties of neurons located in the various sectors. Mirror neurons are located mostly in F5c, whereas canonical neurons are frequently found in F5p. No neurophysiological data exist on F5a. A functional magnetic resonance imaging study of awake monkeys showed an interesting difference between F5c, on one side, and F5a on the other. Whereas a full view of the action's agent activated both these sectors of area F5, the vision of a grasping hand, without the vision of the agent, activated only F5a. These data suggest that the action coding done by the rostral part of F5 enables action understanding, even when only a part of its elements are present. The interpretation of the responses of the caudal part is more difficult. One possibility is that the use of information provided by the full view of the agent is used differently by the two F5 sectors. F5a uses it for action understanding, whereas F5c uses it for preparing future actions according to who is doing the action.

Area F4 (Caudal Ventral Premotor Cortex)

Area F4 forms the dorsocaudal part of the ventral premotor cortex. Its main parietal input originates from area VIP, an area located in the fundus of

Figure 6 Areas forming monkey ventral premotor cortex (PMv). Area F5 consists of three different subareas: F5c, F5p, and F5a. The large rectangle showing PMv areas is an enlarged projection of the rectangle indicated on the lateral view of the monkey brain.

the intraparietal sulcus (Figure 1). Area VIP is the target of various visual areas of the dorsal stream. It also receives somatosensory input from the parietal cortex.

Electrical stimulation studies showed that F4 contains a representation of arm, neck, and face movements. Single neuron recordings confirmed these findings. They also showed that, similar to F5 neurons, F4 neurons do not discharge in association with elementary movements but, rather, in relation to the goal of the motor act defined, in this case, as the achievement of a spatial location.

Most F4 neurons respond to sensory stimuli. According to their effective stimulus, F4 neurons have been subdivided into somatosensory, bimodal (somatosensory and visual), and polymodal (somatosensory, visual, and auditory) neurons.

Somatosensory F4 neurons are typically activated by light tactile stimuli. Their receptive fields (RFs), which are generally large, are located on the face, chest, arms, and hands. Examples are shown in Figure 7. The preferred visual stimuli of F4 neurons are 3-D (especially moving) objects. These neurons respond when visual stimuli are presented in a specific space portion located around the monkey (spatial visual RF). In most F4 neurons, the position of the RF does not change when the gaze moves. This indicates that unlike the visual responses of visual cortical areas, which are coded in retinal coordinates, F4 visual responses are coded in spatial coordinates. This conclusion is confirmed by the observation that visual RFs, anchored to different body parts, do not change location when the body part on which the tactile RF is located is moved.

There are no systematic studies in which sensory and motor properties of F4 neurons have been investigated in the same neuron. In those rare neurons in which this relation was examined, a good congruence was found between the neuron's visual RF location and the motor field of that neuron.

The description of the properties of F4 neurons has strongly influenced the conceptualization of how space is represented in the brain. First, the presence of RFs anchored to the body demonstrated that space around the body ('peripersonal space') is coded in structures that are different from those coding space far from it ('extrapersonal space'). Second, the response properties of F4 neurons showed that spatially directed movements, such as reaching movements, are organized not according to a single reference system (e.g., head) but, rather, according to a multiplicity of reference systems anchored to different body parts. Finally, lesion experiments showed that damage to F4 results in profound deficits in space perception (spatial neglect). This indicates that action organization in space also plays an important role in space perception.

Area F2 (Caudal Dorsal Premotor Cortex)

Area F2 occupies the caudal part of the dorsal sector of area 6. F2 is not homogeneous in terms of its cortical connections. The part located around the superior precentral dimple (F2d) receives its major projections from the parietal areas PEc and PEip, two areas mostly involved in the processing of somatosensory stimuli. In contrast, the rostroventral part of F2 (F2vr; Figure 1) receives its major projections from

Figure 7 Examples of different types of tactile and visual receptive fields of F4 bimodal neurons. Gray shaded areas indicate tactile receptive fields. Solid lines around the tactile receptive fields indicate visual receptive fields.

areas MIP and V6A, two areas in which neurons have visual, somatosensory, or both visual and somatosensory responses. This anatomical organization has been confirmed by physiological data showing that whereas in F2d most neurons respond to proprioceptive stimuli, neurons in F2vr also respond to somatosensory as well as visual stimuli.

Electrical stimulation of F2 revealed that this area has a somatotopic organization, with a leg representation located dorsal to the superior precentral dimple and an arm representation located ventral to it. In addition, single neuron studies showed that within the arm field there is a particular sector where distal movements (hand and wrist) are represented. Some of these hand and wrist neurons respond to 3-D visual stimuli showing congruence between visual responses and motor properties, similar to those described for F5 neurons.

F2 neurons have been classified according to their activity before and during movements. Some F2 neurons discharge in association with movement onset (movement-related activity), some become active during the delay period when the monkey is waiting for a go signal (set-related activity), and others discharge at the appearance of the instruction stimulus (signal-related activity).

Motor properties of F2 neurons have been further investigated in two studies. The main result of the first study was that in F2vr there are a large number of neurons that code both the arm that the monkey uses to reach a target and the position in space that the monkey has to reach. In the other study, it was shown that F2 neurons respond when the monkey prepares to reach a target inside a restricted region of space, the neuron's reach field. This reach field is coded neither in retinal coordinates nor in hand coordinates, but it is a function of the spatial relationship between the target, the hand, and the eyes.

In summary, F2d appears to be involved in the control and preparation of arm and leg movement on the basis of somatosensory information. F2vr appears to have more complex properties and to be involved in the organization and control of arm movement in space.

A new dimension to the processing occurring in F2 has been identified in a study in which monkeys observed sensory events (a cursor moved on the screen) associated with a well-learned motor task. The results showed that most F2 task-related neurons exhibited the same activity pattern when the monkey actively performed the task and when

it merely observed the cursor motion. It was suggested that this F2 activity might be the neuron correlate of the monkey's internal rehearsal of the task.

Area F7 (Rostral Dorsal Premotor Cortex)

Area F7 is functionally heterogeneous. Its dorsal part contains the supplementary eye field (SEF). This field, which is richly interconnected with the frontal eye field (FEF), is primarily involved in the control of eye movements. The remaining part of F7 (ventral F7) receives its major input from the prefrontal lobe and specifically from dorsal area 46 and area 8b. A minor input to ventral F7 originates from parietal areas PGm and V6A. On the basis of this prominence of frontal connections with respect to the parietal ones, typical of the premotor areas, it has been suggested that F7 is a functional component of the prefrontal cortex rather than of premotor areas.

In accordance with this view are the results of electrical stimulation, which in contrast with F2, do not evoke consistent motor responses. Recording studies showed, however, that in F7 there are neurons that discharge in relation to arm movements. Some of them fire before movement onset; others are active also in response to visual stimuli even in the absence of a subsequent motor action.

In summary, the functions of this area, except for the part related to eye movements, are largely unknown. The available data suggest that F7 is involved in coding space and in planning actions according to information on locations of targets either present in the space around the animal or kept in memory.

Organization of the Premotor Cortex in Humans

There are no detailed physiological data on the functional properties of human premotor cortex comparable to those of the monkey. Important new findings, however, on the functional organization of human premotor areas have been obtained by brain imaging studies. These studies showed that all premotor areas are active during action execution. Some of them are also active during motor imagery and action observation.

We will not review all human studies in detail but, rather, we examine whether the general organization of the premotor region found in the monkey is maintained in humans. We first discuss the possible anatomical homologies between human and monkey premotor areas and then examine the human functional data within this anatomical framework.

Homologies between Human and Monkey Premotor Areas

The monkey lateral premotor cortex is formed by two major parts: the dorsal (PMd) and ventral (PMv) premotor cortex. The border between these two parts roughly corresponds to the spur of the arcuate sulcus. An anatomical marker that subdivides PMd from PMv is absent in humans. However, a border between these two parts may be tentatively drawn in humans on the basis of embryological data. These data suggest that the monkey superior limb of the arcuate sulcus plus the spur represents the human homolog of the superior frontal sulcus plus the superior precentral sulcus. If this homology is accepted, the border between human PMd and PMv should lie approximately at *Z* level 50 in Talairach coordinates (Figure 6).

This hypothesis is supported by the location of the FEF in the two species. In monkeys, the FEF lies in the anterior bank of the arcuate sulcus, bordering posteriorly the sector of PMv (area F4) where head and proximal arm movements are represented. In humans, the FEF is located in the anterior bank of the superior precentral sulcus. Thus, the position of the FEF appears to be a good indicator of the border between PMd and PMv.

A second important issue concerns the presence and location in humans of the two main areas of PMv (F4 and F5) and of the three subareas (F5c, F5p, and F5a) that form F5. In humans, there is no obvious histological distinction between the upper part and the lower part of PMv. The only part of premotor cortex that may be clearly differentiated from the rest of it is area 44. Classical anatomical studies suggested that the whole F5 (area FCBm of von Bonin and Bailey) should be the macaque homolog of area 44. Recent data indicate, however, that this homology is valid only for the rostral part of area F5–area F5a.

Figure 6 illustrates the possible localization of the different areas found in the monkey on the lateral premotor region of humans, as suggested by gross anatomy and the considerations previously described. In the next section, we examine the functional validity of these subdivisions.

Different Functional Roles of the Various Sectors Forming the Human Premotor Cortex

As previously mentioned, both PMd and PMv are active during action execution. However, differences in the activation of the two areas have been observed during the phase that precedes overt action execution. When individuals are asked to prepare a movement that they subsequently have to execute, PMd is strongly

activated, whereas such an activation is typically lacking in PMv. Both PMd and PMv are active during motor imagery. During action observation, PMv is strongly and consistently activated, whereas activation of PMd is only occasionally observed.

These findings suggest a clear functional similarity between human PMd and monkey F2, on the one side, and human PMv and monkey F5 on the other. This conclusion has been supported by a repetitive transcranial magnetic stimulation study in which human PMd and PMv were stimulated during grasping and lifting of a manipulandum. Disrupting the neural processing in PMv impaired positioning of the fingers on the manipulandum, whereas disrupting PMd affected the generation of proximal arm movements necessary for lifting the manipulandum. These data provide clear evidence for a dissociation between the functional roles of PMv and PMd, with PMv shaping the hand before lifting and PMd initiating motor commands for lifting.

Other imaging studies, exploiting PMv activation during the observation of actions done by others, have investigated whether this area is somatotopically organized. Actions done with different effectors (mouth, arm/hand, and leg/foot) were used as stimuli. The results showed that the observation of mouth movements determined activation of the lower part of PMv and of area 44 bilaterally. Observation of hand/arm movements determined two areas of activation: one in area 44 and the other located in the precentral gyrus, dorsal to that found during the observation of mouth movements. Finally, the observation of foot/leg actions determined an activation of a dorsal sector of the precentral gyrus.

These data should be considered with caution, however. In fact, although it is possible that PMv is organized in terms of effectors, like the primary motor cortex, it might also be possible that given its higher functional complexity, PMv is organized, at least in part, in terms of action goal. This possibility has not been studied. Despite this, the available data allow some important conclusions.

First, a somatotopic trend is undoubtedly present in PMv, with the mouth located ventrally and the foot in the dorsalmost part of PMv. Second, a representation of hand/arm movements is present in the dorsal part of PMv. It is likely that this representation corresponds to that found in monkey F4 (Figure 8). This possibility is supported by brain imaging studies that showed polymodal responses, a characteristic of monkey F4, in dorsal PMv. Third, there is a representation of hand actions in area 44. This finding may seem surprising. Area 44 is part of Broca's area, an area traditionally considered to be a speech area. In recent years, however, a large amount of evidence

Figure 8 Lateral view of human frontal lobe showing a parcellation of the motor cortex according to the proposed homologies with the monkey motor cortex. In gray: areas 6aα and 44. PrePMd (F7) corresponds to area 6aβ of Vogts. In blue: superior frontal sulcus (SF) and the upper part of the superior precentral sulcus (SP). In red: inferior frontal sulcus (IF), the ascending branch of the inferior precentral sulcus (IPa), and the descending branch of the inferior precentral sulcus (IPd). C, central sulcus.

has shown that human area 44, in addition to being a speech area, also contains a representation of finger movements and is strongly active during object manipulation. Precision grip is especially represented. These properties, also present in monkey F5, confirm the cytoarchitectonic homology between monkey F5 (particularly F5a) and area 44.

In summary, the comparison of human and monkey premotor regions clearly indicates that the basic functional organization of this region has been maintained in evolution. The most dramatic modifications have been those due to the appearance of speech and related evolution of areas mediating this function. Yet, even in this case, the presence of hand-action representation in human area 44 indicates continuity with monkey F5, where mouth and hand actions are also represented. Thus, it is likely that the development of area 44 from monkey area F5 is not only in part related to the necessity for a sophisticated motor control of the orolaryngeal tract but also, in part, to its mirror properties that before speech evolution mediated facial and gesture communication.

Prepulse Inhibition of Startle in Humans and Laboratory Models

N R Swerdlow, University of California at San Diego School of Medicine, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Mechanisms within the central nervous system (CNS) normally serve to inhibit responses to sequential or repetitive stimuli. This inhibition can be demonstrated in a variety of ways, from the millisecond refractory period that follows an action potential to the few milliseconds of suppressed cortical excitability that follow a pulse of transcranial magnetic stimulation (TMS) to the inhibition of P50 and N100 cortical event-related potentials (ERPs) when auditory click pairs are spaced at 500 ms intervals. At a clinical level, a number of neuropsychiatric disorders are characterized by failures of inhibition – deficits in mechanisms that normally inhibit the intrusion into consciousness of unwanted repetitive sensations, images, or thoughts or the expression of unwanted repetitive movements or sounds. Significantly, the neural bases for these inhibitory deficits in patients can be studied through the use of laboratory measures that assess the amount of neuronal, cognitive, sensory, or motor inhibition elicited by specific types of controlled stimuli.

Prepulse inhibition (PPI) is the normal reduction in startle magnitude that occurs when a startling stimulus is preceded 30–300 ms by a weak prestimulus (Figure 1). The inhibitory processes activated by the weak prepulse and the resulting decrement in startle amplitude are used in an operational definition of sensorimotor gating – the degree to which a motor response (the startle reflex) is inhibited (gated) by a sensory event (the prepulse) is a measure of the amount of sensorimotor gating. PPI occurs whether the prepulse and startling stimuli are in the same or different sensory modalities. It is not a form of conditioning because it occurs on the first exposure to the prepulse and pulse stimuli. Whereas the inhibitory effect of the prepulse on startle is exerted in the pons, descending forebrain influences regulate the inhibitory tone within the pons and determine the degree to which the prepulse inhibits the subsequent motor response. PPI thus appears to reflect the activation of ubiquitous hardwired centrally mediated behavioral gating processes that are regulated by forebrain circuitry.

In a conceptual model of PPI, a weak stimulus activates neural processes that blunt responsivity to sensory events during a brief temporal window. The gating window is empirically determined to be approximately 20–300 ms in duration in both rats and humans; in humans, inhibition during the initial 30–60 ms after a prepulse appears to be automatic (preconscious), whereas inhibition at longer intervals (e.g., 120–240 ms) appears to be sensitive to attentional mechanisms and conscious manipulation. Some of the earliest experimental demonstrations of PPI came in studies of the time order error in the 1930s, in which the presentation of paired S1–S2 acoustic stimuli, separated by 177 ms, resulted in a reduction in the perceived intensity of S2 and a suppression of the blink response to that stimulus. More recent studies have shown that prepulses reduce the perceived intensity of a forehead tap, a 105 dB acoustic noise, a 40 psi air puff, and a 170 V cutaneous shock. It has been suggested that the period of reduced responsivity after the prepulse momentarily protects information contained in this weak stimulus so that it can be processed without interference from subsequent stimuli.

In humans, PPI appears to increase from childhood to adulthood, reaching maximal levels by the end of the second decade, although the development of PPI prior to the age of 6 or 7 years in humans has not been fully studied. In adulthood, PPI exhibits robust test–test reliability in normal comparisons subjects over intervals of several weeks. Thus, intraclass correlations exceed 0.9 for PPI elicited over 3 consecutive weeks, using relatively intense prepulses and long prepulse intervals (e.g., 120 ms). PPI is sexually dimorphic, with higher levels in men than in women under many experimental conditions, and has also been reported to vary across the normal menstrual cycle.

In the laboratory, PPI is studied under controlled conditions. In this environment, PPI is highly sensitive to experimental conditions, including stimulus modalities and parameters, background noise type and levels, test instructions, attentional demands, and methods of response acquisition. For example, although they may generalize to many other conditions, the findings of human PPI described in this article refer primarily to uninstructed PPI acquired using discrete acoustic noise bursts as prepulses and startle pulses with 60–120 ms stimulus onset asynchronies (SOAs) and with eyeblink reponses assessed via electromyographic (EMG) measures of orbicularis oculi (OO). This artificial and very specific sampling of inhibitory CNS tone is used as a basis for understanding the more complex construct of sensorimotor gating, which, under natural circumstances, is conceptualized as being continuously active in waking humans, triggered differentially by the wide range of stimuli that constitute the natural environment. Under these

Figure 1 Stimuli for and measurements of PPI: (a) schematic representation of stimuli used to elicit PPI in laboratory measures; (b) superimposed tracings of EMG of the right OO in a normal adult male subject, from sequential trials that included either a prepulse (20 ms 4 dB noise burst over a 70 dB(A) background) followed 100 ms later by a 118 dB(A) 40 ms startle noise pulse (black shaded area) or the startle pulse alone (open area). The amount of inhibition generated by the prepulse can be appreciated visually by subtracting the shaded area from the open area. Also note the latency facilitation (shorter peak reflex latency on trial with prepulses).

natural conditions, PPI is thought to contribute adaptive value by enhancing the ability to segregate a continuous stream of sensory and cognitive information and to selectively allocate attentional resources to salient stimuli.

Specific characteristics of an individual's gating processes are viewed to be plastic, shaped by genetic and developmental forces, but also to be sensitive to changes in environment, stressors, or the neurochemical milieu of the nervous system. There is some evidence that, in clinically normal individuals, levels of PPI correlate positively with performance on certain neurocognitive tasks and, conversely, that PPI deteriorates with increasing mental fatigue. A more substantial pathological breakdown in the gating window might be expected to impair the orderly, hierarchical processing of sensory events and result in flooding of sensory information, with a fragmenting impact on cognition.

PPI in Animal Models and Preclinical Studies

One of the major advantages of PPI as a measure of CNS function and dysfunction is that it can be measured across species. Studies of PPI in rodents have been particularly valuable in delineating the neural control of PPI and in starting to identify genes and gene products that impact this neural circuitry to influence the PPI phenotype.

Measurement and Interpretation of Prepulse Inhibition

As noted earlier, PPI is most often measured in humans using EMG of the OO muscle to capture the blink component of startle. In rodents, including mice, rats, and guinea pigs, PPI is generally assessed using measures of whole-body startle. Here, the startling stimulus triggers a contraction of the skeletal muscles, which shortens the torso and elevates the back, causing the equal and opposite force to be directed through the feet to the floor of a test chamber. This force is then captured by a sensor, often integrated across a 50–200 ms window, and quantified as a peak amplitude or an area-under-the-curve magnitude. Prepulses with appropriate stimulus characteristics reduce or inhibit this force. Both whole-body and OO EMG measures have been used to measure PPI in infrahuman primates.

Whereas most measures of PPI are based on a ratio of startle magnitude elicited by a pulse under conditions with versus without a prepulse, other approaches use a measure of startle probability to quantify both the startling effect of pulses and the startle-modifying effects of prepulses. One complexity introduced by the latter approach is that it requires the categorical assessment that any nonzero level of motor activity constitutes a startle response. In practice, the sensitivity of many startle measurements is such that low levels of background motor activity (<1% of a startle signal) are often detected, even on no-stim trials (when no stimuli are presented to the subject). The interpretation of the response probability measures of PPI depends greatly on the distinction between spontaneous and stimulus-evoked motor

activity; at very low (nonzero) levels, this distinction is quite difficult.

Under certain conditions (e.g., weak prepulses or very short or long prepulse intervals) or after certain experimental manipulations (e.g., high doses of direct dopamine (DA) agonists in some strains of rats), prepulses can actually increase startle response magnitude. There is no clear consensus as to whether PPI and prepulse potentiation (PPP) reflect distinct neurobiological processes or, instead, are simply part of a continuum of prestimulus effects, with an arbitrary zero point. From a practical standpoint, many clinical and preclinical data sets ignore this possible distinction and combine trials that elicit PPI and those that elicit PPP into a single mean value; similarly, group means often reflect the combination of subjects who exhibit PPI with those who exhibit PPP. Clearly, if these reflect two distinct biological processes, an observed mean reduction of PPI might actually reflect an enhancement of PPP, and vice versa.

Except at extreme floor and ceiling levels, PPI is relatively insensitive to differences in startle magnitude to the pulse (S2) stimulus. For example, it is often the case that drug effects on startle magnitude and PPI can be dissociated experimentally, either via the use of both weak and intense startle stimuli or via analytic approaches that control for levels of startle magnitude. However, at extremely low startle values, it becomes impossible to reliably detect PPI (i.e., you cannot inhibit something that is not there), and the resulting artificial values of percentage of PPI (%PPI) can introduce substantial variability into a data set. For example, under conditions in which a startling stimulus typically elicits a response magnitude of 100 arbitrary units, a deaf rat (e.g., resulting from the use of inappropriate ear bars during stereotaxic surgery) might register a response magnitude of 1 or 2 units simply by shifting body position within the 100 ms recording window. If, by chance, this value registers on a trial that includes a prepulse, the calculated (artificial) value of %PPI might be quite extreme (e.g., −500%). Even among normal subjects, it becomes prudent to exclude a small percentage from analysis based on nonresponse criteria (which can be derived empirically from a normal distribution), as long as it can be determined that such an approach does not introduce a systematic error into the analysis.

Above certain intensities, prepulses (S1s) can elicit startle responses, and the sensitivity to this S1-elicited motor responsivity is influenced by a number of experimental factors. The relationship between the paired-pulse inhibition and PPI elicited by nonstartling cues is an area of ongoing study. At short prepulse intervals in humans (e.g., 30 ms), prepulses also reduce the latency to reflex onset and peak amplitude. This latency facilitation provides useful evidence of sensory registration. Thus, several clinical conditions characterized by a loss of prepulse effects on startle magnitude (i.e., PPI) exhibit normal latency facilitation. In these cases, the loss of PPI cannot be attributed to a failure of the CNS to detect or register the prepulse because the prepulse clearly produces a physiological change in reflex latency.

Under specific conditions, prepulses are known to inhibit the perceived intensity of the startling stimulus in addition to the motor response elicited by that stimulus. The PPI of perceived stimulus intensity (PPIPSI) has been demonstrated using startling stimuli ranging from noise bursts to air puffs to intense cutaneous shocks. PPI and PPIPSI exhibit both similarities and differences in their responses to experimental manipulations, probably reflecting both convergence and divergence in their underlying neurobiological substrates. The ability of prepulses to inhibit the perceived intensity of painful stimuli suggests that they may have clinical utility in the delivery of therapeutic shocks.

Pharmacology of PPI

PPI can be studied using laboratory measures that are largely automated, objective, and under tight parametric control and that can be adapted across several mammalian species. Because of this, PPI is a measure that is well suited to rapid throughput studies, and an active laboratory with a few test chambers can generate agonist–antagonist dose–response curves in a single day. It is thus not surprising that the pharmacology of PPI has been extensively studied in mice, rats, guinea pigs, pigs, infrahuman primates, and humans. Most of these studies have been conducted in rats, and almost all have focused on acute drug effects on the amount of PPI across a limited set of stimulus parameters. For example, relatively less is known about the pharmacology that regulates the sensitivity of PPI to different prepulse intervals, frequencies, or background noise levels; under common experimental conditions, the amount of PPI is regulated by many different neurotransmitters and neuropeptides. Although there are clear species differences, the most common findings reveal that the amount of PPI is reduced by systemic administration of DA or serotonin (5-HT) agonists or *N*-methyl-D-aspartate (NMDA) antagonists; under specific conditions, the amount of PPI is increased by atypical antipsychotics and nicotine. Neuropeptides most often implicated in the regulation of PPI are neurotensin, cholecystokinin, and corticotropin-releasing hormone (CRH).

Of the major neurotransmitters, perhaps most studied is the regulation of PPI by DA. The PPI-disruptive effects of direct DA agonists (e.g., apomorphine or

quinpirole) are generally more robust than those of indirect agonists (e.g., amphetamine or cocaine). Among direct DA agonists, PPI-disruptive effects in rats appear to require the stimulation of D2-family receptors, although such effects may be augmented by concomitant D1 stimulation. Interestingly, PPI can also be disrupted by the systemic administration of the D1 antagonist, SCH 23390. The PPI-disruptive effects of the direct D1–D2 agonist apomorphine are opposed by clinically effective antipsychotics, and the potency of antipsychotics in this model predicts their clinical antipsychotic potency ($r = 0.991$). Related models have demonstrated the ability of acute administration of atypical (but not of typical) antipsychotics to prevent the PPI-disruptive effects of the NMDA antagonist phencyclidine and the ability of typical and atypical antipsychotics to restore normal levels of PPI in adult rats that had been reared in social isolation.

Neural Substrates of PPI

PPI is mediated at the level of the pons and remains intact in the acutely decerebrate rat. Preclinical studies have demonstrated that PPI in rodents is regulated by cortical structures (mesial temporal and medial prefrontal cortex) and subcortical structures (striatum, pallidum, and pontine tegmentum). This limbic cortico-striato-pallido-pontine circuitry converges with the primary startle circuit at the level of the nucleus reticularis pontis caudalis (NRPC). Representative examples of regionally specific neurochemical manipulations that disrupt PPI in rodents are listed in Table 1.

Studies of the neurobiology of PPI in humans reveal both similarities and differences from findings in animal models. For example, evidence of profound PPI deficits in patients with Huntington's disease (HD) supports the role of the striatum in the regulation of PPI in humans, and parallel findings demonstrate PPI deficits after excitotoxic lesions of the striatum in rats and in mice transgenic for the HD gene. Neuroimaging studies in schizophrenia patients and normal comparison subjects confirm both the role of limbic cortico-striato-pallido-thalamic (CSPT) circuitry in the normal regulation of PPI (Table 1) and the association between CSPT abnormalities and PPI deficits in patients. Also consistent with a number of preclinical findings is the fact that PPI deficits are observed in other clinical populations, ranging from Tourette syndrome to seizure disorders, with known or presumed pathology in limbic CSPT circuitry.

On the other hand, pharmacological studies of PPI in normal humans raise questions as to whether the PPI neural circuit blueprint in rodents can be easily translated across species. Thus, although the indirect DA agonist D-amphetamine reduces PPI in both normal humans and some rodent strains, the NMDA antagonist ketamine and the serotonin releaser, 4-methylenedioxy-*N*-methylamphetamine (MDMA) have opposite effects on PPI across species – disrupting PPI in rodents but increasing PPI in clinically normal humans. A similar pattern is observed with the mixed DA agonist–NMDA antagonist amantadine. Direct DA agonists potently disrupt PPI in rats, but their effects in humans are not as convincing. Both atypical antipsychotics and nicotine have been reported to increase PPI across species but perhaps only under certain experimental conditions. Clearly, substantial cross-species differences in drug doses, routes of administration, and drug disposition (based on species differences in pharmacokinetics and -dynamics) complicate the comparison of PPI drug effects in rodents versus humans. Even simple mechanical differences, such as the relative distances required for impulse conduction through PPI-regulatory circuitry, might be expected to impact the temporal sensitivity of prepulse effects to drug challenges. Indeed, drugs can have opposite effects on PPI with short (10–30 ms) versus longer (60–120 ms) prepulse intervals in rodents. An additional level of complexity is added by findings that some drug effects on PPI in both rodents and humans depend substantially on the basal levels of PPI; for example, normal humans and rats with high basal levels of PPI appear to be most sensitive to the PPI-disruptive effects of DA agonists, whereas those with low basal PPI levels appear to be most sensitive to the PPI-enhancing effects of atypical antipsychotics. Last, given the considerable strain differences in PPI drug sensitivity in rodents, it is clear that different mouse and rat strains might exhibit more or less homology to humans in terms of PPI sensitivity to various drugs.

Table 1 Examples of neurochemical manipulations that disrupt PPI in rats

Brain region	*Manipulation that disrupts PPI*
Medial prefrontal cortex	D1 blockade
Basolateral amygdala	NMDA receptor blockade
Ventral hippocampus	NMDA
Nucleus accumbens core	D2 stimulation
Ventral pallidum	GABA receptor blockade
Dorsomedial thalamus	GABA receptor stimulation
Pedunculopontine nucleus	GABA receptor stimulation

D1, D2, dopamine receptors; GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate; PPI, prepulse inhibition.

Genetics of PPI

Because PPI is regulated by brain circuitry, it follows that genes that control the function of that brain

circuitry should also impact the level of PPI. Although this relationship must hold for all brain-mediated processes, the relative simplicity of PPI and the fact that it can be quantified via automated measures in laboratory animals in rapid throughput screening in controlled environments with precise parametric control have made it a popular focus for studies exploring gene–behavior relationships. Furthermore, because PPI is aberrant in several brain disorders, the identification of the genes associated with PPI carries the additional potential that PPI genes might contribute to the vulnerability for, or expression of, these disorders.

Heritability Very convincing evidence for the genetic control of PPI comes from studies in rodents. For example, Francis et al. reported that mice generated via embryonic transplants into a different maternal strain exhibited PPI phenotypes of the embryo and not of the maternal uterine or rearing environments; this contrasted with several other behavioral phenotypes, which exhibited characteristics linked to the pre- and postnatal environments. Thus, PPI appears to be linked closely to genotype in mice. PPI levels differ substantially across mouse strains, and strain-specific PPI phenotypes are stable over multiple generations.

Both basal and drug-modified PPI also exhibit profound differences across several rodent strains. For example, compared to Harlan Sprague Dawley (SD) rats, Harlan Brown Norway (BN) rats exhibit significantly greater levels of PPI at short prepulse intervals and significantly lower levels of PPI at long prepulse intervals. SD rats are also significantly more sensitive than Harlan Long–Evans (LE) rats to the PPI-disruptive effects of DA agonists; such a difference is also observed between SD and Harlan Wistar rats. This strain difference in PPI sensitivity between SD and LE rats has been found to be (1) neurochemically specific to DA agonists (i.e., not seen with NMDA antagonists or 5-HT agonists); (2) stable across breeding and testing facilities; (3) evident on or before day 18 of life and after systemic or central drug administration; and (4) inherited through F1 (SD × LE) and N2 backcross (F1 × SD) generations via an orderly pattern of DA agonist sensitivity (SD > N2 > F1 > LE), which suggests the additive effects of multiple genes. The latter heritable differences are unaffected by cross fostering and do not appear to be related to presynaptic forebrain processes but, rather, to D2-receptor-linked G-protein functions.

Only one published study has directly assessed heritability of PPI in humans. Anokhin et al. assessed PPI in 40 monozygotic and 31 dizygotic female twin pairs and used structural equation modeling to demonstrate significant heritability of PPI that accounted for over 50% of PPI variance. Menstrual cycle phase was not matched in these twin pairs, suggesting that heritability may have actually been higher given the likely added variance in this sample based on the differential hormonal state influences on PPI.

Specific genes Based on the neurobiology of PPI, it is reasonable to hypothesize that genes that impair the normal development or function of limbic CSPT circuitry should be associated with reduced PPI. Three types of evidence have been used to implicate specific genes or gene regions in the regulation of PPI. First, PPI deficits in both HD and 22q11-deletion syndrome suggest that the genes affected in both of these disorders modify brain circuitry that regulates PPI. In both of these instances, animal models with homologous genetic defects also exhibit PPI deficits. Second, quantitative trait loci (QTLs) have been identified, either through interval mapping in inbred rat strains (on chromosomes 2 and 18) or recombinant congenic mouse strains (five QTLs across chromosomes 3, 5, 7, and 16) or through the use of chromosome substitution strains in mice (two QTLs on chromosome 16). Third, reverse genetic approaches have identified a long list of genes (and molecules that they encode) that are associated with a reduction in PPI or alterations in the effects of a drug on PPI when inactivated via constitutive or conditional knockout techniques (Table 2).

Significantly, most genes and molecules associated with lower versus higher levels of PPI in mutant animals are most likely unrelated to reduced PPI in schizophrenia or other disease states. The most potent physiological influence on acoustic PPI is hearing threshold because an organism that cannot detect an acoustic prepulse does not exhibit acoustic PPI. Many studies reporting PPI deficits in mice after genetic alterations test neither hearing threshold nor levels of nonacoustic PPI. Similarly, PPI gene-mapping strategies in inbred and recombinant rodents might be expected to identify genes associated with hearing threshold. Beyond the level of sensory registration, the most potent physiological influence on PPI is exerted at the level of the pedunculopontine nucleus (PPTg), which mediates PPI via its impact on the NRPC. For the same reasons noted for hearing threshold, genetic studies of PPI are likely to be influenced strongly by genes coding for the normal function of the PPTg. And although the PPTg has been hypothesized to be abnormal in some individuals with schizophrenia, it does not play a central role in models for the pathophysiology of this disorder (although it may be relevant to other conditions characterized by PPI deficits, e.g., nocturnal enuresis). In contrast, the prefrontal cortex (PFC) – which is suspected to be a critical substrate for some symptoms of schizophrenia – is likely to be three or four synapses removed from the

Table 2 Examples of genes and molecules that have been implicated in the regulation of PPI through reverse genetic strategies in animal models

α2A-Adrenergic receptors	HD gene
Calcineurin	Homer-1
Catna2	Interleukin-2
Cell adhesion molecule L1	Lysophosphatidic acid receptor-1
CRH1 and 2 receptors	mGluR-1 and -5 receptors
DA transporter	NCAM-180
DA D2-S receptor	Nicotinic receptor β3 subunit
Dvl1	NMDA receptor subunits NR1, 2A, 2B, 3A
Fmr1	Npas3
G(s)α	Reelin
GABA transporter subtype 1	Superoxide dismutase-2
$GABA_A$ α3 and -B1 subunits	Stable tubule-only polypeptide
Glutamic acid decarboxylase 65	Tbx1
Glycine transporter subtype 1	Telencephalin
Glycogen synthase kinase 3 β	Zic2
Gnb1l	

CRH, corticotropin-releasing hormone; DA, dopamine; HD, Huntington's disease; mGluR, metabotropic glutamate receptor; NCAM, neural cell adhesion molecule; PPI, prepulse inhibition.

primary startle circuit, and in a normal human or rodent, genes controlling the PFC probably contribute only weakly to any gene mapping a signal based on levels of PPI.

Conversely, it is known that the HD gene exerts a powerful control on the viability of striatal circuitry that regulates PPI and that the pathology effected by this gene is strongly associated with low or absent levels of PPI in humans and animal models. Yet, despite this, it is almost certain that no gene-mapping efforts based on the PPI phenotype in normal rodent strains or reverse genetic models based on constitutive or conditional knockout strategies (not including the insertion of the HD gene) will ever link the HD gene to low levels of PPI. Significantly, PPI is a measure that reflects the normal function of specific brain circuits, and genes associated with PPI deficits in neuropsychiatric disorders are likely to be ones that contribute uniquely to dysfunction in those brain circuits. Such genes will be most effectively identified through the use of affected and at-risk individuals, in whom deficient PPI is used as an endophenotype – a surrogate marker for neural circuit dysfunction encoded by disease genes that contributes to the vulnerability for the expression of the full clinical phenotype.

PPI in Clinical Populations

PPI has been studied extensively as an example of normal CNS plasticity and an index of early information processing, but it is also used as a means to investigate CNS dysfunction in neuropsychiatric disorders. Deficits in PPI suggest abnormal neural activity either within the primary PPI circuitry within the pons or, more often, within the forebrain circuitry that regulates PPI. Under different testing conditions, PPI has been reported to be deficient in schizophrenia, schizotypal personality disorder, 22q11-deletion syndrome, mania, Tourette syndrome, obsessive–compulsive disorder, panic disorder, HD, blepharospasm, autism, Asperger's syndrome, fragile-X syndrome, and noturnal enuresis. Normal levels of PPI have been reported in major depressive disorder, euthymic bipolar disorder, borderline personality disorder, Alzheimer's disease, and stuttering; conflicting reports have described either reduced or normal levels of PPI in different populations of patients with posttraumatic stress disorder (PTSD).

Schizophrenia

Among these patient groups, PPI has been most extensively studied in schizophrenia. Deficient PPI has been reported not only in schizophrenia patients but also in their clinically unaffected relatives, suggesting that these deficits may be a trait marker for individuals at-risk for developing the disorder (rather than a marker of schizophrenia *per se*). The relationship between PPI deficits and clinical features of schizophrenia is not well understood. Studies report weak or no significant correlations between PPI and symptom severity. Some evidence links deficient PPI to the core schizophrenia trait (rather than symptoms) or cognitive and functional impairment. Other studies report deficient PPI only in symptomatic patients, which partially or completely resolves with medication treatment. In a study of more than 100 schizophrenia probands, we failed to detect significant relationships between PPI deficits and a number of neuropsychological measures, despite the fact that these PPI deficits did correlate significantly with measures of long-term functional impairment (e.g., Global Assessment of Function (GAF) score and level of independent living).

Relatively few studies have assessed the longitudinal stability of PPI deficits in schizophrenia patients. Whereas several groups reported PPI deficits in relatively stable, medicated outpatient schizophrenia cohorts, others reported that PPI deficits occurred only in patients who are in an acute symptomatic phase of a psychotic episode and resolve in these same patients as symptoms subside. One complexity in interpreting such state-related changes in PPI relates to the role of antipsychotic medications in both symptomatic improvement and potentiation of

PPI. Thus, it is not clear whether PPI is sensitive to the state of psychotic symptoms, the state of antipsychotic medications, or both.

Factors That Commonly Impact PPI in Clinical Studies

The interpretation of PPI levels in clinical populations is complicated by a number of factors that impact PPI in humans.

Antipsychotics In preclinical models, antipsychotics oppose the PPI-disruptive effects of pharmacological (e.g., DA agonists and NMDA antagonists), surgical (e.g., adult lesions of the basolateral amygdala or neonatal lesions of the ventral hippocampus), or developmental (e.g., isolation rearing) challenges. Some atypical antipsychotics (e.g., quetiapine and clozapine) are capable of increasing basal levels of PPI in rats and mice under conditions that elicit submaximal levels of PPI (e.g., weak prepulses and prepubertal age). Significantly, this suggests that, under some physiological conditions, antipsychotics modify processes responsible for the normal regulation of sensorimotor gating and not simply its disruption by pathological states.

Relatively little is known about the effects of antipsychotics on PPI in normal human subjects. Published studies using the typical antipsychotic haloperidol reported either no effect or PPI-reducing effects of this drug, consistent with observations in infrahumans. These reports used different sets of experimental conditions, including pure tones versus noise bursts and a range of prepulse intensities. We reported that 12.5 mg of quetiapine has no significant effects on PPI (10–120 ms intervals) in normal men; this was also observed by Graham et al., with both 12.5 and 25 mg doses of quetiapine. However, we also demonstrated that quetiapine (12.5 mg) significantly increases short-interval (20 ms) PPI in clinically normal, low-gating men (defined by basal PPI levels in the lowest quartile of a normal distribution). This latter finding, together with similar findings in normal and low-gating rodent strains, suggests that elevations in PPI by antipsychotics may not reflect processes linked specifically to the pathophysiology of schizophrenia *per se*.

The initial report of PPI deficits in schizophrenia patients predated the use of atypical antipsychotics. Preclinical studies later demonstrated that, in addition to preventing the PPI-disruptive effects of various experimental manipulations, atypical antipsychotics also enhance baseline PPI in some rodent strains and species. Subsequent clinical reports suggested that atypical antipsychotics are associated with greater and potentially normalized PPI levels in schizophrenia patients. In our recent study of over 100 schizophrenia patients, only 17% of patients were not being treated with atypical antipsychotics. Clearly, if atypical antipsychotics increase PPI in some groups of patients, the result of such pervasive use of atypical antipsychotics in schizophrenia patients (or other populations, e.g., those with Tourette syndrome) will be to diminish or eliminate the ability to detect PPI deficits between patients and normal controls and to diminish estimates of PPI heritability in any sample in which antipsychotics are used. Some studies also suggest that these schizophrenia-linked deficits are partially normalized by typical antipsychotics, and our recent findings are consistent with these reports. Because the overwhelming number of schizophrenia patients are currently treated with atypical antipsychotics, it is possible that PPI deficits in this population are a vanishing biomarker. Alternative strategies for understanding the biology and clinical implications of deficient sensorimotor gating have become increasingly important, including the use of optimized stimulus features (e.g., 60 ms prepulse intervals), broadband stimuli and prominent background noise, unmedicated schizophrenia and schizophrenia spectrum patients, and populations of low-gating controls.

Nicotine The pro-gating effects of nicotine have been reported in measures of both PPI and P50 event-related potential (ERP) suppression. If nicotine use *per se* is associated with increased PPI, then the higher rates of smoking among schizophrenia patients would be expected to diminish the patient- versus control-group differences in PPI measures and to diminish measures of heritability. However, nicotine has a complex pharmacology, characterized by rapid shifts in both blood levels and states of receptor sensitization that can influence PPI. Because of the difficulty in controlling for the time interval between PPI testing and smoking, the amount smoked, smoking history, or the interindividual differences in nicotine receptor sensitivity, the impact of smoking on measures of PPI is effectively to increase uncontrolled variance. Studies with adequate power to compare nonsmoking patients (particularly males) with normal controls revealed group PPI differences (controls > patients) with greater group separation than is observed across the inclusive group of smokers and nonsmokers. Furthermore, among patients, PPI is significantly greater among heavier smokers.

Sex differences Sex differences (male > female) and menstrual cyclicity (peak levels in early follicular phase, and trough levels in mid-luteal phase) in PPI have been reported by several different groups and may have important implications for the interpretation

of PPI differences in schizophrenia versus control populations. Typically, open subject recruitment in schizophrenia studies favors ascertainment of male patients and female controls. Because men exhibit more PPI than women, this ascertainment bias artificially diminishes the control- versus schizophrenia-group differences. Menstrual cyclicity of PPI adds uncontrolled variance that may differentially affect control versus patient samples based on the hormonal effects of neuroleptics, and without carefully timed measurements, this state-sensitive cyclicity of PPI must diminish apparent heritability. Nevertheless, PPI deficits have been reported in both male and female schizophrenia patients. Lower PPI in female versus male patients has implications for studies attempting to assess the clinical or functional correlates of PPI in schizophrenia; sex differences in PPI among patients may obscure the impact of many other moderating variables or correlates.

One group has reported that PPI differs among normal subjects based on sexual orientation. In this study, heterosexual adults demonstrated the previously reported male > female difference in PPI levels. In contrast, among self-identified homosexuals, PPI did not differ between men and women. Specifically, PPI among female homosexuals was significantly elevated compared to female heterosexuals but was comparable to levels exhibited by heterosexual males.

Other subject characteristics PPI appears to be sensitive to a number of state and trait features. As noted earlier, PPI declines with mental fatigue. It is unclear how this change relates to the inverse correlation of PPI and spontaneous blink rate because the latter also increases with fatigue. Certainly, the potential impact of mental fatigue on PPI should be considered when it is used as part of an extended phenotyping battery in patient populations. In terms of traits, PPI does not seem to be related in any robust way with personality, although some significant (negative) correlations have been reported between PPI and personality features that are conceptually linked to psychosis. Differences in PPI have been reported between normal Caucasian and Asian individuals that appear to reflect significantly lower levels of eyeblink startle magnitude in Asian subjects, associated with relatively reduced mass of the OO muscle in the Asian sample. The potential effects of botulinum toxin injections of OO on startle magnitude and PPI may also be worth considering as a source of artifact, but they have not yet been evaluated.

Summary

PPI is a simple form of behavioral plasticity that serves as an operational measure of sensorimotor gating. It is easily quantified using laboratory measures that are largely automated, objective, and under tight parametric control and that can be adapted across several mammalian species. Studies of PPI have demonstrated its regulation by forebrain circuitry, which is of relevance to a number of neuropsychiatric disorders, and clinical studies have detected PPI deficits in several of these disorders. PPI is perfectly suited to rapid throughput screening, and this, together with a well-described pharmacology, make it an ideal model for drug discovery. Our evolving understanding of the genetic control of PPI suggests that measures of PPI may play an important role in identifying the genes that convey a vulnerability to certain brain disorders, including schizophrenia. Despite the great promise of this measure to be highly informative about a number of basic and clinical issues, its sensitivity to experimental parameters, subject characteristics, and potential analytic and behavioral artifacts make it a measure that is both deceptively complex and demanding of careful, systematic study and interpretation.

Introduction

Chemical synapses are specialized sites of cell–cell contact designed for the transmission of signals between neurons and their targets – muscles, glands, or other neurons. Synaptic transmission depends on the tightly regulated secretion of neurotransmitters by the presynaptic cell and the reception of this signal by postsynaptic neurotransmitter receptors. The directional nature of synaptic transmission is manifested in the asymmetric structure of pre- and postsynaptic compartments. Structurally, presynaptic compartments are characterized by the presence of hundreds to thousands of neurotransmitter-filled synaptic vesicles (SVs) and by active zones (AZs) – specialized regions of the presynaptic plasma membrane where SVs dock, fuse, and release neurotransmitter into the synaptic cleft (Figure 1). The AZ is characterized by an electron-dense matrix or lattice of proteins (the cytoskeleton of the active zone (CAZ)), arranged into regular arrays of electron-dense tufts linked together by fine filamentous material. This structure, known as the presynaptic web or grid, is thought to define the AZ as the site of SV docking and fusion. The postsynaptic reception apparatus is also characterized by an electron-dense thickening referred to as the postsynaptic density (PSD), the central function of which is to confine receptors of the appropriate type beneath the AZ. The PSD and CAZ are held in register by transsynaptic cell adhesion molecules and extracellular matrix proteins.

Although presynaptic specializations can contain hundreds to thousands of SVs (the so-called 'reserve pool'), at any given moment only a few are 'tethered' or 'docked' at the AZ. A depolarizing action potential and the consequential opening of voltage-dependent calcium channels leads to an influx of Ca^{2+}, triggering the fusion of some docked vesicles with the presynaptic plasma membrane. SV membrane proteins are then retrieved by clathrin-mediated endocytosis in a periactive zonal region or possibly by direct retrieval of vesicles at AZs. Endocytosed vesicles are refilled with neurotransmitter, possibly after passage through specialized endosomal compartments, and returned to the reserve pool.

The formation of a new functional presynapse is a demanding process that calls for the recruitment of numerous components. These include molecules involved in SV docking, fusion and endocytosis; structural AZ proteins; Ca^{2+} channels; proteins that confine SVs to the presynaptic bouton; and the SVs themselves. In addition, presynapse formation must be tightly coordinated with the formation of the appropriate postsynaptic receptive apparatus. Here, the current state of knowledge on cellular and molecular mechanisms involved in presynapse development is summarized.

Presynaptic Development: Initial Events

Most presynaptic sites are formed during development as axons grow out and establish connections with their targets. Much of our understanding of presynapse formation comes from studies on the vertebrate neuromuscular junction (NMJ). These synapses, formed between motor neurons and skeletal muscle cells, begin to form within a few hours after the closure of the neural tube. Motor neuron axons, guided by growth cones at their tips, establish contacts with muscle targets in their final stages of differentiation. These axons grow a short distance down the midline of the differentiating muscle, giving rise to side branches in the process. Eventually, these growth cones develop into bulbous enlargements that possess a rudimentary capacity for spontaneous and evoked release of neurotransmitter. With time (many hours to days), these structures differentiate into typical presynaptic terminals and gradually acquire mature functional characteristics.

Studies concerning NMJ formation have traditionally emphasized the roles of axonal growth cones in setting off the series of events that ultimately lead to NMJ differentiation. This neurocentric view seemed natural given the motility of axonal growth cones compared to the relative immobility of developing muscles, their ability to release neurotransmitter before they contact their targets, and their capacity for inducing postsynaptic receptor clustering when placed in nerve–muscle co-cultures. Recent evidence, however, reveals that not all instructive cues are axonally derived: it has been known for many years that small neurotransmitter receptor clusters form spontaneously in muscle cells even in the absence of innervation, although the role of such receptor clusters was not clear. Recent *in vivo* experiments, however, reveal that elongating axons tend to grow toward preformed receptor clusters concentrated along the midline of differentiating muscles, and

Figure 1 A schematic illustration of a vertebrate CNS, *en passant* spine glutamatergic synapse. The active zone, including CAZ molecules, voltage-gated Ca^{2+} channels, and docked vesicles, is shaded in gray. Clathrin-dependent endocytosis of synaptic vesicles is shown to occur along the margins of the active zone (the periactive zonal area). Distal to the active zone is the reserve pool, composed of numerous synaptic vesicles enmeshed and bound to a matrix of filamentous actin (cytoskeletal elements are not illustrated for purposes of clarity). Presynaptic compartments often contain mitochondria, a small number of dense core vesicles, and additional organelles such as endosomes.

these axons subsequently develop presynaptic specializations at these sites. This phenomenon serves to indicate that presynaptic differentiation is most likely specified by postsynaptic membrane factors. Interestingly, these factors are probably not the receptors themselves. Instead, studies suggest that components of the extracellular matrix, confined to muscle midline regions, may facilitate this process. This phenomenon also serves to highlight the fact that signals that specify pre- and postsynaptic differentiation are bidirectional, and thus the historic question (that is still raised occasionally) whether synaptic differentiation is induced by pre- or postsynaptic members is somewhat irrelevant.

In contrast to motor neuron axons which do not form synapses en route to their final destinations, axons of the vertebrate central nervous system (CNS) establish presynaptic sites along their lengths in the form of small swellings, or varicosities, known as presynaptic boutons. This arrangement allows one axon to form *en passant* synaptic connections with many dendrites along its route. *En passant* presynaptic boutons are often formed behind advancing axonal growth cones as they weave their way through the developing neuropil. However, the potential to form presynaptic boutons is not limited to the terminal growth cones and seems to be distributed along the entire axonal membrane. *In vitro* and *in vivo* studies indicate that presynaptic boutons may form along existing axonal segments in response to axodendritic contacts initiated by dendritic protrusive structures, namely growth cones at the tips of elongating dendritic branches or filopodia extended laterally from dendritic shafts. Axons also extend highly protrusive lateral structures that might also give rise to presynaptic boutons at positions far behind leading-edge growth cones. Thus, new presynaptic boutons can be formed from axonal growth cones, immediately behind advancing axonal growth cones and along established axonal segments.

Recent progress in imaging techniques, such as the introduction of green fluorescent protein (GFP) and the advent of multiphoton confocal microscopy, has provided unprecedented information on the cellular dynamics associated with presynapse development, both in cell culture and in the intact developing CNS of tadpoles, zebra fish, and mice. A consistent observation made in such imaging studies is that presynapse development is an extremely dynamic process. Specifically, these studies reveal that (1) many contacts formed between axons and dendrites are transient, resulting from exploratory-like growth and retraction

of axonal and dendritic processes; and (2) many, perhaps most, nascent presynaptic structures are transient in nature and often disappear within hours or less of their initial formation. These dynamics may be taken to indicate that the formation of a persistent presynaptic site is at odds with opposing mechanical forces that act to 'tear apart' the nascent axodendritic junctions – forces generated by axons and dendrites as these extend through the developing neuropil and by dendritic and axonal filopodia as they undergo cycles of extension and retraction. In this respect, it is interesting to note that *in vivo* imaging of axon and synaptic vesicle dynamics of retinal ganglion neurons in developing zebra fish embryos and *Xenopus* tadpoles indicates that the formation of a presynaptic site along an axonal branch stabilizes that branch and protects it from subsequent retraction, as if synapses form 'spot welds' between axons and dendrites. Furthermore, new axonal branches were observed to emerge preferentially from sites of presynaptic specializations. It was proposed that iterative rounds of branch extension from existing presynaptic sites and selective branch stabilization by synapse formation at tips of new branches would guide axon arbor growth in a manner reminiscent of the 'synaptotrophic hypothesis' proposed by James Vaughn several decades ago (Figure 2).

Figure 2 The synaptotrophic hypothesis as applied to axonal growth and presynapse formation. Axonal growth is governed by two principles: (1) the formation of a presynaptic specialization by an elongating axonal branch stabilizes this branch, whereas the failure to form such a connection entails subsequent branch retraction; and (2) new branches form preferentially from sites of newly formed presynaptic specializations. Iterative rounds of growth/retraction and branching according to these principles consequently result in the preferential establishment of presynaptic specializations within appropriate postsynaptic target regions.

Maturation of Nascent Presynaptic Sites

The differentiation of growth cones or patches of axonal membrane into well-formed functional presynaptic compartments is associated with significant structural changes. Unfortunately, these are mostly beyond the resolving power of light microscopy, including the cutting-edge microscopy techniques that have been so informative in documenting the choreography of synaptogenesis. Electron microscopy (EM) has therefore been used to examine the fine structure of synapses in samples from developing tissue in an attempt to determine the sequence of structural rearrangements that takes place as nascent contacts evolve into mature presynaptic specializations. Collectively, these studies suggest that nascent CNS synapses have parallel, apposed membranes, with varying degrees of structural specializations (electron-dense thickenings). Initially, their presynaptic compartments are very simple, essentially composed of a patch of electron-dense membrane (considered to be the AZ) associated with only a small number (two or three) of SVs. Reserve pools of SVs are virtually nonexistent, as are the mitochondria that are commonly observed in mature presynaptic boutons. On the other hand, pleomorphic vesicular structures, dense core vesicles, some with spicules projecting from their surface, as well as coated vesicles are often observed at nascent presynaptic sites. With development, SV numbers increase and boutons become larger, and the presynaptic membrane becomes more complex.

In addition to structural changes, presynaptic maturation is also associated with changes in functional characteristics. For example, SV exocytosis becomes confined to the presynaptic AZ region; changes occur in the types and subunit composition of voltage-dependent calcium channels involved in evoked neurotransmitter release. Moreover, the sensitivity of SV exocytosis to tetanus toxin is increased, whereas the sensitivity to the vesicle budding inhibitor Brefeldin A is reduced. Finally, changes in the probability of neurotransmitter release are observed. Although details of these maturational changes differ from one type of synapse to another and from one organism to another, it is of note that such changes are protracted, taking place over days or even weeks, at least in vertebrates.

Relationships between structural and functional aspects of synapse maturation are not well understood. However, a combined analysis based on optical methods (recycling of styryl dyes), electrophysiological recordings, and EM indicates that presynaptic boutons of rat hippocampal neurons in primary culture pass through three distinct states. At the onset of detectable synaptic function (about 5 days after plating), synapses lack readily releasable vesicles, although they possess a pool of recycling vesicles that can release neurotransmitters under strong stimulation. During the next 2 days, small pools of docked, readily releasable vesicles begin to appear (presumably reflecting the formation of AZs). Subsequently, reserve pools of SVs start forming, increasing their size concomitantly with a parallel increase in the docked, readily releasable pool size over the rest of the maturation period (several more days).

The long maturation process described previously is seemingly at odds with light microscopy-based observations made in developing neurons that indicate that functional presynaptic sites can form surprisingly fast – within 1 h or less of the establishment of a new axodendritic contact. In these studies, however, new presynaptic sites were recognized as such on the basis of (1) morphological criteria, such as the clustering of a fluorescently tagged presynaptic or SV proteins at the prospective presynaptic site; (2) functional assays, usually the capacity for evoked endocytosis and exocytosis of fluorescent endocytosis tracers such as the styryl dye FM4–64; (3) cytochemical data – that is, retrospective immunohistochemistry using antibodies against synaptic molecules; or (4) combinations of these. These criteria are rather crude in comparison to EM-based ultrastructural analysis, and so, in most of these studies, it remains unknown if the new presynaptic sites had acquired the structural characteristics typical of mature presynaptic terminals or, perhaps, represent nascent structures that are yet to undergo a prolonged maturation process over the days and weeks to come.

Ideally, one would like to monitor the formation of individual synapses in living neurons, determine their functional characteristics, and then examine their ultrastructure by EM. To date, such experiments have been performed in model systems: Experiments performed in *Xenopus* spinal neurons co-cultured with muscle cells revealed that excitatory postsynaptic potentials as well as increases in intra-axonal calcium concentrations can be recorded within seconds to minutes of nerve–muscle contact. During the next few hours, marked increases were observed in the frequency of spontaneous synaptic currents and in the amplitude of both spontaneous and evoked synaptic currents. Surprisingly, practically no well-formed synaptic specializations were found when the same nerve–muscle contact sites were scrutinized by EM, despite their marked capacity for synaptic transmission. In particular, no obvious AZ-like structures were detected. Instead, presynaptic regions contained scattered SVs, some dense core vesicles, and endocytotic profiles. More mature-like presynaptic specializations were observed only a day or so after nerve–muscle contact. Similar experiments performed in nascent CNS synapses formed between hippocampal neurons in primary culture reveal a similar situation – the absence of well-formed AZs or numerous typical SVs at nascent presynaptic sites within 2 or 3 h of their formation, even though a capacity for stimulation-evoked vesicle recycling was demonstrated at the same sites before fixation. Instead, numerous pleomorphic and tubulovesicular structures as well as dense core vesicles were observed. These findings, as well as others, indicate that the ultrastructure of nascent CNS presynaptic sites might be significantly different from that of mature presynaptic boutons.

When considering the issue of presynaptic maturation, it is important to remember that periods of synaptogenesis can last days, weeks, or even months (depending on the organism). As discussed previously, this period is characterized by enormous cellular dynamics during which axons and dendrites grow, branches extend and retract, resulting in the formation and elimination of synaptic contacts at great rates. This means that the population of presynaptic sites is heterogeneous in terms of synaptic age, making it unlikely that all new synapses progress synchronously through well-defined developmental stages such as those described previously. It is more likely that much of this maturation process reflects genetically programmed global changes in neuronal maturational states. The maturational state would dictate the availability and cellular distribution of synaptic building blocks, the dynamics exhibited by

axons and dendrites, the competence of axons and dendrites to evolve into mature synaptic structures, and the functionality of molecular pathways that are involved in coordinating and assembling mature presynaptic structures.

This point is illustrated by several examples. *Xenopus* spinal neurons form rudimentary synapses with co-cultured muscle cells within 1 day in culture. However, synapsin I, a very prominent presynaptic molecule, is not detected before day 3 in culture, nor is it detected *in vivo* during early phases of synaptogenesis. It was therefore suggested that the onset of presynaptic maturation is causally related to the onset of synapsin I expression. Similarly, the expression of dynamin and amphiphysin, two molecules that have crucial roles in SV endocytosis, is delayed considerably in comparison to SV proteins such as synaptotagmin and SV2. Given their roles in presynaptic endocytosis, it is conceivable that the delayed expression of these molecules could be related to the late formation of SV reserve pools at new presynaptic sites.

Another global change that occurs with development is a gradual reduction in axonal and dendritic motility: In fact, *in vivo* imaging in mice (and in macaque monkeys as well) reveals that in adult animals, overall dendritic and axonal structure is remarkably stable, particularly when compared to the incredible dynamics observed during periods of intense synaptogenesis. Conceivably, this reduction in cellular dynamics may promote presynaptic maturation by increasing the likelihood that nascent presynapses will persist and evolve into mature presynaptic structures.

A phenomenon often observed during synaptogenesis is the presence of presynaptic structures that exhibit many ultrastructural or morphological hallmarks of bona fide presynaptic sites but exhibit practically no capacity for evoked neurotransmitter release. The reasons for this dysfunctional state are not known, although it is likely to reflect the presence of incompletely formed AZs or the lack of components essential for SV exocytosis. Interestingly, these presynaptically silent or mute synapses can be converted rapidly to functional presynaptic sites by elevating cAMP levels, by manipulating extracellular Ca^{2+} and Mg^{2+} levels, or by high-frequency stimulation of presynaptic neurons. This unsilencing seems to involve rapid actin polymerization mediated by brain-derived neurotrophic factor (BDNF) and the small GTPase cdc42 (a critical regulator of cytoskeletal rearrangements). Interestingly, the fraction of presynaptically silent synapses gradually diminishes over time, at a rate that parallels the stabilization of axonal and dendritic arbors, indicating that structural stabilization and presynaptic maturation are tightly interconnected developmental processes.

Cellular Mechanisms of Presynaptic Differentiation

Studies based on live imaging microscopy techniques have led to the realization that presynaptic development is a highly dynamic process, occurring over a time scale of minutes to hours. Some of the cellular mechanisms that underlie these dynamics have been characterized and will be discussed next.

As mentioned previously, axons of immature neurons display a capacity for evoked SV recycling along axonal segments, even in the absence of obvious targets. Closer examination has revealed the presence of mobile packets of vesicles or vesicular material that travel along axons at rates of up to 0.1–1 $\mu m\,s^{-1}$. These packets move intermittently in both directions, often pausing, sometimes splitting into smaller packets or merging into larger clusters that sometimes exhibit a capacity for depolarization-evoked exocytosis and endocytosis similar to bona fide synapses. In one study, carried out in cultured hippocampal neurons, mobile SVs (visualized by means of a GFP-tagged variant of the SV molecule VAMP2/Synaptobrevin2) were observed to accumulate rapidly at new axodendritic contacts sites that subsequently exhibited a capacity for stimulation-evoked SV recycling. Intriguingly, retrospective immunohistochemical analysis revealed that these packets were associated with additional presynaptic molecules, including voltage-dependent calcium channels, SV2, synapsin I, and amphiphysin. These findings have led to suggestions that the mobile packets observed in axons might be preassembled precursors ('prototerminals') involved in the rapid formation of true presynaptic structures.

The concept that vesicular structures might be used for presynapse formation was originally put forward several decades ago. As mentioned previously, electron micrographs of developing spinal cord synapses revealed the presence of dense core vesicles with spicules projecting from their surface. On basis of their structural similarity to AZ material and their proximity to presynaptic membranes, it was suggested that these might be involved in the delivery of materials necessary for presynaptic differentiation. In agreement with this idea, a previously unknown 80 nm dense core vesicle was shown to specifically contain multiple AZ components, including the CAZ scaffolding molecules Bassoon, Piccolo, and Rim, but not characteristic SV molecules. Later studies showed that these Piccolo/Bassoon transport vesicles (PTVs) are Golgi derived and that the formation of new functional SV release sites is preceded by the recruitment of two to five mobile Piccolo/Bassoon packets to these sites. These findings suggest that at

least some AZ proteins are incorporated into nascent presynaptic sites in a unitary fashion.

Time-lapse microscopy of SVs labeled with styryl dyes such as FM1–43 revealed that functional release sites occasionally give rise to small mobile vesicle clusters that moved along axons, sometimes merging with nearby presynaptic sites. Interestingly, such mobile clusters often display a capacity for SV release en route, even when they are not juxtaposed to postsynaptic structures or even dendrites, although they do contain the CAZ molecule Bassoon. These features suggested that these mobile structures might represent 'orphan' SV release sites. Intriguingly, orphan release sites were sometimes observed to give rise to new presynaptic sites at axodendritic contacts, indicating that new presynaptic compartments might sometimes be formed from 'units' of SV release machinery that 'bud off' preexisting synapses.

Presynaptic proteins are synthesized in the cell body and then 'shipped out' to axons by means of various axonal transport mechanisms. In principle, components of new presynaptic sites could arrive directly from somatic biosynthetic sources. However, studies such as those mentioned previously indicate that such components can also be 'pilfered' from nearby synapses. Intriguingly, studies show that typical SV membrane proteins (e.g., synaptobrevin-2/VAMP-2 and synaptotagmin-1) are also exchanged among neighboring presynapses by another route that involves SV fusion with the presynaptic membrane, lateral diffusion along the axonal membrane, and endocytosis at nearby presynaptic locations. These findings suggest that presynaptic proteins, SVs, and SV membrane proteins are, in fact, shared resources that are dynamically redistributed among or even competed over by neighboring presynaptic boutons, and that these pools may be drawn upon for the establishment of new presynaptic sites.

The finding that SV proteins are present in significant amounts on the axonal plasma membrane is relevant to another facet of presynaptic differentiation – the source of the numerous SVs found in presynaptic compartment. There seem to be two distinct sources for SVs. The first is the Golgi apparatus in the cell body, where SVs are formed and then transported into axons. These vesicles differ in several respects – both morphologically and in their molecular contents – from the typical clear core vesicles found at mature presynaptic sites, and they have thus been called SV precursors. It seems that such vesicles fuse with the axonal plasma membrane in growth cones and along its entire length in a relatively nonspecific manner. These fusion events, possibly mediated by the exocyst (a conserved protein complex essential for trafficking secretory vesicles to the plasma membrane), deposit SV membrane proteins in the axonal plasma membrane. This pool of SV membrane proteins is then used for the biogenesis of typical SVs by rounds of membrane protein sorting, clathrin-mediated endocytosis, endosomal processing, and local confinement to presynaptic compartments. This scenario may explain the presence of pleomorphic and tubulovesicular structures (SV precursors?) and the paucity of typical SVs observed at nascent presynaptic sites (as described previously) and also explain why the delayed expression of presynaptic molecules involved in SV endocytosis, biogenesis, and confinement would delay the formation of large SV pools at developing presynaptic sites.

The cellular events involved in presynapse formation may be summarized as follows (**Figure 3**): During early stages of neuronal differentiation, as axons are growing toward their targets, an inherent capacity for rudimentary SV recycling exists at axonal growth cones and along the axonal plasma membrane. Mobile packets of SVs, SV precursors, and AZ precursors travel up and down axons. As axons reach their target regions, fleeting axodendritic contacts, initiated by axonal and dendritic growth cones and filopodia, induce the clustering of such mobile packets at contact sites. Most of these contacts break up, and the transport packets disperse and renew their migration. As neurons mature, an increasing proportion of transient contacts do not break up and instead are stabilized by cytoskeletal rearrangements and cell adhesion interactions with postsynaptic membranes. These subsequently develop into functional presynaptic boutons, presumably by the fusion of PTVs with the presynaptic membrane, the recruitment of SV precursor transport packets, the recruitment of SV packets, and the local biogenesis of SVs. The new presynaptic sites are not completely stable, however, and occasionally 'orphan release sites' are uncoupled from their nascent postsynaptic partner and migrate to adjacent presynaptic sites or participate in the formation of new ones, presumably at sites of contact with dendritic structures. With time, genetically controlled processes stabilize axonal and dendritic arbors, reduce protrusive activity, and promote the structural and functional maturation of presynaptic structures.

Molecular Mechanisms of Presynaptic Differentiation

Mature presynaptic specializations are almost always found at sites of contact with postsynaptic targets, implying an exchange of signals that either induce the formation or promote the stabilization of presynaptic structures at these locations. Decades of research has resulted in the identification of numerous molecules

Figure 3 A model for presynaptic development. The formation of presynaptic specializations is envisioned to occur by multiple processes that take place over several time scales. (a) The axons of developing neurons contain several types of transport packets that are used for the assembly of nascent presynaptic structures. These include synaptic vesicle packets, pleomorphic tubulovesicular structures (synaptic vesicle precursors?), and active zone precursor vesicles such as PTVs. (b) In immature axons, primitive sites of synaptic vesicle recycling form spontaneously along axonal segments. (c) Contacts between axons and targets lead to the accumulation of various transport packets at contact sites, resulting in the formation of primitive presynaptic boutons. These sites display some capacity for synaptic vesicle recycling but lack the ultrastructural features of mature presynaptic boutons. (d) Alternatively, the establishment of an axodendritic contact might lead to the rapid formation of an active zone by the fusion of active zone precursor vesicles (such as PTVs) and the subsequent recruitment of synaptic vesicles. It is possible that this scenario becomes more common as neurons mature. (e) With time (days), synapses form larger synaptic vesicle reserve pools and gradually acquire the structural and functional characteristics of mature synapses. During this period, synaptic vesicles, plasma and synaptic vesicle membrane molecules, presynaptic matrix molecules, and even units of active zone material with cognate synaptic vesicles clusters (orphan release sites) are exchanged among nearby presynapses, sometimes giving rise to new presynaptic sites at nascent axodendritic junctions. It should be noted that uncertainty exists concerning some details of this scheme. For example, it is not known whether presynaptic sites form with a precise temporal order of events. Primitive presynaptic sites (c) could form first, followed by active zone formation (arrow from (c) to (d), or primitive sites could fall apart (arrow from (c) to (a) and reform later according to scheme (d) (arrow from (a) to (d). Similarly, axonal release sites (b) might form first and then become synaptic (arrow from (b) to (c) or eventually fall apart (arrow from (b) to (a). Adapted from Ziv NE and Garner C (2004) Cellular and molecular mechanisms of presynaptic assembly. *Nature Reviews Neuroscience* 5(5): 385–399.

involved in such bidirectional signaling. Yet, at the same time, it has become apparent that presynaptic differentiation is a dynamic, multistep process controlled by a host of molecular pathways. Thus, not all of the molecules identified so far are directly involved in specifying presynapse differentiation at specific locations and times, even though they do play roles in processes essential for the ultimate formation of presynaptic specializations, such as appropriate timing of presynaptic protein expression, axonal pathfinding, target recognition, arresting axonal growth motility, or stabilizing initial axon–target cell contacts. Unfor-

tunately, a comprehensive description of all molecules identified to date is beyond the scope of this article, and thus the focus is on a small number of relatively well-characterized molecules that do seem to be directly involved in presynapse formation induction.

Earlier work on NMJ formation led to the identification of Agrin, a large proteoglycan secreted by motor neurons that exhibits an ability to induce acetycholine receptor clustering beneath presynaptic axon terminals. This molecule was thus considered to be a major inducer of NMJ postsynaptic differentiation. Less is known about the reciprocal pathway – that is, the molecules responsible for inducing AZ formation in motor neuron terminals. However, laminin β_2, a component of the NMJ basal lamina, was shown to play an important role in presynaptic organization. Furthermore, it was shown to exert its effects via interactions with extracellular domains of presynaptic voltage-gated calcium channels, particularly P/Q and N type, the major subtypes found in NMJ AZs. Interestingly, however, laminin β_2 appears to be dispensable for the initial formation of AZs but is required for their subsequent stabilization. In this respect, it is also interesting to note that recent work implies that Agrin too is not required for acetylcholine receptor clustering *per se*, but it is required for counteracting neurotransmission-induced dispersion of these receptors. These findings highlight the importance of studying synaptic differentiation in a framework of molecular dynamics and stabilizing forces, rather than rigid molecular interactions and assembly processes.

Whereas secreted molecules clearly play crucial roles in NMJ formation, there are good reasons to believe that many of the bidirectional signals that pass between prospective pre- and postsynaptic partners rely on interactions between extracellular domains of axonal and target cell membranes proteins, particularly interactions mediated by various classes of cell adhesion molecules (CAMs). The cadherin family of calcium-dependent adhesion molecules has long been suspected of playing important roles in inducing presynaptic development, and there is evidence that this may be the case for some invertebrate synapses, such as those formed between photoreceptor cell axons and their targets in *Drosophila*. At vertebrate CNS synapses, however, classical cadherins do not seem to possess the capacity to induce presynaptic specialization on their own and appear to be more important for the stabilization of nascent presynaptic structures.

Several other classes of CAMs, however appear to perform similar functions. The best characterized is neuroligin, a member of the Ig superfamily of CAMs. Its presynaptic binding partners include members of the α- and β-neurexin families of cell surface proteins. Of these, the α-neurexins have been implicated in mediating the recruitment of voltage-gated calcium channels into the presynaptic AZ, whereas β-neurexins (essentially truncated α-neurexins) have been implicated in inducing AZ formation and SV clustering by actin polymerization promoted by their cytoplasmic, C-terminal tails or by interactions of these domains with presynaptic scaffolding molecules, such as CIPP, CASK/Lin-2, and Mint/Lin-10/X11α. When expressed in nonneuronal cells, Neuroligin can induce the formation of functional SV release sites in axons growing along these cells and this activity appears to require β-neurexin. When overexpressed in cultured hippocampal neurons, a large increase in morphologically identified synapses is observed. Conversely, RNAi-based knockdown of Neuroligin1–3 (the three functional forms in mice) in cultured hippocampal neurons reduces the number of morphologically identified synapses. Surprisingly, however, such increases or reductions in morphologically identified synapse number are not always associated with similar changes in functional synapse numbers as determined by miniature excitatory/inhibitory synaptic potential frequency. This puzzling discrepancy may indicate that additional molecules are required for inducing the formation of functional presynaptic compartments, a conclusion supported by the finding that normal numbers of synapses are formed in triple knockout mice lacking all three forms of murine neuroligin. It is worth mentioning, however, that the mice die soon after birth due to respiratory failure, which seems to be a consequence of reduced GABAergic/glycinergic and glutamatergic synaptic transmission in brain stem centers that control respiration.

A second molecule that exhibits a capacity to induce presynaptic specialization when expressed in nonneuronal cells is SynCAM, a member of the Ig superfamily of CAMs. Here, induction is via homotypic interactions with SynCAM present on both pre- and postsynaptic membranes. Interestingly, SynCAM overexpression in cultured hippocampal neurons leads to a large increase in functional synapse number but not an increase in morphologically identified synapse number – exactly the opposite of the phenotype observed for Neuroligin1. Furthermore, SynCAM effects seem to be specific for excitatory synapses, whereas Neuroligins seem to have a larger effect on inhibitory synapse formation.

Other cell adhesion molecule families, such as N-CAM and γ-protocadherins, have been implicated in controlling various aspects of presynapse development in vertebrate synapses. However, their roles and mode of action are not completely clear. In contrast, fascinating information concerning cell adhesion

molecules and presynaptic development has been obtained in invertebrate models, namely *Drosophila* and *Caenorhabditis elegans*, by harnessing the powerful genetic methods these systems offer. In one striking example from *C. elegans*, the expression of Syg2 in vulval epithelial cells (which are neither pre-nor postsynaptic cells) was shown to instruct hermaphrodite-specific neurons (HSNs) to form presynaptic specializations on specific motor neurons at the site where the three cells intersect. The effects of Syg2 on the HSNs is mediated by interactions with Syg1, both members of the Ig superfamily of CAMs, that are similar to the vertebrate molecules Nephrin and NEPH1. However, apparently normal presynaptic specializations still form in the absence of Syg1 or Syg2, albeit at erroneous locations, pointing to the difficulty in separating presynapse induction from more subtle roles such as a confinement of presynaptic structures to preferred locations.

Cell surface molecules that induce presynaptic differentiation do so by means of direct interactions with intracellular scaffolding/cytoskeletal molecules and by setting off various intracellular signaling cascades. Progress in identifying such molecular pathways has come from genetic screens in *Drosophila* and *C. elegans*. Such screens have led to the identification of several genes from several families that affect the morphology of presynaptic structures during development. For example, sad-1, a member of the microtubule affinity-regulating kinase (MARK) family, was found to be important for confining SVs to active zonal regions, whereas α-liprins were shown to control AZ size and complexity. Similarly, Pam/Highwire/Regulator of Presynaptic Morphology-1 (RPM-1) was found to play essential roles in organizing AZ and presynaptic structure, perhaps by direct interactions with other molecules but more likely by regulating multiple signaling cascades, including ubiquitination-dependent degradation of synaptic growth-promoting molecules and the MAP kinase pathway. Despite this progress, a satisfactory understanding of presynaptic differentiation in molecular terms is yet to be attained.

In summary, it seems that the induction of presynaptic differentiation involves multiple molecules and molecular cascades that act in parallel but probably differ in subtle ways. Even for molecules intimately linked to individual presynapse formation, it is not always clear if these actually trigger new presynapse formation or, rather, selectively promote the stabilization of presynaptic specializations that form spontaneously or migrate up and down axons in partially of fully assembled form. Further work is necessary to clarify the roles, interactions, and functional overlaps of these signaling cascades.

Structural Features of Central Synapses

Chemical synapses are intercellular junctions critical for information transfer and processing in the nervous system. They consist of two compartments physically juxtaposed within several nanometers of each other: presynaptic terminals and postsynaptic specializations. Presynaptic terminals store and release neurotransmitter substances in membranous organelles named synaptic vesicles, whereas postsynaptic structures contain signaling molecules responsible for generation of neuronal responses to released neurotransmitters. Presynaptic terminals are highly organized subcellular structures. At the electron microscopic level, clusters of synaptic vesicles around the plasma membrane regions called active zones can readily distinguish them from other structures within a neuron. Synaptic vesicle exocytosis is thought to take place exclusively at the active zone, whereas synaptic vesicle endocytosis may occur within the vicinity of this region. Active zones are characterized by enrichment of scaffolding molecules, and enable assembly of proteins required for regulated vesicle fusion and recycling. Juxtaposed to the presynaptic terminal, the postsynaptic site is characterized by electron-dense material called the postsynaptic density. Postsynaptic density is enriched in scaffolding molecules that anchor neurotransmitter receptors and organize signaling in response to second messenger cascades activated by the neurotransmitter receptors. The pre- and postsynaptic sides of the synapse are held together with adhesion molecules spanning the synaptic cleft (Figure 1). The size of the active zone and the number of docked vesicles are critical determinants of the functional responses of a presynaptic terminal. These structural markers are continually modified during synapse maturation. Depending on the type of synapse, presynaptic terminals in a given synapse contain varying number of synaptic vesicles, some of which are physically attached or docked at the plasma membrane.

The most striking difference of synapses from other cell–cell junctions is the asymmetry of structures on both sides of the synaptic junction. Such asymmetry implies that two compartments must respond differently to the signal(s) that initiate synaptogenesis. This asymmetry is partially achieved through differential distribution of synaptic components to axonal and dendritic compartments within a neuron. Asymmetric interaction of cell adhesion molecules can also account for triggering divergent cascades of downstream events and induction of pre- and postsynaptic sites. However, it is important to note that despite this asymmetry the sizes of the structures on both sides of the synaptic cleft are all correlated, suggesting that the structural synapse assembly is significantly coordinated across the cleft.

In a mature presynaptic terminal, vesicles can be divided into two pools. The first pool contains a relatively small fraction of vesicles close to release sites. These vesicles can be released by brief Ca^{2+}-dependent stimuli or by hypertonic stimulation, which is Ca^{2+} independent. This release-ready pool of vesicles is referred to as the immediately releasable pool or the readily releasable pool (RRP). RRP vesicles are considered to be in a morphologically docked state, although not all morphologically docked vesicles are necessarily release competent at any given time. A priming step in addition to the morphological docking is required to make vesicles fully release competent. A secondary pool of vesicles, the reserve pool, is spatially distant from the release sites and constantly replaces the vesicles in the RRP that have been exocytosed. The rate of replenishment of RRP vesicles from the reserve pool is a critical parameter that determines the response of synapses to repetitive stimulation. Recent evidence indicates that intrasynaptic Ca^{2+} can facilitate the rate of replenishment. The number of vesicles contained in the RRP is a critical parameter that regulates the probability of release, which is defined as the probability that a presynaptic action potential can result in an exocytotic event. Therefore, the number of vesicles in the RRP and the rate and pathways by which they are replenished is a crucial determinant of presynaptic efficacy and of several forms of short- and long-term synaptic plasticity. Several lines of evidence support the presence of the non-recycling pool of vesicles in the synapse. Mechanisms that can render this pool functional remain to be determined.

Multiple Stages of Synapse Assembly

In the mammalian central nervous system (CNS), synapse formation is a precisely timed process. Synapses appear within days in a given brain region. At later stages of development, synapse proliferation

Figure 1 Structural organization of a central synapse. In electron micrographs, synapses can be readily distinguished by the cluster of synaptic vesicles around protein-rich (thus electron-dense) regions called the active zone. The size of the active zone is tightly correlated with the size of postsynaptic density, another protein-rich region associated with the postsynaptic dendrite. Synaptic cell adhesion molecules structurally linking the two sides of the synapse span the synaptic cleft between the presynaptic and postsynaptic regions. These molecules are thought to coordinate synapse maturation in pre- and postsynaptic compartments and also enable functional interactions between the two sides of the synapse. PSD, postsynaptic density.

is thought to be balanced by synapse elimination and pruning of synaptic contacts through activity-dependent mechanisms. Several lines of evidence suggest that synapse formation *per se* does not require neuronal activity. Initial events that establish immature synaptic contacts in neuromuscular junctions involve the interaction of axonal growth cones with target muscle membrane. In the central synapses, however, initial synapse formation is thought to take place between the axonal shaft and filopodial processes that extend from the dendrites. This type of interaction results in the formation of *en passant* synaptic boutons along the axonal shaft, which is a common feature of most CNS synapses. Retraction and stabilization of these filopodial processes together with contacted axonal regions or nascent presynaptic terminals marks the beginning of synapse maturation. Further maturation involves structural modifications that increase the anatomical complexity of the synaptic boutons, including an increase in the number of synaptic vesicles, the size of the synaptic boutons, and, in some cases, the number of active zones. An interesting aspect of synapse maturation is the matching change in the pre- and postsynaptic regions that results in a strong correlation between the size and complexity of both sides of a synapse.

The sequence of events leading to synapse formation has recently been studied in detail using time-lapse imaging techniques in dissociated hippocampal cultures. These studies took advantage of action potential-dependent, rapid synaptic vesicle recycling as the earliest indicator of synaptogenesis following the initiation of axo-dendritic contacts. These findings support the scenario that prepackaged presynaptic molecules are rapidly released at sites of axo-dendritic contact, forming functional presynaptic terminals. However, it has been previously shown that isolated synaptic vesicles in axons can also recycle in an activity-dependent manner prior to target contact. This immature form of synaptic vesicle recycling proceeds with slower kinetics compared to mature synapses. In some cases, this immature form of synaptic vesicle recycling has been shown to be resistant to tetanus toxin implicating the requirement for a vesicular SNARE (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors) protein other than synaptobrevin-2 (VAMP-2), which is tetanus toxin sensitive. In the developing neuromuscular junction, unlike mature junctions, synaptic vesicle recycling is highly sensitive to Brefeldin A, which disrupts synaptic vesicle trafficking thorough endosomal intermediates.

Maturation of presynaptic terminals occurs in structurally and functionally distinguishable stages (**Figure 2**). During early synapse maturation, synapses are unresponsive to action potential stimulation or hypertonicity (which normally induces swift fusion of docked vesicles), although they can release neurotransmitters and recycle synaptic vesicles during strong stimulation such as induced by elevated extracellular potassium. This form of vesicle recycling detected in these nascent synapses is mechanistically analogous to the form observed in the absence of critical components of the synaptic SNARE machinery. This is consistent with the observation that synaptic vesicle recycling at this stage is tetanus toxin insensitive. Following this initial stage, synapses undergo a transition to become responsive to action potential stimulation and rapidly recycle synaptic vesicles. Examination of electron micrographs of nascent synapses reveals a strong correlation between this functional switch and the formation of the active zone, leading to the assembly of the RRP.

Indeed electron microscopic analysis of immature hippocampal cultures shows that synaptic vesicles are not as closely associated with plasma membrane as they are in mature synapses. These vesicles recycle in a calcium-dependent manner as they travel in the axon, indicating that basic machinery needed for

Figure 2 Sequence of events leading to maturation of presynaptic terminals during synaptic development. Nascent synapses typically contain synaptic vesicles that recycle only in response to strong stimulation. However, at these early stages of synapse assembly, vesicles are not tightly associated with the plasma membrane, presumably due to the immature state of active zones. These synapses lack a set of readily releasable vesicles; thus, they do not effectively respond to presynaptic action potentials. Formation of an active zone coincides with functional maturation of a presynaptic terminal. This stage may also involve actin cytoskeleton increasing association of the synaptic vesicle clusters with the active zone and the surface membrane release machinery. After these initial stages, synapse maturation involves a gradual increase in the size of the total vesicle pool, which also reflected an increase in the number of vesicles available for release. SV, synaptic vesicle; AZ, active zone.

docking and fusion is distributed loosely along the axon. Nevertheless, these hot spots of glutamate release sites may have an important role during the initial stages of synaptogenesis. The released glutamate can stimulate filopodial motility of both dendrites and axons, thereby increasing the chance of axo-dendritic encounter. However, in more mature cultures, glutamate strongly inhibits filopodial motility and stabilizes connections. These contradictory observations can be reconciled if during development changes in protein expression make filopodia less responsive to glutamate, or, alternatively, there is a concentration threshold for glutamate above which its activity has opposite effects.

Besides glutamate, many other secreted molecules increase the number and motility of dendritic and axonal filopodia prior to contact. These include brain-derived neurotrophic factor (BDNF) and neurotrophin-3 (NT-3), which have been shown to promote axonal arborization, dendritic growth, and synapse maturation. BDNF-coated beads can increase Ca^{2+} levels and trigger neurotransmitter release in contacting axons in a protein synthesis-dependent manner. Some members of the fibroblast growth factor (FGF) family of proteins (e.g., FGF22, FGF7, FGF10) can induce presynaptic organization via FGF receptor-2. In a recent study, Sanes and colleagues used a combination of chromatographic steps to isolate factors that cause axon branching and vesicle aggregation in chick motorneurons and purified FGF22 as an active component. Secreted Wnt proteins (Wnt-7a, Wnt-3) can also induce remodeling of growth cones and accumulation of synaptic vesicles. Wnt-7 knockout mice show a delay in maturation of multisynaptic glomerular rosettes formed between mossy fibers and granule cells in the cerebellum. Deficiency of a Wnt homolog in *Drosophila*, Wingless (Wg), causes abnormal pre- and postsynaptic differentiation indicating possible conservation of function.

The peak of synapse formation in the mammalian brain coincides with extensive proliferation of glia, in particular astrocytes. Astrocytic protrusions engulf potential contact sites between axonal and dendritic processes, implicating their possible role in synaptogenesis. Astrocytes release several factors that impact synaptic differentiation. Initial studies by Pfrieger and Barres showed that in the absence of glia the number of synapses formed between retinal ganglion cells in culture are reduced and individual synapses are less efficient in neurotransmitter release. Later work by Pfrieger and colleagues led to isolation of Apolipoprotein E (Apo-E) as the factor upregulated in the presence of glia. Apo-E is a carrier for cholesterol. In these experiments, application of cholesterol to retinal cultures caused a massive increase in spontaneous excitatory postsynaptic currents and the number of presynaptic nerve terminals. In parallel, Barres and colleagues identified thrombospondins 1 and 2 as additional glia-derived synaptogenic molecules, which specifically cause an increase in the number of synapses. Thrombospondins are multidomain extracellular matrix proteins, initially identified in platelet activation.

Role of Synaptic Cell Adhesion Molecules in Synapse Assembly

Whereas soluble factors play an important role in mediating the initial stages of vesicle aggregation and

priming axons for synapse assembly, synaptic cell adhesion molecules mediate the physical contact and functional communication between axonal and dendritic protrusions leading to the formation of synaptic junctions. These molecules are composed of several large families, which include N-cadherins, protocadherins, neural cell adhesion molecules (NCAMs), nectins, neurexins, and neuroligins. In most cases, extensive alternative splicing and differential glycosylation patterns create enormous variability in the possible repertoire of protein products. This high level of variety in individual protein products and the large number of combinatorial possibilities for intermolecular interactions between these molecules may contribute to the specificity of synaptic connections in the brain. However, the process of synapse formation itself seems to be somewhat promiscuous as evidenced by three observations. First, injury or degeneration in the brain can trigger extensive synaptic rewiring, which leads to formation of ectopic synapses between cells that do not normally make synapses with each other. Second, neurons in dissociated cultures form synapses rather promiscuously, where, in some conditions, cells can even form autapses with themselves regardless of their proper *in vivo* partners. Finally, axonal contacts onto polylysine-coated glass beads can induce assembly of presynaptic specializations. Taken together, these results indicate that the basic mechanism for synapse formation is inherent to all neurons. Furthermore, these observations suggest that synaptogenesis is not an event triggered by a single molecule, but rather a vast repertoire of molecular interactions that can lead to synaptogenesis between neurons. Activity-dependent processes test these connections over time and direct stabilization of the most resilient connections.

Neuroligin is the first adhesion molecule identified to be a direct inducer of presynaptic terminal assembly. When expressed in nonneuronal cells, they can cause an accumulation of presynaptic vesicle clusters on contacting axons. These synapses are fully functional as demonstrated by fluorescence imaging of synaptic vesicle recycling and electrophysiological detection of neurotransmitter release. The soluble extracellular domain of neurexin can mask this effect of neuroligin, indicating that neurexin is the mediator of the synapse-inducing activity of neuroligins within the presynaptic axon. An attractive part of the neurexin–neuroligin system is that it satisfies the necessary asymmetry required to induce different signaling events on pre- and postsynaptic sides of the synapse. Neurexins are primarily associated with the presynaptic site and intracellularly bind to calcium/calmodulin-dependent serine protein kinase (CASK) and syntenin. In contrast, neuroligins are located on the postsynaptic site and their C-termini interact with PSD-95.

SynCAM is the only other molecule shown to be sufficient to induce synapse formation when expressed in nonneuronal cells. It is a member of the immunoglobulin (Ig) superfamily, and mediates homophilic interaction through extracellular Ig domains. Similar to neuroligin, synapses induced *in vitro* by SynCAM are fully functional. Overexpression of SynCAM in dissociated cultures has a dominant positive effect in the functioning and formation of synapses. In contrast, the overexpression of dominant negative SynCAM lacking extracellular domain impairs presynaptic assembly. Unlike the neurexin–neuroligin interaction, SynCAM mediates a homophilic interaction, indicating that different downstream cues are present on different sides of the synapse (**Figure 3**).

How does the interaction of cell adhesion molecules translate into changes within the cell? Following initial contact, assembly of synapses takes 1–2 h and may occur in either of two ways. First, following contact, each molecule could be captured from the stream of axonal cytoplasm, and a synapse can be built depending on protein–protein interactions. A second model suggests that synaptic molecules are pre-assembled in small units in other parts of the neuron and transported to the axon. The speed of assembly favors a pre-assembled trafficking model. The evidence for the existence of cytoplasmic transport packages came from studies of Garner and colleagues. They have been able to isolate large dense vesicles from developing axons containing active zone proteins such as piccolo, bassoon, and RIM. Pre-assembled packages of active zone vesicles fuse with the axonal plasma membrane to create a scaffolding framework for other components. In addition to the active zone components, synaptic vesicles also assemble as clusters in a unitary fashion. Nevertheless, these two components do not seem to travel together along the axon. There is also evidence that at the end of this initial stage of synapse assembly, synaptic vesicles switch to a docked state and associate more closely with the plasma membrane in a synapsin-dependent manner.

Analysis of the intracellular interactions of neurexin and SynCAM reveals CASK as a converging downstream target. CASK is a member of the membrane-associated guanylate kinase family (MAGUK) and strongly interacts with neurexin and SynCAM cytoplasmic tail. Upon interaction with neuroligin, neurexin oligomerizes and recruits CASK. Given the multidomain structure of CASK, it is usually envisaged as a recruiter to the newly formed contact sites for both neurexin and SynCAM. CASK also

Figure 3 Putative molecular interactions that link synaptic cell adhesion molecules to the active zone and to the neurotransmitter release machinery. Cytoplasmic tails of neurexins and SynCAM can interact with a modular adaptor protein CASK which in turn binds another adaptor protein Mint interacting with the release machinery (munc-18 which interacts with syntaxin) as well as the voltage-gated calcium channels. Active zone components such as RIM can interact with synaptic vesicle-associated molecules, which include rab3, thus bridging synaptic junctional scaffold to the synaptic vesicle cluster.

forms a well-conserved tripartite complex with Mint and Veli, multidomain PDZ molecules. This complex is proposed to be responsible for the recruitment of vesicle fusion machinery. CASK has also been shown to interact with liprin, which organizes the presynaptic active zone in *Caenorhabditis elegans*. By tightly interacting with the active zone proteins RIM and ERC, liprins constitute the insoluble backbone of the active zone.

As mentioned above, synaptic vesicles are tethered at the vicinity of the active zone by the actin cytoskeleton. Actin depolymerizing agents have a strong disruptive effect on nascent synapses but not on mature synapses, implying a role for actin during synapse formation. CASK can polymerize actin on the neurexin C-tail and stabilize it by interacting with protein 4.1. In this way, synaptic adhesion molecules neurexin and SynCAM (and possibly other CASK-interacting adhesion molecules such as syndecans) can induce local polymerization of actin at contact sites and trap traveling synaptic components.

As discussed above, free-moving vesicle clusters have different cycling properties than mature ones. How maturation changes vesicle identity is not known. It could be achieved through transport of mature vesicles or conversion of the identity of existing vesicles. One can speculate that these initial synaptic vesicles are still present in mature synapses but in a reduced capacity for synaptic vesicle recycling. This may explain the presence of the enormous number of vesicles at synapses, while only a fraction of them are functional.

There are a multitude of possible pathways that can lead to eventual assembly of synaptic terminals. This redundancy can increase the robustness of the synapse assembly process and also contribute to the functional and structural versatility of synapses.

Stabilization of Synapses

Synapse formation is rather error prone at the initial stage, and a certain degree of mismatch often occurs. Therefore, initial promiscuous synapses either are usually secured by help of additional and more specific adhesion molecules, or are eliminated. Like previous stages, this process also occurs in a hierarchical manner. The synaptogenic molecules neurexin and neuroligin could be good candidates for helping to achieve this specificity. Neurexins undergoes extensive splicing, and recently Boucard and colleagues demonstrated that they interact according to a splice code. However, several other cell adhesion molecules

are also postulated to play a role in late stages of synaptic development.

One of the best-characterized synaptic cell adhesion proteins is N-cadherin. Similar to neurexins, they link the extracellular adhesive function to actin cytoskeleton via α- and β-catenins. Even though the function of cadherins at the synapse is not clear, several recent experiments provide significant insights. Overexpression of an N-cadherin construct lacking the extracellular domain while maintaining the ability to bind cytosolic partners markedly reduced the number of presynaptic boutons, indicating the importance of the adhesive function. In another set of experiments, expression of mutant α-N-catenin prevented the interaction of cadherin with the actin cytoskeleton but did not strongly affect presynaptic assembly. These experiments imply that cadherins have a rather adhesive function during early synaptogenesis. Therefore, they could act at an intermediate stage between initial contact and final maturation by prolonging the brief lifetime of axo-dendritic contacts. Disruption of cadherin function in mature synapses, however, does not have a strong effect. This finding raises the possibility that some of the cadherin functions are redundant with protocadherins, a subset of the cadherin superfamily. Protocadherins are composed of nearly 60 members expressed by three gene clusters that are expressed in distinct patterns in the nervous system and undergo extensive splicing.

Molecular Components of the Presynaptic Active Zone and the Cytomatrix

Active zones are the principal sites of synaptic vesicle fusion in synapses. The molecular components of the active zone are thought to serve a structural role by clustering synaptic vesicles around the active zone and increasing proximity between molecules on the synaptic vesicle membrane and the plasma membrane. Active zone proteins are also involved in priming the vesicles for release and perhaps in vesicle retrieval after fusion. Proteins, such as Bassoon and Piccolo, are recruited to activate the synapses during synaptogenesis. For instance, in experiments conducted by Garner, Ziv, and colleagues, Bassoon was detected in nascent synapses capable of action-potential-dependent uptake and release of FM dyes. In addition, dense core active zone precursor vesicles contain multiple synaptic proteins, including the active zone proteins, Bassoon and Piccolo. Fusion of these vesicles with the plasma membrane can rapidly assemble active zone. Despite extensive data on their localization, the functional properties of these active zone proteins are still unclear. However, for RIM1 and CASK, there are several well-characterized biochemical interactions with multiple proteins. As discussed above, in the case of CASK, these molecular interactions suggest a central role in the bridging of neurexins to munc-18, a critical component of presynaptic release machinery. Recent mouse knockouts of munc-13 and RIM1 uncovered critical functional roles for these molecules. Synapses deficient in munc-13-1 are severely impaired in their function. The remaining munc-13-2-dependent synaptic transmission displays marked synaptic facilitation. RIM1 knockout mice, on the other hand, have a less severe but significantly altered properties of short- and long-term plasticity. Interestingly, loss of these molecules does not lead to structural alterations in the synapse, which are presumably due to the redundancy of molecular interactions that assemble synapse structure.

How do the active zone proteins regulate synaptic function? This regulation is likely achieved by the ability of active zone proteins to recruit the components of fusion machinery, such as SNAREs and munc-18. An important step in the chain of events leading to vesicle fusion is the formation of the SNARE core complex between target membrane SNARE proteins (i.e., syntaxin and SNAP-25) and the synaptic vesicle SNARE, synaptobrevin/VAMP. Active zone proteins can exert significant functional effects by regulating the formation and dissociation of SNARE complexes. Replenishment of vesicles released at the active zone requires SNARE core complex assembly and disassembly. This assembly process in the synapse is much faster than the rates of SNARE core complex assembly *in vitro*. Therefore, the assembly process is most likely facilitated by protein–protein interactions between the components of the presynaptic active zone and synaptic vesicles. For instance, munc-18, a protein required for fusion, could be recruited to the active zone through its interaction with Mint (munc-18 interacting protein), which in turn binds to CASK.

Functional Maturation of Presynaptic Terminals and the Role of Activity

Following the initial assembly of synaptic terminals, a large number of synapses are functionally silent. In some cases, these functionally silent synapses can be rendered operational in response to activity. The most commonly studied models of silent synapses propose a postsynaptic mechanism that underlies this silence. According to this model, a fully functional presynaptic terminal may exist but the postsynaptic site does not possess α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors although it contains *N*-methyl-D-aspartate (NMDA) receptors. Activity, in turn, induces the insertion of functional AMPA receptors, making silent synapses functional under physiological conditions. In contrast,

studies in dissociated hippocampal cultures have also identified a developmental stage where synapses are presynaptically silent after assembly. This model possesses the same apparent features of an NMDA-only synapse, but the NMDA-only nature of these synapses is explained by a presynaptic mechanism and not by lack of postsynaptic AMPA receptors. According to this scheme, activation of postsynaptic AMPA or NMDA receptors can be determined by the kinetics of fusion pore opening and the release profile of glutamate. In young nerve terminals, neurotransmitter release occurs through a narrow fusion pore leading to exclusive activation of NMDA receptors as they have a higher affinity for glutamate. Synapse maturation in turn leads to an increase in preponderance of full fusion events, thus activating NMDA as well as AMPA receptors. An alternative model suggests that immature synapses do not readily respond to action potential stimulation leading to a full presynaptic neurotransmitter failure due to some inadequacy in fusion competence or localization of synaptic vesicles. This model is consistent with the previously discussed findings on the gradual reorganization of synaptic vesicle clusters after synaptogenesis. In a recent study, Shumin Duan and colleagues showed that a burst of action potentials can rapidly awaken these silent synapses by increasing the availability of synaptic vesicles for fusion through BDNF-triggered presynaptic actin remodeling mediated by the small GTPase Cdc42.

In most synapses, the initial structural assembly and functional unsilencing is followed by a gradual maturation process that typically involves alterations in short-term plasticity. Studies conducted in acutely isolated brain slices have described functional alterations that are solely of presynaptic origin. One finding of these experiments was an apparent decrease in release probability during synaptic development. This result is rather surprising, given the prevalent structural observation that the number of vesicles within a synapse increases during maturation implying an increase in synaptic reliability and release. Another interesting observation in cortical as well as hippocampal mossy fiber synapses is target-dependent alterations in short-term and some long-term forms of plasticity during the course of development. Cellular mechanisms underlying these developmental changes in short-term plasticity are postulated to involve altered Ca^{2+} dependence of fusion and regulation of vesicle mobilization in presynaptic terminals. It is tempting to speculate that synaptic cell adhesion molecules either individually or in combination may regulate these target specific functional alterations in the output of single neurons.

As exemplified by the presynaptic unsilencing process discussed above, several aspects of synaptic functional maturation during early development can be influenced by activity and neuromodulators. Most neuronal networks exhibit spontaneous action potential firing patterns and synaptic potentials in the absence of extrinsic influences. The background activity that arises from the properties of individual neurons and their characteristic synaptic connections has been shown to be critical for the refinement of synaptic connectivity within the nervous system. Most of the signaling cascades that play a role in synapse maturation can be physiologically activated or regulated by the background activity. These include several signal transduction pathways, including Ca^{2+}-signaling mechanisms and the activation of protein kinase C (PKC) and protein kinase A (PKA). For example, direct involvement of cyclic adenosine monophosphate (cAMP)-dependent signaling in synaptic development was demonstrated in hippocampal slices, as well as at the level of individual synapses in culture. Activation of Ca^{2+}, cAMP, or diacylglycerol second messenger cascades can be triggered either directly by neuronal activity through Ca^{2+} influx or indirectly by the release of glutamate and activation of metabotropic glutamate receptors.

Recent studies have shown that chronic alterations in spontaneous activity levels modify several synaptic properties including the size of postsynaptic responses, probability of neurotransmitter release, as well as the number of synapses. These experiments strongly support a role for background activity in regulating the proper functional maturation of individual synapses. Although activity is an indispensable component of synaptic development, the mechanism through which it influences synapse maturation and the elimination process is still elusive.

Endocytic Intermediates in Presynaptic Terminals

Endosomes are distinct membrane-bound endocytic organelles inside cells. Classically, receptors and their ligands are taken up into clathrin-coated vesicles from the plasma membrane surface during endocytosis. They are sorted to the early endosome and then targeted to various intracellular destinations. They may be either transferred to the recycling endosome and then exposed back to the surface, or directed to degradation by transport to multivesicular bodies and then to late endosomal compartments and lysosomes. Each of these compartments is characterized by a distinct protein–lipid composition, morphology, and intraluminal pH, which become more acidic as the degradation pathway progresses.

Like other peripheral cellular compartments, nerve terminals contain structures involved in the renewal and recycling of plasma membrane components and the constitutive and/or regulated internalization of receptors and ion channels. Some pathogens, such as viruses and toxins, also accumulate in these membrane compartments. During synaptic activity the nerve terminal contains a variety of endocytic intermediates derived from fused synaptic vesicles (Figure 1).

Endocytic intermediates are represented by clathrin-coated pits of various sizes, vesicles and by larger irregular membrane compartments, such as vacuoles, cysternae, and tubular invaginations. Large endocytic compartments, which are temporarily observed in nerve terminals during stimulation, represent a functionally heterogeneous population. Most of the vacuoles are generated by bulk endocytosis from the plasma membrane. The membrane of these vacuoles is structurally and functionally equivalent to the plasma membrane. Accordingly, these structures are disassembled into vesicles in resting synapses via clathrin-mediated endocytosis. Some of the organelles, however, are indeed represented in classical sorting endosomes downstream of clathrin-coated vesicle formation. It remains a matter of debate whether early endosomes are composed of a single population of organelles, in which recycling of the membrane components may intersect with synaptic vesicle cycling, or if they represent a multiple population, specialized for a particular pathway. Recent studies of epidermal growth factor (EGF) receptor trafficking in nonneuronal cells have identified proteins which are confined only to a subpopulation of peripheral endosomes, thus indicating the possibility for multiple sorting pathways. Late endosomes (multivesicular bodies) may also be present at synapses. These organelles are eventually delivered to lysosomes in the soma-dendritic compartment of the neuron.

Sorting of Receptors

An important process that depends on endosomal trafficking is the uptake, processing, and recycling of presynaptic receptors. Little is known about the pathways directly linked to presynaptic terminals, mostly because of the limited size of this neuronal compartment, but it is evident that these endocytic events may play a crucial role in synaptic plasticity. Trafficking of several receptor subtypes, including alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) glutamate receptors, has been followed in the postsynaptic compartment. They showed that recycling endosomes, rather than *trans*-Golgi network (TGN)-derived vesicles, supply AMPA receptors during long-term potentiation (LTP) in hippocampal neurons. Blocking exit from recycling endosomes by expression of dominant-negative mutants of the GTPase Rab11a or the EH-domain containing accessory protein EHD1/Rme1 trapped internalization of the receptors in recycling endosomes and prevented expression of LTP in hippocampal neurons. It should be noted, however, that the postsynaptic endosomal compartments in neurons are significantly larger compared to the ones in presynaptic terminals, which suggests less significant physiological effects of receptor turnover in the presynapse.

Thus, the degree of similarity between these mechanisms in the presynaptic and postsynaptic compartments still needs to be clarified. It seems generally important that the presence of certain subunits determines the chosen sorting pathway. Homomeric GluR1 receptors, for example, are retained in recycling endosomes, whereas GluR3 homomers enter the late endosomal/lysosomal pathway regardless of stimulation. In the case of heteromers, endosomal sorting is apparently governed by GluR2, which exerts dominant effects, perhaps by recruiting adaptor proteins after undergoing posttranslational modifications including tyrosine phosphorylation and

Figure 1 Membrane-trafficking pathways in presynaptic terminals. Synaptic vesicles releasing neurotransmitter into the synaptic cleft at the active zone (thick line) may be retrieved via the 'kiss and run' mechanism and via clathrin-mediated endocytosis, which occurs lateral to the active zone. During intense activity and massive fusion of synaptic vesicles deep plasma membrane folds are formed. During the synaptic vesicle cycle, the vesicles can be reformed directly from uncoated clathrin-coated vesicles or through an endosomal compartment. The 'classical' endosomal trafficking may regulate internalization and surface expression of receptors, transporters, and ion channels within the presynaptic compartment. The recycling pathway includes early and recycling endosomes. It may also involve late endosomal compartments (also referred to as multivesicular bodies) if the cargo is designated for degradation.

ubiquitination. In nonneuronal cells, sorting of ubiquitinated cargo is achieved by ubiquitin-interaction motif (UIM) and ubiquitin-associated domain (UBA) containing proteins, which include the phospholipid-binding protein epsin and the endocytic accessory protein Eps15. Both epsin and Eps15 are highly expressed in presynaptic terminals and thus may serve functions in presynaptic receptor sorting within the endosomal system in addition to their involvement in synaptic vesicle recycling.

Role of Endosomes in Synaptic Vesicle Recycling

The role of endosomes in synaptic membrane recycling also remains a matter of debate. A large proportion of vesicles in synapses are reformed via clathrin-mediated endocytosis, which occurs in the regions around active synapses referred to as periactive zones. Clathrin-coated intermediates formed in this region have the same diameter as functional synaptic vesicles. Thus, vesicles formed at the periactive zone may miss the endosomal compartment during the synaptic vesicle cycle, and thus originate directly from clathrin-coated vesicles pinched off from the plasma membrane or by the closing of a transient fusion pore ('kiss-and-run'). Studies in hippocampal synapses using the fluorescent membrane dye FM1–43 to trace the membrane of a recycled vesicle have shown that most of the vesicles recycle through the pathways independent of endosomal compartments. They have demonstrated that the amount of dye per vesicle taken up by endocytosis equals the amount of dye a vesicle releases upon exocytosis. It was thus concluded that the internalized vesicles participating in endo–exo recycling do not communicate with intermediate endosomal compartments during the recycling process. These experiments, however, did not exclude the possibility that a remaining population of vesicles not participating in exo–endocytic recycling could exchange membrane with an endosome or that this organelle could be recruited upon a certain activity demand. The sorting endosomal compartment could also be critical for long-term

maintenance of synaptic vesicle trafficking, since vesicles may become fusion incompetent following depletion of their protein content during repeated rounds of release. Evidence for an involvement of endosomes in synaptic vesicle cycling has recently been provided by studies using specific molecular endosomal markers.

The classical case of functionally distinct cellular microdomains is defined by the presence of specific Rab GTPases and their effector molecules. Three GTPases, Rab5, Rab4, and Rab11, are present on early endosomes. Cargo destined for degradation or recycling enters the early endosome via the Rab5 domain. Subsequently, cargo is sorted either for recycling via the Rab4 and Rab11 domains or for degradation via the Rab7 domain on late endosomes.

Rab5, initially delivered to the endosomal membrane in an inactive, GTP-bound form, undergoes activation catalyzed by specific effectors (GEFs), such as the Rabex5–Rabaptin5 complex, Ras interference 1 (RIN1), RIN2, or RIN3. Active Rab5 recruits two phosphatidylinositol-3-kinases, PI(3)-kinases p110/p85 and VPS34/p150, which trigger a local enrichment of phosphatidylinositol-3-phosphate, PI(3)P, in the endosomal membrane. PI(3)P specifically binds to the FYVE zinc finger domain (named after Fab1p, YOTB, Vac1p, and EEA1) of endosomal factors such as EEA1 and Rabenosyn-5 or Rabankyrin 5, which ultimately mediate endocytic vesicle tethering and fusion with early endosomes. Both Rab5 and the FYVE domain, which binds to PI(3)P within an intact lipid bilayer, can thus be considered markers for PI(3)P-containing endosomes.

The presence of Rab5-positive, PI(3)P-containing endosomes at the presynaptic terminal of *Drosophila* neuromuscular junctions has been determined using expression of GFP-tagged FYVE domains and antibodies against Rab5. Under conditions in which the synaptic vesicle pool was depleted, endosomes were drastically reduced in size and recovered by dynamin-mediated endocytosis. Interfering with Rab5 function using a dominant-negative version of Rab5 caused a reduction in the number of released quanta during synaptic transmission, whereas elevated levels of Rab5 increased the quantal content. These data strongly indicated that Rab5-dependent trafficking pathway plays a role in presynaptic vesicle cycling.

Live imaging of EGFP-Rab5a was also achieved in cultured neurons from mammalian hippocampus. For a number of years it has been known that the small GTPase Rab5 is present in vesicles isolated from synaptosomes. Moreover, overexpression of Rab5a has been shown to target the protein to synaptic terminals and to vesicular and endosome-like structures. The imaging data confirmed that EGFP-Rab5a is accumulated in clusters along the axon, forming green puncta, which colocalized with synaptic markers. Upon stimulation, Rab5a showed a minimum dispersion, far less than that seen with EGFP-Rab3a, which undergoes a cycle of association and dissociation with synaptic vesicles. These data suggested that like in *Drosophila,* mammalian Rab5 is confined to a specific population of vesicular structures most probably representing a recycling compartment.

Fusion of vesicles with the endosomal compartment would require a soluble N-ethylmaleimide-sensitive factor attachment protein (SNAP) receptor (soluble N-ethylmaleimide-sensitive factor attachment protein receptors (SNARE)) complex. The proteins Vti1b and Vti1a-β have been found on small vesicles isolated from nerve terminals. Vti1a-β was co-purified with synaptobrevin and was able to interact with N-ethylmaleimide-sensitive factor (NSF) and aSNAP, suggesting that it might form a SNARE complex. The protein complex, containing Vti1a-β, did not contain synaxin 1 and SNAP-25, and thus was different from the SNARE complex involved in fusion of synaptic vesicles with the plasma membrane. This Vti1a-β-containing protein complex is currently suggested as a potential SNARE for fusion with the endosomal compartment.

The formation of vesicles from the endosomal compartment also assumes a budding step. This budding step is thought to be dependent on the adaptor complex AP-3. The neuron-specific isoform of AP-3 (AP-3B) as well as ADP ribosylation factor 1 (ARF1) are required for the biogenesis of synaptic-like microvesicles budding from PC12 cell endosomes, but a similar function in nerve terminals has not yet been confirmed. It is known, however, that mutations in the AP-3 gene are linked to a variety of neurological defects. The *mocha* mouse, a null mutation of the δ-subunit of AP-3, exhibits balance and hearing problems, is hyperactive, and is prone to seizures. Mice in which the neuron-specific AP-3B subunit μ3B has been genetically deleted show specific defects related to the biogenesis of GABA-containing SSVs, suggesting a particularly important function for AP-3B at inhibitory synapses.

Another potential function for endosome-derived synaptic vesicles is in the recovery of membrane components of dense-core vesicles (DCVs) that have just undergone exocytosis. Membrane retrieval of this type has been detected in PC12 cells transfected with a chimeric P-selectin. Thus, neuronal AP-3B may recapture protein components of DCV proteins. It is believed that a recapture step could sequester selected DCV proteins from degradation and allow them to be incorporated into the synaptic vesicle cycle.

Signaling Endosomes

A population of 'signaling endosomes' has been recently described. These organelles avoid the classical lysosomal targeting system but deliver compounds to the cell body in biologically active form. Interestingly, some of these membrane structures may orient the intracellular domains of receptors to face the cytoplasm, making the receptors available to interact with cytoplasmic proteins and thus increasing the signaling possibilities (Figure 2).

Nerve growth factor (NGF) binds to and activates presynaptic neurotrophin receptors TrkA and p75 and triggers their endocytosis and transport to the endosomal compartments. In sciatic nerve preparations, the stimulation with NGF induces early endosomes, positive for Rab5B and EEA1. These endosomes become signaling endosomes that are retrogradely trafficked to the cell soma to initiate local signal transduction cascades and transcription of specific genes. On the other hand, NGF induces the formation of signaling endosomes. The EH domain protein Pincher/EHD4 regulates the formation and cellular fate of these endosomes. Pincher/EHD4 overexpression enhances NGF-induced internalization, sorting and trafficking of TrkA-containing vesicles. In contrast, a dominant negative version of Pincher/EHD4 blocks TrkA internalization. Thus, Pincher/EHD4-containing Trk endosomes represent a pathway opposite to lysosomal degradation and ensure persistent signaling through extracellular signal-regulated kinase 5 (Erk5), an important effector of retrograde survival signaling in neurons.

Transport of the clostridial tetanus toxin (TnT) to the somatodendritic compartment of motoneurons displays many similarities to the transport of NGF receptors. The TnT is composed of two chains: a heavy chain (TnT-HC) and a light (TnT-LC) chain. The TnT-LC is a zinc-endopetidase that specifically cleaves synaptobrevin/VAMP, and the TnT-HC is responsible for the presynaptic uptake and retrograde transport of the toxin. The toxin is then taken up into the neuromuscular junction by endocytosis and is sequestered into signaling endosomes. The endosomes undergo fast axonal retrograde transport and carry the toxin to the soma and dendrites of motor neurons located in the spinal cord. Once there, the endosomes fuse with the plasma membrane releasing the toxin. It reaches the presynaptic terminals of inhibitory interneurons and at this level incorporates into the synapses through recycled synaptic vesicles.

Figure 2 'Signaling' endosomal compartment involved in the retrograde transport of neurotrophin receptors and tetanus toxin. Target released nerve growth factor (NFG) binds and activates TrkA or p75 neurotrophin receptor. Pincher/EHD4 activates internalization of the complexes to signaling endosomes. The tetanus toxin binds to the presynaptic membrane and is endocytosed to the presynaptic endosome to be delivered to the somatodendritic neuronal compartment.

This process is referred to as transcytosis. The tetanus toxin blocks neurotransmission in synapses through the cleavage of synaptic vesicle protein synaptobrevin/VAMP, which is essential for vesicle fusion. Importantly, the TnT-HC and NGF appear to share the same retrograde transport organelle, which is characterized by the presence of the neurotrophin receptor p75. This coincidence implies that during evolution, bacteria have adapted their toxins to benefit from an essential neuronal membrane trafficking pathway in order to invade the nervous system.

Introduction

Because of its accessibility, the neuromuscular junction (NMJ) is the most studied vertebrate synapse. The NMJ is also the simplest synapse – a relay, so called because its function is to relay information, traveling on motor axons originating from within the central nervous system, to the membrane of muscle fibers. The information is digital, in the form of all-or-nothing depolarizing pulses, or action potentials (APs). Each pulse instructs the muscle fibers to contract or (for most fibers) twitch. Thus the NMJ amplifies a weak control signal (current supplied by the axonal AP) into a stronger one capable of depolarizing the muscle fiber, which is much larger than the axon. In contrast, and as described elsewhere in this encyclopedia, synapses within the brain and spinal cord are thought to serve far more complex functions – those that underlie behavior, such as learning, memory, emotion, and addiction. To do so, brain synapses utilize various kinds of use-dependent behavior, such as depression, potentiation, and facilitation. They are also able to integrate, or combine, multiple inputs (APs originating from many neurons) and arrive at a single decision – namely, whether or not to generate an output AP.

With such disparate roles, it seems remarkable that the simple NMJ can serve as the model synapse, as it is called, for understanding synaptic function throughout the vertebrate nervous system. There are two reasons. First, many of the characteristics of brain synapses are found at the NMJ, albeit in more rudimentary form, and indeed were discovered there. Second, and most relevant for what follows herein, is the fact that much still remains to be learned. One key aspect of all synapses – how the presynaptic nerve terminal, or presynapse, releases its chemical signal – remains poorly understood. The importance of gaining this knowledge becomes clear if one considers the output side of the synapse, where the postsynaptic receptors convert an increased concentration of the chemical neurotransmitter, in the synaptic cleft, into the depolarization that triggers muscle excitation. Here, a great deal is known. Early information came exclusively from the NMJ, but many classes of receptors at different synapses are now studied in detail. Knowledge of precisely how these receptors work has advanced substantially in recent years, and continues to advance. As a result, pharmacological intervention is possible, and many successful drugs have postsynaptic receptors as their target. A similar arsenal of presynaptic drugs, if available, could alter neurotransmitter release directly, providing additional avenues for intervention. Such drugs would have a profound impact on the treatment of disease, as have those that modify synaptic function by acting on receptors. But, unlike receptors, the basic physiology of nerve terminals remains to be elucidated. If history serves, the synapse most likely to reveal these secrets is the simplest and most accessible one, the NMJ.

Anatomy of Motor Nerve Terminals

Presynaptic function derives from extreme evolutionary specialization. Cells in early animals communicated with each other via hormones, which are chemicals released by certain cells into the extracellular milieu; these chemical signals are detected by other cells, often some distance away, that express the appropriate receptors. One problem with this scheme is that each signal to be communicated requires a unique hormone. Another is that chemical communication over long distances is slow. Though still extant today (the endocrine system), some hormonal communication evolved into neural communication precisely to avoid these problems. Neural communication occurs only between adjacent cells. The cells are so close (~50 nm for NMJs) that only a tiny amount of chemical released by one is sufficient to rapidly influence receptors of the other. After the signal is delivered, the chemical diffuses away and is harmlessly diluted, influencing no other cells. Alternatively, it is degraded (as at the NMJ) or taken up for reuse. The most remarkable aspect of this specialization is that, during development, one cell, the presynaptic neuron, extends a thin process, its axon, over a distance of up to 1 m or so (in humans) and finds its target muscle fibers with precision. Thus a motor neuron in the spinal cord becomes, in effect, adjacent to a muscle cell in the foot (or more than one cell – the axon can branch). The specialization at which the terminal of the axon comes in near-contact with the receptors of the muscle cell is the NMJ. As a result, many muscle cells can be independently and rapidly controlled by their innervating motor neurons, using only one chemical neurotransmitter. In vertebrates, this transmitter is acetylcholine (ACh).

A consequence of this system is that each motor nerve terminal undertakes its function without much

help from the motor neuron's distant cell body. Although the latter contains the nucleus and protein-making machinery, axonal transport of molecules from cell body to the motor terminal of the NMJ, or vice versa, can require up to several months. In particular, the need for independent function requires that motor terminals supply their own energy and continuously resynthesize and package ACh for reuse (see later, vesicle recycling).

Nerve Terminals at NMJs of Different Vertebrate Species

The most fundamental, unitary synapse comprises a presynaptic bouton (button), a narrow cleft, and a cluster of membrane-bound postsynaptic receptors (Figure 1). The bouton contains, principally, mitochondria (M), synaptic vesicles (SVs) that contain neurotransmitter, and additional transmitter within the cytoplasm. Active zones (AZs), sites of neurotransmitter release, are located within the presynaptic membrane, the portion of the plasma membrane that apposes postsynaptic receptors. Interestingly, solitary boutons are common within the central and autonomic nervous system, but rarely serve as NMJs. However, the structure of NMJs of various species is essentially a cluster of boutons, each with its own postsynaptic receptor specialization. In amphibians (frog), thousands of boutons are linearly arranged, each containing a single AZ. In reptiles, ~60 boutons are clustered, much like a bunch of grapes, and each contains ~60 AZs (Figure 2). In mammals, such as mice, the NMJ resembles a tangle of worms. Each worm appears to be formed by the fusion of several reptilian boutons, and indeed, during development, the not-yet-fused individual boutons are evident. Interestingly, human NMJs retain separate boutons to some extent and thereby resemble those of reptiles more than rodents! Thus the NMJs of different species are homologous, with reptilian (and human) NMJs most resembling the discrete bouton synapses found in the mammalian central nervous system.

Anatomical Correlates of Synaptic Strength

The strength, or efficacy of a motor terminal (amount of transmitter released) is reflected in its size, which in turn is matched to the requirements of its target muscle fiber. Thus larger fibers receive larger terminals. So do faster ones, such as those involved in fright-or-flight response. These are important for survival and therefore receive more transmitter than is minimally required for initiating contraction (the safety factor). Conversely, smaller fibers, as well as slow, chronically used muscle fibers that are relatively unimportant to acute survival, receive smaller terminals (e.g., eye muscles, anal sphincter). In the snake and probably other species as well, postsynaptic receptors are more efficient in fibers that are larger, faster, or more important for survival. Thus nerve terminal size is not the only determinant of synaptic strength. Boutons in small and large terminals are roughly the same size – it is the number of boutons that changes.

The Active Zone

In the 1950s, when Sir Bernard Katz and his colleagues elucidated the basis of synaptic function at the frog NMJ, transmission electron microscopy had recently become available to provide images of

Figure 1 Cross section of typical presynaptic bouton. (Left) Diagrammatic representation showing bouton (yellow) capped by Schwann cell (purple) and innervating the postsynaptic membrane (endplate) of muscle fiber (blue). Mitochondria (M; green) reside toward the back of the bouton, away from the presynaptic membrane. Synaptic vesicles (SVs) are clustered throughout the bouton, but particularly near active zones (AZ; blue). Deep invaginations, or folds, within the postsynaptic muscle membrane precisely appose AZs. (Right) Electron micrograph thin section of a bouton at the snake neuromuscular junction. Contractile proteins in the muscle fiber (seen along the bottom of the micrograph) appear in cross section. Folds are continuous along the postsynaptic surface with active zones spaced along them (see Figure 2). Thus some (or all) folds may lack active zones in a particular electron micrograph thin section.

Figure 2 Light-level image of snake neuromuscular junction from the single-fiber-thick transversus abdominis muscle. The postsynaptic membrane of the muscle fiber has been stained with a lectin (fluorescein–*Vicia villosa* agglutinin; green) to reveal the location of acetylcholine receptors (AChRs). Each concave, bowl-like cluster of AChRs corresponds to the dimpling of the endplate membrane where it contacts boutons (blue in diagram of **Figure 1**). The repeated stripes within each bowl, resembling fingerprints, are postsynaptic folds where AChR density is highest. Boutons are labeled with sulforhodamine 101 (red), a fluorescent marker of endocytosed structures (see **Figure 6**). Larger structures are endosomes (arrows); small dots are vesicle clusters near active zones. Particularly near the edges of boutons, it can be appreciated that the clusters appose folds. Confocal 3-D reconstruction from 115 image planes.

synapses at high magnification. The numerous small (~50 nm) vesicles that filled boutons were thought to be the anatomical correlate of the singular electrical events, or quanta, observed with intracellular electrophysiological recording. Similarly, electron-dense structures located in the presynaptic membrane, precisely opposite infoldings of the postsynaptic membrane and often surrounded by vesicles, were thought to be likely sites of transmitter release. Two more recent advances in electron microscopy (EM) – the freeze-fracture technique used by J Heuser and colleagues and electron tomography used by UJ McMahan and colleagues – have provided additional detail about the structure of AZs (**Figure 3**). Freeze-fracture EM replicas reveal that AZs contain arrays of large intramembraneous particles that are thought to be calcium channels, or calcium-dependent potassium channels, or both. The arrangement of particles is in striking quadruple or double rows of various lengths. Associated with the particles are rows of vesicles are evidently captured or docked, awaiting release. The specific arrangement and number of vesicles docked at the AZ (~4–40, the latter in frog) depend not only on species (frog, lizard, rat, etc.) but also on fiber type (twitch, tonic) within a particular species. Tomography has revealed further structural components, named pegs, ribs, and beams, whose functions are still unknown. This technique promises to relate high-resolution anatomical images of AZs with structures (e.g., the SNARE complex, so named for the soluble NSF (*N*-ethylmaleimide-sensitive factor) attachment receptor) conceived from the molecular biological study of transmitter release. Eventually, molecules known to participate in docking vesicles for release at AZs will be visible, along with a detailed view of the vesicles.

EM provides only a static picture of the AZ and associated vesicles, but (as discussed later), vesicle release is a transient phenomenon. An ingenious technique – rapid, or slam, freezing – was developed by Heuser in an attempt to overcome the static nature of EM. In lieu of chemical fixation, living tissue is instantaneously frozen by slamming it against a cold metal block. By stimulating a frog NMJ at the time of freezing, Heuser hoped to capture a dynamic snapshot of vesicles just as they were released from AZs. This proved unsuccessful, presumably because two very brief yet independent transient events, vesicle release and the freezing of the NMJ, were unlikely to coincide. Only by utilizing a chemical agent to prolong and enhance transmitter release was it possible to capture such a snapshot, albeit under nonphysiological conditions.

Although long suspected, actual proof that AZs release transmitter under normal conditions came only recently. Zefirov and colleagues, using three recording electrodes to triangulate the source of synaptic currents at an active frog NMJ, found that the loci of all such currents (spontaneous and evoked) correspond precisely to the anatomical positions of AZs.

Classical (Katz) Theory of Transmitter Release

The standard model of transmitter release is based on the work of Katz and his colleagues, mainly over the period 1950–80 that followed the introduction of intracellular recording in 1949. In a series of experiments, they established the following events:

Figure 3 Electron microscopic visualization of active zones at the vertebrate neuromuscular junction. (a) Transmission electron micrograph of thin (~70 nm) sections of snake neuromuscular junction reveals electron-dense structures (active zones; arrows) surrounded by vesicles. The active zones are within the bouton (note vesicles and mitochondria (M)) and are associated with its presynaptic membrane. Each active zone precisely apposes a fold in the postsynaptic membrane of the muscle fiber. (b) Freeze-fracture electron microscopy separates regions of the presynaptic lipid bilayer membrane into outer and inner leaflets, thereby allowing imaging of intramembraneous proteins. Shown are several active zones (blue) within the presynaptic membrane of a bouton at the snake neuromuscular junction. The orientation is as if the bouton in micrograph a were viewed looking in the direction of the arrows. Each active zone appears as two double rows of particles (Ca^{2+} channels; rows are colored blue). One active zone (arrow) is shown at higher magnification in the insert (upper right; scale bar applies to both micrographs (a) and (b). (c) Electron tomography produces high-resolution surface models; shown is a portion of one active zone at the frog neuromuscular junction. The upper image shows docked synaptic vesicles (dark blue), presynaptic membrane (pale blue), and active zone material (gold). The active zone material is composed of a network of filamentous macromolecules, many of which contact the docked vesicles and presynaptic membrane. The lower image is of the superficial 15 nm of active zone material, showing beams (arrows), which lie in the midline of the active zone material, and ribs, which extend from the beams to the docked vesicles. (d) Schematic of the frog active zone derived from electron tomography and freeze-fracture electron microscopy. Shown is the presynaptic membrane (pale blue-gray), docked synaptic vesicles (darker blue), and the superficial 15 nm of the active zone material, consisting of beams (brown gold), ribs (yellow-gold), and pegs (orange-gold). Positions of macromolecules, which include calcium channels, in the presynaptic membrane are shown in green (compare to (b)). (a, b) Image provided by J Heuser. 1. Activation of frog motor terminals by nerve stimulation produced potentials that could be recorded from muscle fibers near the endplate (i.e., endplate potentials, or EPPs).
2. Depolarizing electrical events (miniature endplate potentials, or mEPPs) occurred spontaneously at endplates; mEPPs (~0.5 mV) resembled EPPs but were smaller.
3. The amplitude of EPPs evoked by nerve stimulation varied randomly, and the occurrence of spontaneous mEPPs was random in time.
4. The concentration of Ca^{2+} in the bath determined the range of EPP amplitudes: EPPs were absent when Ca^{2+} was zero, fluctuated among amplitudes corresponding to 0, 1, 2, 3, 4, etc. mEPPs when Ca^{2+} was low (~0.2 mM), and rose to ~20–40 mV at physiological bath Ca^{2+} levels (2–3 mM).

These experiments, together with subsequent ones by AR Martin (who had been Katz's student), resulted in a series of hypotheses that comprise the classical theory.

The Quantal Hypothesis

Katz's observations indicated that motor terminals secrete relatively uniform packages of ACh called quanta. Individual quanta are released randomly, and create mEPPs. Classical experiments conducted by Kuffler and Yoshikami, using the snake NMJ, demonstrated that one quantum does not correspond to a single ACh molecule but rather to 5–10 thousand molecules, synchronously released. This number is consistent with what might be packed into a single vesicle, furthering evidence that the quantum and the synaptic vesicle are one and the same. With nerve stimulation, several quanta are released nearly simultaneously, so that the postsynaptic currents they cause add together into a summed endplate current (the EPC). The EPC, in turn, develops a potential, the EPP, across the muscle fiber's membrane resistance (Ohm's law). To activate the muscle fiber, some

minimum number of quanta is required, either to directly activate contraction in tonic fibers (which we do not consider further) or to drive the fiber's membrane well above the threshold for action potential initiation (twitch fibers). The actual number of quanta released with each stimulus is in principle random, but it varies little and is statistically quite unlikely to be below threshold (see the section titled 'Binomial statistics with normal extracellular calcium').

The Calcium Hypothesis

Rise in intracellular Ca^{2+} is now well understood as a ubiquitous signaling mechanism in animals. Calcium entry (or its release from intracellular stores) triggers hormone secretion, muscle contraction, and fertilization of eggs, as well as transmitter release. Thus Katz's fundamental observation regarding the dependence of transmitter release on calcium entry into the nerve terminal was seminal far beyond synaptic physiology. At the NMJ, entry of Ca^{2+} via voltage-dependent Ca^{2+} channels causes a transient increase in the intracellular level of Ca^{2+} in the bouton, particularly near AZs where the channels are heavily concentrated. The increase triggers the fusion with the plasma membrane of some of the vesicles already poised for release at the AZ. With the vesicle lumens now continuous with the extracellular face of the plasma membrane, their vesicular contents, including ACh, diffuse into the synaptic cleft.

In motor terminals, probability of release is a steep (~fourth power) function of intracellular Ca^{2+}. At rest, low levels of Ca^{2+} (~40 nM) are associated with the release of an occasional vesicle every second or so (mEPPs) from an entire terminal. There is some evidence that mEPPs may serve a trophic or tropic function, or they may simply represent the inability of the system to turn off release completely. With the arrival of an AP from the motor neuron, the voltage-dependent channels open, and extracellular Ca^{2+} flows passively into the terminal (down both concentration and electrical gradients). In the snake, intracellular levels rise to ~300 nM (Figure 4), and hot spots near AZs are probably at micromolar concentrations. Just as rapidly, buffers within the terminal (including mitochondria) return Ca^{2+} levels to near the resting level. The result is a rapid, transient increase in release probability. A terminal (containing, say, 3000 AZs) releases ~50–100 vesicles in the ~1 ms during which Ca^{2+} was elevated, rather than a single vesicle per second – a rise in release probability by a factor of ~10^5!

Poisson Statistics with Low Extracellular Calcium

Lowering bath Ca^{2+} by a factor of ~5–10, and/or increasing the concentration of magnesium or other divalent cations that compete with it, will decrease the activity of extracellular Ca^{2+} and decrease the gradients that support its entry. Instead of releasing 50–100 vesicles per AP, a terminal releases a much smaller number. Katz estimated this number by dividing the EPP amplitudes he observed under these conditions by the mean amplitude of spontaneous mEPPs. The number fluctuated dramatically! For

Figure 4 Intracellular Ca^{2+} transient in a snake motor terminal during a 5 Hz, 30 s stimulation. The Ca^{2+}-sensitive dye fura-2 was loaded into the muscle nerve to permit measurement of bulk intrabouton Ca^{2+} concentration. Stimulation increased Ca^{2+} level from 50 nM at rest (left) to 300 nM during activity (center). Levels remained elevated for ~30 s after the end of stimulation, after which they rapidly returned to baseline (right).

example, a terminal might release on average 5 quanta per stimulus (called the mean quantal content, m). But the actual number varies about that mean with each AP delivered – 8, 4, 1, 7, 0, 10, etc. Katz, and later Martin, showed that the EPPs generated by frog motor terminals with low bath calcium obeyed Poisson statistics. Poisson's formulation allows one to assess the probability of transmitter release, p, by recording the distribution of EPP amplitudes after many trials. It was found that the distribution fit Poisson's theory (meaning that quantal events appeared to be independent and therefore randomly distributed about their mean), p was low ($\sim$0.01), and p increased with increasing bath Ca^{2+}.

Binomial Statistics with Normal Extracellular Calcium

Poisson's statistical treatment is applicable only for probabilities below $\sim$0.02, which was indeed the case in early experiments where bath Ca^{2+} was deliberately lowered. The more general statistical model of random two-state phenomena (i.e., a vesicle is either released with the arrival of an AP or it is not) is binomial statistics, which must be used under physiological conditions where p is known to be higher (normal bath Ca^{2+}). Unfortunately, p is not as easily measurable as it is with Poisson statistics. The binomial distribution depends on p plus a second parameter, n, the binomial number of release sites. For binomial statistics to apply, the release sites must be presumed independent; that is, release from one must not influence release from another. The mean quantal content is $m = np$. Events are said to be simply binomially distributed (and therefore truly random, or independent) if and only if their fluctuations about the mean, m, correspond to those predicted by a particular pair of n and p. The expected fluctuations are given by

$$N_x = N_{\text{tot}} n! p^x (1-p)^{n-x} / (n-x)! x!$$

where N_{tot} is the number of stimuli delivered and N_x is the number of responses having the amplitude $x = 0, 1, 2, \ldots, n$ quanta (the symbol ! means factorial). For example, if p is 1 (certainty), then each of n sites releases one vesicle and $m = n$; there are no fluctuations. If p is 1/2 (the same probability as that of obtaining heads in a coin flip), then $m = n/2$. If a bouton contained, say, four binomial release sites and p were 1/2, on average $m = 2$ vesicles would be released per stimulus, just as flipping four coins at once would on average produce two heads per flip. But how often would one expect to see exactly two heads? Our equation answers that question, giving the number of trials for which one would expect 0 (all tails), 1, 2, 3, or 4 (all) heads (1, 4, 6, 4, and 1 out of 16 trials, respectively). Note that release of the mean number of quanta (2) is the most probable, but this particular outcome is expected in only 6 of 16, or $\sim$38% of the trials.

There are several other general features of binomial statistics. Fluctuations about the mean increase with decreasing p, as can be inferred from the preceding comments. The variance (standard deviation squared) is given by $np(1-p)$. Variance is zero if p is 1 and increases until, with $p < 0.02$, it approaches equaling the mean, m (as it does with Poisson statistics). Fluctuations also depend upon n, but in a different way. If 1000 coins are flipped simultaneously, it is unlikely that exactly 500 will be heads, just as in the preceding example (500 is the most likely single outcome, but there are very many other possibilities). However, it is also unlikely that the distribution will deviate far from the mean. Fluctuations over the range from 480 to 520 heads are feasible, but the probability of 499 heads and only one tail would be akin to winning the lottery.

The properties of the parameters p and n as discussed here make difficult the statistical analysis of quantal release at NMJs under physiological conditions. Quantal fluctuations are quite small in normal bath calcium, presumably because n is so large. EPP fluctuations due to thermal 'noise,' change in membrane properties, etc. mask EPP fluctuations due to varying quantal release. One way to overcome this difficulty, although it is not completely satisfactory, is to attempt to isolate small portions of the NMJ in order to lower n. Because snake NMJs comprise $\sim$60 discrete boutons, about 2% of the nerve terminal is studied by activating a single isolated bouton. At this small synapse, quantal fluctuations are indeed evident in normal Ca^{2+} bath (Figure 5), and binomial analysis suggests that p is $\sim$0.4 and n is $\sim$4. Mean quantal content, m, is $\sim$1.6 vesicles per bouton. These data are for low-frequency (1–5 Hz) continuous stimulation; m is often higher for the first stimulus or two after rest, and lower after sustained stimulation at high frequency. In other NMJ preparations (human, frog), p has usually been reported in the range from 0.1 to 0.3, measured or estimated using a variety of techniques.

The Binomial *n* and the Countable Number of AZs

If the Katz theory is correct, the binomial n should have an anatomical correlate corresponding to the number of vesicles that are independently available for release upon arrival of an AP. EPPs are generally sufficient to depolarize the muscle fiber above threshold with a safety factor of $\sim$2–4, meaning that m is $\sim$100. Thus, with p in the range from 0.1 to 0.4,

Figure 5 Quantal fluctuations recorded from a snake motor bouton in normal Ca^{2+} concentration bath. Endplate potentials were recorded intracellularly from a muscle fiber endplate, the entire nerve terminal of which, save a single bouton, was removed. Shown superimposed are the responses to five stimuli (negative-going artifact at left) delivered at 1 s intervals. Either zero, 1–2, or 2–4 quanta were released. Two spontaneous miniature endplate potentials (arrows) are contained in the records, showing approximate quantal size.

n is ~250–1000. In contrast, by direct count, an average snake terminal comprising ~60 boutons contains ~3600 AZs. A similar number of AZs is present at the frog NMJ, and probably at other NMJs as well. These rough estimates ignore important systematic variations among NMJs of various species, and among different types of muscle within one animal. Nevertheless, it seems likely that *N*, the anatomical number of AZs, exceeds *n*, the number of release sites calculated from binomial statistics, perhaps by as much as an order of magnitude. Moreover, as already discussed, each AZ contains two or more apparently releasable vesicles. If each such vesicle acts independently (which is unknown), *N* is still larger.

There is at present no conclusive explanation for the disparity between *n* and *N*, although several models have been proposed. One is that some AZs have higher *p* than others, and thus form a functional pool of release sites whose number approximates *n*, not *N*. Presumably, these AZs are employed under conditions of normal use, with the others awaiting recruitment when needed. A second model is that the mEPP, or quantum, actually comprises several vesicles that are synchronously released. Thus the anatomical correlate of *n* is not one AZ, but rather several AZs. A third explanation is that transmitter release viewed at the level of single boutons, not whole NMJs, is partly deterministic, not random. Put another way, the AZs within one bouton act cooperatively, not independently. For example, an AZ that has recently released a vesicle may wait its turn before it releases again. Any sort of systematic cooperation among AZs would reduce the observed variance, and, consequently, the calculated *n*. There is currently some support, but no conclusive evidence, for each of these models.

Factors Underlying the Binomial *p*

The dependence of *p* on Ca^{2+} levels indicates that one contributing factor is the opening probability of Ca^{2+} channels and K^+ channels associated with the AZ. This probability could change dynamically, influencing release from particular AZs. A second factor, operating on a slower time scale, might originate in the postsynapse. Retrograde feedback from the effect of activating receptors apposing an AZ could regulate that AZ's efficacy. Alternatively, vesicle membrane proteins might regulate an AZ once the proteins are inserted into the plasma membrane – signaling that transmitter release from that AZ has occurred. Two vesicle proteins, SV2 and synaptotagmin, have already been found to interact with other proteins within the synaptic cleft. All of the preceding mechanisms have the potential to add a deterministic component to transmitter release, thereby explaining the disparity between *n* and *N*.

Both *p* and *n* vary systematically with various paradigms of use, although the mechanisms are not fully understood. A recent finding is that use regulates release by influencing the rate at which vesicles are made available for re-release. Also, the response of NMJs to various paradigms of use is highly dependent on species and type of innervated muscle. Of the many factors involved, some potentiate *m*, while others depress it; the behavior of a particular synapse is the algebraic sum of many genetic and use-dependent influences.

Asynchronous Transmitter Release

Ca^{2+} levels, and consequently the probability of vesicle fusion and transmitter release, increase dramatically when a terminal is invaded by an AP, as already discussed. But intracellular Ca^{2+} does not return to resting levels immediately. When several APs arrive in rapid sequence, residual elevated Ca^{2+} in the terminal can increase *p* between APs (as shown in Figure 4) and for a period (seconds to minutes) after the train is completed. Among the consequences is an increase in mEPP frequency. This release is in addition to that ascribed to the quantal content, *m*. It is evoked, but not synchronized, with the stimulus. At NMJs, the role of asynchronous release is unknown. At certain other synapses, it may be the dominant form of release under certain conditions.

Vesicle Processing

The number of vesicles stored within a typical motor terminal is in the range from 10^5 to 10^6. There is evidence that not all are releasable; for example, measurements in snake set the releasable number at

130 000 (the functional releasable pool). As mentioned previously, motor terminals must rely on their own machinery to remake spent vesicles. The process includes reuptake of vesicular membrane, formation of new vesicles, separation of vesicle proteins from those endogenous to the plasma membrane, reintroduction of these proteins into the vesicular membrane, reuptake of choline (ACh is hydrolyzed into choline and acetate), synthesis of new ACh, packaging of ACh (and other molecules) into vesicles, and, finally, mobilization of reformed vesicles into the releasable pool.

Reuptake of Vesicular Membrane by Endocytosis

Endocytosis is used by cells for many purposes – for example, to sample and obtain nutrients from the extracellular milieu. There are several variants, including bulk membrane invagination (phagocytosis and pinocytosis, which mean, respectively, to eat and to drink the contents of the extracellular fluid) and clathrin-mediated endocytosis (CME), which is often associated with specific receptors. At NMJs, both bulk membrane invagination (which we call macroendocytosis) and CME are utilized. The function of endocytosis at nerve terminals (and other secretory cells) is unique, however, and is called compensatory – compensating for vesicular exocytosis and thereby maintaining a relatively constant plasma membrane area. Without endocytosis (as, e.g., in muscles treated with black widow spider venom, nerve terminals swell and are no longer congruent with the postsynaptic membrane.

Methods for Observing Endocytosis

Compensatory endocytosis was documented in 1973 at the frog NMJ by two independent groups, led by J Heuser, and B Ceccarelli. Both groups utilized transmission EM and a bath-applied marker (horseradish peroxidase or dextran) which is endocytosed and thereby labels the internalized endocytic structures (see Figure 6). Heuser observed CME (evidenced by a clathrin coat surrounding endocytosed vesicles loaded with horseradish peroxidase) at some distance from AZs, while Ceccarelli observed virtually the opposite: labeled vesicles located near AZs, and lacking clathrin coats. Endosomes (called cisternae), now known to be the products of macroendocytosis (ME), were also labeled. These were initially thought to be formed by fusion of vesicles internalized by CME, just as similar endosomes are formed in nonneuronal cells.

An optical method for visualizing endocytosis at NMJs, particularly in living terminals, emerged with the development of sensitive fluorescent endocytic probes (see Figure 7) by Betz and colleagues in 1992. Use of optical probes, and other recent techniques, has confirmed Heuser's observations and possibly Ceccarelli's as well. The current model of endocytosis (Figure 6) includes three different endocytic mechanisms. The first is consistent with Ceccarelli's model and is called kiss-and-run transmitter release – the brief fusion of a vesicle with the plasma membrane to release its contents, followed by immediate withdrawal. This occurs at the AZ, and clathrin is not required. Kiss-and-run has been observed in central synapses but remains putative at vertebrate NMJs. The second is CME (Heuser's model), which can occur, depending on the species, either near or away from the AZ. The third is ME, which can also occur both near and away from the AZ. Macroendocytosis directly produces most, if not all, of the endosomes, that were first thought to be created by vesicle fusion. These endosomes in turn dissipate, via a clathrin-dependent process, into vesicles. While the three processes may differ in speed, location, and other details, their product is the same: vesicles of the proper size (~50 nm) for refilling with transmitter.

Refilling of Vesicles for Reuse

An enzyme within the nerve terminal, choline acetyltransferase (ChAT), resynthesizes ACh from choline that has been taken up from the cleft. Loading of vesicles involves acidification of the vesicle's lumen via a proton pump, and use of the resulting proton gradient to drive a proton–ACh exchanger, or transporter. Both the pump and the ACh transporter are among the proteins resident in the vesicle membrane. The time required for refilling is ~1 min or more in snake (at room temperature), and probably much faster in mammals.

Mobilization of Reformed Vesicles to AZs

Pathways for recycling vesicles have been studied extensively at the frog and snake NMJ, each providing a different model. In frog, there are two distinct recycling strategies, which are differentially recruited according to levels of use. Each strategy employs its own vesicle pool, either a small (local) pool associated with a particular AZ, or a global (reserve) pool that occupies much of the bouton (see Figure 6). The first strategy, associated with low levels of use (e.g., brief low-frequency stimulation), comprises exocytosis at the AZ, endocytosis near the AZ (either CME or putative kiss-and-run), mobilization of spent vesicles into the local pool (which is not anatomically distinct, but distributed among vesicles of the reserve pool), and return of the same vesicles to the AZ for preferential reuse. Thus a particular vesicle is locally

Figure 6 Current models of vesicle processing at the vertebrate neuromuscular junction. (a–c) Electron micrographs of snake boutons, illustrating structures common to all models. Endocytosed structures are labeled with horseradish peroxidase (a) or photoconverted fluorescent endocytic probe FM1-43 (b, c). Fuzzy clathrin coats are visible on vesicles that have been recently endocytosed by clathrin-mediated endocytosis (white arrowheads in (b) and (c) as well as on those still continuous with the presynaptic membrane (yellow arrowheads). A large, recently internalized endosome in a has budded several vesicles, some still clathrin coated (white arrowhead in (a). In (b), note the active zone (white arrow), local clathrin-mediated endocytosis (labeled, coated vesicle just left of the active zone), and macroendocytosis (deep membrane invagination already in the process of budding; red arrowhead). (d) Diagram depicting three types of endocytosis. On the left, macroendocytosis and clathrin-mediated endocytosis occur away from active zone 1 (AZ_1); vesicles budded from the membrane, and from the endosome, enter the reserve pool (RES), which then repopulates the readily releasable (RR) pool near AZ_1. In the center, clathrin-mediated endocytosis occurs locally near AZ_2, and reformed vesicles immediately repopulate the RR pool of AZ_2. On the right, a vesicle undergoes partial membrane fusion at AZ_3, then returns to the RR pool of AZ_3 via kiss-and-run transmitter release.

exo- and endocytosed repeatedly, without involvement of the reserve pool, and without involvement of plasma membrane distal to the AZ. The second strategy, associated with high levels of use (e.g., prolonged high-frequency stimulation), comprises exocytosis at the AZ but endocytosis some distance away, followed by mobilization of the vesicle to the reserve pool, where it remains for some time before it makes its way to the AZ for reuse (possibly via a myosin–actin motor). Endocytosis in this case is via ME (followed by budding of vesicles from the endosome) and probably CME directly from the membrane as well. In effect, mechanisms very similar to those proposed early on by Heuser and Ceccarelli are both used, albeit under different conditions. This two-tiered system of recycling has been observed at other synapses – for example, the glutamatergic NMJs of most *Drosophila* muscles. In contrast, snake NMJs utilize the same endocytic strategies as in frog (CME, particularly near the AZ, and ME), but both operate concomitantly at high and low levels of use. Moreover, both strategies supply vesicles exclusively to the reserve pool; local recycling has not been observed at the snake NMJ.

Vesicle Processing as a Presynaptic Determinant of Synaptic Strength

Endocytosis, filling with transmitter, and mobilization of vesicles to release sites require time and energy (hydrolysis of ATP or GTP). Consequently, these

processing steps have the potential to limit the availability of reformed vesicles for release, particularly with high levels of use. Recent studies indicate that this is indeed the case. Thus *m*, the mean quantal content, depends not only on the exocytotic mechanisms discussed herein but on recycling as well. Once viewed as simple housekeeping, vesicle processing can be rate limiting for transmitter release. Vesicle processing is therefore a subject of considerable research interest, particularly as a potential new substrate for the pharmacological regulation of synaptic strength.

Introduction

Synaptic plasticity has long been thought to be a fundamental mechanism of learning and memory. However, the cellular and molecular changes that underlie memory have proven difficult to study in the mammalian brain because the effects are often modest and the contribution of individual synapses to the learning process is not yet well defined. To bridge this gap, the more tractable nervous systems of higher invertebrates have proven useful for the analysis of behavioral problems and have enhanced our knowledge about the synaptic loci and mechanisms that underlie various elementary forms of learning and memory. One such model system has been the gill- and siphon-withdrawal reflex of the marine invertebrate *Aplysia californica*. This reflex exhibits several forms of learning including dishabituation, sensitization, and classical conditioning that have many of the behavioral features of learning in mammals, suggesting that learning in *Aplysia* and mammals may share common mechanisms.

Recent studies of a variety of memory processes, ranging in complexity from simple forms of memory in invertebrates to more complex forms in mammals, have supported the view that changes in the strength and structure of synaptic connections contribute critically to these diverse forms of memory storage. Studies of *Aplysia* have focused on presynaptic changes, whereas studies on mammals have focused primarily on postsynaptic changes. However, there is evidence for both pre- and postsynaptic mechanisms in both experimental systems, and recent experiments suggest that they have additional similarities. In particular, for both invertebrates and mammals, two general types of storage mechanisms have been described: short-term memory lasting minutes and long-term memory lasting days, weeks, or longer. This temporal distinction in behavior is reflected in specific forms of synaptic plasticity that underlie each form of behavioral memory as well as specific molecular requirements for each of these two forms of synaptic plasticity. The short-term forms involve the covalent modifications of preexisting proteins by a variety of kinases and are expressed as alterations in the effectiveness of preexisting connections. By contrast, in addition to protein phosphorylation, the long-term form also requires CREB-mediated gene expression and new mRNA and protein synthesis. Moreover, the long-term form often is associated with the growth of new synaptic connections, which is thought to represent the final and self-sustaining change that stabilizes the long-term process. In addition to short- and long-term memory, a family of intermediate processes that last one or more hours and often require translation but not transcription can be produced by various training protocols using repeated or prolonged stimulation.

In this article, we discuss and compare the underlying cellular and molecular mechanisms of short- and intermediate-term (Figure 1) and long-term (Figure 2) memory storage that have been identified by neurobiological studies of elementary forms of learning in *Aplysia*.

Sensitization and Classical Conditioning of the Gill-Withdrawal Reflex in *Aplysia*: Two Elementary Forms of Learning

The nervous system of *Aplysia* contains only approximately 20 000 large, identifiable nerve cells, clustered into 10 major ganglia. The ability to identify individual neurons and record their activity has made it possible to define the major components of the neuronal circuits of specific behaviors and to delineate the critical sites and underlying mechanisms used to store memory-related representations.

The molecular mechanisms contributing to memory storage have been extensively studied for the gill- and siphon-withdrawal reflex of *Aplysia*. As is true for other types of defensive reflexes, the gill- and siphon-withdrawal reflex can be modified by several different forms of learning. We begin by focusing on sensitization, an elementary form of nonassociative learning by which an animal learns about the properties of a single noxious stimulus and enables the formation of a learned fear response. When a light touch is applied to the siphon of the snail, the snail responds by withdrawing its gill and siphon. This response is enhanced when the animal is given a noxious, sensitizing stimulus. As with other forms of defensive behaviors, the memory for sensitization of the withdrawal reflex is graded, and repeated tail shocks lead to a longer-lasting memory. A single tail shock produces short-term sensitization that lasts for minutes, whereas repeated tail shocks given at spaced intervals produce long-term sensitization that lasts for up to several weeks. The reflex also exhibits

Figure 1 Mechanisms of short- and intermediate-term memory formation in *Aplysia*. Different forms of short- and intermediate-term synaptic plasticity contributing to learning in *Aplysia* involve different combinations of molecular pathways including (1) presynaptic PKA, (2) presynaptic Ca^{2+} and CamKII, (3) presynaptic PKC, (4) postsynaptic Ca^{2+}, and (5) recruitment of pre- and possibly postsynaptic molecules to new sites. See the text for details.

classical conditioning, an associative form of learning by which an animal learns about the predictive relationship between two stimuli. Enhancement of the withdrawal reflex is greater and longer lasting if the siphon is touched just before the noxious, sensitizing stimulus (paired training), compared to unpaired training or training with either stimulus alone.

The simplicity of the neuronal circuit underlying these behavioral modifications – including direct monosynaptic connections between identified mechanoreceptor sensory neurons and their follower cells – has allowed reduction of the analysis of the short- and long-term memory for sensitization to the cellular and molecular level. This monosynaptic sensory to motor neuron connection, which is thought to be glutamatergic, can be reconstituted in dissociated cell culture. A number of studies have demonstrated that this simplified *in vitro* model system reproduces what is observed during behavioral training by replacing the tail shocks with brief applications of serotonin (5-HT), a modulatory transmitter normally released by sensitizing stimuli in the intact animal. A single brief application of 5-HT produces a short-term change in synaptic effectiveness (short-term facilitation or STF), whereas repeated and spaced applications produce changes in synaptic strength that can last for more than a week (long-term facilitation, or LTF). The facilitation is also larger and longer lasting if the presynaptic sensory neuron fires action potentials just before the 5-HT application, analogous to classical conditioning.

Figure 2 Mechanisms of long-term memory formation. Long-term synaptic plasticity contributing to learning involves a sequence of cellular and molecular mechanisms including (1) neurotransmitter release and short-term strengthening of synaptic connections, (2) equilibrium between kinase and phosphatase activities at the synapse, (3) retrograde transport from the synapse to the nucleus, (4) activation of nuclear transcription factors, (5) activity-dependent induction of gene expression, (6) chromatin alteration and epigenetic changes in gene expression, (7) synaptic capture of newly synthesized gene products, (8) local protein synthesis at active synapses, (9) synaptic growth and the formation of new synapses, (10) activation of preexisting silent synapses, and (11) self-perpetuating mechanisms and the molecular basis of memory persistence. The location of these events, which may act in part to stabilize some of the changes that occur during short- and intermediate-term plasticity, moves from the synapse (1–2) to the nucleus (3–6) and then back to the synapse (7–11). Molecular details are discussed in the text.

Cellular and Molecular Mechanisms Underlying Short- and Intermediate-Term Forms of Memory Storage

STF of Synaptic Connections Involves Enhanced Transmitter Release from the Sensory Neurons

S-HT released *in vivo* during sensitization or applied directly to cultured neurons binds to cell surface receptors on the sensory neurons and promotes the production of the diffusible second messenger cAMP by activating the enzyme adenylyl cyclase (AC). This increase in intracellular concentration of cAMP results in short-term behavioral sensitization lasting minutes and correlates with an increase in synaptic strength of the sensory to motor neuron connection referred to as STF. This facilitation is due to the enhanced release of the transmitter glutamate by the sensory neuron onto its follower cells and is accompanied by an increase in excitability of the sensory neuron attributable to the depression of specific sets of potassium channels. In addition, the changes in cAMP and Ca^{2+} levels triggered by the activation of S-HT receptors and ionic channels regulate the activity of different kinase and phosphatase activities that control the duration and strength of the changes in synaptic efficiency, as we discuss later. These second messengers mediate the transient reinforcement of synaptic connections by covalent modifications of channel activation and the enhancement of neurotransmitter release at presynaptic terminals.

Different *In Vitro* Training Protocols Elicit Facilitation That Involves Different Molecular Mechanisms

Previous studies have shown that facilitation of the sensory to motor neuron synaptic connection

involves different mechanisms depending on the duration of exposure to 5-HT and the state (rested or depressed) of the synapse. Facilitation at rested synapses by a relatively brief exposure to 5-HT involves activation of AC and cAMP-dependent protein kinase A (PKA) in the sensory neuron, leading to reduced K^+ current, increased action potential duration, increased Ca^{2+} influx, and increased transmitter release, as described above. A longer exposure to 5-HT recruits activation of protein kinase C (PKC), which can also increase the duration of presynaptic action potentials. Facilitation at depressed synapses involves PKC as well, but in this case it acts through a mechanism that is independent of spike broadening and is thought to involve vesicle mobilization. Facilitation by short or longer exposure to 5-HT at rested synapses may also involve Ca^{2+}/calmodulin-dependent protein kinase (CamKII). In addition, longer exposure to 5-HT can induce intermediate-term facilitation, which requires protein synthesis and involves it mitogen-activated protein (MAP) kinase as well as PKA or (under some circumstances) PKC, and can involve postsynaptic mechanisms as well.

Behavioral Dishabituation and Sensitization Involve Different Molecular Mechanisms of Facilitation
