A major question in psychology is how different forms of learning such as dishabituation, sensitization, and classical conditioning are related. The sensory–motor neuron synapses exhibit cellular analogs of these forms of learning with temporal parameters similar to behavioral learning, making it possible to examine how the analogs are related at the molecular level. However, these studies of synaptic changes in the isolated nervous system have not been able to address directly the contribution of the different molecular mechanisms of plasticity to behavior. That question can be addressed in a simplified preparation for studying the siphon-withdrawal reflex of *Aplysia*, with which it is relatively easy to record the activity of identified neurons and their synaptic connections simultaneously with behavioral learning. This preparation undergoes dishabituation, sensitization, and classical conditioning that are similar parametrically to learning in intact animals. The neural circuit mediating the withdrawal reflex in the simplified preparation has been well characterized, and consists in part of monosynaptic connections from LE siphon sensory neurons to LFS siphon motor neurons.

During behavioral dishabituation and sensitization of siphon withdrawal, monosynaptic postsynaptic potentials (PSPs) from LE neurons that either fire during the siphon tap (on-field) or do not (off-field) change approximately in parallel with changes in the behavior, supporting the idea that both forms of learning involve heterosynaptic facilitation of sensory–motor neuron PSPs. However, pharmacological studies suggest that sensitization involves both presynaptic PKA and CamKII whereas dishabituation involves PKC, similar to facilitation at nondepressed and depressed synapses *in vitro*.

Activity-Dependent Plasticity in *Aplysia* Involves Both Pre- and Postsynaptic Mechanisms

In addition to these nonassociative, neuromodulatory forms of plasticity, *Aplysia* sensory–motor neuron synapses also exhibit two associative, activity-dependent cellular mechanisms: *N*-methyl-D-aspartate (NMDA)-dependent long-term potentiation (LTP), which occurs when presynaptic spike activity is temporally paired with postsynaptic depolarization (Pre–Post), and activity-dependent facilitation, which occurs when presynaptic spike activity is temporally paired with 5-HT (Pre–Mod). During activity-dependent facilitation, the spike activity is thought to cause an influx of Ca^{2+} that 'primes' the AC, leading to enhanced activation of the PKA pathway. Consistent with that idea, activity-dependent facilitation can be blocked by injecting either the slow Ca^{2+} chelator EGTA or a peptide inhibitor of (PKAi) into the sensory neuron. However, it can also be blocked by injecting the fast Ca^{2+} chelator BAPTA into the motor neuron, suggesting that activity-dependent facilitation involves both pre- and postsynaptic mechanisms.

Classical Conditioning Involves Both Activity-Dependent Facilitation and Hebbian LTP

The siphon-withdrawal reflex in the simplified preparation also exhibits an associative form of learning, classical conditioning. Paired training in which the conditioned stimulus (CS; mechanical stimulation of the siphon) occurs just before the unconditioned stimulus (US; a shock to the tail) produces a greater increase in the withdrawal reflex than unpaired, CS-alone, or US-alone training. Compared with unpaired training, paired training also produces greater facilitation of monosynaptic PSPs from LE neurons that fire during the siphon tap (on-field), supporting the idea that conditioning involves associative, activity-dependent plasticity at sensory–motor neuron synapses.

In addition to changes in the PSP, there are also associative, activity-dependent increases in both the evoked firing and input resistance of the LE sensory neurons during conditioning, consistent with the idea that the synaptic plasticity involves activity-dependent presynaptic facilitation. However, it could also involve Hebbian LTP because the CS causes firing of LE

sensory neurons and the US causes firing of both facilitatory interneurons and the LFS motor neurons. Consistent with that idea, exposing the abdominal ganglia to either the PKA inhibitor KT5720 or the NMDA antagonist 2-amino-5-phosphonopentanoic acid (APV) blocks behavioral conditioning. Similarly, either injecting several LE sensory neurons with a PKAi or injecting two to three LFS motor neurons with BAPTA significantly reduces behavioral conditioning. These results suggest that both activity-dependent presynaptic facilitation and Hebbian LTP are required for the conditioning.

Furthermore, either injecting an LE neuron with PKAi or an LFS neuron with BAPTA significantly reduces pairing-specific facilitation of the PSP between the neurons during conditioning, providing the strongest evidence to date that either activity-dependent presynaptic facilitation or Hebbian LTP contributes to synaptic plasticity underlying behavioral learning. Moreover, the facilitation is almost completely blocked by either injection, suggesting that the pre- and postsynaptic mechanisms are more than additive. Surprisingly, either injecting an LE neuron with PKAi or injecting an LFS motor neuron with BAPTA also significantly reduces the effects of pairing on evoked firing and membrane resistance of the LE sensory neuron, suggesting that the pre- and postsynaptic neurons interact through retrograde signaling. Collectively, the results of these experiments suggest that the synaptic plasticity during conditioning does not simply involve separate and independent pre- and postsynaptic mechanisms. Rather, they fit better with the idea that facilitation of the PSP during conditioning involves both pre- and postsynaptic changes coordinated by transsynaptic interactions.

Cellular and Molecular Mechanisms Underlying Long-Term Forms of Memory Storage

Gating Signals at the Synapse: A Balance between the Activities of Protein Kinases and Phosphatases

Synaptic stimulation of *Aplysia* sensory neurons leads to a local increase in cAMP and the activation of the cAMP-dependent PKA by causing the catalytic subunits of this enzyme to dissociate from the regulatory subunits. The catalytic subunits can then phosphorylate different substrates in the synaptic terminals, such as potassium channels and proteins involved in exocytosis, leading to enhanced transmitter availability and release as described above for the storage of short-term memory. When synaptic stimulation reaches a given threshold or is repeated a number of times, it causes a persistent increase in the level of cAMP and leads to longer-lasting forms of synaptic plasticity. At the molecular level, this more robust pattern of stimulation causes the catalytic subunit of PKA to recruit p42 MAPK and both then move to the nucleus where they phosphorylate nuclear targets, including other kinases that, in turn, can phosphorylate transcription factors and activate gene expression required for the induction of long-term memory.

In addition to protein kinases, synaptic protein phosphatases also play a key role in regulating the initiation of long-term synaptic changes. Various protein phosphatases, such as PP1 and calcineurin, counteract the local activity of PKA acting as inhibitory constraints of memory formation. For example, recent experiments in cultured *Aplysia* neurons indicate that calcineurin may act as a memory suppressor for sensitization in this organism. Thus, an equilibrium between both kinase and phosphatase activities at a given synapse gates the synaptic signals that reach the nucleus and, thus, can regulate both memory storage and retrieval.

Retrograde Signaling from the Synapse to the Nucleus

One of the features that fundamentally distinguishes the storage of long-term memory from short-term cellular changes is the requirement for the activation of gene expression. Given this requirement at the nucleus, one might expect that LTF would have to be cell wide. However, experiments using local applications of 5-HT in an *Aplysia* bifurcated sensory neuron–two motor neuron culture preparation, as well as parallel experiments in the hippocampus, demonstrated that each synapse could be modified independently in a protein synthesis-dependent manner. Thus, LTF and the associated presynaptic changes are synapse specific. This implies that there must be not only anterograde signaling from the nucleus to the synapse, but also retrograde signaling from the synapse back to the nucleus. 5-HT stimulation which produces LTF triggers the nuclear translocation of importins, proteins involved in carrying cargoes through nuclear pore complexes, suggesting that importins may play important roles in the nuclear signaling during LTF.

Activation of Nuclear Transcription Factors and Induction of cAMP-Responsive Genes

Long-term memory is represented at the cellular level by activity-dependent modulation of both the function and the structure of specific synaptic connections that, in turn, depends on the activation of specific patterns

of gene expression. As mentioned above, the inhibition of transcription or translation blocks the formation of long-term memory in a variety of model systems, but does not affect short-term memory.

Studies in *Aplysia* revealed the participation of the cAMP/PKA-signaling pathway in LTF and sensitization. In mammalian cells, PKA activates gene expression by the phosphorylation of transcription factors that bind to the cAMP-responsive element (CRE). The CRE is one of the DNA response elements contained within the control region of a gene. The binding of different transcription factors to these response elements regulates the activity of RNA polymerase, thereby determining when and to what level a gene is expressed. One of the major transcription factors that recognizes the CRE is a protein called CRE-binding protein (CREB1), which functions as a transcriptional activator only after it is phosphorylated by either PKA, MAPK, or CamK. The role of CREB1 in *Aplysia* LTF was examined by microinjecting CRE oligonucleotides into sensory neurons cocultured with motor neurons. This oligonucleotide inhibits the function of CREB1 by binding to the CREB1 protein within the cell, thereby preventing it from binding to CRE sites in the regulatory regions of cAMP-responsive genes and activating gene expression. While injection of the CRE oligonucleotide had no effect on STF, it selectively blocked LTF. Several studies by a number of laboratories have now revealed that different members of the CREB family of transcription factors participate in the molecular switch that regulates LTF formation. Both the CREB activator ApCREB1 and the repressor ApCREB2 contribute to this process. The formation of LTF requires the activation of ApCREB1 by PKA and the concomitant downregulation of ApCREB2 by MAPK. Injection of anti-ApCREB2 antibodies into *Aplysia* sensory neurons causes a single pulse of 5-HT, which normally induces STF lasting minutes, to evoke LTF that lasts several days. Conversely, the injection of pApCREB1 can by itself trigger facilitation lasting 24 h and this can be stabilized by a single pulse of 5-HT.

The activity of ApCREB1 leads to the expression of several immediate-response genes, such as ubiquitin hydrolase that stabilizes STF, and the transcription factor CCAAT-box-enhanced binding-protein (C/EPB), whose induction has been shown to be critical for LTF. This induced transcription factor (in concert with other constitutively expressed molecules such as ApAF) activate a second wave of downstream genes that lead to the growth of new synaptic connections. These genes represent only two of a family of physiological relevant examples of gene products generated by CREB activity.

Chromatin Alteration and Epigenetic Changes in Gene Expression with Memory Storage

Although epigenetic mechanisms were widely known to be involved in the formation and long-term storage of cellular information in response to transient environmental signals during development, the discovery of their putative relevance in adult brain function is relatively recent. The epigenetic marking of chromatin, such as histone modification, chromatin remodeling, and the activity of retrotransposons, may have long-term consequences in the transcriptional regulation of specific loci involved for long-term synaptic changes.

Histone tail acetylation, a modification that favors transcription and is associated with active loci, contributes to LTF formation in *Aplysia* neurons. Both facilitatory and inhibitory stimuli bidirectionally alter the degree of acetylation and the accessibility of promoters driven by the expression of genes involved in the maintenance of LTF, such as C/EBP. In addition, enhancing histone acetylation with deacetylase (HDAC) inhibitors facilitates the induction of LTF. These results indicate that critical chromatin changes occur during the formation of long-term memory and that these changes are required for the stable maintenance of these memories.

Synaptic Capture of Learning-Induced Gene Products

Following transcriptional activation, newly synthesized gene products, both mRNAs and proteins, have to be delivered specifically to the synapses whose activation originally triggered the wave of gene expression. The synaptic capture hypothesis has been proposed to explain how this specificity can be achieved in a biologically economical way in spite of the massive number of synapses in a single neuron. This hypothesis, also referred to sometimes as synaptic tagging, suggests that the products of gene expression are delivered throughout the cell, but are only functionally incorporated in those synapses that have been tagged by previous synaptic activity. The 'synaptic tag' model has been supported by a number of studies both in the rodent hippocampus and *Aplysia*.

Studies of synaptic capture at the synapses between the sensory and motor neurons of the gill-withdrawal reflex in *Aplysia* have demonstrated that to achieve synapse-specific LTF, more than the production of CRE-driven gene products in the nucleus is necessary. One also needs a PKA-mediated covalent signal to mark the stimulated synapses and local protein synthesis to stabilize that mark. Thus, injection into the cell body of phosphorylated CREB-1 gives rise to

LTF at all the synapses of the sensory neuron by seeding these synapses with the protein products of CRE-driven genes. However, this facilitation is not maintained beyond 24–48 h unless the synapse is also marked by the short-term process, a single pulse of 5-HT.

Local Protein Synthesis at Active Synapses

A number of distinct mRNAs have now been localized in the axons of *Aplysia* and the dendrites of mouse hippocampal neurons. The molecular mechanisms that carry these mRNAs to the synapse are largely unknown, but they are thought to involve the recognition of *cis*-acting elements in their 3′ untranslated region by specific RNA-binding proteins that interact with the cytoskeleton. Once translocated to synaptic compartments, these mRNAs are efficiently translated only after docking at active synaptic sites, a process frequently referred to as synaptic or local protein synthesis. Recent studies indicate that regulation of local protein synthesis may play a major role in the control of synaptic strength.

The role of local protein synthesis in the maintenance of synapse-specific LTF in *Aplysia* has been investigated using a culture system in which a single bifurcated sensory neuron was plated in contact with two spatially separated motor neurons. In this culture system, repeated application of 5-HT to one synapse produces a CREB-mediated, synapse-specific LTF that can be blocked by the local application of inhibitors of translation, suggesting that local protein synthesis at the synapse is required for the initiation of synapse-specific LTF.

The control of translation at the synapse is likely to be complex and involves several different mechanisms, including mRNA transport and docking, cytoplasmic polyadenylation, and the phosphorylation of different translation factors. Many of the molecules contributing to the regulation of this process have been found to be required for both LTF in *Aplysia* and L-LTP in the hippocampus. This is the case for the kinase mTOR (mammalian target of rapamycin), which is the target of the selective protein synthesis inhibitor rapamycin, the brain-derivate neurotrophic factor (BDNF), which promotes local protein synthesis, and the cytoplasmic polyadenylation element binding protein (CPEB), which activates dormant mRNAs.

Synaptic Growth and the Formation of New Synapses

Synaptic remodeling and the growth of new synaptic connections have been found to accompany various forms of long-term memory. This is particularly well documented at the connections of identified sensory neurons in *Aplysia*. The storage of long-term memory for sensitization (lasting several weeks) is accompanied by an increase in the number of sensory neuron active zones (transmitter release sites) as well as an increase in the total number of presynaptic varicosities (boutons) per sensory neuron, both of which parallel the duration of the behavioral memory. This synaptic growth can be reconstituted in dissociated sensory–motor neuron co-cultures by repeated applications of 5-HT, and requires altered gene expression and new protein synthesis. The 5-HT-induced synaptic growth is also associated with the modulation of neural cell adhesion molecule (NCAM)-related cell adhesion molecules and reorganization of the presynaptic actin network.

Activation of Silent Synapses

To monitor continuously the functional and structural changes during LTF, recent studies have combined time-lapse confocal imaging of individual presynaptic sensory neuron varicosities labeled with different fluorescent markers. Repeated pulses of 5-HT induce two distinct classes of presynaptic changes: (1) a rapid (3–6 h) activation of silent presynaptic terminals through the filling of preexisting empty varicosities with synaptic vesicles, which requires translation but not transcription, and (2) somewhat slower (12–18 h) generation of new synaptic varicosities, which requires both transcription and translation. The rapid activation of silent presynaptic terminals suggests that in addition to its role in LTF, this modification of preexisting synapses may also contribute to the intermediate phase of synaptic plasticity and memory storage. The activation of silent synapses also plays a major role in LTP in the hippocampus, although in that case the term refers to membrane insertion of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors at postsynaptic sites previously lacking them. A similar regulation involving the insertion and clustering of postsynaptic neurotransmitter receptors has recently been described during LTF at sensory–motor neuron synapses in *Aplysia*.

Self-Perpetuating Mechanisms and the Molecular Basis of Memory Persistence

What is the nature of the enduring molecular changes that underlie long-term memory storage? One possible answer to this elusive question is that some type of self-sustained alteration at the synaptic level is required to confer stability to memory storage. Several molecular mechanisms have been proposed as potential candidates for this process. We discuss here one recent model to account for the stable maintenance and persistence of LTF in *Aplysia*.

Prion-like proteins represent autoreplicative structures that may serve as a persistent form of information. It has recently been proposed that the persistence of long-term synaptic plasticity might be explained by the prion-like properties of *Aplysia* neuronal CPEB. Neuronal CPEB can activate the translation of dormant mRNAs through the elongation of their poly-A tail. *Aplysia* CPEB has two conformational states: one is inactive or acts as a repressor, while the other is active. In a naïve synapse, the basal level of CPEB expression is low and its state is inactive or repressive. According to the model, 5-HT induces an increase in the amount of neuronal CPEB and, if a given threshold is reached, causes the conversion to the aggregated prion-like state, which is more active and lacks the inhibitory function of the basal state. Once the prion state is established at an activated synapse, dormant mRNAs, made in the cell body and distributed cell wide, would be translated only at the activated synapses. Because the activated CPEB can be self-perpetuating, it could contribute to a self-sustaining synapse-specific long-term molecular change and provide a mechanism for the stabilization of learning-related synaptic growth and the persistence of memory storage.

An Overall View

Long-lasting forms of learning-related synaptic plasticity are often associated with changes in both the number and structure of synapses. Some of the best evidence for changes in synapse number has come from studies of long-term (days to weeks) plasticity in *Aplysia*, where long-term sensitization *in vivo* and LTF *in vitro* are both accompanied by increases in the number of presynaptic sensory neuron varicosities. The late (hours) protein synthesis-dependent phase of hippocampal LTP is also accompanied by increases in both postsynaptic and presynaptic structures, consistent with an increase in synapse number.

By contrast, short-term (up to about 1 h) plasticity and the early phases of long-term plasticity in *Aplysia* and hippocampus have been thought to involve a completely different type of mechanism, covalent modification of existing proteins in either presynaptic (*Aplysia*) or postsynaptic (hippocampus) structures. However, the discovery of intermediate (2–3 h) forms of plasticity that involve elements of the short-term and long-term mechanisms in both *Aplysia* and hippocampus questioned this dichotomy, and in recent years it has been challenged by two additional types of evidence. First, at least under some conditions, pre- as well as postsynaptic mechanisms have been found to contribute to early-phase LTP in hippocampus and to a variety of types of short-term plasticity in *Aplysia* including homosynaptic potentiation, heterosynaptic facilitation by longer exposure to 5-HT, activity-dependent facilitation, and the synaptic plasticity during behavioral conditioning. In many cases, inhibitors injected into the pre- and postsynaptic neurons have more than additive effects, suggesting that the pre- and postsynaptic mechanisms are not independent but rather act synergistically. Furthermore, in some cases, postsynaptic inhibitors have been shown to affect presynaptic properties, suggesting transynaptic signaling.

Second, imaging studies have shown that even the earliest phases of hippocampal LTP are accompanied by pre- and postsynaptic structural alterations. Tens of minutes after the induction of LTP there is an outgrowth of new pre- and postsynaptic processes, and even earlier (minutes) there are increases in spine size, clusters of postsynaptic glutamate receptors, and clusters of presynaptic vesicle-associated proteins and sites where the pre- and postsynaptic clusters co-localize. Moreover, the presynaptic alterations appear to depend on retrograde signaling from the postsynaptic cells. Similar to clustering of synaptic proteins during LTP, intermediate-term facilitation in *Aplysia* is accompanied by filling of preexisting empty presynaptic varicosities with synaptic vesicles. However, these intermediate-term changes do not persist for 24 h unless they are stabilized by additional molecular events (including the machinery for translational activation) recruited during LTF. LTF is also accompanied by clustering of postsynaptic proteins including the *Aplysia* homologs of NMDA and AMPA receptors. It is not yet known whether intermediate-term facilitation is accompanied by similar postsynaptic changes. However, presynaptic microstructural changes can occur during even earlier phases of learning-related synaptic plasticity in *Aplysia*: homosynaptic potentiation induced by moderate tetanic stimulation of the presynaptic neuron is accompanied by rapid (less than 10 min) aggregation of the vesicle-associated protein synaptophysin into new clusters or puncta, as occurs during early-phase LTP in hippocampal neurons and 5-HT-induced intermediate-term facilitation in *Aplysia*.

Combined, these results suggest that even the early phases of learning-related synaptic plasticity can involve pre- and postsynaptic microstructural alterations that may lead to the formation of new functional synapses, which can then be stabilized or maintained by additional long-term training. This emerging view is likely to supplement (rather than replace) the more established hypothesis that early-phase plasticity exclusively involves either pre- or postsynaptic covalent modifications. In some ways, this new appreciation represents a paradigm shift in thinking about the

cellular and molecular bases of learning and memory, because it suggests that aspects of the pre- and postsynaptic mechanisms that underlie both early- and late-phase plasticity may not be fundamentally different and independent. Rather, these mechanisms appear to have certain structural features in common that may contribute to the transition between short-term and long-term memory storage.

Presynaptic Molecular and Morphological Factors

Synaptic Transmission

Action potential invasion and depolarization of presynaptic terminals induces a Ca^{2+} influx through voltage-gated Ca^{2+} channels. The resulting increase in cytosolic Ca^{2+} concentration triggers vesicle fusion and neurotransmitter release. Neurotransmitter diffusing across the synaptic cleft binds to and activates postsynaptic receptors, usually leading to postsynaptic currents that may be recorded electrophysiologically. Although the tight Ca^{2+}-dependency of vesicle fusion and neurotransmitter release was demonstrated over 40 years ago, the specific mechanisms and the proteins that mediate vesicle fusion are still under investigation.

Recent work has demonstrated that a group of presynaptic proteins constituting the soluble *N*-ethylmaleimide-sensitive factor attached protein receptor (SNARE) complex is necessary for exocytosis. This complex is composed of a bundle of four α-helices thought to bridge synaptic vesicle and cell membranes. These α-helices are donated by three proteins: syntaxin and synaptosomal-associated protein (SNAP)-25, located in the synaptic active zone; and synaptobrevin, in the synaptic vesicle membrane. Synaptotagmin interacts with the C-terminal region of the SNARE complex during Ca^{2+}-dependent fusion and represents a likely candidate Ca^{2+} sensor for transmitter release. Synaptic vesicles fuse with the plasma membrane in microseconds. Consequently, they are located very near to the point of fusion, the active zone, at the presynaptic terminal. This organization is termed docking. It is believed that there is a pool of ready-to-fuse synaptic vesicles that have undergone a further maturation step, priming, that requires adenosine triphosphate (ATP), submicromolar Ca^{2+} concentrations, and alterations in membrane lipids by lipid transferases and kinases. Evoked synaptic fusion is thought to require high (hundreds of micromolar) local concentrations of Ca^{2+} following the action potential invasion of the nerve terminal; and small modifications of this Ca^{2+} entry may cause large changes in neurotransmitter release.

Neurotransmitter release Seminal work by Del Castillo and Katz analyzing synaptic transmission at the frog neuromuscular junction combined with electron microscopic studies demonstrating compensatory endocytosis of vesicle membrane formed the vesicle theory of neurotransmitter release. This theory predicts that vesicle size, and the amount of neurotransmitter contained within the vesicle, determines the lowest unitary response (1 quantum). Thus, in response to increases in Ca^{2+} concentration, vesicles fuse and release neurotransmitter in an all-or-none event. The predicted uniform nature of vesicles and their neurotransmitter cargo led to the interpretation that presynaptic plasticity must be due to changes in the number of quanta (or vesicles) released from the presynaptic terminal in response to a single action potential (a change in probability). Furthermore, changes in the amplitude of individual quantal events must be due to changes in the number or properties of postsynaptic receptors. However, recent evidence suggests that presynaptic factors may also regulate changes in quantal size.

Presynaptic changes in the mean excitatory postsynaptic current (EPSC) amplitude might, therefore, result from a change either in neurotransmitter concentration at each synaptic site or in the number of vesicles released distributed across all of these sites (Figure 1). This distinction is significant because synaptic strength and variability may be determined presynaptically by (1) the quantal size of individual fusion events, (2) the number of active zones within a synaptic connection, or (3) the probability of vesicle fusion at individual synapses. All these starting conditions are affected by a range of variables across synapses.

Before we discuss the mechanisms underlying presynaptic inhibition we must, therefore, consider a range of synaptic substrates on which it plays out.

Synapse Structure

A synapse is most commonly understood as an individual contact between electron-dense pre- and postsynaptic membranes. This is most generally a small contact area with rapid diffusional loss of neurotransmitter from the synapse, although the synapse may have a more complex topography in which the neurotransmitter is temporarily trapped. An extreme example of the latter may be found at the unipolar brush cell in the cerebellum, but similar examples may be found in sensory inputs (e.g., to the olfactory bulb). Synaptic responses from recordings between pre- and postsynaptic neurons typically represent a summed synaptic current from a number of such release sites.

The structure of the axon may profoundly affect presynaptic inhibitory mechanisms. Although many synapses exist as varicosities along a single axon

Figure 1 Many different mechanisms exist for ionotropic receptors to mediate presynaptic inhibition. An action potential (1) reaching axonal synaptic terminals may be modified by, for example, GABA receptors activated by axo-axonic inputs (blue). $GABA_A$ receptors in isolated presynaptic boutons (2) may reduce the action potential amplitude. Receptors at branch points (3) may cause a failure of the action potential to invade large or small areas of the axon terminal arborization. Receptors at *en-passant* boutons (4) may reduce the action potential duration. All these effects ultimately modify Ca^{2+} entry (red) to the presynaptic terminal and consequently reduce neurotransmitter release. GABA, γ-aminobutyric acid. From Dunlap K and Fischbach GD (1978) Neurotransmitters decrease the calcium component of sensory neuron action potentials. *Nature* 276: 837–839.

trunk, others are found at the terminations of elaborate axon branches (Figure 1). The complexity of these structures may impede the action potential invasion of distal synaptic active zones. Depending on the location within the structure of the axon, presynaptic inhibition might therefore selectively reduce or completely prevent action potential depolarization of active zones within distinct axon branches.

Voltage Dependence of Release

Because the relationship between presynaptic Ca^{2+} entry and neurotransmitter release is supralinear, changes in the duration or magnitude of action potential depolarization ultimately alter the neurotransmitter-release probability by altering Ca^{2+} entry. Changes in presynaptic depolarization may result from impeding action potential invasion of the axon, as already mentioned. Alternatively, the distribution and molecular properties of voltage-gated Na^+ channels in the presynaptic terminal also determine the duration or magnitude of action potential-induced depolarization and subsequently voltage-dependant Ca^{2+} entry. Similarly, the molecular properties of voltage-operated Ca^{2+} channels and their location relative to vesicular release apparatus determine the Ca^{2+} cooperativity of release and, therefore, probability.

Kiss-and-Run versus Full Vesicle Fusion

Many of the underlying assumptions concerning presynaptic inhibition have been predicated on the quantal nature of synaptic transmission itself. That is, if synaptic transmission requires the fusion of a synaptic vesicle and a synaptic vesicle necessarily releases all of its neurotransmitter when it fuses with the presynaptic membrane, then presynaptic inhibition must involve a reduction in release probability. However, synaptic neurotransmitter release may be more subtle and complex because complete fusion may not always occur. Three hypotheses have been proposed to account for the recycling of vesicle membrane after exocytosis. Heuser and colleagues proposed that vesicles are recycled through an endosome. Concern that this process is too slow to account for recycling observed experimentally led De Camilli and colleagues to propose a model by which the vesicle completely fuses with the presynaptic membrane and is recovered directly into function vesicles. However, it is apparent that large dense core vesicles can fuse with the membrane and then return to a pool of vesicles available for release without fully collapsing into the presynaptic membrane, and this may lead to variability in transmitter release (kiss-and-run fusion). Measurements of catecholamine release from adrenal chromaffin large dense core vesicles provide direct evidence that variable amounts of hormone may be released during vesicle fusion. More recently, it was proposed that changes in interactions between synaptotagmin (a putative Ca^{2+} sensor) and SNAP-25 may govern a mode of fusion shift. It has been suggested that synaptotagmin-I may govern complete fusion and synaptotagmin-IV incomplete fusion (i.e., kiss-and-run). The role of kiss-and-run fusion in the central nervous system (CNS) has proved contentious, but it is becoming more accepted.

Presynaptic Receptors Inhibiting Neurotransmitter Release

Synaptic transmission is presynaptically inhibited by both ionotropic (receptors with an integral ion

channel) and metabotropic receptors (G-protein-coupled receptors (GPCRs)) within the nervous system. These receptors have been identified variously as autoreceptors (activated by the release of transmitter from the terminal on which they are located) or axo-axonic (in which the transmitter is released from a second presynaptic terminal).

The mechanism by which presynaptic receptors modify neurotransmitter release remains open to some question, although some insights have been derived from the study of the activation of the γ-aminobutyric acid (GABA) receptor $GABA_A$ as a component of primary afferent depolarization. The concept that a distal or perhaps precentral mechanism might inhibit sensory inputs to the spinal cord was first proposed as early as 1957 by Frank and Fuortes. Dubbed remote inhibition, reflecting what was then known of the phenomenon, the theory was based on the finding that sensory excitatory potentials could be depressed with no visible effect on the membrane potential of the recorded spinal motor neuron receiving that input. This early work in the mammalian nervous system was paralleled by a series of markedly similar findings within arthropod preparations first outlined by Eckert. Thus, in both vertebrate and invertebrate preparations, it was found that presynaptic inhibition modifies sensory inflow to the CNS. Later recordings from primary afferent nerve terminals gave the name primary afferent depolarization (PAD) to this phenomenon, in which the sensory nerve terminal is depolarized causing presynaptic inhibition.

It is clear that a large component of PAD is caused by the activation of presynaptic $GABA_A$ receptors that evoke a Cl^-current. This current is depolarizing because Cl^-pumps at the primary afferent terminal actively raise the intracellular Cl^- concentration above its equilibrium. Since these seminal studies, a number of additional mechanisms have been proposed as underlying PAD. Recently, ionotropic glutamate receptors were identified at the presynaptic terminals in a number of systems, including the lamprey. Ionotropic glutamate receptors, including kainate receptors, *N*-methyl-D-aspartate (NMDA) receptors, and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors have been identified at presynaptic terminals throughout the vertebrate neuroaxis. It has been proposed that these receptors may contribute to PAD at spinal afferent terminals, perhaps by spillover of glutamate from neighboring synapses. Metabotropic receptors (e.g., serotonin (5-HT) receptors) may also contribute to PAD and certainly contribute to the central inhibition of afferents to the spinal cord.

How Do Presynaptic Ionotropic Receptors Modify Release?

Ionotropic presynaptic receptors How does the activation of an ionotropic receptor on the presynaptic axon or terminal lead to a reduction in neurotransmitter release from that terminal? Perhaps the simplest answer is that regardless of whether GABA depolarizes or hyperpolarizes the terminal, a conductance shunt occurs in the terminal to decrease the amplitude of the action potential. Put more simply, the resting conductance of the axon is raised, and therefore during an action potential the current flowing through Na^+ channels leads to less potential change and a smaller action potential (Figure 1). This has been recorded directly in the lamprey spinal cord, although not at primary afferents. The smaller action potential may reduce the amount of Ca^{2+} that enters the terminal through Ca^{2+} channels. However, the precise effects may be more complex. For example, depolarizing the terminal may serve to inactivate Ca^{2+} channels partially, but also may reduce the driving force for Ca^{2+} entry at the start of the action potential. Finally, it is possible that $GABA_A$ receptor activation can prevent the action potential invasion of entire terminal regions of primary afferents (Figure 1). There is good evidence for this in a number of invertebrate preparations, although the evidence in vertebrates is less compelling.

Presynaptic mechanisms may also have effects more distal to the presynaptic terminals themselves to alter sensory inflow to the CNS. Ionotropic receptor activation can inhibit sensory receptor potentials in vertebrates and invertebrates alike, depending on the location of the receptor with respect to the CNS. In the crayfish, mechanosensitivity is modified by peptides and 5-HT; in the vertebrate lamprey spinal cord it is modified by GABA and peptidergic transmission. In the mammalian cochlear, outer hair-cell receptors can be activated by efferent output to drive sufficient motility to cause detectable noise output from the ear.

Metabotropic presynaptic receptors It is perhaps not overstating the case that every synaptic terminal possesses a complement of GPCRs. GPCRs, the largest known family of cell-surface receptors are integral membrane proteins comprising seven membrane-spanning α-helices, connected by extracellular and intracellular loops. Following activation by a GPCR, heterotrimeric G-proteins dissociate into activated G_α-guanosine triphosphate (GTP) and free $G_{\beta\gamma}$ subunits. Given the overwhelming number of pathways that G_α-GTP and free $G_{\beta\gamma}$ can activate, it is far from surprising that a similarly overwhelming number of

mechanisms have been proposed to explain presynaptic inhibition by G-proteins (see Figure 2(a)). Uncertainty over mechanisms by which G-proteins alter transmitter release reflects both the variety of effector targets from both $G_{\beta\gamma}$ and G_{α}-GTP and also the difficulty in gaining experimental access to presynaptic terminals, which, in most cases, are small and particularly difficult to record from in real time.

Figure 2 GPCR-mediated presynaptic inhibition: (a) mechanisms; (b) effectiveness. In (a), mirroring the complexity of GPCR signaling, many possible means of altering synaptic transmission have been proposed in the presynaptic terminal. Presynaptic inhibition may be mediated by axo-axonic inputs to the presynaptic terminal (blue) or by autoreceptors activated by release of transmitter from the presynaptic terminal itself (green). After the receptor is activated, either $G_{\beta\gamma}$ or G_{α} signaling may lead to the modification of neurotransmitter release, although $G_{\beta\gamma}$ has been more often implicated in presynaptic inhibition. Downstream in G-protein signaling pathways, the targets may be presynaptic Ca^{2+} channels, the release machinery (e.g., the SNARE complex), vesicle recycling or neurotransmitter loading of vesicles. In (b), an example of the effectiveness of presynaptic inhibition is shown. In this case, action potentials in one presynaptic axon were stimulated through a recording electrode (bottom trace, 10 in sequence). These action potentials evoked postsynaptic currents (top traces) that vary in amplitude depending on the number of vesicles released following each stimulus. Injection of $G_{\beta\gamma}$ into the presynaptic terminal, to mimic the receptor activation of a G-protein, almost abolishes this synaptic transmission (middle trace). EPSC, excitatory postsynaptic current; GPCR, G-protein-coupled receptor; SNARE, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor.

The seminal finding of Dunlap and Fischbach set the stage for a long-standing theory on the means by which all these receptors might function in the presynaptic terminal, whether activated by peptides, monoamines, or amino acids. In the cell body of sensory nerve cells in the dorsal root ganglion, a number of neurotransmitters reduce Ca^{2+} entry through voltage-gated Ca^{2+} channels. Although this finding was repeated and expanded on in many nerve cells, it was not until Forsythe and colleagues developed the calyx synapse of Held as a model system in the 1990s that definitive proof was provided that GPCRs directly alter presynaptic Ca^{2+} entry. GPCRs reduce Ca^{2+} entry by $G_{\beta\gamma}$ binding to the Ca^{2+} channel responsible for release – principally, P/Q, N, or R type channels (now named Cav2.1–Cav2.3) in which $G_{\beta\gamma}$ may bind to one or more sites and change gating properties. In a number of examples, this modification of channel properties has also been linked to a channel relationship with the SNARE protein syntaxin 1A that in turn is necessary for synaptic vesicle fusion. The efficacy of this channel inhibition may depend to a great extent on the very recent history of synaptic activity at the presynaptic terminal.

In addition to direct effects of the $G_{\beta\gamma}$ on activation of voltage-gated Ca^{2+} channels responsible for neurotransmitter release, Ca^{2+} entry may be altered by activation of K^{+} channels (G-protein-activated inwardly rectifying potassium channels (GIRKs)). G-proteins may also modulate presynaptic Na^{+} channels. It should be stressed, however, that at present little evidence supports or refutes these mechanisms at the presynaptic terminal.

$G_{\beta\gamma}$ may also inhibit synaptic transmission without altering Ca^{2+} entry. Spontaneous release, which occurs independently of Ca^{2+} entry, can be detected by recording miniature postsynaptic currents (mPSCs). These mPSCs are modulated by many GPCRs. G-proteins can inhibit exocytosis after cell permeabilization, suggesting a role very late in exocytosis that does not rely on Ca^{2+} entry. In addition, exocytosis in pancreatic β cells, mast cells, chromaffin cells, PC12 cells, and secretory granules are regulated independently of Ca^{2+} entry by G-proteins, and $G_{\beta\gamma}$ interacts directly with the fusion machinery in rat mast cells. In the lamprey giant synapse, 5-HT-mediated synaptic inhibition does not reduce Ca^{2+} entry to the synapse, and its effect is blocked by presynaptic intracellular scavenging of free $G_{\beta\gamma}$. $G_{\beta\gamma}$ can interact with the core vesicle fusion machinery; it directly binds SNARE proteins syntaxin and SNAP-25 and the ternary SNARE complex.

Intriguingly, $G_{\beta\gamma}$ interacts with the C-terminal region of the SNARE complex, a region that may play a role in linking synaptotagmin, a putative Ca^{2+} sensor, to SNARE at the C-terminal region of SNAP-25. Interaction of SNAP-25 and syntaxin with synaptotagmin links Ca^{2+} entry with vesicle fusion, but may also control the stability of the fusion pore leading to a kiss-and-run form of fusion.

This finding essentially parallels findings of the effect of $G_{\beta\gamma}$ in the lamprey and in chromaffin cells in culture, suggesting a vital role for synaptotagmin–SNARE complex interactions in fusion pore stability and neurotransmitter release. Thus, it is possible that presynaptic inhibition involves not just a change in the probability of neurotransmitter release but a change in the vesicle fusion mechanism that leads to neurotransmitter release.

Finally, it may be possible to inhibit synaptic transmission by lowering the amount of glutamate in synaptic vesicles prior to fusion. Indeed, quantitative immunogold electron microscopy of glutamatergic Schaffer collateral and parallel fiber terminals reveals that some synaptic vesicles contain G_{β} subunits. Furthermore, G-protein activation inhibits glutamate uptake into mouse and rat brain vesicular preparations. In addition to changing the concentration of neurotransmitter, it also appears possible to alter the volume of the vesicle and, therefore, alter the total amount of neurotransmitter within the vesicle.

Patterns of Neuronal Activity That Are Likely to Activate These Receptors, Autoreceptors, Heteroreceptors, and Spillover

Presynaptic inhibition can have very different functional implications for the synapse depending on the source of the inhibition. Broadly, we may break down presynaptic inhibition into two categories: (1) inhibition mediated by axo-axonic or dendro-axonic projections (i.e., a third party interferes with the transmission of synaptic responses between a synaptically coupled pair of two neurons), which we may describe as heterosynaptic inhibition; and (2) inhibition mediated by the release of neurotransmitter from the active presynaptic terminal itself, or autoreceptive inhibition.

Heterosynaptic presynaptic inhibition The best example of this phenomenon is undoubtedly PAD. Animals are subject to a constant barrage of sensory inflow, only a small fraction of which we pay attention to at each moment. Thus, somewhere in the passage of information from the periphery to the higher centers of cognition, animals must curtail the flow of nonessential information. It is believed that presynaptic inhibition provides this role. For example, when an animal walks, its response to a touch on the foot varies depending on whether that foot is raised or on the ground. Phasic primary afferent depolarization, driven by central pattern generators in the spinal cord, is thought to represent a component of such sensory gating. Thus, heterosynaptic presynaptic inhibition can allow one central nervous function (motor drive in this case) to modify a related but separate function (sensory inflow). A corollary to heteroreceptor-mediated presynaptic inhibition has also been identified in a variety of synapses. Spillover, or cross-talk between synapses, can occur in which neurotransmitter released from one terminal may reach neighboring terminals, albeit at a reduced concentration. The resultant lower neurotransmitter concentration may allow the selective activation of higher-affinity receptors at the affected terminal, both presynaptically and postsynaptically.

Autoreceptor-mediated presynaptic inhibition Inhibition mediated by receptors activated by release of neurotransmitter from the same presynaptic terminal necessarily implies a very different function. This form of presynaptic inhibition induces short-term use dependent effects at the presynaptic terminal in question. The effect of the activation of the presynaptic receptors are frequency- and pattern-dependent. Because the release of transmitter from earlier stimuli activates presynaptic receptors that modify future release, the time delay between stimuli can significantly alter the subsequent release of neurotransmitter. However, we must also consider the properties of the receptors activated and their downstream effect.

Ionotropic autoreceptors. Examples of these at the presynaptic terminal are GABA receptors, NMDA receptors, kainate receptors, and AMPA receptors. However, there is not a great deal of consensus on the mechanisms of action of presynaptic glutamate receptors. Both kainate and AMPA receptors appear to show convergence of signaling with metabotropic receptor effects in the presynaptic terminal to inhibit release, although it is not yet clear how this occurs.

Metabotropic autoreceptors. By far the greater attention has been paid to GPCRs acting as autoreceptors. We have already discussed the variety of possible mechanisms by which GPCRs may modify release. However, the mechanism also has important implications for the function of these receptors during the repetitive stimulation that is necessary to activate the autoreceptor under conditions at which it might actually inhibit neurotransmitter release. For example, GPCRs inhibit Ca^{2+} entry to the presynaptic terminal, but this inhibition is attenuated by depolarization associated with action potential firing because the GPCR-mediated inhibition of Ca^{2+} dependence is transiently relieved by membrane depolarization. Thus, paradoxically, depending on the initial state

of GPCR activation, paired pulse facilitation or depression may follow autoreceptor activation and the inhibition of presynaptic Ca^{2+} channels. In fact, at central glutamatergic synapses known to contain inhibitory metabotropic glutamate receptors, pharmacological block of the receptor may have little effect on neurotransmitter release during trains of stimuli, but may profoundly alter recovery of neurotransmitter release shortly after the train ends.

More recent work on the interaction between $G_{\beta\gamma}$ and the SNARE complex also opens the possibility for complex interactions between inhibition of release by direct effects on the fusion machinery and effects on Ca^{2+} entry to the terminal. We might expect synergistic effects of $G_{\beta\gamma}$ because it can both reduce the efficacy of Ca^{2+} to cause synaptic vesicle fusion and reduce the Ca^{2+} entry that is necessary to drive vesicle fusion.

Conclusion

The extent of presynaptic inhibition following receptor activation is determined by (1) the morphology of the axon, (2) the molecular properties of the proteins involved in vesicle fusion, and (3) recent activity of the axon. It therefore appears that unique forms of presynaptic inhibition exist that may be activated by distinct patterns of neuronal activity. For example, presynaptic $GABA_A$ receptor depolarization decreases Ca^{2+} influx and therefore inhibits synaptic transmission by lowering release probability (decreasing the number of vesicle that fuse in response to an action potential). Nevertheless, the amount of neurotransmitter released in to the synaptic cleft from the remaining vesicles that fuse remain the same. An alternative mechanism has, however, been proposed in which the activation of presynaptic GPCRs inhibits synaptic transmission downstream of Ca^{2+} entry through a direct interaction with vesicle fusion proteins. Recent work demonstrates that $G_{\beta\gamma}$ alters the mode of vesicle fusion, resulting in a lesser release of neurotransmitter, perhaps from each vesicle. This form of synaptic modification may, in turn, lead to a differentially greater inhibition of lower-affinity receptors compared to receptors with a higher affinity at the same synapse.

Finally, we must ask why presynaptic inhibition exists? Ultimately, the presynaptic terminal provides one more source of computational ability in the nervous system. However, we may break these mechanisms down into some clearly important uses:

1. *Sensory gating*. Presynaptic inhibition represents an early step in the modification of sensory inflow, depending on the state of motor output or related sensory inputs.
2. *Receptor selectivity*. If presynaptic inhibition can modify the fusion properties of a synaptic vesicle sufficiently to reduce synaptic concentrations of neurotransmitter, then this mechanism can readily alter the population and activity of activated postsynaptic receptors.
3. *Selective activation of synapses*. If one axon can selectively activate different synaptic terminals, depending on the state of presynaptic inhibitory inputs, then the computational power of the circuit in which the axon is embedded will be increased.

Fifty Years of Presynaptic Receptors

The notion of presynaptic receptors dates from the discovery of presynaptic inhibition, which itself followed the understanding of postsynaptic inhibition and postsynaptic excitation. In the 1950s, it was established that postsynaptic potentials (PSPS) are produced by a change of ionic conductances. The demonstration was based on the measure of the reversal potential of the PSPS. It was shown that inhibitory PSPSs differed from excitatory synaptic potentials by the fact that their reversal potential was more negative than the threshold of the action potential, whereas for EPSPs the reversal potential was more depolarized than the threshold. The functional result of coincident excitatory and inhibitory inputs was seen as determined by the algebraic sum of the changes they produce in membrane potential.

These concepts had barely been established before exceptions appeared. In some preparations, the EPSP produced by an excitatory axon A was reduced by stimulation of an inhibitory axon B, which by itself did not produce a change of conductance in the postsynaptic cell. The explanation, first proposed by Frank and Fuortes in 1957 and then developed by the groups of Eccles and Kuffler, was that the inhibitory axon terminal synapsed with the excitatory terminal and produced a change in conductance in this terminal. Soon, both Gray and Kidd provided electron microscopy pictures which established the existence of axo-axonic synapses ('serial' synapses) and gave a structural basis to the prediction of the physiologists (Figure 1). Presynaptic inhibition was then observed in a variety of other systems. The concept of presynaptic facilitation soon followed (it was first proposed by Tauc and Kandel in 1964).

Presynaptic inhibition and presynaptic facilitation were initially viewed as heterosynaptic and based on serial synapses. In 1971, four laboratories proposed that in the peripheral nervous system, norepinephrine can inhibit its own release by acting on 'autoreceptors.' It was later found that in other cases presynaptic autoreceptors facilitate the release of transmitter. Autoreceptors and heteroreceptors can nowadays be visualized by combining immunochemistry and electron microscopy, as illustrated in Figure 2. However, this simple classification became insufficient when retrograde signals were discovered and when it became clear that presynaptic receptors can also be activated by glial signals and by long-range messages.

In the 1960s, the mechanisms proposed for the action of presynaptic receptors all assumed that the receptor activation opens ionic channels. Later, it was realized that presynaptic receptors could modulate channels that they did not open, particularly Ca channels, which, although they carry only small currents, play a major role in transmitter release. The key experiment, performed by Dunlap and Fischbach in 1978, showed that in sensory ganglion cells, a variety of transmitters reduced the Ca current activated by a depolarization and shortened the plateau of Ca action potentials. This effect could not be explained by the opening of ionic channels by the transmitter. It required receptors modulating the Ca channels activated by depolarization.

In 1979, Eccles and McGeer formalized the need for two types of receptors by introducing the distinction between ionotropic receptors and metabotropic receptors. Ionotropic receptors corresponded to the classical view of a receptor opening an ionic channel for short durations (in the millisecond range). Metabotropic receptors were defined slightly vaguely as receptors with a slow mode of action. At that time, G-proteins had not been identified, and it was only in approximately 1985 that it was realized that G-protein-coupled receptors (GPCRs) can be coupled to ion channels. It took a few more years to accept that in many cases this coupling is 'membrane delimited' and does not require second messengers. In this article, we use the distinction proposed by Eccles and McGeer to analyze how ionotropic receptors and metabotropic receptors control transmitter release. We then discuss how presynaptic receptors are activated.

Technical Problems Associated with the Study of Presynaptic Receptors

The postsynaptic somatodendritic compartment is usually accessible to electrical measurement and control through electrodes placed in the soma. In contrast, presynaptic terminals are often too small to be recorded from and too far from the soma to be accurately recorded by electrodes placed in the soma. These morphological considerations explain why understanding the mechanisms of presynaptic control has benefited disproportionately from experimental preparations with very large presynaptic elements, such as invertebrate synapses, the synapses made by mossy fibers in the hippocampus and the cerebellum, and the synapse between the calyx of Held and the soma of neurons

Figure 1 The first observation of a serial synapse made by M Kidd in 1962 in the retina of the pigeon. The postsynaptic process labeled 'post' is contacted by a presynaptic process labeled 'b.' The presynaptic side is identified by the presence of synaptic vesicles (sv; modern techniques would make these appear much more clearly, but they are nevertheless unmistakable). The vesicles identify a typical chemical synapse, a well-established notion since 1955. The novelty here was the second chemical synapse, in which the presynaptic process with synaptic vesicles, labeled 'pre,' contacts the structure b. b is therefore postsynaptic for 'pre' and presynaptic for 'post.' Reprinted from Kidd M (1962) Electron microscopy of the inner plexiform layer of the retina in the cat and the pigeon. *Journal of Anatomy (London)* 96: 179–187, plate 3, figure 16.

from the medial nucleus of the trapezoid body (MNTB) in vertebrate brain stem. In this latter synapse, the postsynaptic cell body is enveloped by a 'giant' presynaptic element (the calyx). In these giant synapses, it is possible to record simultaneously the presynaptic events (Ca currents and Ca concentration changes) and the postsynaptic response which makes it possible to evaluate transmitter release (Figure 3). However, even in these systems it is difficult to measure the concentration and the distribution of the presynaptic modulators. This has been achieved in only a few cases, such as by the study of the modulation by dopamine of glutamate release in the striatum, in which it has been possible to follow the dopamine concentration by amperometry.

Presynaptic Ionotropic Receptors and Transmitter Release

Presynaptic receptors were first described in the crayfish neuromuscular junction and in the spinal cord. In both cases, the inhibition involved ionotropic receptors opening Cl channels. It has since been found that the opening of Cl channels can also lead to facilitation, and that some presynaptic ionotropic receptors open cationic channels.

Ionotropic Receptors Opening Presynaptic Cl Channels Can Produce Inhibition or Excitation

Figure 4(a) illustrates the mechanism which was found to operate at the crayfish neuromuscular junction. The presynaptic terminal of the axon bears $GABA_A$ receptors which, when activated by GABA, open Cl channels. Intracellular recording from the presynaptic excitatory axon showed that its resting potential is approximately −80 mV, whereas the reversal potential of the GABA current is −85 mV. Hence, the opening of Cl channels induces a net entry of Cl and a hyperpolarization. This hyperpolarization is likely to impede the propagation of the action potential in the terminal part of the axon.

Figure 4(b) illustrates the case of presynaptic inhibition of the primary afferents of the spinal cord. Here again, the inhibitory transmitter, GABA, opens Cl channels, but in these axon terminals the Cl concentration is high and the GABA reversal potential is less negative than the resting potential. As a result, the terminal is depolarized by GABA. Because the phenomenon affects a large number of presynaptic axons, the depolarization can be recorded extracellularly as a relatively large signal known as the primary afferent depolarization. A similar situation is found in the posterior pituitary, where it was possible to record intracellularly from presynaptic terminals. It was found that the GABA reversal potential was approximately −48 mV, whereas the resting potential was approximately −60 mV. Shunting by GABA had relatively little effect on transmitter release, with the main effect being caused by the depolarization-induced inactivation of Na channels. A depolarization from −60 to −45 mV in voltage clamp inactivated 90% of the Na channels. As a result, the propagation of action potential in the terminal was reduced, as was transmitter release.

Figure 4(c) illustrates a case in which opening of Cl channels can lead to facilitation. The calyx of Held (Figure 3) bears ionotropic glycine receptors. Activation of these receptors opens Cl channels. In this terminal, the Cl concentration is high, as in the primary afferents of the spinal cord. The glycine reversal potential was found to be at −50 mV, whereas the resting potential was approximately − 60mV. Thus, the effect of glycine is depolarizing, as in Figure 4(b). However, the functional effect of glycine is a facilitation likely due to the opening of Ca channels by the depolarization and to the subsequent increase in the basal level of Ca

Figure 2 Direct visualization of presynaptic receptors. Electron micrographs showing immunoreactivity for mGluR8a and mGluR8b in the stratum oriens of the CA1 area of hippocampus in rat. (a, c) Immunogold/silver labeling for mGluR8a is concentrated in the presynaptic active zone facing the postsynaptic membrane specialization of type I (arrowhead in (a)) or type II (arrow in (c)) synapses on dendritic shafts. (b, d) Immunoperoxidase labeling for mGluR8b spreads from the presynaptic membrane specialization in boutons forming a type I (arrowhead in (b)) or a type II (arrow in (d)) synapse on dendritic shafts. Type I synapses are glutamatergic, whereas type II synapses are GABAergic. Thus, the glutamate presynaptic receptors are autoreceptors in the case of (a) and (b) and heteroreceptors in the case of (c) and (d). Scale bars = 0.2 μm. At, axon terminal; d, dendritic shaft. Reprinted from Ferraguti F, Klausberger T, Cobden P, et al. (2005) Metabotropic glutamate receptor 8-expressing nerve terminals target subsets of GABAergic neurons in the hippocampus. *Journal of Neuroscience* 25: 10520–10536, with permission.

(which was documented using Ca indicators). The relation between Ca_i and release is known to be very steep, and a small increase in basal Ca can give rise to a significant increase in transmitter release.

The two effects described in Figures 4(b) and 4(c) may coexist at the same synapse, as has been suggested for the effects of presynaptic $GABA_A$ receptors on the mossy fibers in hippocampus. Globally, the balance between facilitation and inhibition is difficult to predict because it depends on multiple factors, such as the presynaptic resting potential, the Ca dependence of transmitter release, the voltage dependence of Na and Ca channel activation and inactivation, and the activity of Cl transporters.

Ionotropic Receptors Opening Cationic Channels Can Facilitate or Inhibit Transmitter Release

Cationic channels are defined here as channels which allow the flow of both Na and K ions and which have similar permeabilities for these two ions. In such channels, the current through the channels reverses at approximately 0 mV and the opening of the channels is therefore depolarizing. Some cationic channels are permeable to Ca and/or Mg, and in these channels the flow of divalent cations, although quantitatively much smaller than that of monovalent cations, also contributes to the depolarization.

Figures 4(b) and 4(c) show that depolarization of the presynaptic terminal by opening of Cl channels can lead to either inhibition or facilitation. Similarly, when the presynaptic transmitter opens cationic channels, depolarization can inactivate Na channels and thus reduce the presynaptic spike (Figure 4(d)) and/or it can open voltage-dependent Ca channels and thus increase Ca_i, which will lead to facilitation of release (Figure 4(e)). Inhibition by inactivation of Na channels has been proposed in the case of central terminals (primary afferents) of dorsal root ganglion

Figure 3 The calyx of Held. Top view of the three-dimensional reconstruction of a calyx of Held and of the cell body of the MTNB principal neuron in a P9 rat. Three-dimensional reconstruction was made by alignment of serial electron microscopy images. The calyx (left) is shown in yellow and the principal neuron (right) in blue. The nerve terminal forms a cuplike structure covering approximately 40% of the surface area of the principal neuron. The final part of the preterminal axon that gives rise to the giant terminal is seen on the left. The cell body measures 18 μm in the vertical axis and 23 μm in the horizontal axis. Reprinted from Sätzler K, Söhl LF, Bollman JH, et al. (2002) Three-dimensional reconstruction of a calyx of Held and its postsynaptic principal neuron in the medial nucleus of the trapezoid body. *Journal of Neuroscience* 22: 10567–10579, with permission.

neurons, in which activation of AMPA receptors produces the same effect as that of neighboring $GABA_A$ receptors. Facilitation of release has been observed for kainate receptors on GABA–glycine terminals in the dorsal horn and for nicotinic receptors.

It must also be mentioned that if the presynaptic axon contains K channels which show a voltage-dependent inactivation, depolarization could inactivate them and facilitate release by prolonging the action potential. This explanation has been proposed, but not demonstrated, in the case of the kainate receptors in the presynaptic terminals of mossy fibers in the CA3 region of hippocampus.

Ionotropic Receptors Opening Cationic Channels Permeable to Ca Can Facilitate Release by Allowing Direct Entry of Ca

Ionotropic cationic receptors show variable degrees of Ca permeability, from very low (as for some glutamate AMPA-Rs) to very high (for some nicotinic receptors and glutamate NMDA receptors). At some presynaptic terminals bearing ionotropic receptors with a high Ca permeability, the influx of Ca through these receptors can facilitate release without requiring a substantial depolarization and the recruitment of voltage-dependent Ca channels.

An example of presynaptic involvement of such receptors is that of the nicotinic presynaptic receptors. Many glutamatergic or GABAergic terminals have been shown to increase their release of transmitter under the action of nicotine. In a fraction of cases, the effect of nicotine disappeared when analyzed in the presence of TTX, and it was therefore concluded that the mechanism involved the depolarization induced by nicotine, which led to the opening of voltage-dependent Ca channels in the axon and increased the intracellular Ca concentration. This mechanism is therefore of the same type as that described previously for other transmitters depolarizing the terminal. However, in other synapses, the facilitation of release persisted in the presence of TTX, as did the increase in Ca in the presynaptic terminal (Figure 4(f)). In such cases, it was concluded that the changes in transmitter release are dependent on Ca entry through the ionotropic nAChRs.

A similar situation has been found for NMDA receptors and some AMPA receptors. The terminals of the cerebellar inhibitory interneurons (INs) synapsing with the Purkinje neuron (PN) bear NMDA receptors. These receptors are activated by glutamate released by the depolarization of the PN, and this inhibits the release of their transmitter (GABA). Similar effects have been observed in the spinal cord, cortex, and amygdala. A presynaptic facilitation involving Ca-permeable AMPA receptors has been described in a retinal neuron which does not elicit action potentials.

Presynaptic Metabotropic Receptors and Transmitter Release

Although not all metabotropic receptors are GPCRs, all known examples of presynaptic metabotropic receptors are GPCRs. GPCRs can control ion channels either directly, by a 'membrane delimited' process, or indirectly through second messengers. Presynaptic GPCRs can also act on the release machinery without involving ion channels. It is not always known by which way the control is exerted. We briefly examine a few well-understood cases.

Most Presynaptic Metabotropic Receptors Inhibit Release by Inhibiting the Activation of Ca Channels

The α-adrenergic inhibition of catecholamine release, which was the observation that led to the notion of autoreceptors in 1971, was reanalyzed in 1989 in frog sympathetic neurons by combining single-channel electrophysiology and measurement of radiolabeled transmitter release. Norepinephrine was found to act specifically on one class of Ca channels, the N-type Ca channels, without an effect on L-type channels. It had no effect on transmitter release when the activity of Ca channels was bypassed by a Ca ionophore.

Figure 4 Presynaptic ionotropic receptors. (a) Chloride conductances hyperpolarize the presynaptic element when its internal chloride concentration is low. Hyperpolarization decreases the excitability and hence inhibits the synapse. (b, c) Chloride conductances depolarize the presynaptic element when its internal chloride concentration is high. This may result in inactivation of sodium channels and inhibition of transmitter release (b) or in activation of calcium currents and facilitation of release (c). (d, e) Cationic conductances depolarize the synaptic bouton. Again, this may result in inactivation of sodium channels and inhibition of transmitter release (d) or in activation of calcium currents and facilitation of release (e). (f) Activation of calcium-permeable conductances may enhance presynaptic calcium levels and thus facilitate transmitter release. The white arrow under the membrane (a) indicates hyperpolarization. The black arrows under the membrane (b–e) indicate depolarization. The green arrow (f) indicates that calcium entry affects vesicle recruitment. A pink presynaptic element indicates facilitation of release. A blue presynaptic element indicates inhibition of release. Yellow rectangles, sodium channels; green rectangles, calcium channels; red circles, synaptic vesicles; short arrows, ion fluxes; +, increased channel activation; −, decreased channel activation; Inact., channel inactivation.

The calyx of Held bears several kinds of presynaptic metabotropic receptors, including those activated by glutamate (mGluR) and GABA ($GABA_B$), which both inhibit release by acting on Ca channels. The action of GABA has been particularly well studied. Presynaptic loading with analogs of guanosine diphosphate or with various G subunits indicated that presynaptic inhibition occurs by a direct interaction of G_o β/γ subunits with presynaptic Ca channels. The biophysical analysis of the effects of GABA on Ca currents showed that this interaction led to a slowing of the Ca channel activation kinetics at moderate depolarizations, whereas strong depolarization relieved the inhibition.

A recently identified mechanism of presynaptic modulation through Ca channel inhibition is that of endocannabinoids (CBs). The synthesis of CBs is triggered in the postsynaptic cell by a rise in Ca_i. The enzymatic machinery producing the cannabinoids seems to be localized preferentially at the bottom of the postsynaptic spines. CBs, which are amphiphilic, diffuse out of the postsynaptic cell and can reach CB receptors on presynaptic terminals. CB receptors inhibit release by inhibiting the presynaptic Ca channels.

Presynaptic Metabotropic Receptors Can Inhibit Release by Activating K Channels

In the spinal cord of the lamprey, Cochilla and Alford recorded simultaneously from the presynaptic terminals of reticulospinal neurons and from the postsynaptic neurons. They obtained evidence that presynaptic mGluRs depress transmitter release by activating a presynaptic outwardly rectifying K current without altering the presynaptic Ca current. This is a mirror image of what happens at the calyx of Held, in which mGluRs reduce the Ca current without altering the K current.

Cochilla and Alford noted that the fact that the K current was rectifying

> is ideal for the decrement of axonal action potentials and synaptic transmission. Activation of a hyperpolarizing response alone might increase the amplitude of the presynaptic action potential, whereas an outward current that does not hyperpolarize the axon because it rectifies at resting membrane potentials will be much more effective in shunting the series resistance of the axon during the depolarizing action potential.

Despite the perfection of this mechanism, it has not been observed at other synapses.

Presynaptic Metabotropic Receptors Can Increase Release by Blocking K Channels

When first proposed by Kandel and Tauc in 1964, the concept of presynaptic facilitation had problems associated with the fact that, at that time, opening presynaptic monovalent ion channels seemed to always lead to inhibition of the action potential and thus presynaptic inhibition. The discovery of Ca channels permitted to envision a facilitation of the Ca channel activation, and it has been shown that ionotropic receptors can produce such a facilitation. However, metabotropic receptors inducing a facilitation by direct modulation of Ca channels have not been described, and the historical example described by Kandel and Tauc seems to involve a broadening of the action potential caused by the closure of K channels. The mechanism of this broadening has been particularly well studied in a sensory neuron activated by peripheral mechanical stimuli in *Aplysia*. Serotonin increases release by increasing the duration of the action potential in the presynaptic terminal. This results from a decrease in the slowly activating outwardly rectifying K current. A small change in duration of the action potential (10–20%) is sufficient to increase release by 1.5- to 2-fold. Spike broadening was found to be necessary for facilitation. The effect of serotonin appears to involve the activation of both protein kinase A and protein kinase C, with each of these pathways playing a role at different timescales. No similar system has been identified at vertebrate synapses.

Metabotropic Receptors Can Influence Vesicle Recruitment to the Readily Releasable Pool

Rapid transmitter release involves an extraordinarily high number of steps, but studies, particularly by the group of Erwin Neher, suggest the existence of two limiting processes: Ca entry and the recruitment of synaptic vesicles to sites where Ca channels cluster. Much evidence indicates that presynaptic receptors control the second step as well as the first.

In the calyx of Held, Sakaba and Neher (Figure 5) analyzed the effects of $GABA_B$ receptor activation on transmitter release. They found that in addition to the inhibition of Ca currents discussed previously, there

Figure 5 Presynaptic metabotropic receptors can act on more than one target. The experiments illustrate two effects produced by the activation of presynaptic $GABA_B$ receptors on transmitter release in the calyx of Held. The records were obtained in brain stem slices from young rats. The presynaptic element (the calyx of Held) and the postsynaptic element (the cell body of the MNTB neuron) were both whole cell clamped. The current labeled I_{Ca} is the presynaptic current recorded after a 1 ms depolarizing pulse to +40 mV was applied to the calyx. The voltage-dependent Na and K currents were blocked pharmacologically. The current labeled EPSC is the excitatory postsynaptic current, which measures the amount of glutamate released by the calyx. Gray traces were obtained during a control period, and black traces were obtained in the presence of baclofen (20 μM), a selective agonist of $GABA_B$ receptors. (a) Activating $GABA_B$ receptors reduces the presynaptic Ca current, and this in turn induces a reduction of EPSC. (b) The time course of the baclofen effect. Baclofen was applied at time 0. (c) Baclofen influences the recovery of the depression observed after applying a train of presynaptic pulses. During a 300 Hz train of action potential-like stimuli (30 pulses), the postsynaptic response decreases. Applying a second train after 200 ms reveals that the response has partially recovered (gray traces). However, in the presence of baclofen (black traces), the recovery is much reduced. This reduced recovery was not due the reduced Ca influx (not shown). Reprinted from Sakaba T and Neher E (2003) Direct modulation of synaptic vesicle priming by GABA(B) receptor activation at a glutamatergic synapse. *Nature* 424: 775–778, with permission.

was also a slowing of the recovery from depression after a 300 Hz train. This was due to modulation of vesicle recruitment. Addition of cAMP to the patch pipette, which was known to increase release, prevented the effect of $GABA_B$ receptors on vesicle recruitment. This suggests that the $GABA_B$ receptors slow down vesicle recruitment by decreasing cAMP concentrations.

Studies have shown that cAMP produces both an increase in the number of readily releasable quanta and an increase in the release probability, with no effect on Ca or K currents. The main target of cAMP appears to be the guanine nucleotide exchanging factor Epac, which interacts with RIM proteins at the active zone. Epac was also found to be involved in a presynaptic facilitation induced by serotonin at the crayfish neuromuscular junction. In this system, serotonin induces the production of cAMP, and cAMP appears to activate Epac.

Vesicle recruitment may not be the only intracellular presynaptic process involved in the modulation of transmitter release by GPCRs. GPCRs can modulate the two intracellular compartments storing intracellular Ca: that responsible for Ca-induced Ca release (CICR) and the IP3 sensitive stores. In many synapses, the increase in Ca following the action potential is amplified by CICR. Modulation of this amplification is likely to alter release. Many GPCRs, particularly some mGluRs, activate IP3 production, which releases Ca from intracellular stores, and the resulting increase in Ca_i can therefore modulate release. It has also been reported that in some cases the activation of protein kinase C associated with the same receptors is capable of modulating transmitter release.

Cooperation between Ionotropic and Metabotropic Receptors

Ionotropic and metabotropic receptors may operate in succession. In one interesting case studied by Kerchner and colleagues, presynaptic kainate receptors facilitate GABA and glycine release in a transient manner by an ionotropic mechanism (which requires Na entry and activation of voltage-dependent Ca channels). GABA then activates presynaptic $GABA_B$ metabotropic receptors which inhibit the release of GABA and glycine. A biphasic effect is observed if kainate is applied exogenously, but in physiological conditions the long-lasting process is inhibition due to the homosynaptic metabotropic $GABA_B$ receptors.

Ionotropic and metabotropic presynaptic receptors may operate synchronously, as has been observed in the study of the long-term depression of the excitatory synapses between pyramidal cells in the L5 layer of the cerebral cortex. This depression was found to depend on the simultaneous activation of cannabinoid receptors and glutamate (NMDA) receptors. In the model proposed by Sjöstrom and colleagues, release of glutamate by the presynaptic neuron depolarizes the postsynaptic neuron. This triggers postsynaptic Ca entry, which induces the production of endocannabinoids. The cannabinoids diffuse in the retrograde direction and activate presynaptic CB1 receptors. At the same time, the glutamate released by the presynaptic terminal activates presynaptic NMDA receptors (autoreceptors). This coincident activation triggers a long-lasting depression of glutamate release.

Where Does the Agonist Come From?

As mentioned previously, the agonists of the presynaptic receptors can come from multiple sources. Figure 6 indicates the six main sources which have been described: the presynaptic cell, the postsynaptic cell,

Figure 6 The sources of presynaptic receptor agonists. The figure illustrates six possible sources of the agonists activating presynaptic receptors. (1) The transmitter released by the presynaptic terminal activates presynaptic autoreceptors. (2) The agonist originates in the postsynaptic target cell. (3 and 4) Serial synapses. The transmitter originates from a presynaptic terminal which makes a synapse with the presynaptic terminal bearing the presynaptic receptors. The receptors can be autoreceptors (if the two presynaptic elements release the same transmitter) or heteroreceptors (if the two transmitters are different). The synapse can either be close to release sites and control Ca fluxes into the presynaptic terminal (3) or be situated on the axon (preterminal receptors) and act by modulating the action potential invasion of the terminal (4). (5) The agonist is released by a neighboring glial cell. (6) The agonist comes from a distance and acts like an 'endocrine' signal.

terminals of a third neuron contacting either the presynaptic terminal or the preterminal axon, glial cells, and distant sources (humoral, vascular, endocrine, etc.). These different pathways are likely to have different functional meanings.

Autoreceptors suggest the presence of a feedback loop, which can be negative or positive depending on the sign of the effect of the presynaptic receptors. However, such schematic expectations are probably oversimplified, as illustrated by the example of the presynaptic mGluRs at the calyx of Held. These presynaptic mGluRs are autoreceptors which depress transmitter release when activated by an exogenous agonist. They were expected to depress release during a repetitive stimulation, and they do, but this depression is surprisingly small compared to that produced by exogenous glutamate agonists. It turns out that the decrease in the release probability is masked by a simultaneous increase in the readily releasable pool, which passively increases when the release probability decreases. Billups et al. proposed that "mGluR autoreceptors function to change the synaptic state and distribute metabolic demand, rather than to depress synaptic amplitude."

Both autoreceptors and heteroreceptors may depend for their activation on the process of spillover, by which transmitters reach the receptors from another terminal. For example, in the amygdala, the presynaptic glutamate receptors found on the cortical terminals can be activated by glutamate released from thalamic afferents. Inside the cerebellar glomerulus, where mossy fibers and Golgi cell axons synapse on the dendrites of granule cells, glutamate released by the mossy fibers activates presynaptic mGluRs on the Golgi terminals and, conversely, GABA released by the Golgi axons activates $GABA_B$ receptors on the mossy fiber terminals. Because spillover implies a dilution of the transmitter, it usually activates receptors with high affinity for the transmitter (i.e., receptors with slow kinetics).

Retrograde signaling may involve classical transmitters such as glutamate and GABA but also liposoluble compounds, such as arachidonic acid, nitric oxide, and endocannabinoids. Retrograde signaling has been well characterized at the cerebellar synapses between GABAergic INs and the PN. Depolarization of the PN triggers the production of endocannabinoids which inhibit the GABA release by the INs. At this synapse, there is also evidence that glutamate can be released by the depolarization and act as a retrograde messenger which acts on presynaptic NMDA receptors of the INs and potentiates release.

Finally, signaling from glial cells or more remote sources may represent a more distributed form of modulation capable of integrating slow signals (or even steady signals) on the global level of network activity or even the general state of the organism.

The receptors involved in the six pathways can in principle be ionotropic or metabotropic, but the different pathways will privilege one type of receptor over another depending on their kinetics. Classical ionotropic receptors (nicotinic ACh receptors, AMPA receptors, and $GABA_A$ receptors) are short-acting receptors. They have a low affinity for the neurotransmitter, which thus rapidly dissociates from its binding site. The decay time constants of such conductances are typically in the millisecond range. These receptors are ill-equipped to trigger long-lasting changes. If such changes are detected, there must be secondary intracellular processes triggered by the initial conductance change. In contrast, metabotropic receptors all have slow kinetics, which is linked with the high affinity of the agonist (the dissociation of the agonist can last tens of milliseconds to seconds). This is also the case for some ionotropic receptors such as the NMDA receptors, some kainate receptors, and some GABA receptors. Such slow receptors are well adapted to the integration of slow signals but also to the detection of small concentrations of agonists. This is why they are the most frequently involved when the agonist comes from a distance, as is the case not only when there is spillover, but also when there is activation by an 'ambient' level of the agonist.

Presynaptic Regulation by Liprins

K Miller, Michigan State University, East Lansing, MI, USA

Introduction

The synapse is the fundamental structure that allows neuronal networks and circuits to form and function. Presynaptic neurotransmission requires the formation and maintenance of a pool of synaptic vesicles through axonal transport, formation of specialized vesicular release sites, and local recycling of synaptic vesicle proteins. Postsynaptically, neuronal transmission involves the targeting and the clustering of synaptic receptors followed by receptor activation through neurotransmitters. The process of organization and localization of pre- and postsynaptic proteins is thought to depend on a variety of scaffolding proteins.

Scaffolding proteins are thought to organize the constituents of the active zone and to provide physical links between the active zone and synaptic vesicle proteins. Several proteins have been identified that may function as synaptic scaffolds: Rab3-interacting molecules (RIMs), which regulate synaptic vesicle exocytosis; Unc13 and Munc13, which are thought to be involved in priming; and three classes of proteins that are speculated to organize the structure of the active zone – the large presynaptic proteins Bassoon and Piccolo/aczonin, found in higher organisms, the well-conserved CAST/CAZ/ERC/Brp family of proteins, and the well-conserved liprin-α family.

Liprin-α (synonyms: LAR-interacting protein 1, LIP.1, SYD-2, Dliprin-α (CG11199), and 'out of step' (oos)) is a 130 kDa protein that is important for efficient neurotransmission and for shaping the structure of neuromuscular junctions (NMJs), synaptic boutons, and active zones. It contains an N-terminal coiled-coil domain that mediates homo- and heteromultimerization and a C-terminal region that contains three sterile alpha motif (SAM) domains that mediate binding to an array of partner proteins (Figure 1(a)). At the sequence level, liprin-α is highly conserved, from vertebrates to *Caenorhabditis elegans* and *Drosophila*. Liprin-α interacts with itself and with proteins of at least eight other classes: liprin-βs 1 and 2, receptor protein tyrosine phosphatases (leukocyte antigen-related protein (LAR), PTPσ, PTPδ), the anaphase-promoting complex/cyclosome (APC/C), RIM, ERC, kinesin-1 and -3, G-protein-coupled receptor kinase-interacting protein (GIT), CASK, and glutamate receptor-interacting protein (GRIP) (Figure 1(b)), all of which appear to be involved in normal synaptic function (Table 1).

Liprin Expression, Localization, and Diversity

In addition to its localization in neurons, liprin-α is widely expressed. In mammals, the mRNAs for liprin-α 1 and -β 1–2 have been found in all tissues that have been examined (heart, brain, placenta, lung, liver (very low levels of β 1 in liver), muscle, kidney, and pancreas). In contrast, liprin-αs 2–4 may play more specialized roles because their expression is restricted. The mRNA for liprin-α 4 is found only in heart, brain, and muscle, and the mRNAs for liprin-αs 2 and 3 are solely expressed in brain tissue. In all cell types, liprin-α has been implicated in the formation of cell–cell contacts.

In nonneuronal cells, liprin-α is enriched at focal adhesions and co-localizes with the receptor protein tyrosine phosphatase (RPTP) LAR, phosphotyrosine, talin, vinculin, paxillin, and pp125^{FAK}. It has been suggested that liprin-α is involved in the disassembly of focal adhesions, recruitment of LAR. Analysis of liprin-α may give insights into parallels between synaptic and focal adhesion assembly. In neurons, liprin-α is found both pre- and postsynaptically and at both excitatory and inhibitory types of synapses. In *Drosophila*, liprin-α localizes to synapses, with a broad distribution. However, synapse-defective *C. elegans* liprin-α (SYD-2) has been shown to cluster at the active zone.

While there are four isotypes of liprin-α in mammals, there is only a single version of liprin-α in *C. elegans* and in *Drosophila*; furthermore, little work has been done on liprin−αs 2–4. In addition, there are different splice forms of liprin-α 1 in mammals, with isoform 1B being the longest (version 1A lacks the last 30 amino acids which contain the GRIP-binding domain and accordingly does not bind to GRIP). Thus, unless otherwise specified, when we use the term liprin-α it will refer to the splice form liprin-α 1B in mammals and the single versions that are the most similar to liprin-α 1B in flies and worms.

Function of Liprin-α at the Synapse

Although liprins were first characterized in nonneuronal cells, the majority of functional data on liprin-α and its binding partners has been obtained from the nervous systems of worms and flies. Liprin-α function at the synapse was first appreciated in *C. elegans*,

Figure 1 (a) Overview of protein-binding sites of liprin-α. (b) Interaction map of liprin interactions. All proteins are drawn to scale based on the number of amino acids. Arrowheads are the C-terminus of the protein. Mapped sites of protein–protein interaction are in matching color. AMPAR, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid receptor.

where SYD-2 was identified in a screen for altered distribution of a synaptic vesicle marker at neuromuscular synapses. Although, like its vertebrate counterpart, the *C. elegans* NMJ is cholinergic, it is formed by muscle projections that reach into the neuropil to find motor axons, thus requiring morphogenetic expansion of presynaptic varicosities along the axon shaft. Behavioral assays, pharmacology, and

ultrastructural characterization showed that neuromuscular synapses function poorly and contain larger presynaptic active zones in mutants lacking liprin-α. Behaviorally, *C. elegans* mutants lacking liprin-α are sluggish in movement and retain twice as many eggs. These defects are fully rescued when liprin-α is selectively expressed in neurons, but not muscles. Since egg laying can be induced by treatment with serotonin (but not imipramine) and SYD-2 worms are resistant to aldicarb (an inhibitor of cholinesterase, which causes wild-type worms to hypercontract and die), these defects are both genetically and pharmologically consistent with a primary defect in presynaptic transmission.

In *Drosophila*, where NMJs are glutamatergic, liprin-α was identified as a binding partner of the RPTP LAR. In this context, liprin-α was shown to localize to the NMJ and was shown to be required for the overall morphological growth of the nerve terminal. In the fly, like in vertebrates, NMJs are branched expanses at the ends of axons where motor neurons make connections with muscles. Synaptic boutons, which are 0.5–2 μm in diameter, lie along NMJs and resemble beads on a string. Each bouton contains multiple active zones, typically between 50 and 100 nm in length. As observed in *C. elegans*, *Drosophila* NMJs lacking liprin-α display larger active zones (~2.5-fold higher mean area), suggesting that the role of liprins in the presynaptic cytomatrix is well conserved.

When liprin-α is disrupted, synaptic transmission is reduced in both flies and worms. Yet, there is an apparently paradoxical increase in the average size of active zones and a proportional increase in the number of presynaptic vesicles. Reassuringly, at the electron microsopic (EM) level, active zones appear less electron dense, and at the light microcopic level the intensities of staining for synaptobrevin, synaptotagmin, syntaxin, and Rab3 are decreased. As disruption of liprin-α has the functional consequence of disrupting synaptic transmission, it is possible that active zone size is increased in a futile attempt to compensate for decreases in evoked release. If so, the observed decreases in protein density at active zones could occur because a fixed amount of material is spread over a larger area. Alternatively, the absence of a key synaptic scaffold may simply reduce the cross-linking within the cytomatrix and result in a loose network of active zone proteins. A failure to recruit all the necessary presynaptic components or a decreased concentration of the remaining proteins could reduce the efficiency of neurotransmitter release.

One great advantage of *Drosophila* as a genetic model organism for studies of synapse biology is the accessibility of the NMJ to electrophysiological characterization. Disruption of *Drosophila* liprin-α (and Dlar (*Drosophila* LAR)) results in a ~30% decrease in evoked postsynaptic potentials and a ~60% decrease in quantal content (excitatory/mini-excitatory junction potentials (EJP/mEJP)). The amplitude and frequency of mini-excitatory junction potentials in these mutants are comparable to those in wild type, inferring that synaptic vesicles are present at the active zones, but there is a defect in evoked release. Similar defects in evoked release are also seen when Dlar, CAST, RIM, and APC/C are disrupted in different organisms. In combination with work on these proteins, this implies that liprin-α directly or indirectly determines the size of the releasable pool. Based on these results, liprin-α may be important in some aspect of docking or priming of presynaptic vesicles. Consistent with this hypothesis, liprin-α mutants display defects in vesicle trafficking.

Disruption of liprin-α results in ectopic accumulation of synaptic vesicle markers along the motor axon shaft (often called 'clogs') and a 25% reduction in both the number of synaptic boutons and the NMJ branches. One hypothesis to explain the effects seen in liprin-α mutants is that they result from an impairment of axonal transport. Indeed, a quantitative analysis of axon transport in living animals reveals that liprin-α positively regulates anterograde transport and negatively regulates retrograde transport. In *Drosophila* cells, liprin-α can associate with a complex including the heavy chain of kinesin-1 (Khc), consistent with the fact that *khc* mutants display similar axon clogs. Thus, liprin-α plays an interesting

role in the delivery of synaptic material. Whether the regulation of axon transport is liprin's primary role or whether this is one of many functions remains to be elucidated.

Partners of Liprin-α

APC/C and Liprin-α

The APC/C is an E3 ubiquitin ligase that regulates the concentration of liprin-α and modulates NMJ morphology in *Drosophila*. It controls the abundance of proteins by regulating their targeting to the ubiquitin-proteasome degradation system. While it has been established that APC/C is a critical mediator of cell-cycle transitions, recent work has demonstrated that it also functions in postmitotic cells. In *Drosophila* muscles, APC/C regulates synaptic transmission by controlling the concentration of a postsynaptic glutamate receptor. While the change in postsynaptic response may be due to an alteration in liprin-α-dependent clustering of glutamate receptors, the observation that mutations in liprin-α do not affect quantal size at the *Drosophila* NMJ suggests that APC/C may be regulating the degradation of other postsynaptic proteins. In neurons, APC/C regulates synaptic growth and synaptic transmission by controlling the concentration of the downstream effector liprin-α. When APC/C is disrupted, liprin-α intensity is increased presynaptically and the number of synaptic boutons is also increased. These changes are consistent with previous work which demonstrated that disruption of liprin-α leads to a decrease in the number of boutons in this system. Together, these findings suggest that the morphology of the NMJ is regulated through the control of liprin-α concentration downstream of APC/C.

MALS/CASK and Liprin-α

Liprin-α has now been shown to be a component of the MALS/Veli–CASK–Mint-1 complex of PDZ proteins. MALS has been implicated in presynaptic vesicle cycling. When all three isoforms of MALS proteins are disrupted in mice, the mice die soon after birth; they have difficulty breathing and show impaired excitatory synaptic transmission. Of particular interest, the MALS complex seems to be important for determining the size of the releasable pool of synaptic vesicles and may be important for replenishing this pool from the reserve pool. The lack of GRIP or α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors in the MALS complex suggests no role for liprin-α in the MALS complex postsynaptically. The lack of liprin-β suggests that this protein is not critical for the MALS/Veli–CASK–Mint-1/liprin-α complex. The Veli–CASK–Mint-1 complex, a homologous counterpart of the LIN-2–LIN-7–LIN-10 complex of *C. elegans*, has also been implicated in several other synaptic protein interactions, such as with voltage-gated N-type calcium channels (Table 1). This work is consistent with a model where a MALS/Veli–CASK–Mint-1/liprin-α complex couples extracellular synaptic interactions to the intercellular organization of the presynaptic secretory machinery.

Liprin-α and CASK

CASK (CAKI or CAMGUK in flies) is a membrane-associated guanylate kinase-associated (MAGUK) protein that has a catalytically inactive N-terminal CaM-kinase domain that interacts with Veli and Mint-1, an SH3 domain that binds N-type Ca^{2+} channels, and a central PDZ domain that interacts with other membrane proteins such as glycophorins, neurexins, and syndecan. The observation of an interaction between CASK and syndecan is particularly interesting in light of the recent demonstration that another liprin-α-interacting protein, LAR, also binds to syndecan. In addition, LAR and CASK both bind liprin-α in the same region (see Figure 1). We raise the possibility that the interaction between these three proteins may be relevant for their function, but determining how these proteins interact will take further investigation.

Disruption of *caki* results in an increase in spontaneous neurotransmitter release and an impairment in the response of the giant fiber pathway to continuous stimulation. These defects appear to involve the loss of presynaptic control of exocytosis, which is similar to the defect seen in liprin-α mutants. The defect in neurotransmission seen in *caki* mutants is one of many possibilities to explain how disruption of liprin-α leads to defects in neurotransmission.

Liprin-α and LAR

LAR family receptor protein tyrosine phosphatases (LAR, PTPδ, and PTPσ) bind liprin-α. Disruption of *Drosophila* LAR results in axonal pathfinding defects and defects in synaptic morphology and neurotransmission that are similar to those seen in liprin-α mutants. The extracellular regions of LAR-RPTP contain three N-terminal immunoglobulin-like domains and a variable number of fibronectin type III-like domains that are well conserved, from insects to humans. This suggests that these phosphatases may function as receptors for cell surface or extracellular matrix proteins. The heparan sulfate proteoglycans (HSPGs) syndecan and dallylike have recently been

shown to bind to the extracellular domains of LAR and to regulate synaptic growth and active zone form and function, respectively. The intracellular region of LAR contains two tandem phosphatase domains: the membrane proximal domain (D1), which has phosphatase activity, and the distal phosphatase domain (D2), which is devoid of catalytic activity but may regulate the substrate specificity of LAR. LAR has been shown to dephosphorylate β-catenin *in vitro*, but not liprin-α, although recent data suggest that liprin-α is tyrosine phosphorylated in some contexts. Liprin-α binds the D2 domain of LAR and co-localizes with it at focal adhesions and at NMJs. Although the functional relationship between liprin-α and LAR is not completely clear, is possible that LAR and liprin-α simply anchor each other at the active zone. In support of this hypothesis, expression of liprin-α 2 by transfection alters the distribution of LAR in cultured cells. Disruption of LAR in *Drosophila* reveals that it is not required for localization of liprin-α to the synapse; however, the reverse may be true. These results suggest that proteins other than Dlar can maintain synaptic liprin-α localization. Work in mammalian neurons suggests that the LAR–liprin-α interaction may contribute to synapse morphogenesis by regulating the synaptic delivery of a protein complex that includes AMPA receptors, GRIP, liprin-α, LAR, cadherin, and β-catenin. How the interaction between LAR and liprin-α relates to cadherin/β-catenin, syndecan, and dallylike function is an important future direction of research. In other contexts, such as epithelial cell polarity and axon guidance, LAR and its signaling partners regulate the structure of actin cytoskeleton, further raising the possibility that synaptic LAR and liprin-α play some role in cytoskeletal remodeling to control presynaptic structure.

Liprin-α, GRIP, and GluR2

GRIP is a multi-PDZ domain-containing protein that binds liprin-α, as well as both ephrin receptors and ligands and the kinesin-3 motor protein family member KIF1A. GRIPs have been suggested to mediate the transport of glutamate receptors, the stabilization of receptors within postsynaptic densities, and the sorting of internalized receptors. GRIP1 is found in synaptic preparations and intracellular compartments. This includes putative transport vesicles for glutamate receptors. Genetic analysis in mice shows that GRIP1 is required early during development, because a GRIP1 knockout is embryonic lethal at day 12 and the embryos suffer from defects in junction formation between dermis and epidermis.

Liprin-α isotypes 1, 3, and 4 interact with GRIP through the last seven amino acids of liprin-α, and liprin-α 1 immunoprecipitation pulls down GRIP and GluR2/3. This interaction is selective because the postsynaptic density 95 kDa protein (PSD-95) and *N*-methyl-D-aspartate (NMDA) do not associate with liprin-α 1. Of note, LAR interaction in this system is weak, as LAR does not immunoprecipate with liprin-α 1 unless it is cross-linked with dithiobissuccinimidylpropinate. In young neurons, GRIP and liprin-α are both present in the axons of cultured mouse hippocampal neurons, but in mature presynaptic regions these proteins do not co-localize, suggesting that the GRIP–liprin interaction may be more important for the assembly of synapses than for their maintenance. Although liprin-α seems to perform both pre- and postsynaptic functions, the interaction with GRIP seems to be most important postsynaptically, since *Drosophila* GRIP is only expressed in muscles and mouse liprin-α and GRIP interactions primarily involve postsynaptic proteins. Transfection with liprin-α 1A that lacks the C-terminus (TYSC) in hippocampal neurons reduces the number of AMPA receptors that cluster along dendrites. In addition, an interaction between GRIP, GIT1, and liprin-α is important for AMPA receptor targeting. This suggests that liprin-α is involved in the localization of AMPA receptors through its interactions with these proteins at postsynaptic sites.

Given the strong evidence that (1) liprin-α interacts with GRIP, (2) DGRIP is found in muscles, and (3) interaction between liprin-α and GRIP has been implicated in the clustering of glutamate receptors, it is surprising that disruption of liprin-α does not result in a decrease in postsynaptic sensitivity (i.e., the amplitude of mini-excitatory junction potentials). Nonetheless, as full rescue of synaptic function can be done by the selective expression of liprin-α (SYD-2) in neurons, it is possible that liprin-α may play a minor role in postsynaptic functioning in invertebrates, and a more important role in vertebrate synapses.

Liprin-α and GIT

GIT1 was originally isolated as a protein interacting with G-protein-coupled receptor kinases. The GIT family of proteins contains two known members, GIT1/Cat-1/p95-APP1 and GIT2/Cat-2/PKL/p95-APP2/KIAA0148. GIT proteins contain a GTPase-activating protein (GAP) domain for ADP-ribosylation factors (ARFs), small GTP-binding proteins implicated in the regulation of membrane traffic, and the actin cytoskeleton. In addition, GIT proteins contain various domains for protein interactions: ankyrin repeats, the Spa2 homology domain (SHD), and the G protein-coupled receptor kinase-binding domain (GRKBD). GIT proteins regulate endocytosis of various membrane proteins and regulate the assembly of focal adhesion

complexes by interacting with the Rho-type guanine nucleotide exchange factor (GEF) PIX, focal adhesion kinase (FAK), the focal adhesion adaptor protein paxillin, and liprin-α When GIT is disrupted, dendritic synapse number and AMPA receptor targeting are decreased. Piccolo has been proposed to play a role in GIT localization at active zones, but given the number of proteins that interact with GIT it seems likely that multiple proteins are influencing its distribution. As liprin-α and GIT are both found at focal adhesions and synapses, interact, and share a role in intracellular trafficking of AMPA receptors (AMPARs), it is tempting to speculate that the same machinery is used for 'trans-Golgi' trafficking, axonal transport, dendritic trafficking, and synaptic vesicle trafficking, but in a context-specific manner.

Liprin-α and ERCs

The ERC family of 'cytomatrix at the active zone' (CAZ) proteins contains two known members and both interact with liprin-α: ERC1/ELKS/Rab6IP2/CAST2 and ERC2/CAST1. Recent analysis of mutations in a *Drosophila* CAST ortholog, bruchpilot (NC82), reveals a requirement for CAST in synaptic development and active zone morphogenesis, consistent with the highly specific localization of this protein to the active zone. In addition, ERC interacts with other CAZ proteins, including RIM, Piccolo, Bassoon, and syntenin. ERC2 has been implicated in modulating liprin-α levels at the synapse: co-expressing ERC2 leads to increased levels of liprin-α. Functionally, the interaction of ERC2 with RIM1 and Bassoon/Piccolo has been shown to regulate neurotransmitter release. As liprin-α binds both ERC2 and RIM, the defect in synaptic evoked release that occurs when liprin-α is disrupted may occur through the disruption of these interactors. Since ERC2 and GIT interact with Rab6 and ARF, it has been suggested that liprin-α might mediate the integration of the Rab6 and ARF signaling pathways for the regulation of membrane traffic.

Liprin-α and RIM

RIM1 is an active zone protein that was initially identified as a putative effector for the synaptic vesicle protein Rab3A. RIM interacts with several active zone molecules, including Munc13–1 and liprin-α, to form a protein scaffold in the presynaptic nerve terminal. RIMs also bind to RIM-BPs through a C-terminal sequence, to cAMP-GEFII through an unknown site, and to Ca^{2+} channels and synaptotagmin 1 through both C2 domains. Abolishing the expression of RIM1 in mice shows that RIM1 is essential for maintaining normal probability of neurotransmitter release and for regulating release during short-term synaptic plasticity. This presumably occurs through a disruption of either vesicle priming or fusion, or both. Based on these observations, it seems likely that the presynaptic defect in evoked release seen when liprin-α is disrupted in *Drosophila* is caused in part through a disruption of RIM localization and/or function; however, mutations in *Drosophila* RIM have not been described.

Note Added in Proof

Sheng and colleagues have a very exciting story showing that the levels of liprin-α are activity-regulated in hippocampal neurons and appear to control the delivery of key components like LAR (consistent with the transport defects observed in Miller and co-authors). Also, the work by Treisman and colleagues on axon guidance is noteworthy.

Although much of the focus on liprin family proteins has been on synaptogenesis, recent work from Treisman and colleagues reveals that *Drosophila* Liprin-α is also necessary for the correct synaptic targeting of specific R7 photoreceptor cells to their targets in the adult medulla; this study challenges the notion the liprin serves only to localize LAR, suggesting that there are LAR-independent functions of liprin-α (Hofmeyer et al., 2006).

The latest work on liprin-α and LAR in mammalian hippocampal synapses suggests that liprin-α links neural activity to the remodeling of synapse structure through Ca(2+)/calmodulin-dependent protein kinase II (CamKII) regulation of liprin-α stability and its ability to deliver LAR to functional dendritic sites (Hoogenraad et al., 2007). This exciting study implies that the regulation of LAR activity will be important to our understanding of synaptic plasticity.

Kinesins, Liprin, and Presynaptic Vesicle Precursor Transport

There are two major subdivisions of axonal transport: fast and slow. Soluble cytoskeletal proteins such as tau, kinesin, dynein, myosin, and tubulin are transported at a rate of approximately $1\,mm\,day^{-1}$ by slow axonal transport. Membrane-bound proteins, associated with organelles such as presynaptic precursor vesicles, are transported at a rate of approximately $1\,\mu m\,s^{-1}$ by fast axonal transport. The kinesin family of molecular motors moves soluble proteins and organelles away from the cell body, and dynein moves these materials toward the cell body. When kinesin-1 is disrupted, axonal clogs that contain synaptic components occur along axons and synaptic transmission is disrupted.

While substantial evidence suggests that liprin-α plays a direct role in determining the form and function of synapses, recent data also reveal that liprin-α is involved

in the fast axonal transport of presynaptic vesicle precursors (PVPs). PVPs contain the raw materials for the assembly of synapses, and while they are thought to be transported primarily by kinesin-3 (Unc-104, Kif1a), kinesin-1 (conventional kinesin) family members may also play a role in their transport. Since axonal accumulations of endogenous synaptotagmin similar to those found in kinesin heavy chain (Khc) alleles are also observed in mutants lacking *Drosophila* liprin-α, we speculate that liprin-α is involved in the transport of a subset of synaptic components and that this subset may be transported by more than one family of kinesin.

At one time is was thought that there were molecules whose sole purpose was to link kinesins to cargos, but it now appears that most adaptors are scaffolding proteins that interact with multiple proteins and do not serve as simple linkers. Liprin-α binds to kinesin-1 and kinesin-3. Yet, the balance of the evidence is against liprin-α acting as a simple linker between PVPs and kinesins. When it is disrupted, the transport of PVPs is not halted. Instead, it shifts the probability of transport from anterograde (kinesin-mediated) to retrograde (dynein-mediated) transport. Thus, liprin-α is not required for the movement of PVPs *per se*. Instead of a simple linker, liprin-α appears as a modulator of axonal transport.

One of the most basic questions in neurobiology is how some types of neuronal components are trafficked to dendrites, and others are selectively transported into axons. Liprin-α is part of a complex that targets postsynaptic components to dendrites and involves GRIP, AMPARs, and kinesin-1. Of note, there are splice variants of liprin-α that lack the GRIP-binding domain. It is tempting to speculate that this differential targeting between axons and dendrites may involve variations in splicing. Yet further work will be required to determine if and how liprin-α could help to selectively guide components into either axonal or dendritic compartments. While several lines of evidence suggest that liprin-α regulates transport, a great deal of work remains to provide a satisfying molecular answer as to how this occurs.

Overview

Throughout this article we have outlined liprin-α function at the synapse and we find three reoccurring themes: (1) liprin-α binds multiple proteins that are required for efficient neurotransmitter release; (2) liprin-α regulates intercellular transport; and (3) liprin-α is involved in the postsynaptic clustering and targeting of AMPARs. A great deal of effort has been devoted to identifying which proteins bind to liprin-α; now the problem is understanding the mechanism of normal functioning.

Presynaptic: Mitochondria and Presynaptic Function

G David, University of Miami Miller School of Medicine, Miami, FL, USA

Motor nerve terminals must be prepared for sudden increases in energy demand associated with vesicular release and recycling. This article summarizes studies using functional fluorescence imaging and electrophysiological recording that demonstrate that vertebrate motor terminals rely on their abundant mitochondria not only for adenosine triphosphate (ATP) production but also for efficient, sustained sequestration of large stimulation-induced calcium loads (Figure 1). Ca^{2+} influx into the mitochondria is essential for sustaining neuromuscular transmission during repetitive stimulation and is a major stimulant for mitochondrial respiration in motor terminals. Their heavy reliance on mitochondria may make motor terminals especially vulnerable to stresses and diseases that impair mitochondrial function.

Distribution of Mitochondria in Motor Nerve Terminals

A general theme governing the distribution of mitochondria in polarized cells (e.g., motor neurons) is their increased density in regions of high metabolic activity. This is especially evident in mature vertebrate motor terminals in which approximately 20–30% of the cytoplasm is occupied by mitochondria. In these terminals, mitochondria tend to cluster away from the active zone regions, which are mostly occupied by synaptic vesicles. This concentration of mitochondria in terminals is thought to be achieved by the complex regulation of their axonal transport by local signals of increased demand for mitochondrial function. Such signals, which include cytosolic adenosine diphosphate (ADP) and Ca^{2+}, are thought to trap mitochondria by arresting/slowing their movement and by inducing their binding to as yet unidentified docking proteins. Axonal transport of mitochondria occurs along microtubules and microfilaments and is powered by the ATP-using molecular motors kinesin and dynein. Anterograde transport of mitochondria from the cell body to axons and terminals uses the adaptor protein Milton, which links the mitochondrial protein Miro to the heavy chain of kinesin.

ATP Demands of Motor Nerve Terminals

Motor nerve terminals are activated by trains of action potentials, which produce influx of Na^+ and Ca^{2+}, and efflux of K^+. Long-term maintenance of the resting transmembrane electrochemical gradients for these ions and their rapid restoration after activity poses a large energetic challenge for the small (2–3 μm in diameter) motor nerve-terminal boutons (in mammals and reptiles) or long processes (in frogs). Because of the terminals' large surface-to-volume ratio, ion influx/efflux can rapidly produce large changes in cytosolic ionic composition. Also, many spinal motor neurons (and probably their motor terminals) have relatively low concentrations of Ca^{2+}-binding proteins to mitigate the elevation of cytosolic [Ca^{2+}] during stimulation-induced influx.

Maintenance of Ionic Electrochemical Gradients

ATP energizes the long-term maintenance of Na^+ and K^+ gradients by a plasma membrane Na^+/K^+-ATPase, which uses the energy derived form ATP hydrolysis to extrude 3 Na^+ from the cytosol and import 2 K^+ from the extracellular fluid. This Na^+/K^+ pump is the main ATP-consuming process in neurons. The Na^+ gradient maintained by this pump also contributes indirectly to extrusion of Ca^{2+} from the cytosol via a plasma membrane Na^+/Ca^{2+} exchanger. ATP also directly fuels a plasma membrane Ca^{2+}-ATPase that extrudes Ca^{2+} from the cytosol.

Neurotransmitter (Acetylcholine) Synthesis, Storage, and Release

The loading of acetylcholine (ACh) into synaptic vesicles, to concentrations of ~0.5 M, is accomplished by the vesicular ACh transporter in the vesicle membrane. This transporter exchanges cytoplasmic ACh for vesicular H^+ and is driven by the H^+ gradient (pH ~6.7 in the vesicle, ~7.2 in cytosol). This H^+ gradient is established by proton extrusion by a vesicular ATPase.

The uptake of choline from the synaptic cleft (where it is generated by the rapid degradation of released ACh by ACh esterase) is essential for maintaining ACh synthesis. The Na^+ gradient established by the Na^+/K^+-ATPase drives choline uptake via a high-affinity Na^+/choline co-transporter in the plasma membrane.

The ATP requirement for exo/endocytosis has not been studied directly in vertebrate motor nerve terminals; but in the ribbon synapse of fish bipolar cells, cytosolic ATP is required to prime synaptic vesicles for Ca^{2+}-dependent fusion. In *Drosophila* motor nerve terminals, ATP is required for the mobilization of the reserve pool of synaptic vesicles.

Signaling Roles of ATP

ATP is present in synaptic vesicles (~0.2 M) and is co-released with ACh. In cultured neuromuscular

Figure 1 Mitochondrial processes: (A) simplified diagram of mitochondrial processes involved in generating and using the proton electromotive force (Δp) and in sequestering and extruding Ca^{2+}; (B) representative experimental recordings of stimulation-induced changes in the shaded components. In (A), Δp is composed of electrical ($\Delta\Psi_m$) and chemical (ΔpH) components. Depicted at the right are the processes involved in generating Δp; and at left are the processes that use Δp (predominantly its $\Delta\Psi$ component) to generate ATP and to temporarily sequester Ca^{2+} entering the cytosol during stimulation. Pathways for Ca^{2+} influx into the mitochondria and extrusion from the mitochondria are shown with red and green arrows, respectively. Shown in (B) are experimental recordings of changes in the components in (A) in response to 50 Hz stimulation of lizard motor nerve terminals. Cytosolic and mitochondrial Ca^{2+} (Ca^{2+}_{cyt} and Ca^{2+}_{mit}) are measured with Ca^{2+}-sensitive fluorescent dyes loaded selectively into the cytosolic or mitochondrial compartments, $\Delta\Psi_m$ is measured with the potentiometric dye rhodamine-123, and NADH is measured by imaging changes in its intrinsic fluorescence. $\Delta\Psi_m$, mitochondrial membrane potential; AcCoA, acetyl-coenzyme A; ACh, acetylcholine; ADP, adenosine diphosphate; ANT, adenine nucleotide translocator; ATP, adenosine triphosphate; CaB_c, calcium bound to cytosolic Ca^{2+}-binding proteins/sites; CaB_m, calcium bound to mitochondrial Ca^{2+}-binding proteins/sites; CaPi, osmotically inactive calcium–phosphate complex; ETC, electron transport chain; NADH, NAD^+, nicotinamide adenine dinucleotide; Pi, inorganic phosphate; stim, stimulation; TCA, tricarboxylic acid cycle; VDCCs, voltage-dependent Ca^{2+} channels. junctions, the retrograde effects of this co-released ATP potentiate spontaneous vesicular ACh release and might play a role in synaptic development. It has been suggested that endogenously released ATP modulates intracellular [Ca^{2+}] in perisynaptic Schwann cells of amphibian neuromuscular junctions. It has also been suggested that presynaptic actions of adenosine, derived from hydrolysis of released ATP, contribute to the depression of transmitter release in frog neuromuscular junctions. Although exogenously applied ATP depresses transmitter release in mammalian neuromuscular junctions, the endogenous release of ATP (or the accumulation of adenosine) might not be sufficient to alter evoked transmitter release under physiological conditions.

ATP Supply by Cytosolic Glycolysis and Mitochondrial Oxidative Phosphorylation

Glucose is the major initial substrate for both these pathways, present at concentrations of approximately 4 mM in peripheral axons. Glucose transport from the extracellular fluid has been demonstrated in mammalian and amphibian motor nerve terminals and is found to proceed faster in terminals of fast (compared to slow) motor units. Because the glycolytic pathway is more prominent in fast terminals, this faster glucose transport might compensate for the smaller yield of ATP production from glycolysis compared to oxidative phosphorylation (see the

section titled 'Mitochondrial oxidative phosphorylation'). An additional source of glucose is glycogen, present at a concentration of approximately 1 mM in some peripheral nerves. Glycogen-phosphorylase breaks down glycogen and delivers glucose-1-phosphate to the glycolytic pathway; this enzyme is present in the somata, axons, and terminals of motor neurons.

Glycolysis

The glycolytic pathway employs cytosolic enzymes to catalyze the net generation of two ATP molecules from ADP via a multistep anaerobic conversion of glucose to lactate. Significantly, two ATPs are actually consumed in the first stage of glycolysis (from glucose to glyceraldehyde 3-phosphate), and four ATPs are produced in the second stage (3-phosphoglycerol phosphate to pyruvate). This need for initial priming of glycolysis by ATP suggests that, under conditions of severe ATP depletion, ATP production by glycolysis might be inhibited. Glycolytically supplied ATP has been shown to delay the rundown of transmitter release in frog motor terminals stimulated by prolonged Ca^{2+} influx under conditions in which mitochondrial ATP generation was inhibited by oligomycin. Glycolytic enzyme activity detected in spinal cord mammalian α-motor neurons did not differ for motor neurons innervating fast versus slow motor units.

Mitochondrial Oxidative Phosphorylation

Under aerobic conditions, pyruvate derived from glycolysis (or amino acids) is imported into the mitochondrial matrix, converted to acetyl-coenzyme A and enters the Krebs (or tricarboxylic acid (TCA)) cycle. Here several reactions result in the reduction of NAD^+ to nicotinamide adenine dinucleotide (NADH), which enters the respiratory chain at complex I. In the respiratory chain complexes, located in the inner mitochondrial membrane, a series of redox reactions involving electron carriers result in the transfer of electrons from NADH (at complex I) and succinate (at complex II) to O_2 (reduced to H_2O at complex IV). This linear series of electron transfer reactions is driven by the large difference between the redox potential of the NAD^+/NADH (~ -300 mV) couple and the O_2/H_2O couple ($\sim +800$ mV). Part of this energy is converted into an electrochemical gradient of H^+ ions across the inner mitochondrial membrane by the parallel extrusion of H^+ from the matrix at complexes I, III, and IV of the respiratory chain. This proton gradient, termed the proton motive force (Δp) is composed of two components: an electrical component ($\Delta\Psi_m$), derived from the negative potential in the matrix (compared to cytosol), and a chemical component ΔpH, derived from the lower concentration of protons (alkalinity) in the matrix compared to cytosol. The relationship between these two components (when converted to millivolts at 25 °C) is embodied in the equation $\Delta p = \Delta\Psi_m - 59\Delta pH$. The respiratory chain is capable of producing a Δp of ~200 mV, which under physiological conditions is mostly (~90%) composed of $\Delta\Psi_m$ (−180 mV in the matrix). Virtually all the metabolic and transport functions of the mitochondria are energized by the Δp (Figure 1). For example, ATP synthesis in the matrix from inorganic phosphate (Pi) and ADP uses the Δp in the following steps:

1. Cytosolic Pi (as $H_2PO_4^-$) is symported into the matrix with an H^+ (electroneutrally) using ΔpH.
2. Cytosolic ADP^{3-} is exchanged with matrix ATP^{4-} by the adenine nucleotide transporter; this net transfer of one positive charge into the matrix is thus facilitated by $\Delta\Psi_m$.
3. ADP phosphorylation to ATP by the F_1,F_0-ATP synthase (complex V) is energized by H^+ influx (driven mainly by $\Delta\Psi_m$) via the F_0 region of this enzyme. This combination of reactions displaces the cytosolic ratio of [ATP]/([ADP][Pi]) well above its equilibrium, creating a phosphorylation potential that supplies the cell's energetic demands. The number of ATP molecules produced from glucose when oxidative phosphorylation operates is approximately 10–20 times greater than the ATP yield from anaerobic glycolysis. Glycolysis can be accelerated under anaerobic conditions. Interestingly, cytosolically generated ATP can act to preserve $\Delta\Psi_m$; this is accomplished by reversing the reaction catalyzed by the F_1,F_0-ATP synthase from its physiological direction (using $\Delta\Psi_m$ to generate ATP) to the ATPase direction (using (and perhaps depleting) ATP to generate/maintain $\Delta\Psi_m$).

The relative contributions of mitochondrial oxidative phosphorylation and glycolysis have not been studied directly in motor nerve terminals, but histochemical measurements of oxidative and glycolytic enzymes in spinal motor neurons indicate that their metabolic profile closely matches that of their target muscle fibers. A classification of skeletal muscle fibers, based on their ability to maintain contraction force during continuous activation, includes slow-twitch (type I) and fast-twitch (type II) fibers. A motor neuron innervates one or more muscle fibers of the same type, forming motor units with type-specific patterns of action potential activity. Slow motor units are activated at low frequencies (10–20 Hz) for sustained periods, whereas fast motor units are activated in higher frequency bursts (50–80 Hz) for briefer periods. In general, ATP production in fast muscle fibers relies more on glycolysis,

whereas that in slow fibers relies more on oxidative phosphorylation. There is evidence that these metabolic pathways are also employed differentially in fast and slow motor neurons and their terminals. For example, oxidative enzyme activity is higher in slow motor neurons, and mitochondrial density in slow motor neurons and their terminals is higher than that in their fast counterparts.

Motor Terminal Function in the Absence of Mitochondrially Supplied ATP

Transmitter release in response to nerve stimulation is abolished after approximately 20 min hypoxia (rat diaphragm, 33–38 °C) in the presence of normal glucose. This neuromuscular block is initiated by decreased evoked transmitter release rather than by axonal conduction block. It is clear that long-term motor nerve terminal function cannot be sustained by anaerobic glycolysis alone, but the deterioration that occurs during normoglycemic hypoxia is accelerated by the depletion of glycolytically supplied ATP by the reversed operation of the F_1,F_0-ATPase previously mentioned. When mitochondrial ATP synthesis is blocked without depolarizing mitochondria (using oligomycin), evoked release persists for longer times (>1 h).

Mitochondria as Regulators of Cytosolic [Ca^{2+}] during Repetitive Stimulation

The concept that mitochondria not only supply ATP but also powerfully sequester Ca^{2+} originated in studies led by Albert Lehninger. The transport mechanisms by which mitochondria accomplish this task were further refined by David Nicholls' laboratory. Consideration of the K_ds for various Ca^{2+} transport mechanisms suggests that in motor terminals the resting cytosolic [Ca^{2+}] concentration (~0.05–0.1 μM) is controlled mainly by high-affinity transport mechanisms such as the plasma membrane Ca^{2+} ATPase. When motor terminals are stimulated repetitively, the resulting elevation of cytosolic [Ca^{2+}] recruits additional Ca^{2+} transport mechanisms, especially those associated with mitochondria. Stimulation at 50 Hz (within the physiological range of discharge frequencies) causes cytosolic [Ca^{2+}] to rise rapidly at first (Figures 2(b) and 3(c)), but then the rate of rise slows dramatically, even though Ca^{2+} continues to enter the terminals (as evidenced by the continued evoked transmitter release). (In most imaging protocols, cytosolic Ca^{2+}-sensitive dyes report a temporal and spatial average of [Ca^{2+}] in the stimulated terminal rather than the larger, more localized [Ca^{2+}] elevations near open Ca^{2+} channels in the plasma membrane.) The plateauing behavior of cytosolic [Ca^{2+}] has been documented in motor terminals from crayfish, lizard, frog, and mouse over frequencies of 20–100 Hz, reaching a range of 0.5–4 μM [Ca^{2+}]. What mechanism limits the elevation of cytosolic [Ca^{2+}] during stimulation? Treatments that inhibit plasma membrane (Ca^{2+}-ATPase and Na^+/Ca^{2+} exchanger) and endoplasmic reticular Ca^{2+} transport have relatively little effect on the magnitude of the [Ca^{2+}] responses in lizard and mouse vertebrate motor terminals, but when mitochondrial Ca^{2+} uptake is inhibited, cytosolic [Ca^{2+}] rises to much higher levels (Figure 2(c)). In frog motor nerve terminals, Ca^{2+} uptake by the endoplasmic reticulum also collaborates with mitochondria in clearing the Ca^{2+} load. Thus, mitochondria are critical to understanding how motor terminals handle large Ca^{2+} loads, as well as the associated energy demands.

Mechanisms of Mitochondrial Ca^{2+} Uptake

Much of our understanding of mitochondrial Ca^{2+} handling has come from studies of isolated mitochondria. Ca^{2+} enters mitochondria passively, down a large electrochemical gradient created mainly by H^+ extrusion by complexes I, III, and IV of the electron transport chain (ETC). The membrane potential ($\Delta\Psi_m$) in resting mitochondria is estimated to be −150 to −200 mV. In spite of this large electrical gradient favoring Ca^{2+} influx, the free Ca^{2+} concentration in the matrix of resting mitochondria is low (~0.1 μM) because the small Ca^{2+} influx at resting conditions is fully balanced (or exceeded) by Ca^{2+} extrusion via the mitochondrial Na^+/Ca^{2+} exchanger. Elevation of cytosolic [Ca^{2+}] opens a Ca^{2+} uniporter channel in the inner mitochondrial membrane. Opening of this uniporter demonstrates a steeper-than-linear (second- to third-power) dependence on cytosolic [Ca^{2+}]. Some studies in isolated mitochondria suggested that large [Ca^{2+}] elevations in the micromolar range were necessary to initiate channel opening. But cytosolic components such as spermine lower the threshold for channel opening, and studies of mitochondria within motor terminals suggest uniporter opening with [Ca^{2+}] elevations of only a few hundred nanomolars.

Regulation of [Ca^{2+}] in the Mitochondrial Matrix

Mitochondria can sequester large amounts of Ca^{2+}, especially when the Ca^{2+} load is delivered gradually. This has been demonstrated in isolated mitochondria by adding known amounts of Ca^{2+} to the surrounding bath and measuring both total mitochondrial Ca^{2+} uptake and free matrix [Ca^{2+}] with Ca^{2+}-sensitive dyes. Total Ca (free + bound) in mitochondria within

Figure 2 Stimulation-induced elevations of cytosolic $[Ca^{2+}]$ in motor terminals stimulated at different frequencies and in the presence of oligomycin and a proton carrier (CCCP): (a) pseudo-color image of an indicator-filled motor terminal and preterminal axon during 50 Hz stimulation of the motor nerve; (b) Changes in cytosolic $[Ca^{2+}]$ evoked in a motor terminal by trains of action potentials (delivered at 100, 50, and 25 Hz); (c) stimulation-induced increase in cytosolic $[Ca^{2+}]$ with and without CCCP. In (a), the image shows an elevation of $[Ca^{2+}]$ (red) localized to the motor terminal. The fluorescent Ca^{2+}-indicator dye was injected via a microelectrode into a distant internode of the axon and allowed to diffuse into the terminal. Image in (a) came from a motor terminal innervating the mouse levator auris longus muscle, injected with the Ca-sensitive dye Oregon green-BAPTA-1. In (b), during stimulation there is a rapid rise followed by a plateau whose amplitude increases with frequency. Following stimulation, there is a rapid decrease followed by a slow decay to baseline. As shown in (c), the stimulation-induced increase in cytosolic $[Ca^{2+}]$ is much greater when mitochondrial Ca^{2+} uptake is inhibited by depolarizing $\Delta\Psi_m$ with CCCP. This effect is due to the blockade of mitochondrial Ca^{2+} uptake rather than to the inhibition of mitochondrial ATP synthesis because oligomycin, which blocks ATP synthesis without depolarizing $\Delta\Psi_m$, did not (in the short term) alter the $[Ca^{2+}]$ response. Recordings in (b) and (c) came from motor terminals innervating the mouse internal oblique muscle using Oregon green-BAPTA-5N. Muscle contractions were inhibited with D-tubocurarine, which blocks muscle acetylcholine receptors; 32–34 °C. F, fluorescence; ATP, adenosine triphosphate. (b, c) Reproduced from David G and Barrett EF (2000) Stimulation-evoked increases in cytosolic $[Ca^{2+}]$ in mouse motor nerve terminals are limited by mitochondrial uptake and are temperature-dependent. *Journal of Neuroscience* 20(19): 7290–7296, with permission from Society for Neuroscience.

cells can also be measured by electron-probe microanalysis. Both techniques demonstrate that mitochondria can accumulate millimolar amounts of Ca. Several mechanisms allow sustained mitochondrial Ca^{2+} uptake. The first mechanism is that the $\Delta\Psi_m$ depolarization produced by Ca^{2+} uptake accelerates H^+ extrusion by the ETC by reducing the electrical gradient against which H^+ extrusion occurs. This acceleration of ETC activity limits the extent of $\Delta\Psi_m$ depolarization, thus maintaining an electrical gradient favoring Ca^{2+} entry. However, the accelerated H^+ efflux via this mechanism would be expected to hinder Ca^{2+} uptake by alkalinizing the matrix and converting the $\Delta\Psi_m$ that drives Ca^{2+} uptake into ΔpH. The second mechanism offsets this potential limitation of Ca^{2+} uptake due to matrix alkalinization by importing H^+ electroneutrally via the mitochondrial Pi/H^+ symporter. The third mechanism, also dependent on Pi influx, limits the increase in free matrix $[Ca^{2+}]$ to only 1–2 μM via the reversible formation of an (insoluble) Ca–phosphate complex (probably amorphous calcium phosphate, $Ca_3(PO_4)_2$) in the matrix, thereby removing Ca^{2+} from solution when the solubility product for this complex is exceeded. It appears that matrix $[Ca^{2+}]$ remains clamped near this level as long as this complex is present, that is, until sufficient Ca^{2+} is extruded to bring matrix $[Ca^{2+}]$ below the critical value required for complex formation. This powerful matrix-buffering mechanism requires metabolic activity because the formation of the CaPi complex is favored by the alkaline pH provided by ETC H^+ extrusion. The buffering of free-matrix $[Ca^{2+}]$ protects this organelle from several deleterious consequences of high free-matrix $[Ca^{2+}]$, including osmotic swelling and the release of cytochrome C, activation of mitochondrial calpains, inhibition of complex I of the ETC, inhibition of cytochrome oxidase by nitric oxide generated by Ca^{2+}-activated mitochondrial nitric oxide synthase,

and possibly opening of the mitochondrial permeability transition pore (MPTP).

How Does Sequestered Calcium Leave the Mitochondria?

Two major mechanisms have been identified in neuronal mitochondria. One is extrusion via the mitochondrial Na^+/Ca^{2+} exchanger (which is distinct from the Na^+/Ca^{2+} exchanger in the plasma membrane). The Na^+ that enters the matrix via this exchanger is, in turn, extruded by a Na^+/H^+ exchanger, so this extrusion mechanism uses the energy of the transmembrane $[H^+]$ gradient produced by ETC activity. The other mechanism is the opening of the MPTP, which can rapidly release Ca^{2+} from the matrix, but at the cost of completely depolarizing $\Delta\Psi_m$ and releasing other mitochondrial components (e.g., cytochrome C) that can trigger cell death. Measurements of mitochondrial $[Ca^{2+}]$ in mouse motor nerve terminals indicate that the predominant method of removing stimulation-induced Ca^{2+} loads from the matrix is the mitochondrial Na^+/Ca^{2+} exchanger. After 50 Hz stimulation under physiological conditions, matrix $[Ca^{2+}]$ declines slowly following stimulation (Figures 3(a4) and 3(b)). After the addition of CGP-37157 to inhibit the mitochondrial Na^+/Ca^{2+} exchanger, matrix $[Ca^{2+}]$ remains elevated (Figure 3(b)); the decrease in Ca^{2+} efflux from the mitochondria is also manifested by a faster decay of poststimulation cytosolic $[Ca^{2+}]$ (Figure 3(c)). In contrast, application of cyclosporin A, which inhibits MPTP opening, had no significant effect on mitochondrial or cytosolic $[Ca^{2+}]$ responses. The Ca^{2+} released from mitochondria to the cytosol after stimulation ends is eventually extruded from the cytosol

Figure 3 Extrusion of mitochondrially sequestered Ca^{2+} into the cytosol: (a) micrographs (1)–(3) showing a motor terminal and axon in a mouse that transgenically expresses yellow fluorescent protein (YFP; shown as green) in neurons and a graph (4) of mitochondrial $[Ca^{2+}]$ during stimulation; (b) mitochondrial $[Ca^{2+}]$ decay after the addition of CGP-37157 to inhibit Ca^{2+} extrusion via the mitochondrial Na^+/Ca^{2+} exchanger; (c) cytosolic $[Ca^{2+}]$ after the addition of CGP-37157 to inhibit Ca^{2+} efflux from the mitochondria. In (a), the YFP image is superimposed on a phase image (1) showing the underlying muscle fibers. Image (2) shows in red the regions in which mitochondrial $[Ca^{2+}]$ increased during stimulation at 50 Hz, indicated by a Ca^{2+}-sensitive dye, Xrhod-5F. Yellow regions in the merged image in (3) show that the increase in mitochondrial $[Ca^{2+}]$ occurred within the terminal arborization. The graph (4) shows that during stimulation mitochondrial $[Ca^{2+}]$ in this terminal exhibited a rapid increase followed by a plateau; when stimulation stopped, mitochondrial $[Ca^{2+}]$ decreased slowly. As shown in (b) mitochondrial $[Ca^{2+}]$ decays even more slowly after the addition of CGP-37157 to inhibit Ca^{2+} extrusion via the mitochondrial Na^+/Ca^{2+} exchanger. In both (a4) and (b), the plateau of matrix $[Ca^{2+}]$ during stimulation and the early posttetanic interval were not due to the saturation of the fluorescent indicator but, rather, to a powerful matrix Ca^{2+}-buffering mechanism. As shown in (c), inhibiting Ca^{2+} efflux from the mitochondria with CGP-37157 decreased the posttetanic tail of cytosolic $[Ca^{2+}]$, demonstrating that the extrusion of sequestered Ca^{2+} from the mitochondria elevates posttetanic $[Ca^{2+}]$ in the cytosol. Recordings are from motor terminals innervating the mouse levator auris longus muscle, in the presence of D-tubocurarine. F, fluorescence. Reproduced from Garcia-Chacon LE, Nguyen KT, David G, and Barrett EF (2006) Extrusion of Ca^{2+} from mouse motor terminal mitochondria via a Na^+/Ca^{2+} exchanger increases post-tetanic evoked release. *Journal of Physiology* 574: 663–675, with permission from Wiley-Blackwell Publishing Ltd.

via the plasma membrane Na^+/Ca^{2+} exchanger and the plasma membrane Ca-ATPase.

Impact of Mitochondrial Ca^{2+} Handling on Transmitter Release

Measurements of transmitter release confirm the importance of mitochondrial Ca^{2+} sequestration and subsequent extrusion to motor terminal function.

When mitochondrial Ca^{2+} uptake is inhibited by depolarizing $\Delta\Psi_m$, phasic transmitter release, which produces the endplate potential recorded in the underlying muscle, depresses rapidly during stimulation (Figure 4(a)). These $\Delta\Psi_m$-depolarizing drugs do not (within the first hour) alter the endplate potential recorded at the onset of stimulation, so the extra depression is not due to the acceleration of the initial phasic release. Rather, the accelerated depression of phasic release appears to be due to the acceleration of asynchronous release, which increases as cytosolic $[Ca^{2+}]$ increases to high levels (Figure 4(b)). This excessive asynchronous release depletes the pool of vesicles available for phasic release. Thus, by limiting the elevation of cytosolic $[Ca^{2+}]$, mitochondrial Ca^{2+} uptake helps preserve the phasic release necessary to sustain muscle contraction during repetitive stimulation. Because mitochondrial $[Ca^{2+}]$ uptake is initiated only after approximately 25–50 action potentials (25–50 Hz), the amplitude and recovery rate of cytosolic $[Ca^{2+}]$ after a single stimulus relies mainly on fast diffusion and binding of subplasmalemmal Ca^{2+} to cytosolic buffers. Thus, mitochondrial Ca^{2+} sequestration does not terminate transmitter release after a single action potential; rather, mitochondrial Ca^{2+} uptake limits the buildup of cytosolic $[Ca^{2+}]$ during repetitive activity, thus protecting the vesicular pool from massive depletion via Ca^{2+}-driven asynchronous release.

Extrusion of Ca^{2+} from mitochondria into the cytosol following stimulation also has important effects on transmitter release (Figure 4(c)). When mitochondrial Ca^{2+} extrusion is inhibited by CGP-37157, posttetanic phasic transmitter release exhibits more depression at high quantal contents and less potentiation at low quantal contents. Also consistent with a contribution of mitochondrial Ca^{2+} extrusion to posttetanic release is the observation that prolonging the tetanus results in the prolongation of both the posttetanic changes in release and the posttetanic decay of mitochondrial $[Ca^{2+}]$. Thus, the rapid sequestration of cytosolic Ca^{2+} by the mitochondria during stimulation protects phasic transmitter release from depletion via asynchronous release; the slow extrusion of this Ca^{2+} back into the cytosol after stimulation augments phasic release, thus speeding its recovery from posttetanic depression. These recent findings thus confirm the hypotheses proposed by Rami Rahamimoff and later by Robert Zucker that mitochondrial Ca^{2+} handling is a critical regulator of transmitter release from motor nerve terminals. Although mitochondria are abundant in most nerve terminals, it is as yet unclear whether mitochondrial Ca^{2+} transport is as important in other terminals as it is in vertebrate motor nerve terminals. Analysis of plasma membrane and organellar Ca^{2+}-handling mechanisms in a large central nervous system (CNS) synapse, the calyx of Held, suggests a less dominant role for mitochondrial Ca^{2+} transport. *Drosophila* mutants whose motor terminals lack mitochondria did not exhibit larger-than-normal cytosolic $[Ca^{2+}]$ responses during short stimulus trains, but in that study stimulation frequencies were limited to 10 Hz. At this relatively low stimulation frequency, mitochondrial Ca^{2+} transport also plays a relatively small role in vertebrate motor terminals. Thus, in assessing mitochondrial contributions to presynaptic Ca^{2+} handling, it is important to consider the magnitude of the Ca^{2+} load. It is also important to consider temperature because mitochondrial contributions to Ca^{2+} handling in mouse motor terminals decrease at lower temperatures. The relative importance of mitochondrial Ca^{2+} handling may also diminish in diseases characterized by impaired mitochondrial function.

Interaction between Mitochondrial Ca^{2+} Uptake and Mitochondrial Metabolism

The information summarized so far demonstrates that nerve stimulation and the ensuing vesicular recycling impose energy demands on the motor terminal and, thus, would be expected to alter mitochondrial metabolism. Two measures of mitochondrial metabolism, [NADH] and $\Delta\Psi_m$, change during stimulation of lizard motor nerve terminals (Figure 5). NADH autofluorescence decreases during the stimulus train, demonstrating a reversible oxidation of fluorescent NADH to nonfluorescent NAD^+. A partial, reversible depolarization of $\Delta\Psi_m$ occurs over roughly the same time course. Both these changes require Ca^{2+} influx into the motor terminal; they disappear when Ca^{2+} is removed from the bath or when the main voltage-dependent Ca^{2+} channels in these motor terminals are blocked with ω-conotoxin GVIA. Surprising to us, the stimulation-induced changes in [NADH] and $\Delta\Psi_m$ persisted when vesicular release was blocked by botulinum toxin A.

What Causes These Changes in [NADH] and $\Delta\Psi_m$?

An unlikely cause of the decrease in [NADH] is the deceleration of the tricarboxylic acid (TCA) cycle, which produces NADH. A more likely cause is the

Figure 4 Mitochondrial Ca^{2+} uptake and subsequent extrusion help to sustain phasic transmitter release during and following tetanic stimulation: (a) five sequential endplate potentials (EPPs) recorded at the beginning and end of the stimulus train before (upper traces) and after (lower traces) $\Delta\Psi_m$ depolarization and the quantal content (*m*, central plot) normalized to the value recorded at the onset of stimulation ($m_{pretrain}$); (b) comparison of the rates of phasic and asynchronous release during stimulus trains; (c) results of tetanic stimulation in normal extracellular [Ca^{2+}] and thus normal quantal content (top) and results of a similar experiment performed when extracellular [Ca^{2+}] was reduced from 1.8 to 0.4 mM (bottom). In (a) the depression of phasic transmitter release during a 50 Hz stimulus train is greater when mitochondrial Ca^{2+} uptake is blocked by depolarizing $\Delta\Psi_m$ (depolarization, red). Phasic release was measured as the peak amplitude of the EPP recorded by a microelectrode inserted into the muscle fiber. In the central plot *m* is calculated as EPP amplitude divided by the average miniature EPP (MEPP) amplitude. The tetanic and posttetanic depression of *m* were not increased when mitochondrial ATP production was blocked without $\Delta\Psi_m$ depolarization (with oligomycin (oligo), shown in green). In (b) the comparison of the rates of phasic (= EPP) and asynchronous (= MEPP) release during stimulus trains show that, when mitochondrial Ca^{2+} uptake is inhibited by depolarizing $\Delta\Psi_m$ (red), the decrease in phasic release is accompanied by a dramatic increase in the rate of asynchronous release, driven by the large increase in cytosolic [Ca^{2+}] recorded in this condition (**Figure 2(c)**). Calculations (not shown) indicate that the increased asynchronous release at the beginning of the train is sufficient to deplete the pool of releasable vesicles. Similar experiments performed using oligomycin alone (green) show sustained phasic release and little asynchronous release, demonstrating that the dramatic increase in asynchronous release during $\Delta\Psi_m$ depolarization was not due to inhibiting mitochondrial ATP production. As shown in (c), following tetanic stimulation in normal extracellular [Ca^{2+}] and thus normal quantal content, the EPP amplitude returns rapidly to control levels (top). This recovery is slowed when mitochondrial Ca^{2+} extrusion is inhibited by CGP-37157. When extracellular [Ca^{2+}] is reduced from 1.8 to 0.4 mM (bottom), posttetanic release is temporarily increased but CGP-37157 blocks this increase. EPP amplitudes are normalized to prestimulation values (EPP_0) and were recorded from endplates in mouse internal oblique (a, b) and levator auris longus (c) muscles; contractions were blocked using μ-conotoxin GIIIB, which blocks muscle, but not axonal, Na^+ channels. The $\Delta\Psi_m$ depolarization in (a) was achieved with either the proton carrier CCCP or the complex III blocker antimycin A1. $\Delta\Psi_m$ depolarizing agents were applied with oligomycin to prevent the rebuilding of $\Delta\Psi_m$ by reverse operation of the F_1,F_0-ATPase. Ψ_m, mitochondrial membrane potential; ATP, adenosine triphosphate. (a, b) Reproduced from David G and Barrett EF (2003) Mitochondrial Ca^{2+} uptake prevents desynchronization of quantal release and minimizes depletion during repetitive stimulation of mouse motor nerve terminals. *Journal of Physiology* 548: 425–438, with permission from Wiley-Blackwell Publishing Ltd. (c) Reproduced from Garcia-Chacon LE, Nguyen KT, David G, and Barrett EF (2006) Extrusion of Ca^{2+} from mouse motor terminal mitochondria via a Na^+/Ca^{2+} exchanger increases post-tetanic evoked release. *Journal of Physiology* 574: 663–675, with permission from Wiley-Blackwell Publishing Ltd.

Figure 5 Stimulation-induced changes requiring Ca^{2+} influx into motor nerve terminals: (a) changes in mitochondrial membrane potential (Ψ_m); (b) changes in NADH fluorescence. Ψ_m depolarization is indicated by the increased fluorescence of rhodamine [Rh]-123. Both Ψ_m and NADH changes were blocked by ω-conotoxin (CTX) GVIA, which blocks the voltage-dependent Ca^{2+} channels (N-type) in the plasma membrane of these lizard motor terminals. Both plots are normalized to pretrain fluorescence (F_0). Recordings are from motor terminals innervating lizard intercostal muscles. NADH, nicotinamide adenine dinucleotide. Reproduced from Talbot JD, Barrett JN, Barrett EF, and David G (2007) Stimulation-induced changes in NADH fluorescence and mitochondrial membrane potential in lizard motor nerve terminals. *Journal of Physiology* 579(3): 783–798, with permission from Wiley-Blackwell Publishing Ltd.

acceleration of ETC activity, which oxidizes NADH. Studies in isolated mitochondria demonstrate that $\Delta\Psi_m$ depolarization accelerates ETC activity by reducing the magnitude of the energy barrier that opposes proton extrusion. One possible cause of the measured $\Delta\Psi_m$ depolarization is increased H^+ influx into the mitochondria via the F_1F_0-ATPase when the cytosolic ATP/ADP ratio decreases (a mechanism called respiratory control). However, this mechanism seems unlikely during short stimulation trains because blocking F_1F_0-ATPase activity with oligomycin did not inhibit the recorded changes in [NADH] or $\Delta\Psi_m$. Another possible cause of $\Delta\Psi_m$ depolarization is the direct Ca^{2+} influx into mitochondria. This mechanism seems likely because of the Ca^{2+} dependence already mentioned and because the measured $\Delta\Psi_m$ depolarization has a time course similar to that expected for Ca^{2+} influx into the mitochondria, occurring during stimulation and terminating quickly thereafter. Thus an overall hypothesis concerning how these changes are interrelated (see Figure 1) is that Ca^{2+} influx depolarizes $\Delta\Psi_m$, leading to easier mitochondrial proton extrusion and, thus, accelerating ETC activity and the oxidation of NADH to NAD^+. The ability of the ETC to accelerate during Ca^{2+} influx limits the magnitude of the $\Delta\Psi_m$ depolarization. When motor terminals are stimulated in the presence of ETC blockers, the depolarization of $\Delta\Psi_m$ is greater and mitochondrial Ca^{2+} uptake becomes less efficient, as indicated by a much larger elevation in cytosolic $[Ca^{2+}]$. Mitochondria in repetitively stimulated motor nerve terminals thus appear to achieve a compromise between their ATP-producing and Ca^{2+}-buffering roles. Both roles require a hyperpolarized $\Delta\Psi_m$. The necessity for Ca^{2+} uptake produces $\Delta\Psi_m$ depolarization (and thus a temporary decrease in ATP synthesis), but this depolarization is kept relatively small due to their ability to accelerate ETC activity. Motor nerve terminals thus appear to tolerate a temporary decrease in mitochondrial ATP production (due perhaps to other energy reserves such as glycolysis) in order to avoid an excessive elevation of cytosolic

[Ca^{2+}] that would rapidly disrupt their main physiological function (i.e., maintaining phasic transmitter release at levels that exceed the threshold for activating muscle contraction).

Other Tissues

The impact of the described Ca^{2+} influx into the mitochondria on [NADH] may be different in other tissues. Measurements of stimulation-induced changes in [NADH] in other tissues (including the CNS) usually show that the most prominent change is not the brief decrease we have described but, rather, a pronounced increase that persists long after stimulation. Such a mechanism would accelerate ATP synthesis to match the increased demand signaled by matrix [Ca^{2+}] elevation. Only a fraction of motor terminals exhibited any poststimulation increase in NADH, and the magnitude of any such increase was small. One way to understand these differences is by considering that the direction of change in [NADH] when the mitochondria take up Ca^{2+} depends on the relative contribution of the two outcomes of this uptake: $\Delta\Psi_m$ depolarization due to Ca^{2+} current into the matrix and the elevation of matrix [Ca^{2+}].

1. $\Delta\Psi_m$ depolarization pulls the ETC toward expending more NADH to accelerate H^+ extrusion. This immediate response allows the mitochondrial Ca^{2+} influx to proceed without progressive $\Delta\Psi_m$ depolarization and seems to dominate in motor terminals.
2. The elevation of matrix [Ca^{2+}] pushes the ETC by stimulating NADH supply via the Krebs cycle. Here, matrix [Ca^{2+}] serves as a signal for the anticipated increase in cytosolic ATP demand which requires NADH-supported H^+ extrusion. This mechanism may dominate in tissues in which mitochondria are not the main mechanism for buffering Ca^{2+} loads.

Mitochondrial Involvement in Nerve Terminal Pathology

Ischemia/Reperfusion

Acute limb ischemia in humans originates from a sudden decrease in arterial blood flow to an extremity, commonly caused by peripheral arterial occlusive disease (PAD), leading to intermittent and repeated episodes of limb ischemia during walking or exercise. Muscle denervation is one of the earliest manifestations of PAD. Animal models of hindlimb ischemia/reperfusion (I/R) injury demonstrate that motor nerve terminals are the most vulnerable neuromuscular component. In the first 4 weeks following an episode of ischemia experimentally applied to rat hindlimbs, morphological studies detected no changes in axons, Schwann cells, or muscle fibers but multiple signs of degeneration in motor nerve terminals. These signs included the disruption of presynaptic membranes and the swelling and degeneration of the mitochondria. Functional measurements also show that the neuromuscular junction is a major site of I/R injury because in postischemic muscle contractions elicited by the activation of axons and their motor terminals recover less than contractions elicited by direct muscle stimulation. Mechanisms for ischemic injury to motor nerve terminals include mitochondrial Ca overload during ischemia and the subsequent oxidative stress during reperfusion, which might collaborate to induce the irreversible opening of the MPTP. The heavy reliance of motor nerve terminals on the mitochondria for Ca^{2+} sequestration (see the section entitled 'Mitochondria as regulators of cytosolic [Ca^{2+}] during repetitive stimulation') might predispose them to degeneration after stresses (e.g., I/R) that damage this organelle.

Amyotrophic Lateral Sclerosis

This adult-onset disease is characterized by the death of upper and lower spinal motor neurons, especially those innervating the limbs. Most cases of amyotrophic lateral sclerosis (ALS) arise sporadically, but approximately 10% are familial. Some familial cases involve mutations in superoxide dismutase I (SOD1), an enzyme that contributes to defense against oxidative stress. These SOD1 mutations produce disease by a dominant gain-of-function mechanism that appears unrelated to whether the mutant SOD1 retains dismutase activity. It is as yet unclear why motor neurons are differentially vulnerable to the mutant protein, which is expressed in all body cells. Mice that transgenically express some of these ALS-inducing mutant human SOD1s develop motor neuron death and thus constitute animal models for familial ALS. Work from multiple laboratories showed that in these mice the first structural signs of motor neuron damage are found in motor nerve terminals and their mitochondria, changes that occur months before the motor neuron somata begin to die. An early functional change in the motor neuron mitochondria is reduced ability to sequester Ca^{2+} loads, which might contribute to the early degeneration of motor terminals. Motor terminals that innervate fast limb muscles degenerate earlier than those innervating slow limb muscles, and these fast motor terminals exhibit increased vulnerability to I/R injury at an early age. Future studies will clarify the link among mutant SOD1, mitochondria, and motor terminal damage and will perhaps suggest strategies for treating this fatal disease.

Primate Communication: Evolution

Vocal Perception in Nonhuman Primates

By comparing the vocal behavior of extant primates with that of humans, one can deduce the behavioral capacities of extinct common ancestors, allowing the identification of homologies and providing clues as to the adaptive functions of such behaviors. By exploring how living nonhuman primate (hereafter, 'primate') species use their vocalizations, numerous investigators are building a rigorous, testable framework for how speech might have evolved. Much of this work has been carried out in the domain of vocal perception (as opposed to production). There are numerous psychophysical investigations of how primates, such as macaques, baboons, vervets, and chimpanzees, process human speech sounds, best for the most part, these studies show that with the appropriate amount of training (usually quite extensive), these species perceive speech sounds in a manner similar to that of humans. A more insightful line of inquiry includes research into how primates perceive their own vocalizations and whether the underlying patterns and processes are similar to those of human speech perception. This article highlights the insights made by this line of inquiry.

Referential Communication

The species-typical vocalizations of many primates, as well as other animals, contain information that can be used by listeners as a source of information about objects, events, and the status of peers in their environment. Of particular interest is the capacity of primate vocalizations to transmit functional ('referential') information about an event or the presence of an object in the environment. That is, based on signal morphology alone, and regardless of the mechanisms that might underlie vocalization production, listeners are able to extract information about a vocalization's putative meaning.

A classic example of referential communication is the use of predator-alarm calls by vervet monkeys (*Cercopithecus aethiops*). Vervets produce unique alarm calls for three different predators: a snake, a leopard, and an eagle. The information that is transmitted to the listeners initiates specific patterns of species-typical behaviors. For example, when vervets hear an eagle-alarm call, they scan the sky for visual cues of the airborne predator, and, in some cases, run to locations that provide overhead coverage. In contrast, when they hear a snake-alarm call, they stand up and scan the ground. Finally, a leopard-alarm call initiates a third distinct behavior: vervets run up the nearest tree while scanning the horizon for the leopard.

The capacity to successfully process referential signals also allows animals to use the referential information that is transmitted by the vocalizations of other species. For example, female Diana monkeys (*Cercopithecus diana*) elicit a predator-alarm call when they hear a male Diana monkey producing a leopard alarm or when they hear the leopard-alarm call of a crested guinea fowl. This observation is important since it suggests that Diana monkeys can form abstract categorical representations of a vocalization's functional meaning that is independent of acoustics and the species generating the signal.

Another example of categorization is the food-associated calls of rhesus macaques (*Macaca mulatta*). When free-ranging rhesus monkeys encounter low-quality food, they elicit coos or grunts. In contrast, when they encounter rare, high-quality food, they elicit harmonic arches or warbles. Both free-ranging and laboratory-housed rhesus monkeys categorize these vocalizations based on differences in their function as opposed to their acoustics. For example, harmonic arches and warbles, despite having distinct acoustic properties, are categorized as being functionally equivalent.

Syntactic Processing of Vocal Sequences

Many primate species produce bouts of vocalizations containing sequences of similar acoustic units and/or different-sounding acoustic units, but we know very little about whether each of these units separately codes meaningful information (like words in a sentence) or whether units can be combined to form only a single meaningful utterance (like syllables in a word). For our purposes here, we will refer to all temporally distinct acoustic pulses as syllables. This criterion is arbitrary in the sense that it is based solely on an acoustic measure, not a behavioral one.

Most of our insights into the units of perception come from studies of the orderly arrangement of syllables within primate 'long calls'. Long calls serve as localization cues for conspecifics and are often produced in the context of territorial encounters, mate attraction, and isolation/group cohesion. These multisyllabic calls are produced by a range of different

primate species, such as the 'whoop–gobble' of mangabeys (*Cercocebus albigena*), the 'chirrup–pant–bellow–pump–honk' call sequences of titi monkeys (*Callicebus moloch*), the 'chirp–trills–squaws' of wedge-capped capuchins (*Cebus olivaceus*), the 'twitters' of squirrel monkeys (*Saimiri sciureus*), the 'whinny' of spider monkeys (*Ateles geoffroyi*), the 'pant–hoot' of chimpanzees (*Pan troglodytes*), the 'songs' of gibbons (*Hylobates* spp.), and the combination long calls of cotton-top tamarins (*Saguinus oedipus*).

In these vocal signals, which consist of multiple syllables, both individual syllables and combinations of syllables may mediate specific aspects of behavior. As a result, for any single vocalization, information may be coded at multiple levels. For example, the chimpanzee 'pant–hoot' consists of a series of 'hoot' calls followed by a series of 'screams.' Since both hoots and screams are produced individually in other contexts, the pant–hoot could either be a single vocalization or a bout of several vocalizations.

To determine the relative importance of single syllables versus combinations of syllables in eliciting behaviors from listeners, one can use playback experiments. For example, early studies of the long calls of titi monkeys and gibbons demonstrated that individual renditions of these calls have stereotypical arrangements of syllables; individual males use these long calls to defend/demarcate their territories. Playback experiments, in which these syllables were artificially rearranged, revealed that both primate species recognized the novel arrangement of syllables and responded as though a new male was in the adjacent territory. Gibbons produced significantly more 'squeak' calls (given during intergroup encounters) when hearing these novel stimuli, whereas titi monkeys produced significantly more 'moaning' responses (also given in response to interspecies and intergroup encounters). These data suggest that, at least in these species, there is recognition of the global order of syllable sequences.

It is also important to understand the smallest invariable acoustic unit that can influence behavior. Cotton-top tamarins proved to be a useful model system for exploring this issue. In response to social isolation, tamarins will emit a long call beginning with one to two chirp syllables and ending with two to five whistle syllables (**Figure 1**). Upon hearing such vocalizations, conspecifics often respond with their own long calls – a behavior called 'antiphonal calling.' Although tamarins can produce chirps and whistles independently, it was hypothesized that the combination of both syllable types would function as a more effective stimulus (i.e., the unit of perception) for eliciting antiphonal long calls than either unit alone. Playback experiments using whole long calls (i.e., both chirps and whistles) versus isolated chirps versus isolated whistles confirmed this hypothesis: whole calls were much more effective in eliciting antiphonal long calls than either single whistles or single chirps. These data suggest that, in this species, the whole call is the most meaningful unit from the perspective of socially isolated receivers.

Figure 1 Cotton-top tamarin combination long call. Time–amplitude waveform (*y*-axis represents voltage in volts) and spectrogram (*y*-axis represents frequency in kilohertz) of a representative combination long call recorded in captivity. Chirps and whistles are labeled. Adapted from Ghazanfar AA, Flombaum JI, Miller CT, et al. (2001) The units of perception in the antiphonal calling behavior of cotton-top tamarins (*Saguinus oedipus*): Playback experiments with long calls. *Journal of Comparative Physiology A* 187: 27–35.

The data described here represent examples of 'phonological syntax,' whereby smaller units are assembled to form larger ones. Are there any examples of 'lexical syntax,' where the different combinations of sounds produce different 'meanings'? Studies of African forest monkeys provide a tentative 'yes' to this question. There are two such examples. First, Diana monkeys seem to comprehend not only the two different alarm calls of a sympatric species (the leopard- and eagle-alarm calls of Campbell's monkeys (*Cercopithecus campbelli*)) but they also seem to understand that if these alarm calls are preceded by a Campbell's monkey's 'boom' call, the threat is less urgent. Importantly, if a Campbell's monkey's boom is placed before a Diana monkey's own alarm calls, it has no effect on the Diana monkeys' behavior. The second example is from the putty-nosed monkey (*Cercopithecus nictitans*). These monkeys also produce two different alarm calls, one for leopards ('pyows') and one for eagles ('hacks'). When heard, each of these calls produces a stereotypical escape response from listeners. However, when the two calls are combined into 'pyow–hack' sequences by the males of a group, this sequence of calls elicits general group movement, not an alarm response. Thus, both of these examples suggest that at least some primates comprehend lexical syntax.

Multisensory Processes

One aspect of speech that is overlooked by comparative biologists seeking to understand its origins is the fact that speech is not a purely auditory phenomenon. Human speech is a multisensory function, perceived through both the visual and auditory channels. Multisensory speech perception is evident even at the earliest stages of human cognitive development (at 2 months of age), its integration across the two modalities is ubiquitous and automatic, and even at the neural level, audiovisual speech integration is evident at the 'earliest' stages of cortical processing. One example of this integration is the integration of speech signals and speech-related facial motion. For example, human adults link high-pitched sounds to facial postures producing an /i/ sound and link low-pitched sounds to faces producing an /a/ sound. Thus, multisensory speech may be the 'primary' mode of speech perception and not simply a capacity that is 'piggybacked' on to auditory speech perception. If its multisensory nature is a fundamental feature of human speech, whereby visual/facial and vocal signals are inextricably linked, then do other primates show similar links in their vocalizations?

Data from a variety of primate species suggests that there is a similar link between acoustic output and facial dynamics. For example, different rhesus monkey vocalizations are produced with unique lip configurations and mandibular positions and the motion of such articulators influences the acoustics of the signal. Coo calls, like /u/ in speech, are produced with the lips protruded, while screams, like the /i/ in speech, are produced with the lips retracted (Figure 2). Moreover, as in humans, the articulation of these expressions has visible consequences on facial motion beyond the oral region. Grimaces, produced during scream vocalizations, for instance, cause the skin folds around the eyes to increase in number. Chimpanzees, though less studied in the domain of multisensory communication, also link

Figure 2 Exemplars of rhesus monkey facial expressions produced concomitantly with vocalizations. Top panels represent a coo call taken at the midpoint of the expression and the corresponding spectrogram. Bottom panel represents a scream call.

facial expressions with vocal acoustics. Video and audio analyses of common chimpanzee vocalizations produced in the wild show that a decline in the fundamental frequency (F0) occured when submissive screams transitioned into aggressive barks. These changes in F0 were correlated with changes in visible articulators such as lip and teeth opening. Taken together, these data suggest that it is likely that many of the facial motion cues that humans use for speech reading are present in at least some apes and monkeys as well.

Given that both humans and other extant primates use both facial and vocal expressions as communication signals, it is unlikely that only humans recognize the correspondence between the visual and auditory components of vocal signals. In behavioral situations similar to those used to study the face/voice-matching abilities of human infants, rhesus monkeys demonstrated that they recognize the auditory–visual correspondences between their 'coo' and 'threat' calls. A similar study using capuchin monkeys (*Cebus apella*) as subjects showed that they could match the appropriate facial expressions to heard vocalizations as well. Chimpanzees can also match familiar voices to familiar faces as well as facial expressions with their corresponding vocalizations (albeit using a training-induced behavioral measure).

Temporal Cues for Vocal Recognition

Humans use temporal cues such as the duration, interval, and order of acoustic features to distinguish among speech sounds. For example, humans distinguish /pa/ from /ba/ on the basis of voice onset time, and /sa/ from /sta/ on the basis of the silent time between consonants and vowels. It has been suggested that speech perception is based on the rapid processing of temporal information.

To what extent do primates use temporal cues to recognize their own vocalizations? Field and lab studies of the coo calls of Japanese macaques (*Macaca fuscata*) suggested that they could distinguish among different coo calls based upon temporal cues (the temporal position of a peak frequencies), and calls defined by this feature were produced in different behavioral contexts. Later studies, however, showed that although they could use temporal cues to discriminate among their own coo calls, this may have been an artificial classification scheme inadvertently imposed by the experimenters.

Studies from two other species provide additional support for the notion that primates use temporal cues for vocal recognition. First, as already mentioned, cotton-top tamarins antiphonally call preferentially to whole calls, compared to signals composed of one of the two syllable types present in their long calls. Further studies revealed that while tamarins did not distinguish between normal calls and time-reversed or pitch-shifted long calls, normal response rates did require the species-typical temporal structure of the amplitude envelope. Furthermore, there was suggestive evidence that the number of syllables and the syllable rate may also influence antiphonal calling responses. Second, in rhesus monkeys, playback experiments using three different call types – shrill barks, grunts, and copulation calls – demonstrated that rhesus monkeys responded differently to shrill barks and grunts than to copulation calls when the intersyllable interval was expanded or contracted beyond the species-typical range. In another experiment, rhesus monkeys' sensitivity to the shape of the amplitude envelope in the shrill barks and harmonic arch calls was tested by using time-reversed calls. This manipulation changes the calls' temporal structure without affecting their spectral content. Rhesus monkeys responded to these calls in a fashion suggesting that they did not recognize these stimuli as species-typical vocalizations.

Overall, the referential, syntactic, multisensory, and temporal features of primate vocalizations, from many different species, suggest striking parallels with human speech processing. Are these processes mediated by homologous neural circuits?

Neural Bases of Primate Vocal Communication

Hemispheric Asymmetries

A classic feature of human speech processing is its lateralization. Although there is no clear dichotomy of function between the cerebral hemispheres, perceptual experiments, studies of brain-damaged patients, and functional imaging studies have indicated that speech perception is usually lateralized to the left temporal lobe (**Figure 3(a)**). A behavioral indication of left-hemispheric specialization for speech processing in intact humans is the performance advantage exhibited by the right ear for the identification of speech sounds, and the left-ear advantage for nonspeech sounds. Behavioral experiments under laboratory and field conditions reveal that primates also exhibit similar asymmetries in the perception of their vocalizations. Psychophysical data from macaques also revealed a right-ear advantage when discriminating conspecific calls, and the orienting asymmetry assay alluded to in the previous section, whereby rhesus monkeys orient with the right ear leading toward conspecific calls, also suggests a lateralization of perceptual processes toward the left cerebral hemisphere. Similar right-ear orienting

Figure 3 (a) The macaque cerebral cortex. (b) Auditory areas within and around the lateral sulcus. The core regions (A1, R, and RT) are thought to be 'primary-like' areas, responding best to pure tones, while the surrounding lateral belt areas (CL, ML, and AL) are more responsive to complex sounds. The response properties of other areas have not been systematically investigated. A1, auditory area 1; AL, anterior lateral belt; CL, caudolateral belt; CM, caudomedial belt; CP, caudal parabelt; ML, middle lateral belt; R, rostral area; RM, rostromedial belt; RT, rostrotemporal area; RP, rostral parabelt; RTL, rostrotemporolateral belt; RTM, rostrotemporomedial belt; Tpt, temporoparietal area. Adapted from Ghazanfar AA and Santos LR (2004) Primate brains in the wild: The sensory bases for social interactions. *Nature Reviews Neuroscience* 5: 603–616.

biases have been reported for chimpanzees and mouse lemurs (*Microcebus murinus*).

More direct evidence for hemispheric asymmetries in processing vocalizations comes from anatomical, lesion, and imaging studies. For humans that show functional left-hemispheric biases for language processing, it has been shown that the Sylvian fissure (bordering auditory cortex) is significantly longer in the left hemisphere than in the right (Figure 3(a)). Using this measurement, potential anatomical asymmetries have similarly been measured in several species of primates. Left Sylvian fissure length was found to be significantly greater than in the right hemisphere in apes (*Pan, Gorilla*, and *Pongo*), Old World macaques (*M. fascicularis* and *M. mulatta*), and New World Callichtrids (cotton-top tamarins and marmosets). These cerebral asymmetries might represent the 'specialized' neural circuitry that mediates the behavioral asymmetries to conspecific vocalizations.

Lesion and imaging studies support this notion. Following lesions of the left auditory cortex, Japanese macaques exhibit a selective impairment for discriminating species-specific vocalizations but not for other types of auditory stimuli. Their performance was unimpaired by similar lesions in the right hemisphere. In rhesus monkeys, a positron emission tomography (PET) imaging study showed that conspecific vocalizations activate the anteriormost portion of the left upper temporal lobe to a greater degree than do other sounds. These studies naturally lead one to wonder how the neurophysiological signals of the neocortex encode vocalizations.

Two key neocortical nodes involved in processing human speech (both auditory and auditory–visual) are the superior temporal gyrus, within which lies the auditory cortex, and the prefrontal cortex. The human imaging data consistently show that the auditory cortex and prefrontal cortex seem to play important roles in speech perception. These two regions are, furthermore, densely interconnected. Neurophysiological evidence suggests that these areas play a similar role in monkeys; this observation is expanded upon in the following sections.

Auditory Cortex

Despite the importance of vocal communication in the lives of primates, we lack a complete understanding of how biologically relevant features of complex sounds are processed at the level of single neurons or small populations of neurons. For many years, the squirrel monkey was the only primate model for investigating the role of auditory cortex in processing species-specific vocalizations. Studies using this species found that many cells in the superior temporal gyrus responded to species-specific vocalizations. However, one of the drawbacks of these studies was that recordings were made across the superior

temporal gyrus without reference to any cytoarchitectural or any other anatomical subdivisions.

Recent anatomical and neurophysiological experiments in rhesus monkeys have, for the most part, eliminated this confound. A series of experiments in anesthetized rhesus monkeys have delineated three cochleotopic areas along the superior temporal gyrus (Figure 3(b)). They were labeled the caudolateral, middle lateral, and anterolateral belt areas (CL, ML, and AL, respectively). Unlike the primary auditory cortex (A1), neurons in these areas responded best to complex sounds, such as band-passed noise and species-specific vocalizations. In fact, neurons in all three lateral belt areas preferred rhesus monkey calls to energy-matched pure-tone stimuli. Furthermore, among the seven call exemplars tested, 90% of lateral belt neurons responded better to certain call types over others, that is, they were 'call selective.'

The lateral belt areas are not the only regions with neurons selectively responsive to species-specific vocalizations. Recent studies reveal that A1 neurons, despite their exquisite pure-tone sensitivity, can also be selective to complex time-varying stimuli as well. In common marmosets (*Callithrix jacchus*) and squirrel monkeys, A1 neurons can even be selective for conspecific calls. In both species, A1 neuronal firing patterns appear to phase-lock to the temporal envelope of the species-specific vocalizations used as stimuli. This phase locking appears to be driven by the global syllabic structure of the vocalizations rather than by the finer acoustic features of the vocalizations. Also, many neurons in the primary auditory cortex and the surrounding belt and parabelt areas of the marmoset are sensitive to the pitch of an auditory stimulus; this information may be used to infer the affective content of a vocalization. Based on these studies of the marmoset and squirrel monkey auditory cortex, it appears that even at early stages of cortical processing, there is selectivity for species-specific communication sounds that may be based on experience-dependent and/or species-specific neural mechanisms.

Recently, auditory cortex has also been shown to integrate multisensory communication signals. Local field potentials and single units in the auditory cortex are capable of integrating facial and vocal signals in monkeys (Figure 4). The vast majority of responses were specific to 'face + voice' integration, and such integration could take the form of either enhancement or suppression. The specificity of these integrative

Figure 4 Auditory cortical responses to multimodal vocalizations from the lateral belt region. Rectified local field potential responses to 'face + voice' (F + V), voice-alone (V), and face-alone (F) components were compared. The solid vertical line indicates the onset of the 'face' signal. Dotted vertical lines indicate the onset and offset of the 'voice' signal. Graphs represent the mean of ten repetitions, with the mean baseline activity subtracted on a trial-by-trial basis. Top panel shows an enhanced response to a multisensory grunt vocalization, while the bottom panel shows a suppressed response to a different grunt vocalization. Adapted from Ghazanfar AA, Maier JX, Hoffman KL, et al. (2005) Multisensory integration of dynamic faces and voices in rhesus monkey auditory cortex. *Journal of Neuroscience* 25: 5004–5012.

responses was tested by replacing the dynamic faces with dynamic disks which mimicked the aperture and displacement of the mouth. In human psychophysical experiments, such artificial dynamic stimuli can still lead to enhanced speech detection in noise, but not to the same degree as a real face. When cortical sites were tested with dynamic disks, far less integration was seen when compared to the real monkey faces.

Prefrontal Cortex

The frontal lobes contain an auditory responsive region that responds robustly to vocalizations. This region, the ventrolateral prefrontal cortex (vPFC), lies below the principal sulcus and receives connections from the anterolateral belt region (Figure 3). The vPFC, an area thought to be part of a circuit involved in auditory–object processing, has been hypothesized to play an important role in processing the more abstract components of vocalizations. Specifically, it has been suggested that the vPFC plays an important role in processing the referential information transmitted by a vocalization.

In one set of experiments, vPFC neurons were hypothesized to be modulated more by the referential information transmitted by a vocalization than by the acoustic features of a vocalization (Figure 5). Consistent with this hypothesis, the activity of vPFC neurons was not modulated by transitions between presentations of food vocalizations that transmitted the same referential information (Figure 5(a)), even though the vocalizations had significantly different acoustic structures. vPFC activity, however, was modulatedby transitions between presentations of food vocalizations that conveyed different types of referential information (high-quality vs. low-quality food; Figure 5(b)). These data suggested that, on average, vPFC neurons

Figure 5 Population responses of vPFC activity in response to transitions between vocalization exemplars. Vocalizations were presented during the repetitive-presentation context and during a baseline condition. During the repetitive-presentation context, a vocalization was presented repeatedly (the 'repeated' vocalization) 7–9 times. This was followed by the presentation of a different vocalization (the 'test' vocalization). During the baseline condition, the test and repeated vocalizations and other stimuli were presented in a random order. The thick gray strip in each panel represents the normalized population firing rates in response to a test vocalization during the baseline condition. The colored strip in each panel represents normalized population firing rates in response to a test vocalization during the repetitive-presentation context. The thickness of the strips indicates activity ranging two standard deviations from the mean response for the population. All data are aligned relative to onset of the test vocalization; the vertical black line indicates stimulus onset. In each panel's schematic, the repeated and test vocalizations are, respectively, denoted to the left and right of the vertical black line indicating stimulus onset. (a) Normalized vPFC population activity to a test vocalization that belonged to a different acoustic class but the same functional category as the repeated vocalization. (b) Normalized vPFC population activity to a test vocalization that belonged to a different acoustic class and different functional category than the repeated vocalization. Adapted from Gifford GW, MacLean KA, Hauser MD, et al. (2005) The neurophysiology of functionally meaningful categories: Macaque ventrolateral prefrontal cortex plays a critical role in spontaneous categorization of species-specific vocalizations. *Journal of Cognitive Neuroscience* 17: 1471–1482.

are modulated preferentially by transitions between presentations of food vocalizations that belong to functionally meaningful and different categories.

Consistent with the proposed role of vPFC in categorical processing, vPFC neurons respond in the same way to different vocalizations that transmit information about different types of food quality (i.e., high-quality and low-quality food). However, vPFC neurons responded 'differently' to different vocalizations that transmitted information about different nonfood events. Importantly, this difference in response patterns cannot be attributed wholly to differences between the acoustics of the food and nonfood vocalizations: the acoustic variability in the food vocalizations was comparable to the variability in the nonfood vocalizations. vPFC neurons also respond similarly to different vocalizations that transmit information about high-quality food, low-quality food, and high-quality or low-quality food. These observations are consistent with the hypothesis that vPFC neurons respond to food and nonfood vocalizations based on their category membership but do not differentiate between categories of food quality.

Together, these two studies provide the first evidence that in the absence of operant training, the vPFC is involved in the recognition and discrimination of natural categories. Also, these studies suggest that the vPFC is part of a circuit involved in contextually dependent vocalization production. These results are also consistent with data from the human literature which posit a role for this area in the maintenance and retrieval of abstract rules and possibly a role in semantic processing and syntactic working memory.

Primate Interneurons

S I Perlmutter, University of Washington, Seattle, WA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

More than a century of experimentation has revealed that spinal interneurons perform complex processing of sensory and supraspinal information for all types of movements, from the most basic somatosensory reflexes to highly skilled voluntary movements of the hand. Yet interneurons have been studied directly for relatively few behaviors, unlike neurons in supraspinal structures. The spinal cord is not as accessible in awake animals as the brain is, and the mobility of the spinal column discourages use of microelectrodes. Consequently, most information about interneurons comes from anesthetized or reduced animal preparations or from indirect measurements in animals and humans. Recently, several labs have overcome the technical difficulties and are recording the activity of spinal neurons in awake animals to provide new insights into interneuron function. This article summarizes recent findings from the cervical cord of macaque monkeys performing trained behaviors of the forelimb. Peter Soja, at the University of British Columbia, also studies spinal neurons in awake animals, elucidating state-dependent processing in somatosensory pathways in cats during sleep and wakefulness.

Methodologies

Classical techniques for chronic recording from brain neurons in behaving animals were first adapted for the cervical spinal cord of the monkey in the lab of Eberhard Fetz, at the University of Washington. Access to the cord is achieved by cementing a chamber to the vertebral column over a laminectomy of several vertebrae. Mobility of the spine during recording is reduced by securing the chamber to the recording apparatus. Monkeys are trained to make hand movements in response to visual cues presented on a video screen or to reach to and grasp food pellets. While the monkey performs the tasks, microelectrodes are advanced into the chamber, penetrate the dura mater, and record the activity of individual spinal neurons.

Correlational linkages of neurons to muscles are detected with spike-triggered averages (STAs) of electromyographic (EMG) activity. Distinctive postspike effects, along with location within the cord and characteristic firing properties, identify motor neurons. Postspike facilitation or suppression of EMG activity at latencies consistent with synaptic actions on motor neurons identify premotor neurons (Figure 1). Such identification is difficult when muscles are inactive and is an advantage of the behaving animal model. Output effects from multiple neurons and fibers within a small region are elicited with intraspinal microstimulation and stimulus-triggered averages of evoked EMG activity.

Traditional classifications of spinal interneurons are based on patterns of input from peripheral afferents and supraspinal structures. In awake monkeys, natural stimuli can be delivered only if the forelimb is removed from the experimental device and manipulated, jeopardizing recording stability. Electrical stimulation of peripheral nerves must be limited to low current strengths to avoid aversive sensations. Thus, interneurons usually cannot be identified by the traditional criteria. Another caveat of identification is important. Even though linkages with muscles can be detected with STAs, other projections of recorded neurons are unknown. Thus, the population of spinal neurons sampled from the awake monkey undoubtedly contains local interneurons, commissural interneurons, propriospinal neurons, and ascending tract neurons (collectively called interneurons in this article, to distinguish them from motor neurons and primary afferents). Nevertheless, response patterns during active movement and STAs of EMG activity, supplemented by responses to passive displacements of joints and electrical stimulation of peripheral nerves at group I intensities, establish a set of distinguishing characteristics for interneurons in the behaving monkey.

In the future, functional MRI will probably allow study of interneuron activity during natural movements in humans. To date, however, technical difficulties have limited the success of spinal fMRI. Recent advances suggest that these will be overcome soon.

Neurons in the Cervical Enlargement

Activity during Movement Execution

Response profiles during hand movement The activity of many interneurons is modulated during hand movements made isometrically or against elastic loads (Figure 1). The responses of premotor neurons and those without identified effects on muscles are similar. At least under the conditions studied to date, the activity of premotor neurons does not have clear distinguishing characteristics.

Many task-related interneurons fire at a constant, background rate when the monkey sits quietly before

Figure 1 Spike-triggered averages (STAs) and response averages of a premotor interneuron located in the C8 segment. Triggering action potential is shown in top left, above the STAs of electromyographic (EMG) activity in three independently recorded coactive muscles. Asterisks indicate muscles with significant postspike effects. The STAs are plotted with the variances in baseline activity normalized to the STA of the muscle with the largest postspike effect (PT). The average activity of the neuron during flexion torques is shown in the discharge histogram at top right, above the average torque trajectory (positive torque in flexion, negative torque in extension) and average responses of the coactive muscles. The neuron exhibited tonic firing during static torques, at a higher rate for flexion. Reproduced from Perlmutter SI, Maier MA, and Fetz EE (1998) Activity of spinal interneurons and their effects on forearm muscles during voluntary wrist movements in the monkey. *Journal of Neurophysiology* 80: 2475–2494, used with permission of The American Physiological Society.

a cue to move is given, and other neurons are silent. They exhibit a variety of activity patterns when ramp-and-hold torque is generated at the wrist (**Figure 2**). Most neurons fire at a steady rate above their background rate during constant torques. This type of activity is called a tonic response component. During the ramp phase of the task, when torque is changing quickly, firing rate most often either tracks the torque trajectory or transiently increases in a burst, falling to the baseline or tonic level near the end of the torque ramp. These bursts are called phasic response components. Tonic, phasic-tonic, or phasic responses are exhibited by nearly 90% of the task-related neurons. Phasic activity of premotor neurons helps bring motor neurons to firing threshold, perhaps overcoming strong inhibition. Tonic activity contributes to the maintenance of a steady level of muscle contraction.

For the majority of neurons, phasic and tonic response components are correlated with movement parameters. Mean tonic firing rate is linearly related to the magnitude of static torque, and the peak firing rate of the phasic burst is linearly related to the maximum rate of change of torque. These parametric relations suggest that interneurons contribute to the coding of movement amplitude and speed. It is worth noting that interneurons have not been studied during tasks without an applied load, or in which force, position, and muscle activity are uncoupled, so there are no data on which movement parameters are best correlated with neuron discharge. Kazuhiko Seki, at the National Institute of Physiological Sciences in Japan, is beginning to address this issue by recording from spinal interneurons during performance of precision grip.

The activity of interneurons is also related to the direction of hand movement, but only one-fourth reflect motor neuron tuning. Flexor and extensor muscles of the forearm are active for wrist flexion and extension, respectively, and are silent for movements in the opposite direction. One-third of interneurons increase their discharge above the baseline rate for both flexion and extension torques, and another third increase their rate for movement in one direction but remain active for the other.

Premotor neurons in primary motor cortex and red nucleus exhibit similar properties, although there are significant differences. For example, corticomotoneuronal (CM) cells exhibit predominantly tonic and phasic-tonic response components, but rarely purely phasic activity, and are almost always silent for movement opposite to their preferred direction. A study from Yifat Prut's laboratory in Israel shows that the sensitivity of spinal and motor cortex neurons to torque direction and amplitude evolves with similar time courses during the task. Activity related to movement direction appears after cue presentation and

Response type	CM	RM	DRG	PreM IN	Sy-IN	U-IN	MU

Examples of each pattern are illustrated on the left, and schematic of populations on the right. Proportions are given for corticomotoneuronal (CM) and rubromotoneuronal (RM) cells, premotor afferents in dorsal root ganglia (DRG), spinal premotor interneurons (PreM-IN), unidentified spinal neurons (U-IN), spinal interneurons with synchrony effects (Sy-IN), and motor neurons (MU). From Fetz EE, Perlmutter SI, Prut Y, and Votaw S (2002) Roles of primate spinal interneurons in preparation and execution of voluntary hand movement. *Brain Research Reviews* 40: 53–65. CM data from Cheney PD, Fetz EE, and Mewes K (1991) Neural mechanisms underlying corticospinal and rubrospinal control of limb movements. *Progress in Brain Research* 87: 213–252; RM data from Mewes K and Cheney PD (1994) Primate rubromotor neuronal cells: Parametric relations and contribution to wrist movement. *Journal of Neurophysiology* 72: 14–30; DRG data from Flament D, Fortier PA, and Fetz EE (1992) Response patterns and postspike effects of peripheral afferents in dorsal root ganglia of behaving monkeys. *Journal of Neurophysiology* 67: 875–889.

increases further after movement onset. In contrast, amplitude-related activity is not exhibited during movement preparation.

In another recent experiment, Prut has used electrical stimulation in primary motor cortex to identify functionally connected sites in the spinal cord. Spinal and cortical neurons from connected sites, but not from unconnected sites, express similar directional tuning and high trial-to-trial covariability of firing at movement onset. This suggests facilitated information transfer between cortex and spinal cord at this time, when directional signals, at least, are transmitted. The experiments from Prut's lab are showing how motor output is shaped by continuous interactions between motor cortex and spinal cord.

Spatial tuning of interneurons Bidirectionally active premotor interneurons produce excitatory postsynaptic potentials in motor neurons of forearm flexor and extensor muscles at times when their target muscles are silent, and inhibitory postsynaptic potentials when their muscles are active. Thus, despite the strong relation between firing rate and wrist torque, the activity of spinal premotor interneurons cannot be accounted for entirely by the pattern of forearm muscle activation. Instead, interneuron activity reflects functionally broader inputs.

Studies of the spatial tuning of interneurons for a wider range of hand movements further elucidate this property. In this experiment, monkeys generate torques in flexion–extension (FE), radial–ulnar deviation (RU) and pronation–supination (PS), and perform a power grip (G) that cocontracts wrist flexor and extensor muscles. Activity varies as a cosine function of torque direction in the FE–RU plane for many interneurons but is more broadly tuned for others. Preferred directions are distributed throughout the FE–RU plane, although more neurons prefer radial to ulnar movements. Most neurons with FE–RU responses are also modulated strongly during PS and/or G (Figure 3), and a few respond only for G. On average, the tuning of interneurons is broader than that of forearm muscle EMG activity. The spatial properties of some premotor interneurons are well matched to those of their target muscles, but many have different preferred directions or significantly broader tuning (Figure 3). These data again suggest that spinal premotor neurons are not exclusively related to the activation patterns of the primary wrist movers.

What function could premotor interneurons play beyond specifying the pattern of muscle activation needed to execute a movement? Broad directional tuning and bidirectional activity of interneurons for wrist movements can be produced by the convergence of inputs that are related to limb stabilization, that set reflex thresholds, that indicate the current posture of the limb, or that participate primarily in other movements for which the same muscles are recruited; these inputs are probably not related to the reciprocal activation of forearm muscles for FE–RU movements.

Figure 3 Responses and Spike-triggered average (STA) for a premotor interneuron during performance of a multidirectional hand task. Left: Discharge histograms of the neuron are plotted alongside pictorial representations of the visual display shown to the monkey during isometric torque/force in 11 directions (open box is target, filled box is cursor controlled by monkey's behavior): radial (R), ulnar (U), flexion (F), extension (E), flexion–radial (FR), flexion–ulnar (FU), extension–radial (ER), and extension–ulnar (EU) directions plus pronation (P), supination (S), and power grip (G). Histograms are aligned at the end of torque/force hold period (schematic of torque shown above histogram for F) and show average firing for 10–16 trials. Upper right: Response tuning curves (polygons, normalized to maximum response of the cell or muscle) and preferred directions in the FE–RU plane (vectors, based on best cosine fit to data) are presented for the neuron and the extensor carpi ulnaris (ECU) muscle. Lines indicating responses to P, S, and G overlie the polygons. Tuning curves show responses for the last second of the static hold period for each movement. Lower right: STA of electromyographic (EMG) activity in the ECU muscle showing a significant postspike facilitation, identifying this cell as a premotor interneuron.

Spinal interneurons are well situated to transform this information, from multiple descending and sensory feedback pathways with competing spatial and task-dependent properties, into motor neuron activity appropriate for the current situation. This interpretation is consistent with the widely held view that transmission through spinal pathways is flexible and dynamically modulated during behavior.

Inhibitory control of interneuron firing One way to modulate transmission through spinal pathways is to regulate their excitability by adjusting the balance of excitation and inhibition, even during behaviors for which they might be expected to alternate. The existence and operation of this balance can be explored by blocking one set of inputs with local application of neurotransmitter antagonists. In the behaving monkey, this has been accomplished with a seven-barrel recording-iontophoresis electrode. The central pipette contains a tungsten electrode for extracellular recording and provides the stiffness needed to penetrate the dura. The surrounding barrels are filled with neuroactive drugs that are applied to neurons near the tip of the electrode with iontophoresis.

Iontophoresis of the inhibitory neurotransmitters glycine or γ-aminobutyric acid (GABA) during wrist movements decreases the activity of most interneurons in a dose-dependent manner. It is interesting that the vast majority of cells tested with both glycine and GABA are inhibited by both.

Ejection of the glycine antagonist strychnine and the GABA antagonist bicuculline increases the discharge of many interneurons, even during strong activation in their preferred direction. However, the spatial tuning of about three-quarters of the neurons is not changed by the antagonists. The antagonists increase the tuning width of some neurons, probably by elevating their excitability above firing threshold for some directions, without a qualitative change in directional preference. The inhibitory input to most interneurons is either independent of movement direction or has the same directional tuning as the excitatory input.

Thus, interneurons appear to be under inhibitory control, even when strongly activated during movement, that does not contribute to directional tuning. Instead inhibition may allow fine adjustments in excitability, related to the specific conditions of the task, that alter transmission through premotor pathways. This hypothesis is consistent with current interpretations of overlapping excitatory and inhibitory drive to cortical neurons, as well as with recent experiments from Jorn Hounsgaards's lab in Denmark showing that excitation and inhibition covary in turtle spinal motor neurons during the scratch reflex.

Sensory Responses and the Modulation of Sensory Input

Many interneurons that are active during hand movements also respond to passive displacements of the wrist. They exhibit three stereotypical response patterns to brief perturbations. A C-type response is characterized by short bursts of firing during the onset, and usually the offset, of displacements in both flexion and extension. C-type responses are consistent with input from fast-adapting cutaneous afferents. B-type responses consist of excitation for passive displacement in one direction and inhibition for the other (Figure 4). This pattern produces responses of opposite polarity at the onset and offset of each perturbation. B-type responses are consistent with input from either muscle or joint receptors. A smaller percentage of neurons show monophasic responses that are difficult to ascribe to muscle or cutaneous afferents alone.

Neurons with B- and C-type responses have different activity patterns during active wrist movement. C-type cells have low firing rates at rest and during maintenance of static torque and bidirectional increases in activity during torque onset and offset. B-type cells tend to have higher firing rates at rest and tonic activity during maintained torques (Figure 4). During generation of dynamic torque, B-type cells are phasically excited for one direction and phasically inhibited for the other. Most B-type cells are excited by perturbations in a direction opposite to the preferred direction for active movement, suggesting a consistent involvement in the recruitment of agonist muscles for both active and passive movements. Centrally and sensory-driven response components during active movement can be deduced for some neurons from their activity during voluntary wrist movements (Figure 4).

What type of sensory processing is performed by spinal interneurons during voluntary movements? The first function studied directly in the primate is the modulation of transmission along sensory pathways. It is known that spinal reflexes and cortical somatosensory potentials are reduced, and psychological thresholds for detecting tactile stimuli are

Figure 4 Histograms of firing during active generation of torque (left) and passive wrist displacement (right) for two interneurons (INs; a, b) with B-type responses to wrist perturbations. Black histograms show activity for the direction of movement that produced the largest response during the active-hold period (i.e., preferred direction for active movements). Gray histograms show activity for the opposite direction. Histograms are aligned on movement onset (left) or stimulus onset (right). Both INs have opposite preferred directions for active and passive movements. Small arrowheads indicate onset times for active movement. Both neurons had earlier onset times for active movements in the preferred than in the nonpreferred direction. In (b), phasic responses (large gray arrow) and decrease (large black arrow) in firing near movement onset probably reflect the neuron's sensory response to wrist displacement (note directional and temporal similarity with passive responses shown to the right). Reproduced from Prut Y and Perlmutter SI (2003) Firing properties of spinal interneurons during voluntary movement. I. State-dependent regularity of firing. *Journal of Neuroscience* 23: 9600–9610. Copyright 2003 by the Society for Neuroscience.

increased, before and during movement. The earliest site at which sensory inflow can be regulated is the synapse between primary afferents and second-order neurons in the dorsal horn of the spinal cord. The responses of second-order neurons to electrical stimulation of the superficial radial (SR) nerve, which contains exclusively cutaneous afferents, can be used to monitor transmission along one somatosensory pathway.

Second-order neurons are identified by SR-evoked responses at monosynaptic segmental latencies, relative to the incoming volley recorded in the cord dorsum potential. The SR-evoked response of 66% of second-order neurons is significantly reduced during

Figure 5 Suppression of monosynaptic, superficial radial (SR)-evoked response during active wrist flexion (left) and extension (right). (a) Peristimulus time histograms below raster plots of the interneuron's activity following SR stimulation (3 Hz, 1.6 times threshold for the afferent volley) aligned with SR stimuli (blue line); trace above shows the cord dorsum potential with afferent volley, CDV, green line). Height of each histogram bin represents the normalized probability of spike occurrence per stimulus. From top to bottom, responses compiled during different task epochs (shading on torque traces to left). Number of stimuli delivered in each epoch shown above each histogram. (b) Averages (±SE) for all second-order neurons of mean firing rate (top) and peak area of SR-evoked response (bottom) for each task epoch, calculated as shown by left insets. Mean firing rate was obtained from mean bin height before (50–1 ms) stimuli. Peak area was sum of bin heights above the mean firing rate during peak (red). Peak duration was time when the bin counts exceeded 2 standard deviations of the mean firing rate. Asterisks: significant differences with rest using a Student's *t*-test. Reproduced from Seki K, Perlmutter SI, and Fetz EE (2003) Sensory input to primate spinal cord is inhibited presynaptically during voluntary movement. *Nature Neuroscience* 6: 1309–1316, with permission from Nature Publishing Group.

voluntary wrist movements (Figure 5). The mean firing rate of most neurons increases during active movement in both directions, suggesting that the suppression of cutaneous input is not related to a decrease of the neurons' excitability due to postsynaptic inhibition. This implicates a presynaptic mechanism, which is also supported by excitability testing of the primary afferents. The magnitude of antidromic volleys recorded in the SR after intraspinal stimulation at sites of second-order neurons increases during active movements, likely due to increased excitability of SR terminals by primary afferent depolarization. The suppression of SR-evoked responses starts before movement onset for more than half of the neurons and does not occur when the wrist is passively moved. Thus, descending commands are the likely source of the presynaptic inhibition.

Electrical microstimulation within the cord at sites of second-order neurons typically produces strong inhibition of task-related EMG activity in forearm muscles, consistent with known inhibitory effects of cutaneous reflexes. Thus, output from these sites could partially suppress ongoing muscle activity. The reduction of cutaneous transmission during movement prevents the sensory-evoked activation of inhibitory pathways to agonist muscles. This might act to reduce inhibition due to expected cutaneous stimulation, including self-induced activation of sensory receptors.

Linkages with Muscles

Postspike effects in forearm muscles are seen for a significant number of spinal neurons active during hand movements. Most premotor interneurons produce effects in only one or two muscles. These 'muscle field' sizes are smaller than those of premotor neurons in the motor cortex or red nucleus. The distribution of effects is also different for premotor supraspinal and spinal neurons. STA features from spinal interneurons are of equal magnitude in flexor and extensor muscles but occur twice as often in flexors than in extensors. Premotor neurons in primary motor cortex produce effects in flexor and extensor muscles with equal frequency, but their magnitude is larger in extensors. Red nucleus neurons produce more effects in extensors. The preferential linkages of spinal interneurons to small numbers of forearm flexors may reflect a greater involvement of spinal processing in the control of individual or small groups of muscles during diverse grasping movements of the hand and less influence over more-stereotyped hand opening and wrist extension movements.

STAs also reveal effects in forearm muscles that have onset latencies too early to be caused by synaptic connections from the recorded neuron to motor neurons. Most of these are synchrony effects, which are typically longer in duration and larger in amplitude than postspike effects and often straddle the trigger time. Such effects are similar to the zero-delay peaks found in cross-correlograms of the activity of neighboring neurons in many nervous system structures. These central peaks are evidence of common synaptic input that increases above chance the probability that the two neurons will discharge synchronously. Analogously, synchrony peaks (or troughs) in STAs of EMG activity reflect common input to the recorded cell and to other neurons with excitatory (or inhibitory) synaptic connections to motor neurons. The frequency with which synchrony effects are produced by interneurons suggests a premotor network of interconnected neurons that receives common supraspinal and feedback signals.

The organization of spinal linkages to muscles has also been studied with intraspinal microstimulation (5–50 μA). In both anesthetized and awake animals, stimulus-triggered averages of EMG activity show short-latency activation of forelimb muscles in response to stimuli delivered at numerous sites. Stimulation usually produces effects in multiple muscles, often in antagonists, and frequently evokes overt movements. Although EMG activity can be evoked from sites throughout the gray and white matter, there is little somatotopic organization within the cervical enlargement for movement or muscle activation, probably due to the excitation by the stimulus of complex mixtures of fibers and cell bodies.

Activity during Preparation for Movement

Cerebral cortex is considered the place in the brain where higher-order computations are processed. However, the cortex and spinal cord are highly interconnected, and interneurons appear likely to carry signals related to some of these functions. One manifestation of higher-order motor processing is activity related to the preparation for movement. Monkeys can be trained to perform isometric wrist flexion–extension with an instructed delay period. At the beginning of this period, a transient visual cue instructs the monkey to generate either flexion or extension torque. However, the monkey is trained to withhold this movement until a second, later visual cue is presented. This task is used to study motor preparation because neural activity can be recorded during a period when the brain is planning, but not executing, a movement. About one-third of spinal interneurons show significant modulation of activity during the delay period, when there is no EMG activity in forearm muscles (Figure 6). Firing rate decreases relative to baseline for 60% of the interneurons and

Figure 6 Two spinal interneurons with significant modulation of activity during an instructed delay period. Discharge histograms are shown above single-trial raster plots for isometric flexion (left) and extension (right) torques at the wrist. Diamonds superimposed on rasters indicate torque onset. Torque trajectories during single trials are shown below. Data are aligned on cue onset. Neuron in (a) showed an increased discharge during the delay period before flexion and a bidirectional increase in rate during torque generation in both directions. Neuron in (b) exhibited a decrease in delay period activity in flexion and extension trials. Copyright (© 2001) from Transformation of descending commands into muscle activity by spinal interneurons in behaving primates. In: Cope TC (ed.) *Motor Neurobiology of the spinal cord*, pp. 193–213. increases for 40%. Most interneurons with delay period activity also respond during the movement itself, usually with elevated discharge. The magnitude of the responses during the delay period is usually smaller than that during movement execution.

The visual cue gives the monkey information about both the direction and amplitude of the upcoming movement. However, delay activity rarely predicts either parameter of the upcoming movement, in contrast to the activity during the movement (as described above). Furthermore, delay activity of many interneurons is not related to the neuron's subsequent response during active torque, often having the opposite polarity (facilitation vs. suppression).

Thus, spinal interneurons are involved in preparing the motor system to move. Two independent processes appear to be at work. First, neurons that have similar delay- and movement-related changes in activity can prime motor neurons with a subthreshold buildup of postsynaptic potentials in the direction needed for movement execution, perhaps shortening reaction times. Second, the widespread inhibition of neuronal activity during the delay period may suppress the expression of any movement, including those elicited by sensory stimuli, until motor preparation is complete. In fact, premotor interneurons are significantly more likely to exhibit delay period activity than are interneurons with no functional linkages to muscles, and this response is usually inhibitory.

Propriospinal Neurons

In the cat, propriospinal neurons in the C3–C4 segments mediate disynaptic excitation of forelimb

motor neurons from the motor cortex. Lesion of this pathway disrupts muscle coordination during forelimb target reaching. It has been hypothesized that the feline motor cortex controls specific forelimb muscle synergies by selective activation of C3–C4 propriospinal neurons and inhibitory networks which focus their outputs. Electrophysiological experiments performed by Tadashi Isa and Bror Alstermark have demonstrated that similar propriospinal neurons exist in monkeys. However, the functional importance of this system in primates is still unclear. In humans, Emmanuel Pierrot-Deseilligny and his colleagues have provided support for a significant role from studies using conditioned H-reflexes and transcranial magnetic stimulation of motor cortex. However, disynaptic cortical excitation of arm motor neurons has been difficult to demonstrate in monkeys without the systemic administration of the glycine receptor antagonist strychnine.

The existing data have led to two current hypotheses. First, as argued by Roger Lemon and his colleagues, propriospinal neurons in the primate exert weak influences on arm motor neuron excitability and serve a relatively minor role in comparison with direct CM connections. Second, as argued by Alstermark and Isa, propriospinal neurons mediate a substantial corticospinal excitation to arm motor neurons that is under strong feed-forward and feedback inhibitory control. Recent experiments on the activity of neurons in the C3–C4 segments of behaving monkeys have added new data to this debate.

Activity of C3–C4 Neurons during Hand and Reaching Movements

Many C3–C4 neurons are strongly modulated during wrist flexion–extension and a reach-and-grasp task. Activity correlated with wrist extension and arm reaching predominates, with far fewer neurons modulated during wrist flexion or hand grasping. Some C3–C4 neurons are activated during wrist movements only, others during reach only, and others during both the wrist and the reach task. This is consistent with involvement in specific movements or the activation of specific combinations of arm muscles, as proposed for propriospinal neurons in the cat. At least some task-related neurons are activated monosynaptically by electrical stimuli delivered to the motor cortex, and antidromically by stimulation in motor nuclei of the cervical enlargement. These cells can mediate disynaptic cortical excitation of arm muscle motor neurons.

Output Effects Evoked with Microstimulation

Intraspinal microstimulation at widespread sites in C3–C4 produces robust output effects in stimulus-triggered averages of arm muscle EMG activity. Most output sites in C3–C4 activate muscles at more than one joint. Qualitatively, the effects from C3–C4 are similar to those evoked from the cervical enlargement, although there are differences in the frequency, distribution, and mean latency of effects from the two levels. Most interesting, effects evoked from C3–C4 have amplitudes that are significantly larger in extensor than in flexor muscles, whereas the effects evoked from C6–T1 are larger in flexors. The neural activity patterns and the stimulation-evoked output effects suggest that non-CM components of motor commands for different movements are routed through different premotor pathways in the spinal cord. Flexion movements of the hand, like grasping, may primarily involve activation of circuits in the cervical enlargement, and arm reaching and hand extension may primarily engage those in the upper cervical segments.

Linkages with Muscles

Neurons that exert strong control on motor neurons should produce postspike effects in STAs of EMG activity. However, the majority of C3–C4 neurons do not produce such effects during the wrist flexion–extension and reach-and-grasp tasks, although many synchrony effects are produced.

Strong responses for reaching and wrist extension, subpopulations with activity correlated with different combinations of movements, and strong stimulation-evoked output effects to extensor muscles in multiple joints are all consistent with an important role for C3–C4 propriospinal neurons in the activation of arm muscles during voluntary movement. However, the paucity of functional linkages to arm muscle motor neurons argues against direct premotor projections from C3–C4. Future studies will have to resolve this discrepancy before the function of upper cervical propriospinal neurons in the primate is completely understood.

Priming

R Henson, MRC Cognition and Brain Sciences Unit, Cambridge, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Priming refers to a change in behavioral response to a stimulus, following prior exposure to the same, or a related, stimulus. Examples include faster reaction times to make a decision about the stimulus, a bias to produce that stimulus when generating responses, or the more accurate identification of a degraded version of the stimulus. From the memory perspective, the most exciting aspect to priming concerns evidence that it can occur in the absence of conscious memory for the prior exposure (an example of so-called 'implicit' or 'nondeclarative' memory). For instance, amnesic patients typically show intact levels of priming, despite their impairments in conscious ('explicit' or 'declarative') memory. Evidence like this led to the proposal that the brain regions supporting priming are different from the medial temporal lobe (MTL) regions believed to support declarative memory. Indeed, it is often assumed that priming is the by-product of prior processing of a stimulus, that is, arising from plasticity in multiple cortical regions whose primary role is perceptual/conceptual processing. As such, priming is likely to be one of the most basic expressions of memory, influencing how we perceive and interpret the world.

A Working Example

Priming can be measured using a range of different stimuli and tasks. To illustrate the breadth of neuroscientific data on priming, we initially focus on one specific paradigm – the word-stem completion paradigm – which has provided some of the most convincing evidence that priming involves memory systems, and associated brain regions, that differ from those involved in declarative memory. In the 'study' phase of this paradigm, participants perform an incidental task on a list of words (normally unaware that their memory for these words will be tested). At some time later, they are presented with three letters that form the start of words (word-stems) (see Figure 1(a)). Some of these stems can be completed with the words from the study phase, though in the 'indirect' version of this task, participants are not informed of any relationship between this test phase and the previous study phase. They are simply asked to complete the stem with the first word that comes to mind. Priming is indexed by the increased probability of completing stems with studied words, relative to the baseline probability of completing the stems when those words were not studied. Importantly, participants normally show this priming without reporting any conscious reference to the prior study phase.

Neuropsychological Evidence

When this task is given to amnesic patients, they typically show priming of equivalent magnitude to controls. However, when the instructions at test are changed, so that participants are asked to use the stems explicitly to recall studied words ('word-stem cued recall,' a 'direct' version of the task), amnesic patients typically perform worse than controls (Figure 1(b)). This dissociation is appealing because the stimuli are kept constant across the indirect and direct versions of the task; all that differs are the instructions. While amnesic patients are also known to have sparing of other forms of memory, such as motor skill-learning, the intriguing aspect of priming is that it can occur after a single stimulus presentation ('one-shot learning'), rather than requiring sustained training. Furthermore, a few patients with more posterior lesions (e.g., in occipital cortex) have shown the reverse pattern of impaired word-stem completion for visually studied words (indirect test), despite intact performance on a recognition memory test (direct test). This double dissociation between the two types of memory test is strong support for different memory systems underlying priming and declarative memory. Further support comes from reports that word-stem completion priming is less susceptible than is cued recall to the effects of healthy aging, and to some dementias like Alzheimer's disease.

Psychological Evidence

This dissociation of priming from declarative memory following brain damage is supported by functional dissociations between direct and indirect versions of the word-stem completion paradigm in healthy individuals. For example, performance on the direct version (word-stem cued-recall) is higher when the corresponding words are generated from semantic cues at study relative to when they are simply read, yet performance on the indirect version (word-stem completion) is higher when the words are read relative to being generated from cues. Similarly, presenting words auditorily rather than visually at study tends to impair performance on visual word-stem completion to a greater extent than on visual word-stem cued

Figure 1 (a) Schematic of the word-stem completion paradigm. (b) Performance of amnesic patients and matched controls on indirect (completion) and direct (cued-recall) versions of the task. (b) Reprinted with permission from Graf P, Squire LR, and Mandler G (1984) The information that amnesic patients do not forget. *Journal of Experimental Psychology*: *Learning, Memory and Cognition* 10: 164–178, APA publishers.

recall, whereas use of a study task that engages semantic versus phonological processing of words tends to improve performance on word-stem cued recall to a greater extent than on word-stem completion. The reduced performance found on word-stem completion when words are generated or heard at study, rather than read, suggests that a component of priming in this task relates to the visual overlap between words and their stems, or more precisely, to overlap in the processes involved in visual word reading.

Nonetheless, though dissociations have been found between direct and indirect tests of memory, care must be taken when using performance on indirect tests as a pure measure of implicit memory: even though an indirect memory test does not refer participants to previous encounters with stimuli, participants may voluntarily, or involuntarily, recollect such encounters. For example, some participants may guess the relationship between the study and test phase of a word-stem completion task, and hence attempt to recall studied items in order to complete the stems. Moreover, even if a completion comes to mind involuntarily, participants may subsequently recognize that word as having come from the study phase. Though the latter eventuality may not affect behavioral measures of priming, it is important when measuring the neural correlates of priming, as discussed in the next two sections. As a consequence, considerable effort has been devoted to developing methods that minimize the contribution of explicit memory to priming.

Neuroimaging Evidence

Some of the first positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies of priming used the word-stem completion paradigm. These studies consistently found reduced hemodynamic responses in extrastriate visual cortex for studied relative to unstudied word-stems (often in both direct and indirect versions of the task). This reduction is attributed to 'more efficient' or 'facilitated' visual processing of the stems corresponding to studied words, owing to the prior exposure to those words. Similar reductions have also been found in a number of regions including left inferior temporal and left inferior frontal cortices. Given that these regions are also generally activated by the task (e.g., vs. passive fixation), the reductions are consistent with facilitated processing within a language-related network that is engaged when reading words and completing word-stems, possibly including phonological, lexical, and semantic processes.

Some imaging studies have also reported hemodynamic increases in MTL cortices, even in indirect versions of the task. This illustrates the problem highlighted earlier that explicit memory may contaminate indirect tasks. In particular, even if this explicit memory is involuntary and does not affect the behavioral response, the poor temporal resolution of hemodynamic imaging techniques means that imaging data may include explicit memory processes arising subsequent to that response. More recent imaging experiments have therefore used variants of the word-stem completion paradigm that attempt to minimize contamination by explicit memory. For example, participants can be asked to complete stems with words from the study phase (i.e., word-stem cued recall), but if they cannot, they are asked to produce the first word coming to mind. Having produced a completion (through either approach), they then indicate whether they remember that word from the study

phase. The critical trials used to isolate the neural correlates of priming are those stems completed with studied words but which participants indicated they did not remember. These trials are likely to provide a purer measure of implicit memory (despite occurring in the context of a direct memory task). When compared to a baseline condition (stems that did not correspond to studied words, but which were completed with a word that was correctly indicated as unstudied), event-related fMRI has replicated the reduced responses found in extrastriate, left inferior temporal, and left inferior frontal cortices (Figure 2(a)). Equivalent reductions in these regions were also found for 'remembered' trials (stems that were completed with a studied word and that word was indicated as studied), unlike in MTL cortex, where greater activity was found for remembered trials relative to primed trials (suggesting that explicit memory had been successfully minimized in primed trials). Furthermore, the reductions for primed and remembered versus baseline trials in these regions were also found when using an indirect version of the task akin to the standard word-stem completion task. Taken together, these results suggest that such hemodynamic reductions are not only implicit, but also automatic, consistent with a role for these regions in the priming observed in healthy individuals and in amnesic patients.

Figure 2 Event-related fMRI data from a word-stem completion paradigm. In the test phase (a), a number of regions including those shown in left inferior frontal, left inferior temporal and occipital cortices, exhibited reduced responses to primed stems (blues), and to remembered stems (reds), relative to baseline stems (greens), regardless of whether participants performed a direct (lighter colors) or indirect (darker colors) version of the paradigm. In the study phase (b), a number of regions including those shown in left inferior frontal and inferior temporal cortices showed reduced responses for subsequently primed relative to subsequently forgotten words (darker bar), whereas regions in medial temporal lobe showed increased responses for subsequently remembered (but not subsequently primed) relative to subsequently forgotten words (lighter bar). Rem, remembered; Pri, primed; Bas, baseline; For, forgotten (see text). (a) Adapted with permission from Schott BH, Henson RN, Richardson-Klavehn A, et al. (2005) Redefining implicit and explicit memory: The functional neuroanatomy of priming, remembering and control of retrieval. *Proceedings of the National Academy of Sciences of United States of America* 102: 1257–1262. (b) Adapted with permission from Schott B, Richardson-Klavehn A, Henson R, et al. (2006) Neuroanatomical dissociation of encoding processes related to priming and explicit memory. *Journal of Neuroscience* 26: 792–800. Copyright (2005) National Academy of Sciences, USA.

One can also use event-related imaging methods to examine differences at the time stimuli are encoded (i.e., during the study phase) as a function of the degree to which those stimuli show later priming (or the degree to which they show explicit memory). Using the same paradigm as above, for example, hemodynamic responses to the words at study differed for those words subsequently primed (completed with the studied word but not remembered) than those subsequently forgotten (completed with a different word). Such differences were found in a number of cortical regions, including the left inferior temporal and frontal regions that showed priming-related reductions at test. Again, the pattern in these regions differed from that in the MTL, which showed greater activity for words subsequently remembered versus words subsequently forgotten (Figure 2(b)). These findings suggest that priming is affected by how stimuli are encoded (on their initial presentation), possibly in addition to how that information is accessed at test. Yet further work has combined event-related fMRI with pharmacological interventions: for example, scopolamine and lorezapam, which are believed to modulate synaptic plasticity, have been shown to attenuate repetition suppression in the same inferior temporal and frontal regions during word-stem completion.

Electrophysiological Evidence

The time course of word-stem completion priming has also been investigating using electroencephalographic (EEG) and magnetoencephalographic (MEG) methods. For example, in a standard indirect completion task, event-related potentials (ERPs) to primed word-stems have been reported to diverge from those to baseline (unstudied) word-stems within 200 ms of the onset of the word-stem (Figure 3(a)). The same ERP effect was reported for words remembered during

Figure 3 Electrophysiological data from a word-stem completion paradigm. In (a), the event-related potentials (ERPs) over right parietotemporal electrodes recorded by EEG diverge between primed and baseline stems (upper plot), and between recalled and baseline stems (lower plot), within 200 ms, whereas the ERPs to primed and recalled stems only differ from 300 ms onwards (topographies also differ). In the upper panel of (b), regions with reliable differential source-reconstructed event-related activity, inferred from MEG data, for repeated versus novel presentation of stems are shown for two time windows. In the lower panel, the reconstructed responses are shown for a number of regions of interest. (a) Data adapted with permission from Badgaiyan RD and Posner MI (1997) Time-course of cortical activations in implicit and explicit recall. *Journal of Neuroscience* 17: 4904–4913. (b) Data adapted with permission from Dhond RP, Buckner RL, Dale AL, Marinkovic K, and Halgren E (2001) Spatiotemporal maps of brain activity underlying word generation and their modification during repetition priming. *Journal of Neuroscience* 10: 3564–3571.

a direct cued-recall version of the task. However, when contrasting primed and remembered word-stems directly, differences only emerged after approximately 300 ms. These data suggest that priming occurs prior to explicit memory retrieval. Furthermore, and consistent with fMRI data described above, qualitative differences have been found in the study between the differential ERPs to words subsequently primed versus those subsequently remembered. More recently, related experiments (in which word-stems were repeatedly completed) have used the superior spatial resolution of MEG (combined with structural information from MRI) in an attempt to localize the evolution of repetition-related effects over the first few hundred milliseconds from stem onset. Interestingly, an initial repetition-related increase in electrical activity has been reported early in left inferior temporal cortex (lateral occipitotemporal sulcus), followed by a later decrease in both this region and left inferior frontal cortex (Figure 3(b)). Such spatiotemporal data suggest rapid interactions between brain regions, which would be invisible to hemodynamic techniques like fMRI. Indeed, such data afford greater opportunity to look at priming-related changes in the connectivity between different brain regions, for example, as a function of plasticity following initial processing of stimuli.

Summary

The above studies using the word-stem completion paradigm provide convergent evidence that priming reflects a form of memory dissociable from conscious memory, and can arise from a number of cortical regions outside the MTL. These regions are normally a subset of those engaged by the specific stimuli and task (in the above cases, a number of left inferior frontal, left inferior temporal, and occipital regions associated with word reading), suggesting that priming reflects a form of plasticity in these regions. The expression of priming is generally associated with reduced neural activity in these regions, possibly reflecting faster and/or more efficient processing (e.g., a 'greasing of the tracks'). This expression appears to occur very rapidly (around 200 ms) and automatically (regardless of precise task). Differences in neural activity have also been found during the initial processing of stimuli as a function of whether they are subsequently primed. This implicates important roles for factors such as attention and the type of processing in the nature of neural/synaptic changes assumed to underlie priming.

Similar conclusions have been reached using a number of other priming paradigms, though the specific network of cortical regions involved may differ. Indeed, the general finding of decreased hemodynamic responses to repeated stimuli (which has been called 'repetition suppression') has been observed repeatedly across a range of stimuli and indirect memory tasks. Interestingly, however, not all regions activated by initial presentations of stimuli show such decreases: early sensory regions, such as V1, for example, do not normally show repetition suppression. One possibility is that not all of the processing stages in a given task show stimulus-specific effects of prior processing (or alternatively, such effects of prior processing have lifetimes shorter than is typically tested). An interesting theoretical question is therefore which stages (and associated brain regions) show the largest effects of prior processing? Are they, for example, stages that involve greatest competition between alternative outputs/interpretations?

Other Common Measures of Priming

Another common measure of priming is the latency to identify (e.g., name) pictures of objects. This measure has shown priming effects that last up to a year. In a common neuropsychological version, in which degraded pictures are gradually clarified (the 'Gollin figures'), amnesic patients show strong priming (i.e., earlier identification for pictures identified previously). Researchers have also used such priming to investigate the representation of visual objects in the brain, by examining the extent to which priming-related effects (e.g., in different brain regions) generalize across different views of an object.

Another common type of priming is semantic priming, where the response to a probe word (e.g., HEAVEN) is speeded when preceded by a related prime word (e.g., HELL) relative to a nonrelated word (e.g., HILL). Such priming tends to be short-lived, often not surviving more than a second between the prime and probe. As with visual object priming, it has also been used as a tool, in this case to investigate the organization of semantic memory. Yet another type of priming that has been influential on a theoretical level is associative priming, where the priming of a probe stimulus is modulated by whether or not it has previously been paired with a context stimulus. According to theories that hypothesize a key role for MTL in forming associations, patients with MTL damage should not show such priming, even if such priming is shown to be implicit. At the moment, the data appear mixed.

There is also much interest in subliminal priming, in which the prime is presented so briefly (around 50 ms; often forward and backward masked) that participants show little to no awareness of the prime, and yet still show behavioral priming to a probe stimulus

presented shortly afterwards (typically within a few hundred milliseconds). Indeed, this type of priming has been recommended for imaging studies of implicit processing, since it is easier to rule out contamination by explicit memory for the prime.

Theories of Priming

A broad distinction has been made between 'perceptual' and 'conceptual' priming. The main difference is that perceptual, but not conceptual, priming is affected by differences in the physical features of the prime and probe stimuli, whereas conceptual, but not perceptual, priming is affected by differences in the degree of semantic processing of the stimuli. This distinction is supported by dissociations in, for example, Alzheimer's patients, who reportedly show intact perceptual priming but impaired conceptual priming, presumably because the early sensory areas believed to be important for perceptual priming are less affected by the disease than anterior temporal regions believed to be important for conceptual priming. A related distinction assumes that priming is supported by specialized 'perceptual representation systems' that are distinct from the MTL memory system. In principle, this allows for dissociable forms of perceptual priming as a function of modality (e.g., visual vs. auditory).

Though useful heuristics, such broad distinctions do not seem sufficient for the varieties of priming that have been investigated. For example, the word-stem completion task discussed above is difficult to fit into the perceptual/conceptual dichotomy, since it is affected by variations in some physical properties, yet residual priming can still occur across modalities (even when voluntary explicit retrieval has been excluded). Furthermore, word-stem completion can be unaffected by the degree of semantic processing of primes (e.g., semantic vs. phonological), yet be reduced following very superficial (e.g., graphemic) processing of primes. These data are consistent with a contribution from a lexical component, in addition to perceptual components. Furthermore, other dimensions along which indirect tasks differ can also produce behavioral dissociations, such as the distinction between competitive and noncompetitive access to conceptual information, for example.

An alternative perspective is the 'component process' view of priming, according to which there are typically several processes involved in a given task that may be facilitated by prior processing. As with the related concept of 'transfer-appropriate processing,' the amount of priming will depend on the degree of overlap between the processes performed on the prime and those performed on the probe (**Figures 4(a) and 4(b)**). These processes may derive from interactions between brain regions that become configured according to the task demands. Therefore, "performance will depend on the interplay of components and the processes they mediate" (Moscovitch, 1994: 301). A behavioral measure like reaction time is likely to reflect the conglomeration of the times taken to perform each component process. Only by varying the stimuli and task can the key components in behavioral priming be isolated (**Figures 4(b) and 4(c)**). Alternatively, the concurrent acquisition of hemodynamic or electrophysiological data allows the opportunity to examine activity within the 'network' of brain regions (and the interactivity between those regions) that are configured for the current task.

Another important theoretical dimension is that between 'structural' and 'episodic' theories of priming. According to structural (or 'abstractionist') theories, priming reflects some modification, such as lowered thresholds of, or residual activity in preexisting representations. According to episodic (or 'instance') theories, any exposure to a stimulus can, in principle, leave some residual trace of its processing. Attempts to test these theories have used priming of novel stimuli (e.g., nonwords, or impossible objects) or examined the effects of context (e.g., novel associations) on priming. In general, this distinction is hard to evaluate in the absence of more detailed theories of the nature of representation in the brain (e.g., even nonwords can consist of familiar bigrams of letters). Nonetheless, one important class of episodic theories assumes that each stimulus and response within a task can become associated together, or bound into a single representation (or 'event record'). In such cases, repetition of the stimulus can directly cue retrieval of the associated response. Such stimulus–response associations have been shown to influence behavior, particularly in the case of subliminal (masked) priming, but also in the case of 'negative priming,' when the response to a probe stimulus is hindered if the same stimulus has previously been presented in the context of a different response (even if an implicit response). Such associations have also been shown to have dramatic effects on imaging data. Though stimulus–response associations can be minimized by ensuring that the response made to the probe is unrelated to the response made to the prime, it is clear that when present, such associations can have important consequences, possibly 'by-passing' several stages of processing that occurred on the prime (**Figure 4(d)**).

Future

One important future direction that provides strong evidence for the direct involvement of circumscribed

Figure 4 Schematic of the component process view of priming. (a) Initial presentation of an object in a semantic classification task (living vs. nonliving) involves interactions between a number of processing stages between the stimulus (left) and response (right). Putative brain regions associated with each stage are shown. (b) Repetition of the same object in the same task causes faster classification by virtue of facilitated processing in some (but not necessarily all) of the stages (facilitation indicated by darker lines). (c) A change in the stimulus involves re-processing in only one of the original stages (in this example), leading to reduced priming (and potential isolation of semantic component). (d) The formation of direct a stimulus–response association (event record) can also cause priming, even though it bypasses the initial processing stages. Inf, inferior; Front, frontal cortex; Temp, temporal.

brain regions in priming is the use of transcranial magnetic stimulation (TMS). In the only such study to date, either left inferior frontal cortex or a control site was stimulated approximately 300 ms after the initial presentation of a visual object. Frontal stimulation reduced the amount of priming for semantic classification of that object when it was repeated later (Figure 5(a)). Moreover, repetition suppression for that object, when later repeated, was abolished in left inferior frontal cortex, but not in occipital cortex (Figure 5(b)). This supports the existence of at least two components to priming in this task: for example, a visual component in occipital cortex and a verbal component in left inferior frontal cortex.

Another important future direction is the combination of multiple imaging modalities, such as the combination of spatial information in fMRI with the temporal information in MEG. Once the detailed time course of activity can be estimated in different brain regions, one can go further and explore changes in the covariance between these time courses, in order to infer directionality and possible causality. It will also be useful to acquire more fMRI and EEG/MEG data on amnesic patients, to confirm that priming-related changes in brain activity persist despite compromised activity in MTL.

From a theoretical perspective, more detailed models of the causes of priming are needed. According to the 'component process view' mentioned above, an important question is: What is the nature of processes that lead to facilitation when they are re-engaged, in a stimulus-specific manner, in relation to other processes that may not show such facilitation? And how does this component process view incorporate other evidence suggesting a role for direct stimulus–response associations, or episodic records? Some computational models have been used to fit behavioral priming; such models now need to be extended to the neural level, to make contact with the imaging and electrophysiological data described above. One important question for these models is: Is there a single neural mechanism underlying priming, or multiple mechanisms operating on different spatial and temporal scales (e.g., long-term potentiation/depression, or synaptic depression, or even firing-rate adaptation)?

A final important question is how priming and explicit memory, if truly dissociable, nonetheless interact in many circumstances. Some have suggested that the cause of priming (often described as increased 'fluency' of processing) can, under some conditions, be utilized by people in order to make an explicit memory judgment. In other words, people can

Figure 5 A transcranial magnetic stimulation (TMS) study of priming. (a) Using a semantic classification task like in **Figure 4**, TMS of left inferior frontal cortex (but not of a control region in left motor cortex) shortly after initial presentation of visual objects reduced subsequent behavioral priming. (b) TMS of the frontal region abolished fMRI repetition suppression in that region when the object was subsequently repeated but did not abolish repetition suppression in occipital cortex. attribute the feeling of faster/easier processing of a stimulus to a past encounter with that stimulus. A current controversy is whether amnesic patients can be encouraged or even taught to use such fluency cues to improve their memory judgments.

Prion Diseases

A Aguzzi, University Hospital of Zurich, Zurich, Switzerland

© 2009 Elsevier Ltd All rights reserved.

Introduction

In the 1980s, the prion was defined as the infectious agent that causes transmissible spongiform encephalopathies (TSEs), or prion diseases, following decades of work by Tikvah Alper and JS Griffith in the 1960s and by then by Nobel Prize winner Stanley B Prusiner, whose team announced in 1982 that they had purified material containing the infectious agent, which was a protein. According to all evidence available to date, the prion (from 'proteinaceous infectious only') is devoid of informational nucleic acids and consists mainly of a prion protein (PrP), a cellular protein of basically unknown function, highly expressed on cells of the nervous system as well as on many other cells of the body, such as lymphocytes. The human gene is designated *PRNP*; its cognate gene, *Prnp*, was identified in hamster by Charles Weissmann and, independently, in mice by Bruce Chesebro. PrP exists in at least two different isoforms. The fundamental event in prion diseases seems to be a conformational change which occurs during the conversion of one form, named PrP^{C} (cellular, normal host prion protein), into another form, named PrP^{Sc} (scrapie-associated, pathological, potentially 'infectious' prion protein).

PrP^{C} has been identified in all mammals and birds examined to date, and it is anchored to the external surface of cells by a glycolipid moiety. Its function is unknown. All attempts to identify a posttranslational chemical modification that distinguishes PrP^{Sc} from PrP^{C} have been unsuccessful to date. PrP^{C} contains ~45% α-helix and is virtually devoid of β-sheet. Conversion to PrP^{Sc} creates a protein that contains ~30% α-helix and 45% β-sheet. The mechanism by which PrP^{C} is converted into PrP^{Sc} remains unknown, but PrP^{C} seems to bind to PrP^{Sc} and to form an intermediate complex during the formation of nascent PrP^{Sc}. Transgenic (Tg) mouse studies have demonstrated that PrP^{Sc} in the inoculum interacts preferentially with homotypic PrP^{C} during the propagation of prions (Tg mice are genetically modified mouse strains expressing at least one foreign or altered gene).

Prnp is transcribed in brain and many other cells of the body in both prion-infected and noninfected animals. Weissmann demonstrated in the 1990s that removal of *Prnp* from the mouse genome leads to complete immunity from prions. The only organ system in which histopathological damage can be demonstrated as a consequence of infection with prions – causing corresponding clinical signs – is the nervous system. This applies to all human TSEs, such as Creutzfeldt–Jakob disease (CJD), Gerstmann–Sträussler–Scheinker (GSS) syndrome, kuru, and fatal familial insomnia (FFI), and to all known prion encephalopathies of animals. The latter diseases comprise scrapie in sheep and goats, bovine spongiform encephalopathy (BSE; formation of sponge-like vacuoles within the gray matter of the brain is a highly characteristic morphological correlate in all TSEs), and chronic wasting diseases of mule, deer, and exotic ungulates. While the prototype of all prion diseases, scrapie, has been known from more than two centuries, BSE was first recognized as an epizootic phenomenon in 1986. The emergence of a new variant form of Creutzfeldt–Jakob disease (vCJD) in young people in the UK has since raised the possibility that BSE has spread to humans by dietary exposure. Experimental evidence claiming that the agent causing BSE is indistinguishable from the vCJD agent has recently supported this view.

The 'Protein-Only' Hypothesis

Although the exact physical nature of the transmissible agent is still controversial, a very large body of experimental data supports the 'protein only' hypothesis, first outlined in general terms by Griffith in 1967 and enunciated in an updated and detailed form by Prusiner. This hypothesis posits that the agent is devoid of nucleic acid and consists solely of an abnormal conformer of the cellular prion protein, PrP^{C}.

Conversion of PrP^{C} into PrP^{Sc}

Accumulation of an abnormal isoform (PrP^{Sc}) of the host-encoded PrP^{C} in the central nervous system is a hallmark of prion diseases. Because no chemical differences have been found between PrP^{C} and PrP^{Sc}, the two species are believed to differ in their conformation. The fine 3-D structure of PrP^{C} has been resolved at the atomic level using both nuclear magnetic resonance spectroscopy and X-ray diffraction crystallography. Only low-resolution structural data existed for PrP^{Sc} until recent work extended the analyses to electron crystallography. The β-sheet content of PrP^{Sc} is high, whereas PrP^{C} contains only a very short β-sheet stretch. Conversion of PrP^{C} into PrP^{Sc} in prion-infected cells is known to be a late posttranslational process, occurring after PrP^{C} has reached its normal extracellular location.

In order to explain the mechanism by which a misfolded form of PrP might induce the refolding of 'native,' normal PrP molecules into the abnormal conformation, two distinct models have been postulated: (1) the template assistance, or 'refolding,' model and (2) the nucleation–polymerization, or 'seeding,' model. In the first model, the conformational change is kinetically controlled; a high activation energy barrier prevents spontaneous conversion at detectable rates. Interaction with exogenously introduced PrP^{Sc} causes PrP^{C} to undergo an induced conformational change to yield PrP^{Sc}. This reaction may involve extensive unfolding and refolding of the protein to explain the postulated high energy barrier and could be dependent on an enzyme or chaperone. In the second model, PrP^{C} and PrP^{Sc} are in equilibrium strongly favoring PrP^{C}. PrP^{Sc} is stabilized only when it adds onto a crystal-like aggregate of PrP^{Sc}, acting as a seed in a nucleation-dependent polymerization process. Cell-free conversion studies suggest that PrP^{Sc} aggregates are able to convert PrP^{C} into a protease-resistant PrP isoform.

The Prion Protein

The cellular prion protein PrP^{C} contains two N-linked complex-type oligosaccharides at positions 181 and 197. Accordingly, Western blot analysis of PrP reveals three major bands, reflecting PrP that has two, one, or no glycosylation signals occupied. Upon translocation of PrP into the endoplasmic reticulum, an NH_2-terminal secretory signal peptide of 22 amino acids is cleaved from PrP, and 23 COOH-terminal residues are processed during addition of the glycosylphosphatidylinositol (GPI) anchor to the amino acid residue serine at position 231. Mature mouse PrP contains 209 amino acids.

PrP^{Sc}, which accumulates in TSE-affected organisms, is a modified form of PrP^{C}. PrP^{C} and PrP^{Sc} have an identical amino acid sequence and share the same posttranslational modifications as assessed by currently available methodology, but differ in their secondary, tertiary, and (presumably) quaternary structure. The physiological isoform PrP^{C} is protease sensitive (consequently sometimes designated as PrP^{sen}), while the pathological isoform PrP^{Sc} is partially protease resistant (thus also called PrP^{res}). The protease-resistant core of PrP^{Sc}, designated PrP^{27-30} according to its molecular weight on sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE), provides a specific and reliable molecular marker for the presence of the infectious agent.

Because of its location at the outer surface of cells, anchored by phosphatidylinositol glycolipid, PrP is a candidate for signaling, cell adhesion, or perhaps even for some transport functions. PrP is expressed on many cell types, including neurons, glial cells, and lymphocytes, and appears to be developmentally regulated during mouse embryogenesis. All prion proteins investigated hitherto contain four to five 'octa repeats,' repetitive sequences of eight amino acids. Amplification of the number of octa repeats has been found in hereditary prion diseases such as familial Creutzfeldt–Jakob disease (fCJD) and GSS syndrome. Several studies have established that mammalian and chicken prion protein octa repeats bind up to four copper atoms. It has been suggested from studies with peptides based on the octa repeat region of PrP that the four highly conserved histidines in the repeat region coordinate four copper atoms, indicating that binding of copper may be essential for the function of PrP^{C}. PrP refolded with copper has been claimed to have an antioxidant activity similar to that of superoxide dismutase, but these claims were not independently reproduced and there is no evidence that PrP^{C} acts as a superoxide dismutase *in vivo*.

Although PrP is predominantly found in brain tissue, high levels are also present in heart, skeletal muscle, and kidney, whereas it is barely detectable in the liver. Several candidate proteins that bind PrP^{C} have been reported. Among them are a member of the amyloid precursor protein (APP) family (the amyloid precursor-like protein 1), the antiapoptotic protein bcl-2, and the 37-kDa human laminin receptor precursor. The observation that PrP binds to amyloid precursor-like protein 1 (APLP1) is intriguing in light of potential analogies of transmissible spongiform encephalopathies to Alzheimer's disease. Evidence that any of these interactions are of physiological relevance is, however, still lacking.

The Gene Encoding PrP

The gene encoding the cellular isoform of the prion protein is located on chromosome 20 in humans and on chromosome 2 in mice, and is termed *Prnp* in mouse and *PRNP* in humans. In all known mammalian and avian genes, PrP^{C} is encoded by a single open reading frame. The *Prnp* genes of mouse, and *PRNP* of sheep and cattle, contain three exons, while these genes in hamsters and humans span over two exons. PrP expression seems to be controlled by the SP1 transcription factor that binds to G+C-rich nonamer regions upstream of exon 1. Within the genome, *Prnp* is present as a single copy gene. A partially homologous gene termed *Prnd*, and encoding the Dpl protein ('downstream of the *Prnp* locus') was identified approximately 16 kb 3′ of the *Prnp* locus. To date, no evidence has surfaced that would incriminate Dpl in the pathogenesis of transmissible prion diseases,

and the physiological function of Dpl seems to be related to male reproduction.

Prnp mRNA is constitutively expressed in the adult organism and is developmentally regulated during mouse embryogenesis. Mutations in the host-encoded PrP gene were shown to be genetically linked to human prion diseases. In addition, polymorphisms in the PrP gene control many features of prion diseases, including incubation time, species barrier, and specificity of recovered prion strain. Mice that lack PrP^C (designated $Prnp^{0/0}$ or $Prnp^{-/-}$) are resistant to infection with prions.

$Prnp^{0/0}$ mice with an N-proximally truncated transgene encoding PrP devoid of the octa repeats and the conserved 106–126 region suffer from ataxia and degeneration of the cerebellar granule cells shortly after birth. Similar (but not identical) phenotypes are observed in mice overexpressing Dpl; these mice experience degeneration of cerebellar Purkinje cells. Introduction of a single intact PrP allele largely rescues this phenotype. These findings may be explained by postulating that PrP interacts with a ligand to obtain an essential signal. An alternative explanation posits that Dpl or N-terminally truncated PrP^C can exist as transmembrane proteins and form oligomers. Lack of the N terminus may create a toxic channel that would be patent for ions and lead to osmotic or excitotoxic damage. Single molecules of PrP^C containing its N-terminal tail may block such channels in a transdominant fashion, and thereby abrogate neurotoxicity.

The Species Barrier

Transmission of prions from one species to another is usually accompanied by a prolongation of the incubation period in the first passage and incomplete penetrance ('attack rate') of the disease. This phenomenon is called the 'species barrier.' Subsequent passage in the same species occurs with high frequency and shortened incubation times. In the case of prion transmission from hamster to mice, this species barrier was overcome by introducing hamster *Prnp* transgenes into recipient wild-type mice. Crucially, the properties of the prions produced were compatible with the prion species used for inoculation: infection with hamster prions led to production of hamster prions, whereas infection with mouse prions gave rise to mouse prions. With respect to the protein-only hypothesis these findings can be interpreted as follows: hamster PrP^C but not murine PrP^C (the latter differing from the former by 10 amino acids) is an appropriate substrate for conversion to hamster PrP^{Sc} by hamster prions, and vice versa. Intriguingly, susceptibility of mice to prions from other species is increased when the corresponding PrP transgene is introduced into a PrP knockout mouse, suggesting that the resident murine gene inhibits the propagation of the alien prions (knockout mice are genetically engineered mice lacking the ability to express a specific protein due to a deletion of a gene of interest).

Understanding Prion Strains

In 1961, distinct isolates or strains of prions were first described in scrapie-diseased goats, in which two dissimilar clinical manifestations ('scratching' and 'drowsy,' respectively) were identified. These strains differ in their incubation times in various inbred mouse lines and by their lesion pattern in the brain. Strikingly, distinct strains of prions can be propagated in an inbred mouse strain that is homozygous with respect to *Prnp* – a perplexing finding with regard to the protein-only hypothesis, meaning that an identical polypeptide chain is able to mediate different strain phenotypes. Both the 'refolding' and the 'seeding' models propose that each strain is associated with a distinct conformation of PrP^{Sc} and that each of these can convert PrP^C of its host into a likeness of itself. Indeed, PrP^{Sc} species associated with two hamster-adapted scrapie strains, hyper (HY) and drowsy (DY), proved to display characteristic clinical and histopathological properties as well as distinct biochemical patterns with respect to proteinase K digestion – which may be explainable by the presence of different conformations of PrP^{Sc}. Analogous findings have been made with other prion strains propagated in mice. In addition, PrP^{Sc} of certain strains differ in the ratio of the diglycosylated to the monoglycosylated form. Based on the fragment size and the relative abundance of individual bands, three distinct patterns (PrP^{Sc} types 1–3) were defined for sporadic and iatrogenic CJD cases. In contrast, all cases of vCJD displayed a novel pattern, designated type 4 by Collinge, and type III by Parchi and Gambetti. Interestingly, brain extracts from BSE-infected cattle as well as from BSE-inoculated macaques exhibited a type 4 pattern. Even more intriguingly, transmission of BSE or vCJD to mice produced mouse PrP^{Sc} with a type 4 pattern indistinguishable from the original inoculum – a finding that impressively supports the hypothesis that vCJD is the human counterpart to BSE. An additional tool, which may eventually serve to characterize prion strains, utilizes the differential affinity of certain antibodies for properly folded and denatured isoforms of PrP, thereby differentiating as many as eight different conformers. This provides further circumstantial evidence for the assumption that strain specificity is encrypted within the physical structure of PrP.

Studies of scrapie in inbred mice led to identification of a single autosomal gene, termed *Sinc* (*scrapie incubation*), controlling incubation time of mice infected with mouse prion strains. Soon after, a link between *Sinc* and a polymorphism in the mouse *Prnp* gene was discovered. Elegant knockin experiments, in which *Prnp* alleles of inbred mice were swapped, have provided strong support for the contention that *Sinc* is identical to *Prnp*.

Spread of Prions

Prion pathogenesis can be broken down into spatially and temporally distinct phases: (1) infection and peripheral replication, (2) migration from the periphery to the central nervous system (CNS; neuroinvasion), and (3) neurodegeneration. The resistance to prions by mice that lack PrP^C expression is amply documented. PrP^C expression is required for transporting the infectious agent from the peripheral sites to the CNS (as monitored by PrP^C-expressing neurografts) and within the CNS. However, reconstitution of $Prnp^{0/0}$ mice with wild-type (wt) bone marrow is insufficient to restore neuroinvasion in engrafted $Prnp^{0/0}$, mice although the capacity of the spleen to accumulate prions of the Rocky Mountain Laboratory (RML) strain (derived from sheep with scrapie) is reconstituted. This suggests that hematopoietic cells transport prions from the entry site to the lymphoreticular system (LRS), which accumulates and replicates prions, but that PrP^C expression in an additional compartment, presumably the peripheral nervous system, is required. B lymphocytes (not necessarily expressing PrP^C) are crucial for peripheral prion spread and neuroinvasion.

The dependence on lymphotoxin (LT)-mediated signaling by B cells may explain – at least in part – the requirement for B cells in peripheral pathogenesis: follicular dendritic cells (FDCs) accumulate PrP^{Sc} following scrapie infection, and maturation of FDCs requires signaling by B cells expressing LT-α/LT-β trimers on their surface. Indeed, blockade of LT-β signaling via administration of soluble LT-β receptor immunoglobulin (LT-βR–Ig) fusion protein ablates mature FDCs and significantly impairs neuroinvasion and accumulation of peripheral PrP^{Sc} and infectivity. FDCs are crucial to disease progression after oral scrapie challenge, but only within a short time window.

FDCs play a role in antigen trapping and in binding opsonized antigens to the CD21/CD35 complement receptors. Two studies have demonstrated that the complement system is relevant to prion pathogenesis. Mice genetically engineered to lack complement factors or mice depleted of the C3 complement component exhibited enhanced resistance to peripheral prion inoculation. Because FDCs are most likely immobile cells, they are unlikely to be responsible for prion transport into the CNS.

But just which cell types are involved in neuroinvasion? The innervation pattern of lymphoid organs is primarily sympathetic. Sympathectomy delays the onset of scrapie, while sympathetic hyperinnervation enhances splenic prion replication and neuroinvasion, suggesting that innervation of secondary lymphoid organs is the rate-limiting step to neuroinvasion. Although there is no physical contact between FDCs and sympathetic nerve endings, the distance between FDCs and splenic nerves affects the velocity of neuroinvasion. It remains to be determined whether this results from passive diffusion of prions or whether mobile cells (e.g., germinal center B cells) are involved in an active transport process.

Inflammation: License to Replicate?

Because lymphoid infectivity is found in most prion diseases, and proinflammatory cytokines and immune cells are involved in lymphoid prion replication, it has been of highest interest to test whether chronic inflammatory conditions in nonlymphoid organs can affect prion distribution. Inclusion body myositis, which is an inflammatory disease of muscle, is reported to lead to strong PrP^{Sc} deposits in muscle.

Indeed, many chronic inflammatory conditions, some of which are very common, including rheumatoid arthritis, type 1 diabetes, and Crohn's, Hashimoto's, and chronic obstructive pulmonary diseases, show organized inflammatory foci of B lymphocytes, FDCs, dendritic cells (DCs), macrophages, and other immune cells associated with germinal centers. Extranodal metastases of Hodgkin's disease and non-Hodgkin's lymphomas may contain neoplastic follicles with FDCs. Moreover, the meninges can also develop ectopic lymphoid follicles under conditions of chronic inflammation. Most importantly, tertiary follicles can be induced in nonlymphoid organs by naturally occurring infections in free-ranging ruminants, and are surprisingly prevalent in nonlymphoid organs.

To investigate whether inflammatory diseases influence prion pathogenesis, mice with a variety of five inflammatory diseases of kidney, pancreas, or liver were inoculated with the RML strain. In all cases and in all organs tested, chronic lymphocytic inflammation enabled prion accumulation in otherwise prion-free organs. Inflammatory foci consistently correlated with upregulation of LTs and ectopic induction of PrP^C-expressing FDC-$M1^+$ cells. Inflamed organs of mice lacking LT-αRs or LT-βRs neither accumulated PrP^{Sc} nor showed infectivity upon prion inoculation. Hence scrapie infection of mice suffering from

nephritis, hepatitis, or pancreatitis induces unexpected prion deposits at the sites of inflammation.

The aforementioned results raised concerns that analogous phenomena might occur also in farm animals, since these are in constant contact with inflammogenic pathogens. Indeed, we found that naturally scrapie-sick sheep suffering from mastitis contain PrP^{Sc} in their mammary glands. Therefore, also in sheep, inflammatory conditions induce accumulation and replication of prions in an organ believed to be previously free of prions. This finding may have an impact on the risk assessment of biologicals (e.g., milk) and could lead to a readjustment of current rules.

Outlook

There is a daunting amount of experimental and theoretical evidence supporting the proposition that the prion (i.e., the transmissible entity of TSEs) is composed of a self-propagating isoform of PrP, and that informational nucleic acids are not required for transmissibility. Many questions remain concerning the portals of entry of prions into the body of the host, and many processes still need to be elucidated, such as the mechanisms and the requirements for the conversion reaction, the transport of prions from the periphery to the CNS, and the mechanisms of pathogenesis. From a clinical point of view, early diagnosis of prion disease and treatments aiming to arrest or cure prion disease in humans are important goals.

Prion Transport

Introduction

Axonal transport of vital cargo within neuronal cells is indispensable for the proper maintenance of cell viability and function. This process involves the active movement along neurites of essential materials such as signaling molecules, RNAs, synaptic vesicle precursors, vesicular and cytoskeletal components, and growth factors. These diverse components arrive at dendritic or axonal termini while certain neurotrophic and other signals travel back from synapses to the cell body in response to various stimuli. The proteins involved in executing fast transport are a number of microtubule-based kinesin and dynein molecular motor proteins which use ATP hydrolysis to transduce chemical energy into kinetic energy and movement along microtubules.

A number of neurodegenerative diseases have been linked to deficits in axonal transport. For example, disruptions in the transport of the amyloid precursor protein (APP) and huntingtin (Htt) result in accumulations of these and other proteins within axons and in phenotypes that are consistent with axonal transport defects in Alzheimer's and Huntington's diseases, respectively. Likewise, in transmissible spongiform encephalopathies (TSEs) or prion diseases such as mad cow disease, scrapie in sheep, and Creutzfeldt-Jacob disease in humans, abnormal intracellular accumulations are numerous. Whether axonal transport defects are also involved in prion pathologies is unknown. This article reviews evidence that the normal endogenous prion protein transports along axons and the putative role of this transport in synaptic function. Transport of infectious prions to the central nervous system (CNS) is necessary for disease pathology, thus this article also reviews current knowledge on the routes of neuroinvasion used by the infectious agent (PrP^{Sc}) to reach the CNS from extracerebral sites and a putative model for PrP^{Sc} entrance into cells.

Localization and Axonal Transport of the Mammalian Prion Protein, PrP^C

Prion diseases cause sporadic, familial, or infectious illnesses that are invariably fatal. In addition to spongiosis and astrocytosis, these diseases are also characterized by neuronal cell death. The main culprits, prions, are protein particles that exist in two forms. The normal nonpathological cellular prion protein (PrP^C) is a glycosyl-phosphatidylinositol (GPI) anchored protein that is widely expressed in a number of neural and nonneural tissues. This endogenous protein contains a number of α-helical domains that, by mechanisms that are still poorly understood, can posttranslationally convert to a β-sheet, protease-resistant, and infectious PrP^{Sc} (scrapie) conformation. It is thought that conversion from normal to scrapie forms necessitates the direct interaction of both types of proteins.

While both cellular and infectious isoforms localize to axonal termini and PrP^C has been shown to transport along axons by fast anterograde transport, the mechanisms underlying these processes have not been elucidated. Studies on the detailed localization of PrP^C in the brain include immunohistochemical analyses and quantitative studies of the ultrastructural localization of PrP^C. With these techniques, PrP^C particles have been found in a number of subcellular locations in the hippocampus, including the endoplasmic reticulum, Golgi complex, endosomes and lysosomes, tubules, vesicles without coats, clathrin-coated vesicles, plasma membrane, mitochondria, and nucleus, among others. In addition, these studies showed a distinctive presence of PrP^C in the neuropil of axonal and dendritic membranes as well as in synaptic and perisynaptic membrane profiles. Immunogold electron micrograph (EM) studies have revealed PrP^C localization mainly at presynaptic sites, and notably at asymmetric excitatory synapses in several brain regions.

The presence of PrP^C at the presynapse suggests that this protein is transported along the axon after it is produced in the cell body. Understanding the role and mechanisms of transport of the PrP^C along axons is important for understanding prion diseases because PrP^C is indispensable for the initiation and maintenance of prion infectivity. Moreover, while PrP^C localizes at synapses, its function remains unclear. Knowledge of PrP^C transport might clarify the role of PrP^C at synapses.

To date, studies on the axonal transport of PrP^C have been performed *in vivo* in the peripheral nervous system (PNS) and CNS using radiolabeled PrP^C. To determine whether PrP^C travels anterogradely at the whole nerve level, [^{35}S]methionine was injected near the dorsal root ganglia (DRG) of the sciatic nerve (in the PNS) and into layer II/III neurons of the entorhinal cortex in rats (in the CNS). These injection sites are located in the cell body layers of the respective tissues. Four hours after injection, radiolabeled PrP^C was immunopurified from distal axons of sciatic nerves and from the most rostral region of

the dentate gyrus. Sciatic nerves are composed primarily of sensory and motor neuron axons, but do not contain neuronal cell bodies, while neurons of layers II/III project to the outer molecular layer of the dentate gyrus in the perforant pathway. In both cases, radiolabeled PrP^C was detected in these remote axonal regions. To verify that detection of PrP^C in axons is the result of transport and not due to diffusion of [^{35}S] methionine, a ligature was applied adjacent to the DRG following injection of radiolabeled PrP^C. This ligation prevented the appearance of labeled PrP^C in remote parts of axons. The 4 h time interval between the injection of [^{35}S]methionine and the collection of distant axonal tissues with radiolabeled PrP^C is consistent with fast anterograde transport which is estimated at 200–400 mm day^{-1} (2.3–4.6 μm s^{-1}).

Using an accumulation paradigm (Figure 1), PrP^C has also been shown to move anterogradely and retrogradely in hamster sciatic nerves. The sciatic nerve was severed at the midsection (Figure 1). Six to 24 h later, proximal and distal regions of the nerve were collected. Proteins moving in a fast anterograde axonal pathway generally accumulate on the proximal side, while those moving in a fast retrograde fashion will accumulate on the distal side of the injury. The level of PrP^C from basal, proximal, and distal regions was analyzed using a two-site immunometric assay. In this assay, sciatic nerve homogenates are applied to wells pre-coated with an anti-PrP^C antibody. After an incubation period, another anti-PrP^C antibody coupled with acetylcholinesterase was added and incubated. Absorbance of wells was measured and PrP^C levels recorded. The absorbance for PrP^C in both the proximal and distal nerve segments was significantly higher as compared to that of the basal segment. This indicated that PrP^C moved in both antero- and retrograde directions. The isoform of the prion protein traveling along axons was a larger form (38 kDa vs. the normal 31–36 kDa size of the protein) not usually detected in axons under basal conditions. Interestingly, the accumulation of PrP^C at the distal end of the sciatic nerve was not readily detectable under standard tissue extraction conditions. An enhanced detection method involving the use of SDS buffer during tissue

Figure 1 Schematic of sciatic nerve accumulation paradigm. (a) An intact nerve bundle prior to cutting. (b) Sciatic nerve after cut at midsection. Shown are the proximal (P) and distal (D) segments where anterograde and retrograde moving proteins accumulate after cut. (c) The proximal (P) and distal (D) segments are removed and analyzed.

homogenization allowed the detection of PrP^C in the distal site, suggesting lower levels of retrogradely traveling PrP^C as compared to that traveling anterogradely. Whether the retrogradely traveling PrP^C is derived from the uptake of PrP^C by presynaptic endings near muscle or other regions or whether anterograde PrP^C reverses direction and returns to the cell body is presently unknown.

Although PrP^C is expressed ubiquitously throughout the brain, its function has not been determined. The presence of PrP^C at synapses suggests a role there, but this role is unclear. Further studies of the axonal transport of PrP^C during nerve regeneration experiments suggest that this protein might be involved in axonal growth. In experiments in which the sciatic nerve of hamsters was crushed at a single position and then allowed to regenerate, the levels of PrP^C expression at the site of injury were found to increase during the period of regrowth of axons. PrP^C levels subsequently decreased to basal levels at the time of complete functional nerve recovery. The isoform of PrP^C with increased levels at the site of injury was the higher molecular weight 38 kDa form, suggesting that only axonally transported PrP^C might be involved in the growth of axons *in vivo*.

Fast anterograde and retrograde transport suggest that a microtubule-based process is involved in transporting the prion protein along axons. Treatment of cultured neuroblastoma cells with the microtubule depolymerizing drug nocodazole caused PrP^C to concentrate in the cytosol with little or no subcellular organelle distribution. Generalized disruption of kinesins and dyneins with agents such as AMP-PNPs and vanadate or with antibodies against unspecified kinesin and dyneins also appears to disrupt movement of PrP^C particles inside neuroblastoma cells. However, whether these effects are the result of specific interactions between PrP^C and microtubule-dependent motor proteins or are a secondary consequence of global disruption of the entire microtubule cytoskeleton has not been determined.

Axonal Transport of Scrapie, PrP^{Sc}

The spread of scrapie infectivity presupposes the presence of PrP^C. Thus, mice that lack PrP^C are immune to prion infections. Understanding the mechanisms of axonal transport of the PrP^C might illuminate how scrapie reaches the CNS and becomes pathological. However, the partially protease-resistant PrP^{Sc} has a distinctively different set of biological properties that distinguish it from PrP^C. For example, its turnover rate, subcellular localization, and distribution are different, and thus it is feasible that the trafficking of PrP^{Sc} might not necessarily involve a mechanism similar to that for PrP^C.

To date, only one study has followed the subcellular localization of fluorescently tagged PrP^{Sc} in cultured cells. Magalhães and colleagues purified infectious scrapie from mice brains and labeled it with a fluorescent probe. The labeled preparation was subsequently applied to the surface of SN56 cultured cells and of dissociated primary cortical cells from hamster brains. SN56 cultured cells are of septal neuronal origin and can be differentiated into neuron-like cells that have projections. Labeled PrP^{Sc} accumulated on the surface of SN56 and cortical primary cells as aggregates. To unequivocally determine the source of infection, small amounts of labeled PrP^{Sc} were directly applied to the surfaces of cells without application to cells in the immediate vicinity. Starting 3 days after exposure, fluorescently labeled PrP^{Sc} was internalized by both types of cells into vesicle-like compartments that moved within the cell body and within neurites at a rate of 0.3–5 $\mu m\, s^{-1}$, a rate consistent with fast axonal transport. These PrP^{Sc} puncta co-localized in fixed SN56 cells with a number of organelle markers, such as LysoTracker, which marks acidic compartments and lysosomes, and dextran, a marker for fluid-phase endocytosis. In contrast, PrP^{Sc} puncta did not co-localize with markers of lipid rafts (cholera toxin) or with early and recycling endosomal markers (transferrin). These data indicate that externally applied PrP^{Sc} sorts into lysosomal and late endosomal compartments within neuronal cells. Interestingly, application of labeled PrP^{Sc} in PrP knockout mice did not affect the internalization of PrP^{Sc}, indicating that an interaction between PrP^C and PrP^{Sc} is not necessary for internalization.

Neuroinvasion by the Scrapie Agent

While PrP^{Sc} has been detected in a number of extracerebral tissues, such as in skeletal muscle and lymphoid organs, histopathological lesions have been identified only in organs of the CNS. Thus, in the case of peripherally acquired prion infection (such as through the ingestion of contaminated tissue), PrP^{Sc} has to migrate to the CNS for pathological signs to appear. The movement of scrapie from extra-CNS sites to the CNS is termed neuroinvasion. Interestingly, in experimental laboratory models, the most effective method for transmission of scrapie infection is through the injection of the scrapie inoculate directly in recipients' brains. If transmission of scrapie is initiated by injection of inoculate extracerebrally, incubation times are usually significantly lengthened. This suggests that the scrapie agent takes time to travel from intake sites

(such as gastrointestinal sites), perhaps via the PNS, to tissues and organs of the CNS.

Transport of PrP^{Sc} in the CNS has been investigated *in vivo* by injecting prions intraocularly in mice. After injection, the first prion lesions were observed in the contralateral projections of the retino-tectal pathway. Based on these and other studies, the rate of scrapie spread was calculated to be around 1 mm/day. This rate is markedly slower than that mediated by fast axonal transport, which is estimated at 200–400 mm day^{-1}. However, this apparent discrepancy does not preclude a role for the axonal transport of PrP^{C} in the spread of scrapie because infectivity might be spread at lower-than-detectable levels through axons before reaching accumulation sites in the CNS where it would become more easily detectable. In fact, the rapid anterograde and retrograde axonal transport of PrP^{C} might suggest a possible mechanism for the spread of scrapie infectivity to the CNS. Because PrP^{C} and PrP^{Sc} must interact for conversion to occur, it is feasible that conversion could occur during transport. Whether spread of scrapie infectivity is mediated via axonal transport or through a domino-like effect by which PrP^{C} is converted to PrP^{Sc} in a step-wise fashion (with or without axonal transport) is still unclear.

Routes of Neuroinvasion of PrP^{Sc}

Neuroinvasion of PrP^{Sc} from peripheral tissues to the PNS and then to the CNS can be roughly classified as a two-step process. The first stage usually requires the accumulation and replication of PrP^{Sc} in 'reservoirs' of the lymphoreticular system (LRS). The second stage is transport of PrP^{Sc} within the PNS and then to the CNS. This is a loose classification, however, since it presumes the existence of the scrapie agent in or near the LRS, while the mechanism of transport to lymphoid organs from extraneuronal tissues such as gastrointestinal sites to LRS is not yet clear.

Although accumulation of PrP^{Sc} in lymphoid organs has not been found in all models of prion disease, this is a common early step in prion infectivity. The cells in the LRS responsible for accumulation and replication of prions are stromal cells such as the follicular dendritic cells (FDCs). Prions appear to accumulate specifically on the plasmalemma of FDCs. Thus, FDCs of the spleen of mice inoculated with prions have been observed to accumulate PrP^{Sc}, while nonstromal cells remain intact. Moreover, mice with impaired FDCs do not show signs of PrP^{Sc} infectivity in the spleen.

From the LRS, the mechanism by which prions reach the PNS has not been determined. Perhaps the location of PrP^{Sc} on the plasmalemma of FDCs positions scrapie near nerve fibers. However, expression of PrP^{Sc} only in neuronal cells or specific application of the infectious agent to nerve terminals results in active neuroinvasion, suggesting that accumulation in stromal cells can be bypassed. These observations suggest that a mechanism of transport independent of accumulation and replication in the LRS could operate during prion infection.

Within the PNS, the mechanisms of PrP^{Sc} transport are unclear. Several studies point to a requirement of the presence of PrP^{C} for scrapie transport. However, whether conversion of PrP^{C} to scrapie occurs during transport or in a domino-step manner is still to be determined. Also, PrP^{Sc} transport within the PNS and CNS has been studied *in vivo* only indirectly, by inoculation of mice with scrapie and then examination of different tissues at later times, or by estimating and comparing incubation times of mice that were inoculated intracerebrally versus those inoculated intraperitoneally. As mentioned earlier, slow rates of spread of prion infectivity have been found (of approximately 1 mm day^{-1}), suggesting that nonaxonal modes of transport of PrP^{Sc} might also be conceivable.

There is still much to be deciphered about the nature of scrapie infectivity and conversion. One of these unknown aspects is how PrP^{Sc} reaches the brain to produce disease. Whether via axonal or other routes, the mechanism of movement of scrapie within and between cells will provide us with a clearer understanding of infection routes and with possible methods to counteract the spread of infection. Knowledge of the function of endogenous PrP^{C} and why and how it travels along axons might also tell us something about scrapie infectivity.

Procedural Learning in Animals

Introduction

According to the multiple memory systems hypothesis, the mammalian brain contains relatively independent neural systems that differ in terms of the type of memory they mediate. This hypothesis is supported by extensive neurobiological research, and several theories have been proposed describing the putative psychological operating principles that distinguish different types of memory. One prominent dual-memory theory draws a distinction between declarative and procedural memory. Declarative memory involves the acquisition, consolidation, and retrieval of relational information for facts and events that allows for flexibility in the expression of learned behaviors. Declarative memory processes appear to rely on a neuroanatomical system composed primarily of various structures in the medial temporal lobe, including the hippocampus. In contrast, procedural memory involves the acquisition, consolidation, and retrieval of invariant information that is expressed in an inflexible manner. Note that in lower animals, the distinction between declarative and procedural memory is similar in many aspects to that drawn by experimental psychologists who were strident proponents of either cognitive or habit theories of animal learning, respectively.

In lower animals, dissociable types of procedural memory are mediated by different neuroanatomical structures, including, for example, the dorsal striatum and amygdala. The dorsal striatum is critically involved in procedural learning and memory involving the formation of stimulus–response habits, whereas the amygdala may selectively mediate procedural learning involving the formation of stimulus–affect associations. This article briefly describes neurobiological evidence in lower animals supporting a role for the dorsal striatum and amygdala in these two forms of procedural learning.

The Dorsal Striatum and Procedural Learning: Lesion Studies

In rats, lesions of the dorsal striatum, a primary anatomical component of the basal ganglia, impair acquisition of several tasks that theoretically can be acquired using a procedural learning mechanism. Examples include one-way and two-way active avoidance behavior; auditory, tactile, and visual simultaneous discrimination learning; operant bar-press behavior; and straight-alley maze behavior. Moreover, consistent with a multiple systems approach to memory organization, evidence indicates that the dorsal striatum selectively mediates procedural learning. An early study that employed dissociation methodology to demonstrate a selective role of the dorsal striatum in procedural learning that involves the formation of stimulus–response habits involved an experiment using two eight-arm radial maze tasks. In a version of the task involving declarative learning and memory, rats obtained food rewards by visiting each arm of the maze once within a daily training session, and reentries into maze arms that were previously visited were scored as errors. Performance in the declarative radial maze task requires rats to remember those arms that have been previously visited within a daily training session. In a different version of the task, involving procedural learning and memory, rats obtained food rewards by visiting four randomly selected and illuminated maze arms twice within a daily training session, and visits to unlit maze arms were scored as errors. Performance in the procedural radial maze task requires rats to learn to approach lit maze arms, and this task is essentially a simultaneous visual discrimination that may involve acquisition of a stimulus–response habit. Lesions of the dorsal striatum severely impair acquisition of the procedural task and do not affect acquisition of the declarative task. Note that the two radial maze tasks used to dissociate the role of the dorsal striatum in procedural and declarative memory share the same motivational (appetitive), sensory (visual), and motor (maze running) characteristics, indicating that the selective impairment observed in the procedural memory task was not due to an influence on nonmnemonic factors.

An additional study used a plus maze task to investigate the selective role of the dorsal striatum in procedural memory. The plus maze apparatus is arranged so that a goal box (e.g., east or west), can be approached from one of two start boxes (e.g., north or south). In a dual-solution version of the task originally introduced by Edward Tolman and colleagues in the mid-1940s, rats were released from the same start box (e.g., south) and trained to obtain food from a consistently baited goal box (e.g., west). Following acquisition of the task, a probe trial was administered in which rats were released from the opposite start box (e.g., north); the choice behavior on this trial was used to assess the type of learning strategy the animals were employing. For example, rats trained in this task might learn the spatial location of the reinforcer and use this declarative or relational information to guide

approach behavior to the baited goal box. Alternatively, rats might learn to approach the baited goal box by acquiring a response tendency (i.e., a specific body turn) at the choice point of the maze and use this form of procedural learning during task acquisition. Note that although either a declarative or a procedural learning mechanism can be used to acquire this task successfully, the use of these types of mnemonic strategies predicts different choice behavior on the critical probe trial. Thus, rats that used declarative knowledge of the spatial location of the reinforcer (i.e., 'place' learning) should continue to approach the baited goal box on the probe trial, whereas rats using a specific body turn response, or procedural memory (i.e., 'response' learning), should choose the opposite goal box on the probe trial. The hypothesis that the dorsal striatum may play a selective role in the expression of procedural, or response, learning in the plus maze has been examined using a reversible brain lesion technique. Specifically, following the rats' acquisition training in the plus maze, and just prior to administration of a probe trial, investigators produced a reversible brain lesion via intracerebral injection of the sodium channel blocker lidocaine. On a probe trial given after 1 week of training in the plus maze, rats receiving saline vehicle injections into the dorsal striatum were predominantly place learners. Moreover, infusions of lidocaine into the dorsal striatum did not impair the expression of declarative, or place, learning. The lack of effect of neural inactivation of the dorsal striatum on the use of place learning is consistent with the radial maze findings described above. However, with extended training in the dual-solution plus maze task, rats eventually switched from the use of place learning to a response learning tendency. Thus, on a second probe trial administered after an additional week of training, rats receiving vehicle injections into the dorsal striatum were then predominantly response learners. In contrast, rats receiving intradorsal striatal injections of lidocaine prior to the second probe trial exhibited place learning, indicating a blockade of the expression of response learning. Again, consistent with the radial maze findings, these results indicate that the dorsal striatum is selectively involved in the expression of procedural learning. In addition, they suggest that the shift or transition from the use of place learning to response learning in a dual-solution plus maze task involves the gradual recruitment of a dorsal striatal-based procedural learning system to guide behavior. Lesions of the dorsal striatum also impair acquisition of a single-solution plus maze task that requires rats to use procedural response learning by varying the start point on each trial and reinforcing the same body turn at the choice point.

The selective role of the dorsal striatum in stimulus–response procedural learning and memory generalizes to aversively motivated behavior. For example, in a two-platform water maze task that requires rats to learn to approach a visible escape platform on the basis of either procedural memory (i.e., a consistent visual appearance but differing spatial location across trials) or declarative memory (i.e., a consistent spatial location but differing visual appearance across trials), lesions of the dorsal striatum selectively impair acquisition of the procedural memory task. In addition, in a single-platform water maze task in which rats are allowed swim to a visible escape platform that is always located in the same spatial location, the relative use of declarative and procedural learning can be assessed on a probe trial in which the cued platform is moved to a new spatial location. On a probe trial administered following extended training in this task, control rats exhibit a procedural memory strategy and swim directly to the visible platform in its new location. In contrast, rats with lesions of the dorsal striatum exhibit a declarative memory strategy and swim to the spatial location that the platform was previously located in.

An important aspect of dorsal striatal involvement in stimulus–response procedural learning concerns the existence of functional heterogeneity in the mnemonic functions of this brain structure. Specifically, lateral, but not medial regions of the dorsal striatum may be particularly critical in stimulus–response habit learning. For example, lesions of the medial dorsal striatum in rats can in some cases produce deficits in acquisition of declarative learning and memory tasks, although these deficits often appear transient in nature. In addition, lesions of the dorsomedial, but not the dorsolateral, striatum block the ability of reinforcer devaluation to reduce instrumental responding, suggesting that the dorsomedial striatum selectively mediates expression of behavior based on action-outcome associations in instrumental conditioning rather than stimulus–response habit formation.

In addition to evidence dissociating the mnemonic functions of medial and lateral regions of the dorsal striatum, other findings indicate that the role of the lateral dorsal striatum in habit learning is organized on the basis of the nature of the sensory information provided by cortical input. Thus, lesions of the ventrolateral dorsal striatum, an area that receives olfactory cortical input, impair procedural leaning involving olfactory, but not visual, sensory information. In contrast, lesions of the posteroventrolateral dorsal striatum, an area that receives visual cortical input, impairs procedural leaning involving visual, but not olfactory, sensory information. The impairing

effect of dorsolateral striatal lesions on response learning in the plus maze may reflect a role for the vestibular and kinesthetic information that this striatal region receives from the somatosensory cortex. Thus, two levels of functional heterogeneity in the mnemonic functions of the dorsal striatum may be present. A medial-to-lateral anatomical gradient may correspond to a differential involvement in declarative and procedural memory, respectively. Second, within the lateral dorsal striatum, stimulus–response procedural learning is organized on the basis of the nature of the specific sensory input that is received from different cortical regions.

Finally, it is important to note that in each of the radial maze, plus maze, and water maze tasks described above, lesions of the dorsal striatum and hippocampal system produce opposite effects. Specifically, in contrast to the effects of dorsal striatal lesions, damage to the hippocampal system selectively impairs behavior in the declarative versions of the tasks. The double dissociations that have been observed in several studies following lesions of the dorsal striatum and hippocampus provide compelling evidence in favor of the hypothesis that these two brain structures are components of memory systems that selectively mediate procedural and declarative memory, respectively.

The Dorsal Striatum and Procedural Learning: Neurochemical Studies

A second line of evidence indicating a selective role for the dorsal striatum in procedural learning is derived from studies investigating the neurochemical bases of memory. For example, corticostriatal projections use glutamate as a neurotransmitter and are hypothesized to provide the sensory stimulus information contained in stimulus–response associations. Dopaminergic projections to the dorsal striatum are thought to provide a reinforcing signal that is critical in the initial formation of stimulus–response associations. Finally, acetylcholine is contained within a population of dorsal striatal interneurons and may interact with dopaminergic function to modulate procedural learning and memory.

Extensive evidence implicates each of these three neurotransmitters in procedural learning and memory. Thus, impairments in the acquisition of various conditioned avoidance behaviors have been observed following depletion of dopamine in the nigrostriatal pathway, and posttraining electrical stimulation of the nigrostriatal bundle enhances consolidation of procedural memory. An enhancement of procedural memory is also observed following posttraining intradorsal striatal injections of indirect (e.g., amphetamine) and direct (e.g., quinpirole) dopamine agonists. The memory-enhancing effects of intradorsal striatal administration of dopamine agonists are task specific: injections facilitate memory consolidation in procedural versions of the radial and water maze tasks described above but have no effect on declarative memory. It is interesting that the role of dorsal striatal dopamine in procedural learning and memory may be relatively restricted to early stages of task acquisition. Consistent with this suggestion, depletion of nigrostriatal dopamine, or administration of dopamine receptor antagonist drugs, does not appear to impair the expression of previously acquired stimulus–response habits. Thus, dopamine release in the dorsal striatum may function during initial procedural learning as a reinforcing signal that acts primarily to 'stamp' together stimulus–response associative bonds.

Findings of several studies also indicate a role for dorsal striatal glutamate in procedural learning and memory. For example, procedural memory consolidation is enhanced by intradorsal striatal injection of glutamate in rats trained to swim to a visible escape platform that is located in a different spatial location on each trial. Moreover, infusions of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor antagonist AP5, or metabotropic glutamate receptor antagonists, impair memory consolidation in this procedural memory water maze task. Similar to the dissociation observed with dopaminergic drugs, posttraining intradorsal striatal infusions of glutamatergic agonist or antagonist drugs have no effect on memory in a declarative version of the water maze task in which rats are trained to swim to a hidden escape platform that is located in the same spatial location across trials. Additional evidence of a selective role for dorsal striatal glutamate in procedural learning and memory was obtained using the dual-solution plus maze task. Specifically, the transition to procedural response learning that normally occurs with extended training can be facilitated by posttraining intradorsal striatal injections of glutamate during early training. Moreover, infusions of the NMDA receptor antagonist AP5 into the dorsolateral striatum impair acquisition of response learning in a single-solution plus maze.

Several studies examining the effects of posttraining injections of cholinergic drugs also implicate dorsal striatal cholinergic activity in procedural memory consolidation. In general, posttraining intrastriatal infusions of cholinergic agonists (e.g., oxotremorine, choline) enhance, whereas cholinergic antagonists (e.g., atropine, scopolamine) impair, consolidation of procedural memory. Experiments using intracerebral microdialysis to monitor neurotransmitter release in the hippocampus and dorsolateral striatum during performance of the dual-solution plus maze task

suggest that the relative amount of acetylcholine release in these two brain regions influences the use of striatal-dependent procedural learning. For example, the transition from hippocampus-dependent place learning to dorsal-striatal response learning that occurs with extended training in the dual-solution plus maze tasks coincides temporally with an asymptotic value of acetylcholine release in the dorsolateral striatum. A similar relationship between gradual increases in acetylcholine release and transition from a spatial strategy to a response strategy was observed in rats trained in a food-rewarded Y-maze task. In addition, following training in the dual-solution plus maze task, rats that exhibit response learning on a subsequent probe trial display a higher ratio of acetylcholine release in the dorsolateral striatum relative to the hippocampus, whereas the opposite pattern of acetylcholine release is observed in rats displaying place learning.

In sum, a selective role for dorsal striatal dopamine, glutamate, and acetylcholine in procedural learning and memory has been observed across several studies. One challenge for future research is to determine the manner in which these neurotransmitters interact to contribute to the various forms of neural plasticity that have been demonstrated in the dorsal striatum (i.e., long-term potentiation and long-term depression) and which presumably form the basis of synaptic changes that underlie procedural learning.

The Amygdala and Stimulus–Affect Conditioning

Whereas the dorsal striatum has been implicated in procedural learning involving stimulus–response habit formation, other research suggests that the mammalian amygdala mediates a form of procedural learning in which stimulus–affect associations may be acquired. A role for the amygdala in 'emotional' procedural memory has been extensively described by researchers employing various fear conditioning paradigms including contextual, discrete cue, and potentiated startle tasks. Thus, lesions of amygdala severely impair acquisition of these tasks, and several elegant experiments have provided a circuit analysis describing the manner in which efferent amygdala projections can influence specific brain stem regions involved in the expression of different conditioned autonomic fear responses. It should be noted that some investigators have argued that a role for the amygdala in learned fear responses should be offered cautiously in view of evidence that damage to this structure may impair some types of unconditioned fear responses (e.g., freezing behavior).

Brain lesion experiments in which the mnemonic functions of the basolateral amygdala and dorsal striatum have been dissociated are of particular relevance to the hypothesis that these two brain structures selectively mediate stimulus–response and stimulus–affect procedural memory, respectively. For example, the functional integrity of the basolateral amygdala, but not the dorsal striatum, is necessary for acquisition of conditioned place preference behavior for both natural rewards and addictive drugs. In a conditioned place preference task, rats are confined, on alternating days, to one distinct environmental context paired with natural or drug rewards and a second context not paired with the rewarding treatment. In a reward-free test session given following training, the amount of time spent in the two environments is measured, and rats demonstrate a reliable preference for the environment previously paired with the rewarding stimulus. The conditioned place preference paradigm has been used primarily by researchers interested in the neurobiological bases of drug addiction and reward. However, as the animals are in a drug-free state on the critical test day, approach behavior to the environmental cues that have been previously paired with reward presumably involves stimulus–affect memory. Pretraining lesions of the basolateral amygdala impair acquisition of conditioned place preference behavior for natural rewards (food and sex) and for drugs of abuse (e.g., amphetamine and cocaine). In addition, memory consolidation underlying the acquisition of conditioned place preferences for food and amphetamine is blocked by posttraining intrabasolateral amygdala infusions of the cholinergic antagonist scopolamine and lidocaine, respectively. In contrast, lesions of the basolateral amygdala have no effect on acquisition of stimulus–response procedural learning in the radial or water maze.

Finally, activation of efferent basolateral amygdala projections can modulate consolidation of procedural memory occurring in other brain structures, including the dorsal striatum. The memory modulatory role of the basolateral amygdala is related in part to the effects of hormone release on emotional arousal. In addition, emotional state may interact with amygdala function to influence the relative use of multiple memory systems. For example, peripheral and intrabasolateral amygdala injections of anxiogenic drugs result in a predominant use of dorsal striatal-dependent procedural learning in the dual-solution plus maze task. It is important to note, however, that the modulatory influence of the basolateral amygdala has been described in multiple memory systems and is therefore not limited to procedural learning. Moreover, although memory storage and modulation theories of amygdala function have been contrasted as mutually exclusive and competing ideas, a time-limited modulatory role

for the basolateral amygdala on some types of learning and memory does not necessarily preclude a long-term role for this structure in memory underlying stimulus–affect procedural learning.

Conclusions

In sum, significant progress has been made in identifying the neurobiological bases of procedural learning and memory. Specifically, extensive evidence implicates the dorsal striatum and basolateral amygdala in stimulus–response and stimulus–affect forms of procedural learning, respectively. Although this article focuses on findings from brain lesion and pharmacological studies, it is important to note that similar evidence for the selective roles of the dorsal striatum and amygdala in procedural learning is also provided by studies employing electrophysiological and molecular approaches in lower animals, including nonhuman primates. Furthermore, findings of human studies employing neuroimaging techniques, as well as neuropsychological investigations of various neurodegenerative diseases and psychopathologies, also indicate that the dissociable roles of the dorsal striatum and amygdala in procedural learning and memory generalize across mammalian species.

Multiple Memory Systems

Human long-term memory consists of multiple distinct types, which appear to rely on separable mechanisms that can be localized to distinct regions of the brain. Early evidence for multiple forms of long-term memory came from studies of patients with neurological damage to the medial temporal lobe (MTL) or related diencephalic structures. Such individuals suffer from a global amnesia characterized by the inability to remember new events or learn new facts (anterograde amnesia), as well as a loss of memory for events prior to the neurological insult (retrograde amnesia), without any deficits in attention, perception, language, or reasoning. This form of memory has been termed 'declarative' or 'explicit' in recognition of the fact that its contents are generally available to conscious awareness and require attention for learning. However, beginning in the late 1960s it became clear that many forms of learning were normal even in the face of dense amnesia. The term 'procedural' was applied to these spared forms of memory because they appeared to reflect changes in how a task was performed ('knowing how') without the necessity of conscious memory for how this learning occurred ('knowing that'). More recently, the term 'nondeclarative memory' has been proposed to cover a broader set of memory phenomena that are spared in amnesia.

Nondeclarative memory encompasses a number of heterogeneous mnemonic functions, one of which is procedural learning, a term that we will use to refer specifically to the acquisition of new skills or abilities which are general to a task domain. As opposed to declarative memory, the knowledge acquired through procedural learning is not necessarily available to conscious awareness, but is instead tied to the routines or procedures involved in task performance. Whereas declarative memory is generally tested through direct assessment about details of a specific episode, procedural learning is observed indirectly as facilitation of performance after training.

Types of Procedural Learning

In the following discussion, we divide procedural learning into the domains of motor, perceptual, and cognitive skills for the sake of organization. These distinctions mainly arise as a result of the tasks used to assess procedural learning. However, it should be recognized that these categories are primarily heuristic and may not necessarily reflect fundamental neurobiological distinctions.

Motor Skill Learning

Motor skill learning involves improvement in the speed and/or accuracy of motor movements with practice. Across the wide range of tasks that have been examined, motor skill learning has commonly been dissociated from declarative memory by showing that amnesic patients can learn the skills normally.

Sequence learning Motor sequence learning is perhaps the most studied motor skill task. In this paradigm, study participants respond manually to the spatial location of a visual stimulus. In implicit sequence-learning paradigms, the stimuli appear in a regular sequence during training, but the participant is not alerted to this regularity. With practice, participants respond more quickly to these sequences compared to randomly ordered stimuli. A substantial proportion of neurologically intact persons routinely report being unaware of the underlying sequence; although the role of awareness remains controversial, awareness of the sequence does not appear to be necessary for learning the skill. Amnesic patients can also show normal learning in this paradigm. In contrast, patients with basal ganglia damage exhibit specific deficits in motor sequence learning. Most neuroimaging studies of implicit motor sequence learning have observed striatal activity, consistent with a role for the striatum in sequence learning. In addition, imaging studies have reported activity in the supplementary motor area (SMA), which is likely involved in motor planning, and the parietal lobe, which appears to be involved in spatial aspects of the task (Figure 1).

Explicit learning of sequences has been examined using a procedure in which participants learn a sequence through trial and error. This type of learning engages regions similar to implicit learning as well as additional prefrontal regions. However, with extended practice, sequence performance becomes more automatic and relies less on prefrontal mechanisms.

With increasing practice, a shift in activity from anterior to posterior cortical and subcortical regions has been observed in several functional magnetic resonance imaging (fMRI) studies. Neurophysiological studies in monkeys have also observed such anterior–posterior shifts in the striatum. Anterior striatal regions are critical for processing feedback, whereas posterior regions appear to be related to performance

Figure 1 (a) Example of repeating sequence used in a serial reaction time (SRT) task. (b) Participants press a button corresponding to the spatial location of the onscreen asterisk. (c) Results from a fMRI study of SRT performance. Participants in this study were trained on an SRT task for three 1 h sessions (top row, brain images prior to the training session; bottom row, brain images after training). Copyright 2005 by the Society for Neuroscience.

of the learned skill *per se*. Findings regarding contributions of the cerebellum are currently mixed. Based on work with patients, neuroimaging studies, and neurophysiological studies, it has been suggested that the cerebellum may be important for the execution of well-learned motor sequence skills rather than the acquisition.

Rotary pursuit In rotary pursuit tasks the participant tracks a small target on a rotating platter with a stylus. The profile of impairment in patients is mixed, with intact performance in amnesics, impairment in Huntington's disease, and some evidence of deficits in Parkinson's disease (PD). According to neuroimaging studies the SMA and posterior parietal cortex are involved in learning; these regions are similar to those engaged in sequence-learning tasks. Striatum and cerebellum activity has been observed in relation to motor execution on a rotary pursuit task, but thus far increases or decreases related to learning have not been observed in these regions.

Mirror tracing Mirror tracing requires subjects to trace the outline of geometric figures while viewing the figures reflected in a mirror. Tracing becomes faster and less error prone with practice. Amnesic patients and PD patients exhibit normal learning on the task, whereas patients with cerebellar damage do not.

Motor adaptation Motor adaptation tasks generally involve adjusting motor behavior in response to an artificial perturbation. In prism adaptation tasks, participants, fitted with prism spectacles that displace the visual field, must learn to reach for objects. In another paradigm, they are required to move a cursor to a target while interacting with a manipulandum that applies a predictable force. They learn to adjust their movements to compensate for the displacement. The parietal cortex appears to be involved in learning in these paradigms, consistent with the importance of spatial translation for accurate behavior. Furthermore, the cerebellum may be important for the acquisition of these types of motor skills. Through the cerebellum's involvement in error correction for movements, specifically the ability to use execution error information to adapt internal models, it allows improvement on subsequent trials. The striatum also appears to play a role in processing errors online, but is perhaps more involved in adapting current behavior and movement goals without affecting adaptation of internal models (Figure 2).

Perceptual Skill Learning

Perceptual skills involve the development of new abilities to recognize or distinguish perceptual stimuli. We do not discuss perceptual learning for low-level perceptual features or expertise in object and face recognition, but limit our discussion to forms of perceptual skill that have been directly dissociated from declarative memory.

Mirror reading Mirror reading has been used extensively to test the acquisition of perceptual skills. Participants are exposed to spatially transformed (e.g., mirror-reversed) text. Amnesic patients show normal acquisition of mirror-reading skill without the ability to remember specific words. There is some evidence that the basal ganglia are important for learning the mirror-reading task, but the results are inconsistent. Neuroimaging studies have implicated both parietal regions and the striatum in mirror-reading skill learning.

Figure 2 (a) Experimental setup for a motor adaptation task. The manipulandum is a very low-friction, planar mechanism powered by two high-performance torque motors. The study participant grips the handle of the robot. The handle houses a force transducer. The video monitor facing the participant displays a cursor corresponding to the position of the handle. A target position is displayed, and the participant makes a reaching movement. With practice, the participant learns to compensate for the forces produced by the robot. (b) (i) Hand path of a typical participant in the null field (the points in all hand paths are 10 ms apart). (ii) An example of a force field produced by the robot. (iii) Hand path of an untrained participant in the field. (iv) Hand path after 300 movements in the field. The trajectory in the field converges to the trajectory observed in the null field. (v) Forces produced by a typical trained participant to counter the effect of the force field as a function of hand position for each movement. These forces are the projection of the forces measured at the interaction point between the participant and robot onto a direction perpendicular to the direction of target. (vi) While training in the field, random targets are presented with null field conditions. The results are aftereffects. Perceptual categorization In perceptual categorization tasks, participants must learn to categorize multidimensional visual stimuli (e.g., Gabor patches varying in spatial frequency and orientation; see Figure 3(a)). In so-called information integration categorization tasks, categories are delineated by a linear or nonlinear decision boundary involving multiple perceptual dimensions, and no simple verbal rule describes the category. Amnesics can learn perceptual categories even with difficult nonlinear decision bounds.

Figure 3 (a) Gabor patches used in perceptual categorization experiments. Spatial frequency and orientation vary from trial to trial. (b) Plot of stimuli that might be used in an information-integration category-learning task. Each plus symbol denotes the spatial frequency and orientation of an exemplar from category A and each circle denotes a category B exemplar. The diagonal line indicates the optimal decision bound, which requires integrating information about orientation and spatial frequency prior to making a decision. (c) Plot of stimuli that might be used in a rule-based category-learning task. The vertical line is the optimal category boundary, a rule that can easily be verbalized. (d) Examples of study items and test items used to assess classification learning of dot patterns. Study items were high distortions of a prototype dot pattern. The test items, illustrated left to right, were presentations of the training prototype, low and high distortions of the training prototype, and random dot patterns. Basal ganglia disorders consistently impair learning of categories with nonlinear bounds, with inconsistent deficits in learning of linear-bound categories.

Visual prototype learning In prototype learning, participants study a set of dot patterns (see Figure 3(b)), which are distortions of a prototype, without being told about the presence of a category. Participants are then required to decide for subsequent test items whether the items are from the same category as the study items. Amnesic patients are able to normally classify new distortions of the prototype-among distortions of different prototypes, but are significantly worse than neurologically intact controls at recognizing studied patterns. Patients with basal ganglia damage are not impaired at dot pattern classification. Imaging studies have suggested that this type of learning may rely upon early perceptual systems, as classifying new distortions of the learned prototype is associated with decreased activity in occipital cortex (BA 17/18) compared to distortions of unstudied prototypes. This seems specific to incidental learning, as classification of new category members after intentional learning is associated with increased activity in the MTL and prefrontal regions.

Cognitive Skill Learning

Cognitive skill learning involves the development of new task procedures or classification abilities, which are not closely tied to new perceptual or motor abilities.

Category learning Cognitive skills are often acquired through performance of tasks requiring classification of novel stimuli; whereas the examples discussed earlier involved development of new perceptual categories, the tasks discussed here are more abstract. In some tasks, participants simply learn by observing a number of category exemplars, whereas other tasks involve learning from feedback on a trial-by-trial basis.

Probabilistic classification learning In this commonly used paradigm, cues are probabilistically associated with categories. The most common cover story (the 'weather prediction task') is that participants must predict the weather based on a set of cards. Participants are shown individual cues or combinations of the cues and must predict the outcome (rain or sunshine) on each trial, based on feedback provided after each response; however, this feedback is probabilistic. The complexity of the task (as well as the probabilistic feedback) makes it difficult to simply memorize the cue-outcome association on each trial, and participants routinely report feeling unable to learn the task. However, they customarily attain around 70–80% optimal responses within less than 100 training trials. Amnesics are sometimes able to perform this task as well as normal controls do, but they have poorer memory for the details of the testing episode. In contrast, patients with basal ganglia damage are consistently impaired at probabilistic classification, but have intact memory for the testing episode. This deficit appears to be related to the need to process feedback, which relies upon dopaminergic prediction error signals. Neuroimaging data have confirmed the involvement of the basal ganglia in classification learning, while also suggesting that, sometimes, normal persons might rely upon the MTL to perform the task. Learning under dual-task conditions can reduce the reliance upon the MTL and drive study participants to rely on the basal ganglia to perform the task instead (Figure 4).

Artificial grammar learning In the artificial grammar paradigm, participants incidentally process letter strings produced using an underlying set of rules (usually a finite-state grammar). After a short delay participants are told that the items were produced according to a set of rules and they must classify a new set of items according to whether or not they follow the same rules. Amnesics show normal grammar learning on this task, yet have poor recognition for individual letter strings, whereas basal ganglia pathology does not appear to lead to impaired artificial grammar learning (AGL) performance. There are multiple forms of knowledge that can underlie learning in this task, including knowledge about specific features (such as chunks of letter strings) as well as more abstract rules for generating the strings. One fMRI study found activity in the caudate associated with rule knowledge and in the hippocampus in association with chunk knowledge. However, amnesics can acquire both of these forms of knowledge normally, suggesting that neither requires the MTL, even though it is active in imaging studies. Neuroimaging studies have found activation in prefrontal and occipital regions during classification of grammatical versus ungrammatical items, suggesting that those regions may be involved in expressing grammar knowledge in the task.

Tower puzzle tasks Procedural learning of a planning skill has been assessed in neurologically impaired populations by using several variations of a problem-solving task (e.g., Towers of Hanoi, London, and Toronto). The Tower puzzles involve three pegs and disks of varying size (or color). The goal is to move all of the disks from the right peg to the left peg, such that the disks end up in the same configuration as on the starting peg. Disks must be moved one at a time and a larger (or darker) disk may not be placed upon a smaller (or lighter) disk. This class of tasks has been used extensively to test cognitive procedural learning, and initial reports indicated that amnesics could solve this problem, whereas patients with basal ganglia damage were impaired. Follow-up studies in amnesics have not consistently confirmed intact learning on these tasks, whereas the deficits in patients with basal ganglia pathology have been largely confirmed. Imaging has shown increased activity in both basal ganglia and prefrontal regions as task complexity increases, suggesting that the involvement of those regions may be closely related to the planning demands of the task rather than learning *per se*.

Characteristics of Procedural Learning

The heterogeneity of behaviors that are supported by procedural learning mechanisms makes it difficult to formulate general principles regarding procedural learning. We focus herein on a number of general features of procedural learning, though there seem to be exceptions to each potential principle.

Automaticity

One general characteristic of procedural learning may be that skills can become automatic with extensive practice, where automaticity refers to the ability to perform a task without the need for executive control. Automaticity is often defined in terms of dual-task performance: if performance of a skill is insensitive to interference from a secondary task, then it is considered automatic. It has long been suggested that the

Figure 4 (a) Example of stimuli used in probabilistic classification tasks. One or more of the cards are presented on each trial and a prediction of sunny or rainy outcome is made. need for executive processes differs between early and late stages of learning. Many studies find that executive control is necessary for learning a skill, although in some domains it appears that executive control is not necessary at any point in learning. Other studies find that interference with executive control processes may affect only the performance, but not the acquisition of a skill. Whatever the role of executive control in early learning, it is clear that procedural learning leads to automaticity in a way that is qualitatively different from declarative memory.

Awareness

The role of awareness in procedural learning is perhaps the most controversial issue surrounding the concept of multiple memory systems. The first difficulty is that the term can refer either to the online awareness of what is being learned (e.g., the grammatical rules in the artificial grammar paradigm, or the particular sequence in the motor sequence-learning task) or to later declarative memory for what was learned. The ability of amnesics to learn skills in the absence of declarative memory for the learning event or insight into their newly acquired abilities provides strong evidence that at least some forms of skill are independent of later declarative memory. Disentangling the role of online awareness from procedural learning is more difficult, since any test for awareness during learning will potentially contaminate the person's strategy for performing the task. Imaging has proved useful in this domain, by showing that the neural basis of performance differs for skills that are learned with awareness versus those learned without awareness. Thus it appears that there are differences in the degree to which procedural learning requires online awareness of task contingencies, but this issue will remain controversial until there

is an adequate account of the functional role of awareness in learning.

Long-Term Retention

Although rates of retention in procedural learning have not been extensively investigated, in some cases procedural learning has been characterized by remarkably long-term retention. Studies of mirror tracing, mirror reading, and AGL have all reported skill retention in excess of 1 year, in amnesics as well as normal controls. Studies of motor sequence learning have reported retention after 1–2 weeks, though one study reported a failure to retain sequence knowledge at 1 year. Whereas forgetting of declarative memories is thought to occur primarily due to interference, this factor may be less relevant for procedural learning. Study participants are unlikely to have much experience outside of the laboratory with the kinds of tasks involved in procedural learning studies (e.g., categorizing dot patterns) and thus there may be less possibility for interference than for declarative memories. Some studies also suggest that procedural memories may become resistant to interference over time due to a consolidation process that requires some number of hours following learning. Interference has mainly been studied in the context of motor adaptation. Other skills (e.g., sequence learning) rely on different neural substrates and the representations may change differently over time.

Neural Bases of Procedural Learning

Much knowledge regarding the neural basis of procedural learning initially came from neuropsychological studies. Early studies of amnesic patients revealed that procedural learning does not require intact MTL structures. Studies in Parkinson's and Huntington's disease patients with damage to the basal ganglia, and other patients with damage to the cerebellum, have shown that both of these brain structures may be important substrates of procedural learning. Neuroimaging has provided additional evidence regarding the neural basis of procedural learning and has highlighted the fact that learning involves dynamic changes in brain activity with practice. There has sometimes been a lack of convergence between neuropsychological data and imaging data, which may reflect the fact that activation in neuroimaging does not indicate that a region is necessary for task performance. On the other hand, imaging studies in healthy populations have revealed that healthy individuals may approach tasks differently than damaged populations do because they have multiple representations or types of knowledge available. Here we outline the major brain structures known to be involved in procedural learning.

Striatum

The striatum appears to be the most widely involved brain structure in procedural learning, based on both lesion evidence and functional imaging results. One potential role for the striatum is in the acquisition of stimulus–response (S–R) associations, likely dependent upon dopamine-modulated synaptic plasticity at corticostriatal synapses. Tasks such as classification learning, which involve learning of responses to specific stimuli based on feedback, are impaired in patients with Huntington's disease (damaging striatal neurons) and PD (disrupting the dopaminergic system). Further, the impairment in PD on classification tasks appears to be specific to learning from feedback. Thus, the reinforcement learning mechanisms supported by the striatum may play an important role in procedural learning.

Feedback does not play a critical role in sequencing tasks, but the basal ganglia also appear to be important for developing unitized action sequences. Through repeated performance of a motor sequence, individual responses become chained into a single chunk or an action sequence. In this way common actions can be executed quicker and more reliably. For example, a forgotten telephone number or password might be successfully completed if one knows the first elements. A chunking mechanism might account for improved performance of motor sequences and perhaps also on Tower puzzles, where optimal performance requires multiple moves in a particular sequence. The best evidence for basal ganglia involvement in such a chunking mechanism comes from recordings from neurons in rodent striatum. During repeated performance of a task, the pattern of neural activity changed from activity occurring throughout the task procedure to activity occurring only at the onset and the offset of the task procedure. A more efficient representation of repeated behaviors could allow more automatic or habitlike performance.

The role of the striatum in procedural learning is increasingly being parsed into more specific functions and related to subregions within the striatum. For example, processing feedback in response to actions is consistently tied to the head of the caudate nucleus, whereas motor learning appears to rely upon the putamen. Separate parallel corticostriatal loops are tied to performance of tasks in various domains, but these loops also communicate throughout the striatum. Different tasks probably rely on the various functions of the basal ganglia to a different degree. Generally, it has been suggested that the basal ganglia may be critical in open-loop skill learning, where behavior is initiated by internally generated plans and subsequently received feedback guides future behavior.

Several neuroimaging studies have found that striatal activity during procedural learning is associated with decreased MTL activity. The meaning of this MTL decrease is not fully understood, but it has been suggested that regions involved in learning declarative knowledge and those involved in procedural learning may be in competition to control behavior. Interestingly, some studies of classification learning and sequence learning using neuroimaging in patients with striatal pathology have observed MTL activity during learning rather than the striatal activity found in normal controls. Thus, for some of these tasks it appears that other strategies may be available when procedural learning is compromised.

Cerebellum

In contrast to the striatum, the cerebellum has been proposed as critical in closed-loop skill learning, where continuous external feedback guides behavior (e.g., mirror tracing), or when novel mappings between motor behavior and visual cues are required (e.g., motor adaptation tasks). As such, a function of the cerebellum may also be thought of as processing feedback, but specifically monitoring and optimizing movements in response to online sensory feedback.

Cerebral Cortex

Several other regions are consistently associated with procedural learning. Whereas the necessity of cerebellum and basal ganglia structures has been studied in various patient populations, the involvement of other regions is generally observed using neuroimaging. Although imaging does not allow inference about necessity, imaging results have generally suggested that procedural learning involves changes in the same areas that are necessary for task performance. For example, the SMA, premotor areas, and primary motor cortex are involved in learning motor skills. Occipital lobe and temporal lobe visual regions are involved in visual perceptual tasks, such as prototype learning. Parietal regions are engaged when tasks require processing of spatial information. These results are consistent with the notion that procedural learning involves online changes in the neural networks involved in task performance. Additionally, prefrontal regions are generally involved during the early stages of learning, likely providing executive control over novice performance.

Conclusion

Although much is still to be learned about how procedural learning is acquired and develops with training, it is clear that humans have a remarkable capacity for acquiring a wide range of skills. These skills can sometimes be retained for years without continued practice and often generalize beyond the studied materials. Conscious memory for the learning event is not necessary, as numerous demonstrations of intact procedural learning by amnesics have shown. The striatum and cerebellum appear to play general roles in procedural learning and, depending on the task, various sensory–motor cortical regions might also be important. Future studies will be needed to further explore how activity changes with practice and better understand what these changes mean.

Introduction

Procedural learning is the acquisition of skills, or knowledge regarding how to perform tasks. In contrast, declarative learning is the acquisition of facts (what, where, and when knowledge). Procedural, or motor, learning was defined by Schmidt in 1988 as "a set of processes associated with practice or experience leading to relatively permanent changes in the capability for responding." Such learning can be either explicit, in which the learner is aware of the learning conditions and the goal to acquire the task, in addition to being able to describe the nature of the task, or implicit, in which learning occurs below the level of awareness of the learner. Under most natural settings, skill learning involves both explicit and implicit components. In the laboratory, however, the two can be isolated and studied independently. Although important debates related to these distinctions are ongoing, they will not be emphasized in this article because the cerebellum is not believed to be an important neural substrate.

Researchers who study skill learning tend to classify motor tasks into at least two categories: sequence learning and sensorimotor adaptation. When acquiring new sequences of action, the learner combines isolated elements of movement into a smooth, coherent action – for example, when a gymnast combines tumbling movements into a floor routine. Sensorimotor adaptation requires a remapping of sensory and motor representations due to either altered sensory input or motor output characteristics. One example is learning the relation between the display of cursor movements on a computer screen and hand–mouse movements. These two types of learning rely on distinct cognitive strategies and engage different neural circuitry. We focus on whether and how the cortico-cerebellar pathways contribute to sequence learning and sensorimotor adaptation. The literature shows that the role played by the cerebellum during procedural learning is task dependent.

Motor Performance versus Motor Learning: A Potential Confound

One potential confound that needs to be dealt with when studying the neural basis of skill acquisition is that the sensory and motor systems reflect motor performance levels, and performance changes as a function of learning. For example, it has been shown that neural activity in the sensorimotor system changes with muscle force, movement rate, movement size, movement duration, reaction time, and the extent of motor errors. These measures are typically altered as a function of practice, with movements becoming faster, more efficient, and more accurate with learning. Therefore, when comparing brain activity between early and late learning, it is difficult to disentangle whether changes in neural activation, particularly in the sensorimotor system, are a true reflection of the learning process or simply reflect the implementation of faster, more accurate movements.

Researchers studying skill learning have attempted to address this confound in one of two ways. The first is to build into the experiments controls for change in performance. For example, participants in experiments on skill learning can be asked to make movements under varying performance levels in the absence of learning. They may make movements at different rates in response to a pacing signal or under conditions of low and high difficulty. The level of error may be manipulated by requiring subjects to make movements to targets of different size; movements at a certain speed to smaller targets will have a larger error than those to large targets at the same speed. Brain activity can be recorded under these conditions and compared to the changes that occur during learning with similar performance changes to determine whether the patterns during learning reflect encoding of new movement representations or simply executing movements at differing performance levels. Another experimental approach is to interfere with changes in performance without affecting learning using manipulations such as dual tasking or varying the level of attention. The extent of learning is then assessed by retesting subjects without the interfering condition. Such manipulations can be used to limit the performance changes that typically occur during learning, allowing one to isolate the neural substrates associated with learning *per se*.

Studies on the role of the cerebellum in procedural learning are particularly susceptible to the performance/learning confound. This is because neural activity in the cerebellum may vary parametrically with changes in motor performance in the absence of learning. For example, cerebellar Purkinje cells in lobules IV–VI produce complex spikes both early and late in a movement. It is thought that the early complex spikes encode the absolute reach destination, or the distance between the start and end points of an

action. The later complex spikes have been interpreted as encoding the relative error at the end of a reaching movement. Understanding cerebellar sensitivity to motor error is important because errors systematically decrease during learning. Additionally, when participants make movements under conditions of high difficulty (aiming to small targets), functional magnetic resonance imaging (fMRI) activation is seen bilaterally in the medial cerebellum. Increasing cerebellar activity was found for slower movements and larger errors. Taken together, these data suggest that cerebellar activity would be high early in learning, when errors are being made, and would then decay as a function of practice, as is typically seen. However, it is not clear whether this pattern simply reflects the steady decrease in motor errors or, rather, indicates a role in encoding of new motor memories.

The cerebellum is also thought to play a role in short-duration (hundreds of milliseconds) motor timing, although there is continuing debate about this in the literature. Its role in timing may be task dependent. For example, the cerebellum seems to be important for the control of discontinuous movements (repetitive tapping on a table top). It has been suggested that such movements require the explicit representation of a temporal goal. Continuous movements, on the other hand, are those that do not have discrete events, such as repeatedly drawing circles. It has been proposed that timing is an emergent feature of movement specification in these tasks. Patients with unilateral cerebellar lesions have great difficulty in performing discontinuous motor tasks with the ipsilesional hand but not the contralesional one. In contrast, they have no difficulty with continuous movements. In addition, patients with damage to the cerebellum have difficulty with other behaviors that require precise timing, such as timing the opening of the hand when throwing a ball or in conditioning the eye-blink response to an auditory tone. Timing demands and temporal coordination may vary during the time course of learning, again complicating the interpretation of the contribution of the cerebellum to skill learning.

In summary, the cerebellar system codes for many variables of movement, including reaction time, motor error, movement speed, and timing. These representations have made it difficult to parse out the specific contributions of this system to procedural learning because performance varies along these dimensions as a function of motor practice.

Cerebellar Contribution to Sensorimotor Adaptation

Sensorimotor adaptation tasks are classified into two general categories: dynamic (or kinetic), in which subjects adapt to an altered motor environment such as a force field, and kinematic, in which subjects adapt movements to a mismatch in the visual and proprioceptive environments such as with the use of wedge prisms glasses that cause refractive displacement. It is thought that sensorimotor adaptation occurs through updating the internal model of the behavior. An internal model is used to predict the effects of a particular object or environment on the body and to calculate the motor output required to perform certain actions. Because the cerebellum appears to contribute to both forms of sensorimotor adaptation, much effort has been expended searching for reflections of internal models in this structure.

Some early positron emission tomography (PET) studies were unable to document activation of the cerebellum during prism adaptation after the motor error effects of performance had been accounted for. However, subsequent fMRI and PET studies of both kinematic and dynamic adaptation have repeatedly shown cerebellar activation associated with the acquisition, storage, and consolidation of new internal models, even after adjusting for performance effects such as detecting and correcting errors and varying movement speeds. Such activation is typically found in the lateral cerebellum in hemispheres V and VI, in the region surrounding the superior posterior fissure. In addition, patients with cerebellar damage do not show adaptive performance changes across trials when making pointing movements during force-field adaptation. The reason for the discrepancy between these recent studies and earlier studies remains unclear. A neural recording study in behaving monkeys also raises questions about the role of the cerebellum in updating internal models in response to a perturbing force field. Purkinje cell activity was recorded while monkeys made arm movements under viscous and elastic loads. There was no relation between the rate of simple spike discharge in Purkinje cells and the force conditions, as would be required for storage of the newly acquired internal model; rather, these neurons showed activity that was related to the kinematics of the arm movements.

Current efforts are focusing on determining the specific role of the cerebellar circuitry during adaptation. Its contribution appears to be in updating internal models from one trial to the next (predictive control), as opposed to performing on line (within a single trial) movement corrections. For example, in one experiment, cerebellar patients walked on a split-belt treadmill. When the two belts were driven at different speeds, the patients showed reactive changes to their locomotor pattern within a few strides of the perturbation. In contrast, they could not make predictive changes over time and did not adapt to the perturbation in the same manner as healthy control

participants. A similar finding has been observed for cerebellar patients in terms of anticipatory postural adjustments (APAs). Typically, when a person holds an object in his or her hand and it is removed by another person, the hand moves upward. This occurs because the person holding the object was not able to plan in advance for the other's actions. In contrast, when the object is removed by the holder's other hand, the hand remains stable because of an APA that compensates for the lifting action. Patients with cerebellar damage do show such APAs during the bimanual manipulation of objects. However, they cannot learn to modify and properly time APAs in response to predictable lifting of an object from their hand by an external agent (robotic device), whereas healthy control participants can do so.

Interestingly, the basal ganglia thalamocortical pathways appear to play a role in error correction that is complementary to that of the cerebellum. Patients with Huntington's disease, a basal ganglia pathology, are able to adapt arm movements to an opposing force field. They show adaptive modifications to their performance from one trial to the next. However, they are not able to show corrective adjustments for motor errors within a single trial in the manner in which cerebellar patients do.

Another form of sensorimotor adaptation that appears to be an important function of the cerebellum is updating of the vestibulo-ocular reflex (VOR). This response allows one to maintain eye gaze on a target during head movement. Head motions, detected by the vestibular system, are canceled out via reflexive, compensatory eye movements. The gain of this response (ratio of head velocity to eye velocity) can be altered by having experimental participants wear minifying or magnifying visual lenses during combined eye and head movements. Animals are unable to acquire new VOR gains after removal of the cerebellum, and human patients with cerebellar damage exhibit similar deficits. Studies have shown that floccular Purkinje cell complex spikes change their sensitivities to head velocity, eye position, and eye velocity during the course of VOR adaptation, providing the necessary substrate for VOR adaptation.

In summary, with the exception of the very special case of the VOR, the exact contribution of the cerebellum to sensorimotor adaptation remains unclear. The focus of future work will be on determining the extent to which internal models are reflected in the activity of the cerebellum.

Cerebellar Contributions to Sequence Learning

A large number of studies have also implicated the cerebellum in learning new sequences of action, although there is evidence to the contrary. The most commonly used sequence learning paradigm for investigating cerebellar contributions is the serial reaction time (SRT) task. In this task, subjects make manual button presses in response to stimuli presented on a computer screen. For explicit SRT learning, participants are told about the existence of the sequence ahead of time and encouraged to use explicit search strategies. For implicit SRT learning, participants are not informed about the presence of the sequence, and it is typically embedded among randomly presented stimuli in an effort to prevent participants from gaining explicit awareness. Patients with cerebellar damage exhibit impaired implicit SRT sequence learning, and neuroimaging investigations of this task have found cerebellar activation occurring during the course of sequence encoding. It has been hypothesized that the cerebellum contributes to sequence learning through facilitating the increase in sensorimotor coordination and temporal precision occurring with practice. Interestingly, work with patients with cerebellar damage and repetitive transcranial magnetic stimulation experiments that inhibit cerebellar function have shown that the right cerebellum is associated with SRT sequence learning regardless of the hand used for performance. One interpretation of this finding is that the right cerebellum interfaces with the parietal and motor regions of the left hemisphere, which have been shown to play a dominant role in motor control and sequence learning for both hands.

Evidence against cerebellar contributions to sequence learning derives from an experiment in which the performance changes that typically occur during the time course of learning were suppressed. Participants performed a secondary, distractor task simultaneously with the SRT sequence learning task. This secondary task served to keep response time and accuracy constant, even though participants were continuing to practice the sequence. This secondary task did not impact sequence encoding, however, because once it was removed, participants showed immediate expression of learning, the magnitude of which was comparable to that seen during single-task SRT studies. In this fMRI study, cerebellar activity was not observed during the sequence learning process in the absence of performance changes; rather, cerebellar activation in the lateral hemispheres (V/VI) was correlated with the response time and error savings observed at expression of learning. These data raise the possibility that cerebellar contributions to sequence learning reported in other studies may be a reflection of changing performance during the time course of learning rather than making a specific contribution to the encoding processes *per se*.

Because of the clear involvement of the cerebellum in timing discussed previously, it may indeed contribute to sequence learning tasks that have a specific temporal component. A PET study that involved both spatial and temporal sequencing components showed early learning activation in the lateral cerebellar hemispheres. This activity was positively correlated with activation in the right dentate nucleus and the left primary motor cortex. As learning progressed, cerebral blood flow in the dentate decreased and the primary motor cortex showed corresponding increases, possibly reflecting storage and consolidation of temporal sequence representations. Additionally, in a manual tracking study, patients with cerebellar damage showed improvements in spatial tracking accuracy with practice that paralleled changes shown by healthy controls. The patients showed no difference in temporal precision, however, between tracking a random and repeating target pattern following 3 days of task practice. Combined, these data imply that although the cerebellar circuitry may support sequence learning that has temporal requirements, it does not appear to play a role in spatial sequence learning.

Procedural Learning: Classical Conditioning

Introduction

Why Classical Conditioning Is a Form of Procedural Memory

Memory is composed of various abilities that depend on different brain systems. Declarative memory provides the capacity for conscious recollection of facts and events. Procedural memory is a type of nondeclarative memory in that it is not accessible to conscious recollection (i.e., it cannot be brought to mind and declared). Rather, procedural memory is expressed through performance. Classical conditioning is a type of procedural memory because learning and memory are indexed by the expression/generation of learned response. Under most circumstances (but not all, see below), declarative knowledge is superfluous to the expression of the classically conditioned response (CR). Accordingly, this form of conditioning is considered a quintessential form of procedural learning and memory.

Classical conditioning is a basic form of associative learning where the organism learns something about the causal fabric of the environment. Stimuli can be arranged so that one stimulus provides the organism with information concerning the occurrence of another stimulus. This type of associative learning is most commonly referred to as classical conditioning, but has also been commonly referred to as Pavlovian conditioning. In the most basic form of classical conditioning, the stimulus that predicts the occurrence of another stimulus is termed the conditioned stimulus (CS). The predicted stimulus is termed the unconditioned stimulus (US). The CS is a relatively neutral stimulus that can be detected by the organism, but does not initially induce a reliable behavioral response. The US is a stimulus that can reliably induce a measurable response from the first presentation. The response that is elicited by the presentation of the US is termed the unconditioned response (UR). The term 'unconditioned' is used to indicate that the response is 'not learned,' but rather it is an innate or reflexive response to the US. With repeated presentations of the CS followed by US (referred to as paired training) the CS begins to elicit a CR. Here the term 'conditioned' is used to indicate that the response is 'learned.'

The Distinction between Classical and Instrumental/Operant Conditioning

In classical conditioning, no contingency exists between the CR and the presentation or omission of the US. In other words, it does not matter if a CR is made or not made; the presentation of the US still occurs and is experienced and processed by the subject. This has been termed stimulus-contingent reinforcement or the 'law of contiguity.' In instrumental or operant conditioning, by contrast, a contingent relationship is arranged between the subject's response and the presentation or nonpresentation of a reinforcer. In other words, this form of conditioning involves response-contingent reinforcement or the 'law of effect.'

Origin of the Term 'Classical Conditioning'

Before the 1940s, the process of classical conditioning was referred to most often as the conditioned reflex, Pavlovian conditioning, or simply as conditioning. However, in the 1930s, scientists began to understand that the laws governing learning, in paradigms where reinforcement was contingent upon the organism's behavior appeared to be fundamentally different from the laws governing the conditioned reflex. The latter type of learning would come be known as instrumental or operant conditioning. This created a need to distinguish different forms of conditioning. It appears that the term classical conditioning developed as a contraction of the descriptive phase 'classical Pavlovian conditioning' which was used to denote the 'well-known' (i.e., classical) type of conditioning used by Pavlov (i.e., Pavlovian).

Different Types of Classical Conditioning based on the Measured Response

Different types of classical conditioning can be characterized by the measured response. Here we focus on two different types of classical conditioning paradigms. First we describe classical conditioning of the emotional response of fear. In the case of fear conditioning the CR to the CS involves a relatively broad change in emotional state. Next we describe classical conditioning of the eyeblink response that is an example of an aversively conditioned somatic motor response. The response is a highly specific motor movement that becomes adaptively timed to the presentation of the US.

Fear Conditioning

Fear in most cases represents the perception and recognition of danger, the learning and remembering of a dangerous experience, and the coordination of defensive behaviors to an environmental threat.

In the laboratory (as with rats) fear typically refers to emotional responses learned with an aversive stimulus. Presentation of an unpleasant stimulus like an electric shock typically elicits a variety of behaviors that are used to infer a central state of fear (Figure 1). After several pairings (or even one) of a several-second tone or light, terminating with a paw-shock, the CS now elicits behaviors initially elicited by the shock US (Figure 1), the CR. The expression of conditioned fear in the rat involves the synchronization of defensive reactions which include autonomic increases in blood pressure, respiration and heart rate, neuroendocrine glucocorticoid release, behavioral immobilization or freezing, and potentiated startle (Table 1). Interestingly, as will be discussed later in more detail, reexposure to the original training context alone is sufficient to trigger conditioned fear.

Brain Substrates of Fear Conditioning

Work in a number of laboratories using lesions, pharmacological and electrophysiological techniques, demonstrates that the amygdala is essential for the acquisition, storage, and expression of conditioned fear.

Anatomical evidence reveals that both CS and US afferents converge on the amygdala. Lesions of the amygdala prevent the acquisition of conditioned fear to all CS modalities (tone, light, and odor). Lesions limited to medial geniculate nucleus, an afferent of

Figure 1 General scheme believed to occur during classical conditioning with an aversive CS. During training, the aversive stimulus (e.g., shock) activates a central fear system that produces a constellation of behaviors generally associated with aversive stimuli (URs). After consistent pairings of some neutral stimulus such as light or tone or puff of air with shock during the training phase, the neutral stimulus is capable of producing a similar fear state and hence the same set of behaviors (conditioned reponses), formerly only produced by the shock. Reproduced from Davis M (1992) The role of amygdala in fear and anxiety. *Annual review of Neuroscience* 15: 353–375.

Table 1 Comparison of measures in animals typically used to index fear and those in the DSM-III manual to index generalized anxiety in people

Measures of fear in animal models	*DSM-III criteria – generalized anxiety*
Increased heart rate	Heart pounding
Decreased salivation	Dry mouth
Stomach ulcers	Upset stomach
Respiration change	Increased respiration
Scanning and vigilance	Scanning and vegilance
Increased startle	Jumpiness, easy startle
Urination	Frequent urination
Defecation	Diarrhea
Grooming	Fidgeting
Freezing	Apprehensive expectation – something bad is going to happen

Reproduced from Davis M (1992) the role of amygdala in fear and anxiety. *Annual review of Neuroscience* 15: 353–375.

the amygdala, block the acquisition of conditioned fear to a tone, but leave conditioning to light intact, suggesting that the amygdala is not part of the sensory pathway in the formation of a memory trace. Furthermore, in untrained animals, amygdala-specific infusions of the *N*-methyl-D-aspartate (NMDA) receptor antagonist AP5 prevent the acquisition of conditioned fear, whereas similar infusions in a well-trained animal show little effect. Alternatively, appropriate lesions of the amygdala in the well-trained animal completely and permanently abolish the expression of all forms of conditioned fear (freezing, tachycardia, changes in respiration and blood pressure). These studies (and others) strongly suggest that memory traces for conditioned fear are established and maintained in the amygdala.

Anatomically, the amygdala is a rather complex system containing several nuclei. In brief, auditory information projects from the medial geniculate nucleus of the thalamus to the dorsal portion of the lateral amygdala (LA), which projects to the basolateral amygdala and on to the major efferent nucleus, the central nucleus of the amygdala (see Figure 2). More complex stimuli, for example, about environmental cues, reach the amygdala via the hippocampus and entorhinal cortex.

As indicated in Figure 2, there are two other aspects to fear conditioning in addition to simple pairing of tone and shock, termed delay conditioning. Animals (and people) develop conditioned fear to the environment (context) where they experience strongly aversive events. Contextual fear conditioning procedures typically involve placing a rat in a novel training box for fixed period of time, then delivering a series of spaced footshocks. The following day the rat is returned to the original context (without shocks) and the total amount of time the rat freezes is recorded as an index of contextual fear conditioning. Lesions of the amygdala abolish all forms of conditioned fear including fear classical conditioning to context. However, unlike delay conditioned fear, lesions of the hippocampus prevent the acquisition and expression of contextual fear conditioning. Lesions of the hippocampus made 1 day after conditioning completely abolished conditioned fear to context, whereas lesions made 28 days later had no effect on this conditioned fear.

Still another form of fear conditioning involves the trace procedure, where a tone is separated for several seconds from the presentation of an aversive footshock. Appropriate lesions of the hippocampus prevent the acquisition of trace-conditioned fear as well.

A Few Caveats

There is an interesting apparent discrepancy between effect of amygdalar lesions in classically conditioned

Figure 2 The basic circuit for fear conditioning organized according to various types of conditional stimuli at the top and conditional fear responses at the bottom. LA refers to the lateral nucleus of the amygdala and BLA refers to the basolateral nucleus of the amygdala. The BLA and the LA are parts of the frontotemporal amygdala and comprise the neuroanatomical hub for learned fear. Reproduced from Fanselow MS and Poulos AM (2005) The neuroscience of mammalian associative learning. *Annual Review of Psychology* 56: 207–234.

fear and instrumental learning of fear. In the instrumental situation (e.g., passive avoidance), on day 1 the rat is placed in a lighted compartment and runs into a dark compartment, where it receives a footshock. When placed in the lighted compartment the next day, the animal typically waits a very long time before entering the dark compartment. Amygdala lesions immediately after training abolish this learning but if done a week after training, do not. When animals are given classically conditioned fear training and tested 16 months later they still showed robust conditioned freezing. Subsequent amygdala lesions dramatically impaired the 16-month-old fear memory. Interestingly, animals with amygdala lesions that completely abolished previously trained conditioned fear (freezing) are able to reacquire normal conditioned fear with additional training. Thus, brain structures other than the amygdala, as yet unknown, would seem to become engaged if the amygdala is no longer available.

Classical Conditioning of the Eyeblink Response

Eyeblink conditioning is the most widely studied form of procedural learning in mammals. In standard delay conditioning, a tone or a light CS precedes and coterminates with a reflex-eliciting US such as periorbital shock or a puff of air to the cornea. In trace conditioning, a period of no stimulation separates CS offset from US onset. Extensive investigation into the neural substrates of this associative memory has resulted in perhaps the most complete description of mammalian memory formation to date.

Brain Substrates of Eyeblink Conditioning

Electrophysiological recordings of neural activity in eyeblink conditioning indicate that a number of brain areas and systems become engaged, most prominently motor nuclei, the hippocampus, and the cerebellum. In all these systems neuronal activity in the CS period increases over the course of learning and precedes the onset of the behavioral CR within trials. Indeed, this increased pattern of action potential discharges in the hippocampus and cerebellum predicts the occurrence and the actual temporal form of the CR (but not the reflex response). In standard delay conditioning when the CS and the US overlap, the cerebellar system is critical but the hippocampal system is not. However, in trace conditioning both the cerebellar and hippocampal systems are critical. Within the cerebellar system, the following regions developed the predictive neuronal response: relevant motor nuclei, a region of the fifth nucleus, various reticular brain stem regions, the cerebellar cortex, the cerebellar interpositus nucleus, the pontine nuclei, and the red nucleus.

The Cerebellar System

Lesions A series of studies have been able to identify a nuclear region in the anterior lateral interpositus nucleus ipsilateral to the trained eye that is essential to the acquisition and retention of the CR. Very large lesions of the cerebellar cortex that did not damage the interpositus nucleus did not abolish the behavioral CR, although CR latency was altered such that the eye closed and opened before the onset of the US – the timing of the behavioral response was no longer adaptive.

In these initial studies it was shown that the interpositus lesion effect was ipsilateral – it abolished the eyeblink CR on the side of the lesion but did not impair eyeblink conditioning of the contralateral eye, providing a control for possible nonspecific or state variables. Furthermore, if the lesion is made before training, learning is completely prevented. These lesions had no effects at all on performance of the UR. Importantly, lesions of the interpositus 1 month after training completely abolish the eyeblink CR – the interpositus is the site of long-term storage of memory.

It is important to emphasize that the cerebellar interpositus nucleus is essential for the learning of all discrete movements trained with an aversive US: eyeblink, limb flexion, head turn, etc. To the extent tested, the memory traces for all those learned movements are stored in the interpositus nucleus in separate loci.

The Pathways

A large literature is in general agreement in identifying the essential circuitry for classical conditioning of eyeblink and other discrete responses (see **Figure 3**). This circuitry follows closely the well-established anatomy of the cerebellar system and is in general accord with classical theories of cerebellar learning.

The UR pathway The eyeblink reflex is a coordinated response involving simultaneous and perfectly correlated external eyelid closure, eyeball retraction, and resulting passive extension of the nictitating membrane, as noted above. In terms of the reflex pathways, there are direct projections from neurons in regions of the trigeminal nucleus to eyeblink motor nuclei.

The CR pathway Neurons in a localized region of the interpositus nucleus ipsilateral to the trained eye develop a neuronal model of the learned behavioral

Figure 3 Simplified schematic (most interneurons omitted) of the putative essential circuitry for delay classical conditioning of eyeblink (and other discrete responses) learned with an aversive US. (The sensory and motor nuclei activated depend of course on the nature of the CS and US – the more central portions of the circuit appear to be general.) The reflex US–UR pathway involves direct and indirect projection from the trigeminal nucleus (NV) to the motor nuclei (for the eyeblink UR and CR, primarily accessory 6 and 7). The tone CS pathway projects from auditory nuclei to the pontine nuclei and to the cerebellum as mossy fibers. The US pathway includes projections from the trigeminal to the inferior olive (IO) and to the cerebellum as climbing fibers. The CR pathway projects from the interpositus to the red nucleus and on to premotor and motor nuclei. There is also a direct GABAergic inhibitory projection from the interpositus to the IO. Omitted from this diagram are feedback projections from the cerebellum to several afferent structures. These projections have generally been described physiologically, not anatomically, and may well be involved in some aspect of CR modulation. See text for discussion. Solid cell bodies and bar terminals indicate inhibitory neurons, open cell bodies and fork terminals indicate excitatory neurons. Stars indicate sites of plasticity based on current evidence. See text for details. Reproduced from Thompson RF (1986) The neurobiology of learning and memory. *Science* 233: 941–947.

CR; lesions of this region selectively abolish the CR with no effect in the UR; electrical stimulation of this region evokes the eyeblink response before training (as noted above). This region of the interpositus projects via the superior cerebellar peduncle (SCP) to a region of the contralateral magnocellular red nucleus. Lesions of the peduncle abolish the CR, as do lesions of the red nucleus, where neurons also show a model of the learned response. Stimulation of the red nucleus also elicits the eyeblink response. The descending rubral pathways project contralaterally to premotor and motor nuclei for external eyelid closure. Overwhelming evidence identifies this circuit as the efferent CR pathway for the conditioned eyeblink response.

The CS pathway The pontine nuclei send axons as mossy fibers directly to the cerebellar cortex and interpositus nucleus, mostly contralaterally. The pontine nuclei in turn receive projections from auditory, visual, somatosensory, and association systems, both cortical and subcortical. Appropriate lesions of the pontine nuclei can abolish the CR established to a tone CS but not a light CS, that is, can be selective for CS modality (interpositus lesions abolish the CR to all modalities of CS). Extensive lesions of the middle cerebellar peduncle (MCP), which conveys mossy fibers from the pontine nuclei and other sources to the cerebellum, abolish the CR to all modalities of CS. Electrical stimulation of the pontine nuclei serves as a 'supernormal' CS, yielding more rapid learning than does a tone or light CS and stimulation of the MCP itself is an effective CS.

The US pathway Neurons in the inferior olive (IO) send climbing fiber projections contralaterally directly to cerebellar cortex and interpositus nucleus. The critical region of the IO for eyeblink conditioning is the dorsal accessory olive (DAO), which receives predominantly somatosensory input relayed from the spinal cord and appropriate cranial nuclei. Lesions of the critical region of the IO, the face representation

in the DAO, completely prevent learning if made before training and result in extinction of the CR if made after training. Neurons in this critical DAO region respond only to US onset, show no learning-related activity, and the US-evoked response decreases as animals learn. Electrical microstimulation of this region serves as a very effective US. All these data argue that the DAO-climbing fibers system is the essential US reinforcing pathway for the learning of discrete responses but the DAO is not the locus of the memory trace.

The interpositus nucleus sends direct GABAergic projections to the DAO. Hence, as learning-induced increases in interpositus neuron activity develop, inhibition of the DAO neurons will increase. This accounts for the fact that US-evoked activity in the DAO decreases as learning develops. This also appears to serve as a part of the neural circuit essential for the behavioral learning phenomenon of 'blocking,' where prior training to one CS, for example, tone, prevents subsequent learning to a light CS when it is then presented together with the tone in paired compound stimulus training. Infusion of picrotoxin in the DAO to block the γ-aminobutyric acid (GABA) inhibition from the interpositus during compound stimulus training completely blocks the development of behavioral blocking.

Conjoint activation of CS and US pathways If the above hypotheses concerning the identities of the CS and US pathways are correct, it should be possible to train behavioral CRs by conjoint stimulation of these pathways. Stimulation of the pontine nuclei – mossy fibers as a CS (below movement threshold) and DAO-climbing fibers as a US yielded normal learning of the response provoked by the US. The US-elicited movements included eyeblink, head turn, and limb flexion. These movements were learned to the mossy fiber stimulation CS, just as was the case for peripheral CSs.

Reversible inactivation Although the evidence cited above is consistent with the interpositus nucleus being the locus of the conditioned eyeblink memory trace, it does not prove this hypothesis. Predictive neuronal models of the CR develop in the interpositus nucleus, the red nucleus, and the motor nuclei, as noted. Further, lesions of the interpositus, of the SCP (conveying all the output from the interpositus), and of the red nucleus, all abolish the CR with no effect on the UR. Lesions of the motor nuclei of course abolish both the CR and the UR. The technique of reversible inactivation was used to determine where within the circuit the memory trace was formed and stored.

Several parts of the cerebellar circuit, illustrated in Figure 4, have been reversibly inactivated for the duration of training (eyeblink conditioning) in 'naïve' animals using muscimol or cooling for neuron somas and tetrodotoxin. In brief, inactivation of the SCP, the

See text for details. Modified from Thompson RF (2005) In search of memory traces. *Annual Review of Psychology* 56: 1–23.

red nucleus, and the motor nuclei prevent expression of the CR but do not prevent learning at all. In contrast, inactivation of the anterior interpositus nucleus not only prevents expression of the CR but also completely prevents learning. Collectively, these data strongly support the hypothesis that the memory trace is formed and stored in the interpositus nucleus.

Mechanisms of memory storage in the interpositus Extremely important direct evidence for a strengthening of the mossy fiber – interpositus neuron synapses – has been demonstrated using eyeblink conditioning in the rat. Thus, highly significant increase in the number of excitatory synapses in the interpositus nucleus was found following eyeblink conditioning with no change in inhibitory synapses. Further, infusion of GABA antagonists during training completely prevents learning. Infusion of AP5 (which blocks the NMDA receptor) into the interpositus markedly impaired acquisition, but not retention of the eyeblink CR. Finally, infusion of protein synthesis inhibitors (both transcription and translation) into the region of the interpositus nucleus impaired acquisition of the eyeblink CR but had no effect on expression of the CR. Thus, protein synthesis in the interpositus nucleus is necessary for learning of the eyeblink CR, but not for its expression once learned. All these results argue for the formation of neuronal/synaptic plasticity, a 'memory trace,' in the interpositus itself.

In sum, the evidence is now very strong from behavioral, physiological, pharmacological, anatomical, and reversible inactivation studies that the basic associative memory trace in eyeblink conditioning is established and maintained in the interpositus nucleus.

Cerebellar cortex It is clear that the cerebellar cortex plays a very important role in normal learning – animals with large cortical lesions learn more slowly than normal and not as well. Indeed, animals with no functional cerebellar cortex (Purkinje cell degeneration mutant mice) do learn, albeit more poorly than normal. A clear result of cortical damage is altered timing of the CR. In normal animals, the CR peaks at the time of onset of the UR; it is maximally adaptive. After cortical lesions, the CR typically peaks prior to US onset and is not adaptive.

Eyeblink Conditioning and the Hippocampus

In eyeblink conditioning, neuronal unit cluster recordings in hippocampal fields increase in discharge frequency during training trials very rapidly, shift forward in time as learning develops, and form a predictive 'temporal model' of the learned behavioral response, both within trials and over the trials of training. To summarize a large body of research, the growth of the hippocampal unit response is, under normal conditions, an invariable and strongly predictive concomitant of subsequent behavioral learning. This increase in neuronal activity in the hippocampus becomes significant by the second or third trial of training, long before behavioral signs of learning develop, as would be expected of a declarative memory system. This initial hippocampal unit increase is in the US period; increases in the CS period appear at about the time point in training when behavioral CRs appear. With continued training, the neuronal model eventually declines and the hippocampus appears to disengage.

Brain Substrates Trace Eyeblink Conditioning

Trace conditioning was first described by Pavlov; the CS terminates and there is a period of no stimulation between CS offset and US onset (as Pavlov stressed, the organism must maintain a 'trace' of the CS in the brain in order for the CS and the US to become associated). As noted above, the acquisition and retention of delay eyeblink conditioning require the cerebellum and associated brain stem structures. No forebrain structures, including the hippocampus, are required. Thus, decerebrate rabbits with no remaining forebrain tissue (removal of cerebral cortex, basal ganglia, limbic system, thalamus, and hypothalamus) exhibited normal retention of delay eyeblink conditioning. Findings in humans are consistent with the animal work. Thus, delay eyeblink conditioning was impaired in patients with cerebellar or brain stem lesions, but was intact in amnesic patients with damage that includes the hippocampus.

Successful trace eyeblink conditioning, like delay conditioning, requires the cerebellum. However, trace conditioning differs from delay conditioning in that it also requires the hippocampus and portions of neocortex. Thus, acquisition and retention of trace conditioning were severely disrupted in rabbits and rats when the hippocampus was damaged and trace conditioning in rabbits was disrupted by damage to prefrontal cortex. Again, findings in humans are consistent. In amnesic patients with damage that includes the hippocampus, trace eyeblink conditioning was mildly impaired with a trace interval of 500 ms, and severely impaired with a trace interval of 1000 ms. Another distinctive feature of trace conditioning is that the importance of the hippocampus is time-limited. When hippocampal lesions were made in rabbits 1 day after acquisition, trace

conditioning was abolished, but lesions made 30 days after acquisition had no effect. Thus, trace conditioning exhibits two important characteristics of declarative memory. First, trace conditioning requires the hippocampus. Second, in trace conditioning, as in other forms of declarative memory, the hippocampus has a time-limited role.

Awareness, Expectancy, and Human Eyeblink Conditioning

The difference between delay and trace eyeblink conditioning has recently come into sharper focus by studies that have explored the importance of awareness. Declarative memory typically includes knowledge (or awareness) about what has been learned. In contrast, nondeclarative memory does not require awareness of any memory content, and when awareness is present it appears to be unrelated to task performance. With respect to eyeblink conditioning, the questions of interest are: when conditioning occurs, do individuals become aware of the relationship between the CS and US, namely, that the CS precedes and predicts the US? Is awareness of the stimulus contingencies necessary for successful conditioning to occur? Does the importance of awareness differ for delay and trace conditioning?

Awareness and Eyeblink Conditioning

When participants were given trace conditioning while watching a silent movie or while performing an attention-demanding digit-monitoring task the participants who watched the movie emitted more CRs, and performed better on a seven-item postconditioning questionnaire that assessed awareness, than did participants who were distracted by the digit-monitoring task. Other participants watched the silent movie during conditioning and took the seven-item questionnaire after the first 10 conditioning trials, again after 60 trials, and finally after all 120 trials were completed. Those who became aware of the CS–US relationship early in the session (after 10 trials) conditioned to a greater extent than those who became aware of the relationship later in the session or who never became aware at all. Further, performance on the questionnaire after the first 10 conditioning trials predicted the magnitude of trace conditioning over the entire 120-trial conditioning session.

In contrast to these findings for trace conditioning, awareness was unrelated to delay conditioning. Thus, participants who became aware of the stimulus contingencies early in the conditioning session conditioned no better than participants who became aware later in the session or did not become aware. Further, there was no relationship between awareness scores obtained early in conditioning and the magnitude of conditioning across the 120-trial conditioning session.

Expectancy of the US and Delay and Trace Conditioning

Individuals who develop awareness of the stimulus contingencies may be successful at trace conditioning because they have acquired a representation that allows them to expect the US when the CS is presented. During the course of conditioning, expectation of the US can be changed in predictable ways by capitalizing on a phenomenon known as 'the gambler's fallacy.' Using this method, expectancy of the US increases during strings of CS-alone trials and decreases during strings of CS + US trials. Accordingly, before each trial, participants are asked to rate how much they 'expect' the US (airpuff) to appear on the next trial.

In one study the performance of participants given delay conditioning was compared with the performance of those given trace conditioning. For both groups, expectancy of the US varied in accordance with the gambler's fallacy. For delay conditioning, the probability of a CR was related not to expectancy but to the associative strength of the CS and US. The results for trace conditioning were opposite. The probability of a CR was positively related to expectancy of the airpuff US. That is, CR probability was high when expectancy of the US was high and low when expectancy of the US was low. These findings show that expectation of the US has a different role in trace conditioning than it does in delay conditioning and support the idea that trace conditioning and delay conditioning are fundamentally different in their dependence on higher-order cognitive processes like awareness.

Summary and Conclusions

The findings outlined above can be understood in terms of the declarative and nondeclarative memory systems that support eyeblink classical conditioning. In both delay and trace conditioning paradigms, individuals sometimes develop declarative (conscious) knowledge about the stimulus contingencies and sometimes do not. For the most commonly studied forms of delay conditioning, declarative knowledge is superfluous to the acquisition of the CR, and cerebellar and brain stem circuits can support performance. Trace conditioning is fundamentally different. Trace conditioning resembles delay conditioning in that it also depends on the cerebellum, but trace conditioning is additionally dependent on the hippocampus

and neocortex. Further, unlike delay conditioning, trace conditioning is strongly related to the acquisition of declarative knowledge (awareness) of the CS–US contingencies and to the degree to which the US is expected.

For both trace and delay conditioning the cerebellum is responsible for the acquisition, storage, and generation of the CR. Trace conditioning may additionally require declarative knowledge because the trace interval makes it difficult for the cerebellum to process the CS and the US and form a motor memory. In trace conditioning, because the US follows the CS by as much as 1000 ms the cerebellum may not be able to maintain a representation of the CS across the trace interval. If, however, the hippocampus and neocortex have represented the stimulus contingencies, then perhaps processed information about the CS can be transmitted to the cerebellum at a time during each trial that is optimal for cerebellar plasticity (immediately before and during the US). Thus, an interesting possibility is that in trace conditioning, the cerebellum receives reformatted information, such that CS and US information arrive at the cerebellum in the temporally overlapping fashion that the cerebellum can use. By this view, awareness of the contingencies, while not directly driving the acquisition of the CR by the cerebellum, serves as an indicator that the hippocampus and related structures are effectively engaged by the task and working with the cerebellum so that the trace-conditioned response can be acquired.

Introduction

Following a century of debate over the rules governing learning and memory, it is now broadly accepted that there are distinctly different kinds of learning, reflecting the operation of multiple memory systems in the brain. In part, this reflects the fact that experience-dependent plasticity is widespread (if not ubiquitous) in the mammalian central nervous system. Beyond this, it is clear that we place on memory a variety of demands, which require different, even conflicting aspects of our experience to be stored. For example, for some purposes, it is important to remember what happened on a particular, unique occasion (e.g., where did I park my car this morning?), but for other purposes, we wish to generalize across different episodes of experience (e.g., which parking area is most likely to have free spots?). Just as the brain uses different visual pathways for processing object identification versus object location, it seems to use distinct brain circuits to preserve or discard different features of our ongoing actions and experiences. The overall function of neural circuits that involve the striatum seems to be to resolve competition between different possible choices (decision making) on the basis of how well they have worked in the past. Choices that lead to desirable outcomes, especially if they are unexpected, provoke plasticity within the striatum, which increases the likelihood that these choices will be selected again. This core algorithm is termed reinforcement learning.

The term procedural (or implicit) learning is defined negatively – it includes a broad range of experience-dependent improvements in behavioral task performance that are not declarative. This means that procedural performance is not dependent on the subject's either being able to recall specific training episodes or being able to explicitly state the acquired knowledge. The best-known forms of procedural learning are within the motor domain, but procedural learning can also include performance on cognitive tasks and emotional/motivational features of memory. Some aspects of procedural learning that have been commonly ascribed to the striatum are habits and skills. Both terms refer not to the specific procedures that are learned but rather to certain attributes of learned performance that develop incrementally with extended practice. Actions become habits when they have been performed so often that they can be done automatically, i.e., without effortful attention. To continue with automotive examples, driving a car along a highly familiar route can easily be done while focusing on a conversation with a passenger. No goal needs to be in mind to perform this habit. Rather, we often need to pay attention to avoid habitual/automatic responding – if engrossed in conversation, we may find ourselves having driven this very familiar route even if another destination had been initially intended. As habits are reactions to familiar configurations of cues, they are sometimes referred to as stimulus–response (S-R) associations, in contrast to action-outcome associations. Because habitual behavior is not goal-directed, it is somewhat inflexible when circumstances change. Habits are relatively persistent even when the consequences of actions are removed (extinction) or made less appealing (outcome devaluation). Finally, practicing a behavior leads to more-skilled performance, in which the components of an action sequence become more fluidly and accurately joined together.

The following paragraphs summarize in turn some of the key anatomical and physiological features of the striatum relevant to learning, the effects of striatal damage and drugs on learning in humans and animals, and results from neuroimaging and electrophysiological investigations of the striatum during learning. Although plasticity within portions of the striatum is indeed responsible for certain forms of procedural learning such as habits, the overall function of striatal plasticity appears to be far more elaborate than simply connecting stimuli with responses.

Basal Ganglia Circuitry and Plasticity

Diverse Information in Afferent Inputs

The striatum is one component of large-scale cortical-basal ganglia loop circuits (Figure 1). Striatal subregions make use of rich patterns of information contained in inputs from almost all cortical (and thalamic) regions. These include sensory association areas that might contribute to the stimulus of S-R habits, motor cortical areas that provide information about current motor commands in the corticospinal pathway (efference copy), and prefrontal areas concerned with cognitive and emotional/motivational information. The striatum projects to other nuclei of the basal ganglia, which in turn project back to thalamus and thence to anterior (motor/premotor/prefrontal) cortical regions. As a rough approximation, the 'motor' loop involves the putamen (lateral/dorsal striatum), the

Figure 1 Simplified anatomy of cortex–basal ganglia loop circuits. The striatum is a convergence zone for a wide range of cortical and thalamic inputs, carrying rich patterns of information of diverse types. The motor loop is shown in green, cognitive loop in blue, and motivational loop in purple. Dopamine (in red) from midbrain neurons acts in the striatum to modulate all loops. For clarity, the connections from thalamus back to cortex and to striatum are truncated, and important additional basal ganglia pathways are omitted altogether. VTA is ventral tegmental area; SNc, substantial nigra pars compacta; VP, ventral pallidum; dlPFC, dorsolateral prefrontal cortex; v/oPFC, ventral/orbital prefrontal cortex; SNr, substantial nigra pars reticulata; GPi, globus pallidus pars interna; MD, medial dorsal thalamic nucleus; VA/VL, ventral anterior/ventral lateral thalamic nucleus.

'cognitive' or 'associative' loop involves the caudate (medial/dorsal striatum) and the 'limbic' loop involves the nucleus accumbens (ventral/medial striatum). However, there are no sharp neurochemical or histological boundaries within striatum that demarcate the different loop circuits, and the number of different loops is essentially arbitrary. The point is that all kinds of information reaches the striatum and can potentially form part of the content of learning.

Convergence of Corticostriatal Information

The architecture of striatal afferents allows the integration of information from different sources. First, the terminals of projections from different cortical regions show considerable intermingling within striatum. In other words, loop circuits bearing different types of information are not strictly segregated to distinct striatal subregions. Second, striatal (principal) neurons each receive thousands of inputs, provided by nearly as many different axons (because each axon makes only a very small number of terminals on any given striatal neuron). Such convergence of information potentially allows striatal neurons to serve as pattern recognition devices, in which their activity is highly dependent on specific combinations of external and internal cues and contexts. Convergence is also implied by the relative number of neurons in cortex and basal ganglia nuclei. There are approximately ten times more cortical than striatal neurons, and the ratio of striatal neurons to their pallidal targets is even larger.

Dendritic Spines and Striatal Plasticity

More than 90% of striatal neurons are the medium spiny cells, which both receive incoming afferents and themselves project out of the striatum. The spines that densely cover the dendrites of these cells (Figure 2) are believed to be sites of synaptic plasticity that support striatum-based learning. It is worth noting that spiny cells are comparably spiny in all striatal subregions – hence, the striatal components of cognitive and/or motivational loops likely have as much capacity to support learning as motor regions of the striatum. Long-term potentiation (LTP) and long-term depression of corticostriatal synapses have been demonstrated both *in vitro* and in anesthetized *in vivo* preparations. In addition to the spiny cells, there are

Figure 2 The dendrites of striatal projection neurons are densely coated in spines. Shown are examples of dendritic segments labeled with green fluorescent protein. Inset: example of whole dendritic field of a medium spiny neuron. Image from Jakub Jedynak and Terry Robinson, University of Michigan.

at least four distinct populations of interneurons, and some of these have been shown to regulate plasticity at spiny cell synapses.

Dopamine Input

A relatively small number of midbrain dopamine cells branch out to innervate wide areas of forebrain. This projection seems especially important to striatal function as the striatum is packed with dopamine terminals and receptors to a far greater extent than other forebrain areas. For the most part, dopamine neurotransmission and intracellular signaling appear set up not for conveying spatially rich patterns of information but rather for providing a more global signal that influences broad regions of striatum in a similar fashion. Most (though not all) investigators believe that this widespread dopamine signal has a central role in striatum-dependent learning (see the section titled 'Dopamine and striatal learning'). This idea is supported by at least some of dopamine's actions within striatum. Dopamine enhances long-term potentiation of corticostriatal synapses, probably at least in part because dopamine D1 receptors are coupled to the intracellular cyclic adenosine monophosphate (cAMP)/protein kinase A/cAMP responsive element-binding protein pathway, leading to increased transcription of plasticity-related genes. Manipulations of striatal dopamine (including chronic administration of addictive drugs) cause changes in striatal dendritic spines that likely reflect alterations in synaptic connectivity. Hence the machinery for dopamine-modulated learning is present and is almost certainly used.

Consequences of Striatal Damage for Learning

It is worth distinguishing between several quite different ways in which the striatum can contribute to learning. First, neural changes within the striatum itself – such as synaptic plasticity at spines – can affect behavior. These mechanisms could be the permanent repository of learning or have a more time-limited role as consolidation proceeds elsewhere. Second, the striatum is an essential part of circuits involved in the cognitive manipulation of information. Striatal damage can thereby affect encoding/plasticity in other structures and also the way information stored in other structures is employed for acute task performance. These different senses of striatum-dependent learning can confound investigators' ability to use striatal damage as a clue to specific striatal functions, and this difficulty has contributed to confusion in the literature.

Humans

Two relatively common neurological disorders have often been used to study striatal learning: Parkinson's disease (PD) involves a progressive degeneration of the dopamine input to the striatum, while Huntington's disease (HD) features progressive degeneration of the striatal spiny neurons themselves. The most obvious behavioral deficits in patients with advanced cases of either disorder are not learning difficulties but rather severe motor difficulties, often extending into the cognitive domain, and the resulting problems in task performance have often complicated the interpretation of learning studies. Both types of patient are relatively unimpaired in tests of declarative memory that stump amnesiacs with medial temporal lobe damage, and both types also learn normally in some procedural tasks. However, on some other tasks considered to be procedural, they have more difficulty. These include select forms of motor skill learning, category–classification learning, and sequence learning.

A well-known example is the weather prediction task, which involves probabilistic classification. On each trial, participants select the outcome (rain or shine) they think most likely after the presentation of a set of stimuli, each of which is associated with a certain outcome probability. The use of combinations of probabilistic cues makes it hard to consciously infer and calculate the most likely answer. Patients with PD or HD show retarded learning in such tasks;

they also often make use of suboptimal strategies, such as being guided by the presence or absence of one cue rather than making use of the full set. An analogous pattern of deficits is observed in information integration forms of category learning, in which good performance requires participants to use multiple aspects of visual patterns (e.g., color, shape, number) when classifying them. PD patients appear to have particular trouble making use of feedback about whether their responses were correct, and (in unmedicated patients) this deficit seems more severe for feedback about correct responses than about incorrect responses. Such deficits tie in well with the anatomy and physiology described above. Much of category–classification learning involves, in essence, using feedback to develop a mapping between a complex stimulus space and a simpler set of responses. PD patients would have a compromised dopamine reinforcement learning signal acting on spiny neurons that integrate multiple sources of information in the selection of actions.

Since an important part of the inputs that striatal spiny neurons receive are axon collaterals from the corticospinal tract, these cells are well positioned to use current motor commands as part of the information used to compute or anticipate the next movement. This may be why striatal damage has often been reported to interfere with sequence learning. Many tests of PD and HD patients have shown deficits in serial reaction time (SRT) tasks, in which participants are sequentially cued to perform a set of actions, and learning is measured as lower reaction times during trained sequences compared with random sequences. However, there is considerable inconsistency in this literature, with a number of reports of preserved SRT learning in PD patients. Recent studies have attempted to break down the demands of SRT tasks, for example by dissociating the spatial and temporal aspects of sequence presentation or the spatial and motor response demands. These studies have suggested that, once again, it is the integration of different forms of information in the service of action selection that presents particular problems for patients with striatal damage.

Striatal damage also frequently produces deficits similar to those seen in patients with damage to the frontal cortex. Both PD and HD patients have difficulty with executive function (broadly construed), attentional set shifting, and the learning and application of abstract rules to guide behavior. For more-focal forms of striatal damage, it has been noted that the behavioral effects of lesions to striatal subregions typically resemble those of focal lesions to the interconnected frontal cortical regions. To follow the distinction drawn earlier, these frontal deficits likely reflect both a problem with engaging intrastriatal plasticity using information provided by frontal cortex and the fact that loop circuits through the basal ganglia play a vital, continuous role in the ongoing manipulation of information in frontal cortical regions.

Experimental Animals

The first suggestion that the striatum is specifically involved in procedural learning came from Mishkin and colleagues in 1984. They had observed that monkeys with medial temporal lobe damage performed very poorly when required to store trial-unique information, such as which of two objects had been baited with food just a few seconds previously. But when given repeated presentations each day of the same pair of objects, these monkeys could progressively learn to select the consistently rewarded object. Comparable results for humans with amnesia due to medial temporal lobe damage have been reported recently. Mishkin proposed that this slow mode of learning relied on information flow from visual object identification areas in temporal cortex to the striatum, and that "this system of [corticostriatal] projections therefore provides a mechanism through which cortically processed sensory inputs could become associated with motor outputs generated in the pallidum and so yield the S-R bonds that constitute habits." Subsequent lesion studies confirmed that this progressive learning to select the consistently rewarded object is impaired by damage to ventrocaudal neostriatum, the portion of monkey striatum that receives input from cortical areas involved in visual object identification (but note results discussed under the section 'Electrophysiology of single striatal neurons and learning'). The suggestion that the striatum can serve as a switchboard connecting patterns of sensory inputs to motor outputs has an attractive simplicity and seems at least superficially consistent with the human deficits in integrating information for action selection that are produced by striatal damage.

The effects of striatal lesions on learning have been most thoroughly investigated in rats, where impressive double dissociations with the effects of hippocampal damage have broadly confirmed the importance of striatum for procedural learning. The deficits produced by striatal damage have been interpreted as problems with S-R learning, although what exactly this means has varied in substantial ways, as the following examples demonstrate.

Consider first performance in a four-arm, or plus, maze, in the classic situation devised by Tolman to distinguish between S-R habits and the use of cognitive maps. Hungry rats are repeatedly placed on the

end of one arm (call it south) with food available at the end of another arm (west). They progressively learn to rapidly move to the food, which involves making (in this example) a left turn to get to the goal. After certain amounts of training, they are given probe trials in which they start at the opposite arm (north) and must choose east or west. Going to the spatial location (west) where food has been presented in the past is called a 'place' strategy, while making the same left turn as before and ending up in the east arm is called a 'response' strategy. A standard finding is that with a few days' training in the task, most rats use a place strategy, but with extended training, most rats use a response strategy. Evidence that these distinct strategies rely on distinct brain systems comes from experiments involving intracerebral infusions of the local anesthetic lidocaine to temporarily block activity in the infused area. On probe trials, lidocaine into dorsal hippocampus causes rats with little pretraining to switch early to the response strategy, while lidocaine into lateral striatum causes even rats with extended training to still use the place strategy. The striatum is therefore important for incrementally acquiring an 'egocentric' (body-centered) response tendency, which seems consistent with an S-R learning role (even if the stimulus in this case is a bit vague).

A clear dissociation between striatal and hippocampal contributions to learning has also been demonstrated between spatial and cued variants of the circular water maze. Dorsal striatal damage interferes with the ability to learn to approach a specific cue that marks a platform allowing escape from the water, but not with the ability to learn that the escape platform is in a consistent spatial location. This has also been interpreted as S-R learning although the nature of the response is quite different. In the plus-maze example, the specific egocentric turn is an arbitrary response that must be learned. By contrast, we have an innate tendency to orient toward and approach stimuli that are attractive (i.e., have motivational significance), making the interpretation of approach responses more complicated.

Another example of learning an approach-type response is in the win-stay version of the radial maze. Striatal damage impairs learning of this task, in which rats are rewarded for choosing arms that are marked with a consistent cue (e.g., lights). By contrast, hippocampal damage causes deficits when rats must make use of trial-unique information, such as which arms have been recently visited (a win-shift task). Such results emphasize the role of the striatum in learning invariances – constant rather than shifting features of the world. In the same vein, rats with striatal damage are impaired in reference memory maze tasks, in which the same set of arms is consistently baited, while hippocampus damage instead causes problems with working memory versions, in which the rat must keep track of and avoid arms that have already been foraged (**Figure 3**).

Figure 3 Striatal damage interferes with win-stay learning. Compared to the control group, rats with damage to dorsal/lateral striatum (here labeled as caudate) are slower to learn to pick the lit arms of a radial maze to receive food rewards. By contrast, rats with damage to the fornix (an important set of hippocampal connections) learn faster than intact rats. This is most likely because the hippocampus helps keep track of which arms have been recently visited as part of a normal foraging strategy, which is unhelpful in this task. Reproduced from Packard MG, Hirsh R, and White NM (1989) Differential effects of fornix and caudate nucleus lesions on two radial maze tasks: Evidence for multiple memory systems. *Journal of Neuroscience* 9: 1465–1472, copyright 1989 by the Society for Neuroscience, with permission.

From these studies and others that have compared the roles of particular striatal subregions, it seems reasonable to conclude that sensorimotor (dorsal/lateral) zones of striatum are important for the incremental acquisition and performance of specific responses to stimuli. A small number of studies have gone further and provided evidence that such striatum-dependent strategies are indeed habits, in the sense of being insensitive to outcome devaluation. By contrast, damage to more medial/ventral striatal regions has more cognitive effects, including difficulties with spatial learning, working memory, and behavioral flexibility. These deficits presumably reflect anatomical relationships to hippocampus and frontal cortex, although investigators currently lack a clear notion about what is particularly striatal about the striatal contributions to more cognitive forms of learning. At least some forms of striatum-dependent learning appear to involve synaptic plasticity within the striatum itself, as suggested by a requirement for functional *N*-methyl-D-aspartate receptors and protein synthesis in the key striatal subregions.

Evidence for a role for the basal ganglia in organizing plasticity elsewhere comes from songbirds. In avian brains, a neural circuit called the anterior forebrain pathway (AFP) has many physiological similarities to the mammalian basal ganglia. The AFP is necessary for initial song learning but not for the production of adult song. If normal adult birds are deafened, their song slowly deteriorates; however, this deterioration does not occur in birds whose AFP has been lesioned. From such results, it has been argued that the AFP is essential for guiding plasticity in motor pathways, comparing sensory feedback to an internally stored target template. At first glance, this seems rather different from the mammalian situation, in which damage to the basal ganglia causes overt problems, not just with learning, but also adult task performance. However, some effects of basal ganglia damage can be paradoxical. For example, observations that the motor problems of PD patients are at least partly alleviated by surgical destruction of regions of pallidum and thalamus suggest that dysregulated basal ganglia may be worse than none at all. Such results have led some to argue that mammalian basal ganglia circuits also are not as critical for routine behavior as for adapting to changing circumstances.

Dopamine and Striatal Learning

Dopamine acting in striatum has an acute influence on behavior; this influence might perhaps be summarized as altering decision thresholds for action selection, but this subject is not the focus of this chapter. The learning deficits of PD patients suggest that dopamine must also be present in the striatum for normal striatum-dependent learning, and this proposition is supported by animal studies. For example, rats without dopamine in dorsal/lateral striatum can still learn to press a lever in response to a cue in order to obtain a food reward (though they learn slowly). However, unlike intact rats, despite extensive overtraining, they stop responding if the food is devalued – indicating that habit formation is disrupted. Complementary studies have shown that drugs that enhance striatal dopamine release can facilitate striatum-dependent learning. For example, systemic or intrastriatal amphetamine injections can accelerate the rate of win-stay learning in rats. This effect is seen even if drugs are given shortly after the training session – indicating that dopamine is able to affect the consolidation of striatum-dependent learning.

Drugs that are addictive in humans share the common property of enhancing striatal dopamine release, and it has been proposed that dopamine-induced striatal plasticity is a key mechanism underlying drug addiction. Drug addiction is characterized by compulsion, the loss of control over drug intake, and this may reflect the development of increasingly strong drug-taking habits – that is, learned actions not under deliberate volitional control. In experimental animals, repeated exposure to psychostimulants and other addictive drugs can alter striatal dendritic spines, with a particular increase in spine density in the dorsal/lateral regions of striatum that are critical for habits.

Brief electrical stimulation of dopamine pathways can produce more-transient striatal dopamine increases that are still highly reinforcing in the sense that animals will learn to perform actions that are followed by such stimulation. The speed with which rats learn to press a lever for electrical stimulation is proportional to the extent that such stimulation enhances striatal LTP. The idea that transient changes in striatal dopamine might be a critical learning signal under normal circumstances as well has gained great traction. Wolfram Schultz and others have recorded from likely midbrain dopamine neurons and observed that they typically show brief increases in firing rate in response to unexpected rewards or cues that predict rewards (e.g., see **Figure 4(b)**). Reward-related cues result in transient increases in striatal dopamine, as detected by voltammetry. Dopamine cells fire less or not at all to predicted rewards or aversive stimuli (though novel stimuli of all kinds continue to provoke firing). In many respects, the activity of dopamine neurons may therefore encode a reward prediction error signal, a key component of reinforcement learning models. The use of error signals seems to be a common property of several brain systems performing various forms of procedural learning, including the striatum and cerebellum.

However, the relationship between dopamine fluctuations and learning is still disputed. Among the remaining problems, it is not clear why striatal dopamine increases on the timescale of minutes can be evoked by a wide variety of arousing events, including stressful stimuli that are not obviously positively reinforcing. Also, the latency of dopamine neurons to respond to stimuli is so short that it has been argued that they must be responding to simple inputs from the superior colliculus rather than from cortical regions that should be better able to judge the current motivational significance of the particular stimulus. Although the activity of dopamine neurons is clearly modulated as the result of prior experience, critical experiments have not yet been devised that would clearly establish that the striatum makes use of their activity specifically as a learning signal, in addition to or instead of more immediate purposes such as dynamically adjusting psychomotor arousal.

Figure 4 Comparison of the firing patterns of a monkey presumed striatal cholinergic interneuron (TAN) and midbrain dopamine cell (DA) in response to visual cues and the juice rewards that they probabilistically predict. Shown are raster plots (black ticks indicate spikes) and above them the averaged responses for each cue (e.g., $p = 0.5$ indicates that this visual cue is followed by reward on half of its trials). Note that the dopamine cell fires more to cues that predict likely reward and to unexpected rewards. By contrast, the cholinergic interneuron shows a pause in firing that does not systematically vary with reward probability. From Morris G, Arkadir D, Nevet A, et al. (2004) Coincident but distinct messages of midbrain dopamine and striatal tonically active neurons. *Neuron* 43: 133–143.

Neuroimaging Studies of Striatal Learning

Recent years have seen a slew of interesting functional magnetic resonance imaging (fMRI) investigations of the human striatum, especially in reinforcement learning tasks. Before addressing the results, it is appropriate to sound one note of caution, namely, that we have essentially no idea what is responsible for activity as assessed by changes by the fMRI signal (using blood oxygenation level as contrast). In sensory cortex, blood oxygenation level signal seems to correlate with the local field potential, which in turn seems to reflect patterns of synaptic input more than the firing rates of local neurons. But the equivalent studies have not been performed

in the striatum, and the relative contributions of glutamatergic synapses, dopaminergic neurotransmission, interneuronal activity, and projection neuron spike firing are simply unknown.

Striatal fMRI activity changes can be observed in the putamen in response to simple, untrained movements, such as self-paced finger or toe flexion–extension. Many groups have examined how striatal fMRI activity changes as a result of procedural learning, often employing the SRT (sequence) tasks. The most common finding is that performing the sequence of finger movements engages more cognitive/associative parts of striatum early in learning, with a progressive shift to sensorimotor regions with further practice. This shift may parallel a change in the encoding of the sequence – while newly learned sequences are performed equally well with the hand used in training or the untrained hand, task performance becomes effector-specific with more practice. It is not clear whether striatal fMRI activity continues to persist even with very extended training; in one study, it was found that as actions become highly automatized (as assessed by sequence performance no longer causing interference with the performance of other tasks), activity in putamen disappeared. A progressive decrease in activity makes some intuitive sense, in that one might expect actions that are performed efficiently, accurately, and nonattentively to also be efficient in terms of neural energy requirements. It is less clear whether these changes in fMRI activity reflect (for example) more efficient neural representations of information stored in the striatum itself, versus (for example) the reduction in performance errors registered by the striatum and used to adjust neural representations elsewhere.

Inspired by the reinforcement learning paradigm, many groups have looked for, and found, correlations between error signals and striatal fMRI signal. All parts of striatum seem to be responsive to feedback, though the particular regions engaged can depend on the task involved. For example, accumbens activity correlates with reward prediction error in both Pavlovian (i.e., no choice) and instrumental (active choice) conditions whereas more-dorsal striatum responds to prediction error only in the instrumental condition. Paralleling the monkey dopamine cell studies, there is some evidence that the accumbens responds more to prediction errors about rewards than prediction errors about losses and that it also responds to salient nonrewarding stimuli. The caudate also responds to salient nonrewards, but only if they require some behavioral response. Prediction errors can activate striatum even if the participant is not aware of them. For example, when a participant is performing a learned probabilistic sequence task, an unsignaled and unnoticed sudden shift in the underlying probabilities causes signal change in the accumbens.

In addition to responding after feedback, striatal fMRI activity shows anticipatory changes that also vary between subregions. While expecting monetary rewards, accumbens activity increases in proportion to the expected reward (at least in nonblock designs in which the size of the signaled reward changes from trial to trial). The accumbens does not respond in the same way to anticipated financial penalties, though the caudate responds to both. However, the idea that the accumbens fundamentally cares about rewards is not supported by other studies, showing accumbens activation during anticipation of an unpleasant electrical current applied to the skin.

Overall, these studies provide good evidence that the striatum is actively involved both in anticipating motivationally significant events and in responding to errors in these expectations, even if the difficulty of knowing the nature of the striatal fMRI signal limits our ability to understand exactly what changes in striatum during learning.

Electrophysiology of Single Striatal Neurons and Learning

An important achievement of striatal electrophysiology has been the ability to distinguish medium spiny projection neurons, which tend to fire infrequently and only at specific parts of a behavioral task, from the much smaller populations of interneurons that are more constantly active – notably the tonically active neurons (TANs) which are thought to correspond to the giant cholinergic interneurons. As in other brain areas, the larger population of projection cells is believed both to carry more-complex patterns of information and to have greater capacity to store new information. Among other functions, interneurons influence plasticity in projection cells, for example, by controlling their spike timing or spritzing them with neuromodulators.

TAN cells do not respond to neutral stimuli, but with conditioning they develop a brief pause or pause–rebound in firing as stimuli become motivationally relevant. Unlike midbrain dopamine cells, they do not discriminate between appetitive and aversive stimuli and do not show responses that are proportional to the expected magnitude of reward (Figure 4). Although their firing pattern is quite distinct from that of dopamine neurons, they require a certain level of dopamine stimulation to show their pause response. They tend to respond as a single, synchronous population, and although some discriminate between, for example, different locations of stimuli or different forthcoming movements, most do not.

Like the dopamine cells, the TANs therefore seem to be a more global, scalar signal rather than conveying complex patterns of information. Why the striatum needs multiple such scalar signals is not currently clear. The effects of acetylcholine (ACh) on striatal plasticity are complex, but blocking striatal muscarinic receptors enhances LTP at corticostriatal synapses. The ACh released by TANs is very rapidly degraded by striatal enzymes, so a synchronized pause in TAN firing may provide an even more temporally precise signal than the increase in dopamine cell activity. It has therefore been suggested that the TAN population instructs striatal neurons precisely 'when' to learn.

The striatal spiny neurons have a much more diverse set of responses – so much so that it seems at least a small proportion of these cells increase firing at each phase of any task studied. Many show activity related to specific ongoing or upcoming movements, though typically in a highly context-specific manner: similar movements outside the task are not associated with increased firing. The context specificity of spiny cell firing likely reflects the wide diversity of inputs that each cell is receiving. Consistent with the fMRI results above, the activity of spiny neurons is very often strongly modulated by reward expectation (though this is also true for neurons in many other brain regions). The combination of movement selectivity and reward expectation may indicate that striatal neurons are encoding action values that could potentially be useful for deciding between different actions. Although some reports have found reward expectancy to be more common in the accumbens, it is a frequent attribute of neurons in more-dorsal striatal regions too.

How might the formation of a procedural memory be expected to alter striatal projection cell firing? A hallmark of procedural memory is smoother, faster, less-error-prone performance, that is, a less diverse range of actions than is seen early in learning. Consistent with fewer different actions would be fewer active neurons and more consistency in neuronal firing, and this has indeed been observed – for example, in the striatum of rats running a maze task. Yet it is very difficult to know whether the observed neurons are the actual site of the key plastic events involved in procedural learning or whether their change in activity simply mirrors the change in behavior, as would be observed, for example, in a set of recordings from different muscles. Such considerations indicate a general conundrum in studying the changing neural representations underlying improved procedural learning. If the behavior changes, then it is hardly surprising that the representation of that behavior changes. Conversely, if neurons were to change firing without behavioral change, we would require some additional form of evidence to be confident that those neurons are actually involved in the behavior.

More specifically, what would an S-R association look like at the single-neuron level? It seems reasonable to assume that it should involve changes in striatal neuron responses to the stimulus that are also selective for the type of response made by the animal. Several studies have examined this possibility. Following the evidence that visual inputs to ventrocaudal striatum may be important for learning to select an object, recordings were made from this part of striatum while monkeys learned to make or withhold a hand movement depending on specific visual stimuli. The striatal neurons showed only visual responses that were generally similar to those in temporal cortex and were not modulated by the learned movement response or expected reward (unlike most parts of striatum). Hence, no evidence was found for neuronal responses related specifically to learning of S-R associations, despite the lesion data suggesting this area was involved.

A set of similar monkey electrophysiology studies examined other parts of striatum during the learning of arbitrary associations between visual stimuli and particular eye or hand movements, using enforced delay periods between stimulus and response to help distinguish between distinct aspects of neural coding. Over the course of the initial learning and beyond, many striatal spiny neurons do develop (or lose) firing increases at specific parts of each trial, though the overall diversity of these learned responses makes it hard to tell a specific story about how the association is encoded. Comparing the time course of activity changes in striatal regions with their afferents, it appears that neurons in putamen and in premotor cortex change at approximately the same rate, consistent with these structures' being part of the same cortex–basal ganglia loop circuit. One recent study compared caudate to dorsolateral prefrontal cortex (dlPFC) during reversal learning of S-R associations and found that the caudate neurons changed their direction selectivity in fewer trials. This finding was interpreted as evidence that the basal ganglia learn before the PFC, although given the wide diversity of inputs to caudate neurons, it might simply indicate the dlPFC is not the right place to look for the fastest changes during reversal learning (especially as orbitofrontal regions are more implicated in reversal).

Although striatal neurons change activity patterns during learning of this S-R association task, the task itself appears not to be a clear example of procedural learning. In contrast to the slow mode of learning proposed by Mishkin to involve the striatum, intact monkeys learn new associations in just a few trials, typically trying out each response in turn until they

find the one that works, then sticking with it. Lesions to hippocampus severely retard learning of these arbitrary visual-motor associations, and hippocampal neurons show some of the fastest learning-related responses. This is strong evidence that this form of learning is at least initially not procedural at all but may instead rely (for example) on the monkeys' remembering the specific episodes in which they tried out the other options. It would be very interesting if future studies examined striatal responses while discouraging a declarative strategy, such as by making the S-R mapping probabilistic or through inactivation of hippocampus. Although it might be hard to train animals, procedural learning could also be usefully assessed by testing interference with performance of a second task, as in some of the human fMRI studies previously mentioned.

Conclusions and Speculations

The striatum, especially dorsal/lateral subregions, is closely involved in certain forms of procedural learning, including the development of S-R habits. Yet the idea of associations is likely too limited to capture the role of striatal plasticity in learning. Borrowing concepts from engineering, recent theoretical work has begun to emphasize the function of cortical-basal ganglia loops as control systems that employ internal models of the organism's interactions with its environment. Internal models involve temporally structured expectations (explicit or implicit) about the consequences of actions, and striatal plasticity might best be described as allowing internal models to be refined when these expectations are not met. The diverse, context-dependent firing of striatal spiny cells during task performance may be a key aspect of such internal models, representing the progression through a learned, structured sequence of actions and expected events. Especially in sensorimotor striatum, such sequences may involve specific cues and movements, while more cognitive zones, such as caudate neurons, may encode more the abstract rules that govern overall task performance (i.e., learning sets). Compared with associations, such richer concepts of basal ganglia function may be essential for progress in the design and interpretation of critical experiments.

Some key unresolved questions include the following: Are the spines of striatal spiny neurons the permanent repository of learned action and expectation sequences, or are the basal ganglia involved primarily in influencing plasticity elsewhere (especially the cortex)? How do we make use of internal models to evaluate distinct courses of action without actually performing them? How can experimenters distinguish between psychomotor arousal and learning aspects of dopamine modulation of striatum, and over what timescales do these functions operate? These are questions that physiology and imaging investigations have just begun to tackle.

Programmed Cell Death

R Oppenheim and C Milligan, Wake Forest University School of Medicine, Winston-Salem, NC, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

During the embryonic, fetal, larval, and early postnatal stages of development, there is a massive loss of undifferentiated and differentiating cells in most tissues and organs, including the central and peripheral nervous systems. This cell loss is a normal part of development, and it occurs by a highly regulated process known as programmed cell death (PCD). Developmental PCD is defined as the spatially and temporally reproducible, tissue and species-specific loss of cells whose occurrence serves diverse functions and is a process required for normal development. Perturbation of this normal process can be maladaptive, resulting in pathology.

History

Although the occurrence of developmental PCD was first reported in the middle of the nineteenth century, it was not until the middle of the twentieth century that the occurrence and significance of PCD in the nervous system began to be appreciated by embryologists and developmental biologists. In a series of seminal papers by Viktor Hamburger and Rita Levi-Montelcini in the 1930s and 1940s, it was shown that the sensory and motor neurons in the spinal cord of the chick embryo are generated in excess during neurogenesis, followed by the PCD of approximately one-half of the original population. The period of cell loss was found to occur as sensory and motor neurons were establishing synaptic connections with their peripheral targets (e.g., muscle in the case of motor neurons). In a conceptual *tour de force*, Hamburger and Levi-Montalcini proposed that developing neurons compete for limiting amounts of target-derived survival-promoting signals (the winners survive and the losers undergo PCD) and in this way neurons are thought to optimize their innervation of targets by a process known as systems matching. It was this conceptual framework that led to the discovery of target-derived neurotrophic molecules and to the formulation of the neurotrophic theory that has been a major factor in fostering progress in this field for over 50 years. According to the neurotrophic theory, neurons that compete successfully for neurotrophic molecules avoid PCD, owing to the expression of survival promoting intracellular molecular genetic programs. The discovery of molecular genetic programs for both survival and death has revolutionized the study of PCD, resulting in the publication of thousands of articles each year since the early 1990s.

Evolution

The occurrence of massive cell death during development is, on the one hand, counterintuitive, whereas, on the other hand, the fact of its existence in many vertebrate and invertebrate species argues for its significance as an adaptively significant and fundamental part of embryogenesis. The death of occasional cells during development is to be expected in biological systems in which accidental deleterious events may be lethal to individual cells. However, because the stereotyped death of large numbers of developing cells in all members of a species cannot be explained in this way, it raises two basic questions regarding the evolution of PCD: (1) because PCD occurs by a metabolically active, genetically regulated process (see the sections titled 'Molecular regulation of cell death and survival by neurotrophic factors' and 'Intracellular regulation of cell death'), how and why did the molecular mechanisms involved arise during evolution; and (2) what are the adaptive reasons for massive developmental cell death in the nervous system (see the section titled 'The functions of PCD in the nervous system')? A plausible answer to the first question is that PCD arose as a defense mechanism for eliminating abnormal cells that threatened the survival of the organism. According to this argument, the death-promoting intracellular machinery arose in host cells to defend against the spread of viral infection and, in response, viruses evolved survival-promoting genetic mechanisms to block or counter the host cell death-promoting defenses. Because these death- and survival-promoting mechanisms have been found to mediate PCD in a diversity of organisms (see the section titled 'Intracellular regulation of cell death'), they are considered to represent an evolutionarily conserved core molecular genetic program that has been coopted by the nervous system for regulating cell numbers.

The Functions of PCD in the Nervous System

PCD in the nervous system involves both neurons and glia, and it occurs in the central and peripheral nervous system, the brain, and spinal cord and in virtually all neuronal and glial cell types. Accordingly, it is

Table 1 Some possible functions of developmental PCD in the nervous system

Differential removal of cells in males and females (sexual dimorphisms)
Deletion of some of the progeny of a specific sublineage that are not needed
Negative selection of cells of an inappropriate phenotype
Pattern formation and morphogenesis
Deletion of cells that act as transient targets or that provide transient guidance cues for axon projections
Removal of cells and tissues that serve a transient physiological or behavioral function
Systems matching by creating optimal quantitative innervation between interconnected groups of neurons and between neurons and their targets (e.g., muscles, sensory receptors)
Systems matching between neurons and their glial partners by regulated glial PCD (e.g., Schwann cells and axons)
Error correction by the removal of ectopically positioned neurons or of neurons with misguided axons or inappropriate synaptic connections
Removal of damaged or harmful cells
Regulation of the size of mitotically active progenitor populations
Production of excess neurons may serve as an ontogenetic buffer for accommodating mutations that require changes in neuronal numbers in order to be evolutionary adaptive (e.g., increases or decreases in limb size may require less or more motor neuron death for optimal innervation)
Regulated survival of subpopulations of adult-generated neurons as a means of experience-dependent plasticity

not surprising that the diversity of adaptive roles for PCD differs according to the animal species, cell type, nervous system region, and stage of development. A list of some of the most common reasons for PCD in the nervous system is provided in Table 1. Of these, the one that has received the most attention because of its central role in establishing optimal functional connectivity in neuronal circuits is systems matching (Figure 1). In birds and mammals, the evidence is compelling that for postmitotic neurons that are establishing interconnections with targets and afferents, systems matching, occurring in the framework of the neurotrophic hypothesis (see the section entitled 'Introduction'), is the primary reason for why a significant proportion of neurons (20–80%) undergo PCD. An analogous kind of systems matching adjusts myelinating glial cell numbers to the number of available axons.

PCD by Autonomous versus Conditional Specification

PCD occurring during systems matching represents a paradigm example of the conditional specification of cell fate during development. Developmental biologists have identified two kinds of pathways that cells use for specifying their differentiated fate or phenotype. One pathway, autonomous specification, involves the differential segregation of cytoplasmic signals into daughter cells following mitosis. In this way, cells become different from one another by the presence or absence of these cytoplasmic signals with little if any contribution from signals from neighboring cells. The other pathway, conditional specification, requires signals from other cells (cell–cell interactions) to progressively restrict differentiation and determine whether a cell lives or dies. These cell–cell interactions can be of four types: (1) juxtacrine (direct cell–cell or cell–matrix contact); (2) autocrine (a secreted signal acts back on the same cell type from which the signal arose); (3) paracrine (a secreted diffusible signal from one cell that acts locally on a different cell type); and (4) endocrine (signaling via the bloodstream). In the developing vertebrate nervous system, neuronal and glial survival is largely dependent on conditional specification involving paracrine interactions that use neurotrophic factors (NTFs). For neurons, the most commonly used NTFs are members of three major families: (1) neurotrophins, (2) the glial cell line-derived family ligands (GFLs), and (3) ciliary NTFs. Each of these contains several distinct members that act preferentially on specific types of neurons via membrane-bound receptors. By contrast, the survival of glial cells depends on different families of trophic factors such as the neuregulins and insulin-like growth factors. Neurons and glial cells use paracrine signaling to promote survival by ligand–receptor interactions. However, there are some situations in which paracrine interactions can signal death versus survival.

Molecular Regulation of Cell Death and Survival by NTFs

The dependence of neurons on NTFs for survival intuitively leads to the conclusion that the inactivation of NTF receptors, and the signal transduction associated with them, leads to the activation of cell death events (Figure 2). This has been best studied with neurotrophins and their receptors, notably the

Figure 1 Schematic illustration of some key steps in neuronal development. Neurons undergoing PCD (●) are observed during neurogenesis in the ventricular zone, during migration and while establishing synaptic contacts. Schwann cells in developing nerves also undergo PCD. represents peripheral glial (Schwann) cells; ● represents CNS glia (astrocytes and oligodendrocytes); ⊙ represents surviving, differentiating neurons (motor neurons) whose targets are skeletal muscle.

Trk receptors and p75 (Table 2). Activation of the trk receptors results in the activation of the phosphatidylinositol-3 kinase (PI3-K) and mitogen-activated protein kinase (MAPK) pathways. Akt, a substrate of PI3-K, has been reported to phosphorylate Bad, promoting its association with 14-3-3 and preventing the inactivation of Bcl-2 and Bcl-x. Activation of PI3-K/Akt, extracellular signal-regulated kinase-1/2 (ERK1/2), protein kinase (PK)C, or PKA promotes the serine phosphorylation of Bad and Bcl-2, and Gsk-3B phosphorylates and inactivates Bax – events that are associated with cell survival. The survival-promoting activity of phosphorylated Bcl-2, however, is controversial, being associated with motor neuron survival-induced trophic support, whereas in neurons treated with microtubule destabilizing agents it appears to promote death. The c-jun N-terminal kinase (JNK) pathway is reported to exhibit increased activity in neurons triggered to die. The activation of one of its substrates, c-jun, is also thought to play a role in mediating neuronal death. For example, the JNK activation of the BH3 proteins Bim and DP5 has been associated with neuronal death, and a JNK–p53–Bax pathway appears to be critical for death in specific cell types. Nonetheless, the JNK pathway has also been reported to be a critical mediator of survival-promoting events such as neurite outgrowth and may serve as a double-edged sword in neurons through changes in intracellular localization or specific activation or inactivation of individual isoforms.

The role of the p75 nerve growth factor (NGF) receptor in promoting neuronal survival or death is complicated. For example, complexes of p75 and the trk receptors bind neurotrophins and promote survival, while complexes of p75 and sortilin appear to promote binding of the proneurotrophins resulting in the death of neurons. Activation of p75 in the absence of Trk activation has most notably been associated with the death of neurons, but this appears to be developmentally regulated. The precise mechanism by which p75 promotes death is unclear. However, p75 is a member of the tumor necrosis factor receptor family, and another member of this family better known for its death promoting activity is Fas/CD95. Engagement of Fas by Fas ligand leads to the activation of caspase 8. This event is dependent on the formation of a death-induced signaling complex (DISC). Homotrimerization is the first step in this process. Engagement of Fas by its ligand can only occur when it is homotrimerized. This family of receptors is characterized by the presence of a death domain (DD) on the cytoplasmic region of the receptors. The Fas-associated death domain-containing protein (FADD) can then bind to Fas. In addition to the DD, FADD also contains a death effector domain (DED). Procaspase 8 binds the DED. The autolytic nature of caspases leads to active capsase 8 that can then go on to directly activate caspase 3 (in type 1 cells, e.g., thymocytes) or cleave Bid leading to changes at the mitochondria (in type 2 cells, e.g., hepatocytes and neurons) and cell death.

Intracellular Regulation of Cell Death

Many of the intracellular mechanisms mediating neuronal cell death were investigated following initial work that suggested that new gene expression was required for the process. Horvitz and coworkers provided some of the first evidence that there was indeed a genetic component of PCD from their work in the 1980s with the free-living nematode *Caenorhabditis elegans*, although it was two decades later

Figure 2 Signals to die. Changes in signal transduction pathways, activation of receptors containing a DD, or changes in intracellular calcium concentrations have been identified as events that can lead to the activation of cell death-specific events. Loss of trophic support results in decreased activation of the phosphatidylinositol-3 kinase (PI3-K), thereby releasing inhibitory factors linked to this pathway. Alternatively, increases in intracellular calcium concentrations, activation of the FAS receptor, and increased c-jun terminal kinase activation are associated with the mitochondrial changes and caspase activation that occurs in cell death. ASK, apoptosis signal-regulating kinase; ER, endoplasmic reticulum; FADD, Fas-associated death domain-containing protein; JNK, c-jun N-terminal kinase; NF-κB, nuclear factor κB; PIKE, phosphatidylinositol-3 kinase enhancer.

that the significance of this work was fully appreciated (Figure 3). As these genes were identified, the sequence of events leading to the death of cells was pieced together.

The presence of Bcl-2 family proteins appears critical for mediating the survival or death of nervous system cells. During development, Bcl-2 expression is correlated with neuronal survival. With continued maturation and development, this expression declines while Bcl-x expression increases. The specific mechanisms responsible for this change in expression are currently not known. On the other hand, the expression of pro-death Bcl-2 family proteins such as Bid or Bax appears to be consistent throughout development, whereas the intracellular localization of these proteins appears to change in cells undergoing death. In healthy cells, Bax is localized more in the cytoplasm, whereas in dying cells the majority of Bax localizes to organelle membranes, including the mitochondria. The localization of Bax to the mitochondria corresponds to the release of cytochrome *c* into the cytoplasm. Once in the cytoplasm, cytochrome *c* binds Apaf-1, causing a conformational change in Apaf-1 to reveal a caspase recruitment (CARD) domain. In the presence of ATP, a heptamer of the cytochrome *c*–Apaf-1 complex is formed. Procaspase 9 has a high affinity for the CARD domain and localizes to the heptamer. This complex is referred to as the apoptosome. With the increased local concentration of procaspase 9, the autolytic property of caspases leads to the generation of active caspase 9. As an initiator caspase, active caspase 9 can cleave procaspase 3, resulting in the active form of this protease (Figure 4). The activation, inactivation, or destruction of specific substrates significantly contributes to the rapid degeneration of the cell. Caspase activity also leads to the activation of endonucleases that may play a role in the changes in nuclear morphologies that are observed in may cell types.

The removal of the dying cell is most likely just as critical an event in the cell death process as any of those already discussed. The event is accomplished by adjacent cells that can be nonprofessional phagocytes (e.g., Schwann cells) but more often involves

dedicated phagocytes such as tissue macrophage (microglia) or circulating monocytes. During central nervous system (CNS) development, resident microglia are not present in large numbers among dying cell populations. Intuitively, some signal must be sent by the dying cells to recruit the phagocytes into the area. One such chemotactic factor has been identified in nonneuronal cells, and interestingly, this factor is the phospholipid lysophosphatidylcholine. Caspase 3 activation appears to be necessary for the release of this factor. Once the phagocytic cells are in the region, they must be able to distinguish dying from healthy cells. Changes on the dying cell's surface include revealing of thrombospondin 1 binding sites, exposure of phosphatidyl serine, ATP-binding cassette (ABC-1) molecules, and carbohydrate changes. The phagocyte, in turn, expresses the phosphatidylserine receptor, as well as thrombospondin receptors that recognize the thrombospondin bound to the binding site on the dying cell, lectins that bind to the carbohydrate changes, and ABC-1 molecules that bind to like molecules. Phagocytosis occurs only when multiple changes are recognized, and this phagocytosis is limited and does not result in macrophage secretion of cytokines that would normally induce an inflammatory or immune response if foreign antigens were phagocytosed.

Different Types of Neuronal Death

Many individuals studying cell death often rely on the critical papers of Currie, Kerr, and Wyllie to define and characterize the different types of cell death. These investigators described in detail two distinct morphological changes associated with cell death. An active process, apoptosis, was characterized by specific morphological changes that included condensation of nuclear chromatin, shrinking of the cytoplasm, and a breaking up of the cell into membrane-bound particles that were phagocytosed. Necrosis, on the other hand, was characterized by a swelling of the cytoplasm with eventual bursting of the cell (Figure 5). In this case, intracellular components are spilled into the extracellular space where they could initiate inflammatory and immune responses. However, electron microscopy studies of the developing nervous system indicated that neuronal death could not be so easily defined by only these two modes of death. During the naturally occurring death of some neurons, initial changes in dying cells are observed in the cytoplasm where there is an increase in the diameter of the cisternae of the rough endoplasmic reticulum (RER). Mitochondrial swelling was also observed, although it was not clear if these changes occur in the same cell. Nonetheless, during normal development initial changes are observed in the cytoplasm with little nuclear alterations in dying cells. The cell then appears to round up and break into pieces that are phagocytosed. Although cytoplasmic cell death appears to be more prominent

Figure 3 Genes for the key regulators of cell death: (a) dying cell; (b) engulfing cell. Many of the key regulators of cell death are evolutionarily conserved. Many of the genes for these proteins were initially identified through genetic mutations in the free living nematode (bold type), with homologs later being identified in *Drosophila* and mammals (italics).

Figure 4 Many of the critical components of neuronal death and their apparent sequence of activation during development. The mitochondria release many regulators that can lead to death with or without caspase activation. Neurons are considered type 2 cells where FAS engagement results in minimal caspase 8 activation, resulting in the cleavage of Bid and its subsequent movement to the mitochondria. The localization of Bax to the mitochondria appears to be a critical event in the death of neurons. Figure 5 Necrotic death and the three most common types of programmed cell death (PCD) observed in the nervous system. Type 1 meets the criteria for apoptosis. In PCD, phagocytes remove the resulting corpses, whereas necrosis in many cases results in inflammation.

during development, nuclear or apoptotic death also occurs. A third type of death is autophagy, characterized by the formation of numerous autophagic vacuoles. Nuclear changes may also occur in this type of death.

It is important to note that all three types of neuronal death appear to reflect a metabolically active process. Accordingly, it appears that a homogeneous mode of suicide does not occur but, rather, that processes leading to death appear to be context and developmentally dependent. One example is a neuronal population undergoing apoptosis when nuclear condensation is a prominent feature. On the other hand, in animals in which caspases have been inhibited or deleted, the same neuronal population undergoes a delayed death with major changes occurring in the cytoplasm.

Pathological Neuronal Death

Many of the mechanisms that have been identified as playing a role in neuronal death during development are reported to be reactivated in the mature pathological nervous system. Alterations in the expression of Bcl-2 proteins are observed in animal models and in postmortem human tissue in Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's chorea (HC), amyotrophic lateral sclerosis (ALS), and stroke. Caspase activation has also been reported in these and other disorders. Interestingly, although reports of apoptotic cells are present in these conditions, the majority of degenerating cells exhibit morphological changes reminiscent of cytoplasmic or autophagic death. This is most notable in the mutant SOD1 mouse model of ALS. During development, dying motor neurons exhibit many features of apoptosis, including possible Fas activation, Bax translocation, mitochondrial dysfunction, and caspase activation and condensation of nuclear chromatin. By contrast, in the adult spinal cord of SOD1 mice, degenerating motor neurons exhibit cytoplasmic vacuolization, mitochondrial dilation, and protein aggregation. Nonetheless, some of the cell death-associated events that occur during development are also observed. It is becoming increasingly recognized that neuronal dysfunction is most likely the event responsible for clinical symptoms in ALS and other neurodegenerative diseases. In experiments in which motor neuron death is inhibited in the SOD1 mouse, disease progression and survival of the animal are only very modestly affected; muscle dennervation still occurs, and the animals die prematurely. Results such as this call into question the practical application of inhibiting cell death as a therapeutic approach for these disorders.

Prolactin and its Neuroendocrine Control

N Ben-Jonathan and C R LaPensee, University of Cincinnati, Cincinnati, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Prolactin (PRL) is produced by the pituitary lactotrophs, which constitute 20–40% of all pituitary cells. Lactotrophs exhibit many distinguished properties, including late ontogenic development, the capacity for proliferation during adulthood, expression of spontaneous electrical activity, the presence of receptors for neurotransmitters, responsiveness to many secretagogues, substantial morphological and functional heterogeneity, the existence of dual hormone secreting cells, and a high intrinsic synthesis and secretory activity. Lactotrophs are under tonic inhibition by hypothalamic dopamine, and this inhibitory activity is counteracted by multiple PRL releasing/regulating factors (PRFs). This article summarizes salient features of PRL and its receptors, highlights comparative aspects of PRL physiology, and evaluates hypothalamic, peripheral, and paracrine/autocrine regulation of PRL production.

Prolactin and the Prolactin Receptor

The Prolactin Gene and Protein

The PRL gene, located as a single copy on human chromosome 6, is evolutionally and functionally related to both growth hormone (GH) and placental lactogen (PL). The rat PRL gene contains five exons and is 10 kb long. It is regulated by a proximal promoter composed of a 2.5 kb sequence at the 5′ flanking region. Several *cis*-acting elements within the promoter bind Pit-1, a pituitary-specific POU-homeodomain transcription factor which confers cell-specific PRL expression. The human PRL gene is composed of six exons and is 18 kb long. An extra noncoding exon 1a is located 5.8 kb upstream of the pituitary start site (Figure 1). In extrapituitary sites such as the decidua, myometrium, and lymphoid cells, exon 1a is spliced to exon 1b, generating an mRNA transcript that is 150 bp longer in the 5′ untranslated region than the pituitary transcript. An alternative, superdistal promoter upstream of exon 1a regulates PRL expression at extrapituitary sites. As judged by biochemical, biological, and immunological criteria, the pituitary and extrapituitary PRL proteins are identical.

The PRL protein is made of a single chain of 199 residues stabilized by three disulfide bridges. PRL adopts a three-dimensional configuration as four antiparallel α-helices organized in an 'up-up-down-down' manner (Figure 1). The four-helix bundle motif is shared with GH, hematopoietic factors, and several cytokines. Alternative splicing, posttranslational modifications, and proteolysis generate PRL variants that differ in size or in functional groups. Larger forms result from aggregation, whereas smaller forms are generated by proteolysis. Some variants retain PRL-like activities, whereas others have unique properties or no known functions.

Structure and Distribution of the Prolactin Receptor

The gene encoding the human PRL receptor (PRL-R) is located on chromosome 5 and consists of 10 exons encompassing 100 kb. PRL-R belongs to the non-tyrosine kinase cytokine/GH/PRL receptor superfamily. These receptors are characterized by a single-pass transmembrane stretch that divides the receptor into an extracellular ligand-binding domain and an intracellular domain. The extracellular domain contains two fibronectin-like regions named S1 and S2. The S1 region has two glycosylation sites and two pairs of disulfide bridges and contains most of the PRL binding sites. The S2 region has a conserved WS motif (Trp-Ser-x-Trp-Ser) that is involved in receptor folding and dimerization (Figure 2). Two binding sites within PRL – site 1 composed of helices 1 and 4 and site 2 composed of helices 1 and 3 – are required for induction of receptor homodimerization and formation of an active trimeric complex. The cytoplasmic domain of the receptor has a proline-rich motif ('box 1') adjacent to the plasma membrane that couples to intracellular signaling molecules.

The PRL-R is expressed in almost all tissues, with the highest expression in the liver, mammary gland, adrenal, and choroid plexus. Human GH and placental lactogens also bind to the PRL-R and mimic some actions of PRL. In humans, alternative splicing generates five PRL-R isoforms that differ in the length and composition of the cytoplasmic domain. Rats express a long, an intermediate, and a short isoform (Figure 2), whereas mice express one long and three short isoforms. A soluble PRL-binding protein which contains only the extracellular domain is generated by proteolysis. The long isoform is responsible for most of the signal transduction properties of the receptor. Short isoforms are expressed at a variable ratio in different tissues, but their precise action is unclear.

Figure 1 Diagram of the human PRL gene, PRL mRNA transcript, and mature PRL protein. Arrows designate transcriptional start sites for the proximal pituitary promoter and the superdistal extrapituitary promoter. Transcription from either promoter produces mRNAs with identical protein coding sequences but differing in the 5′ untranslated sequences (5′ UTR). The mature PRL protein shows the four-helix bundle configuration.

Figure 2 Schematic presentation of the different isoforms of the rat PRL receptor. All isoforms have an identical extracellular binding domain.

Activation of Multiple Signaling Pathways by Prolactin

PRL-R is devoid of intrinsic tyrosine kinase activity and utilizes the Jak2/Stat pathway as its main signaling cascade (Figure 3). Receptor-associated Jak2 is rapidly phosphorylated upon PRL binding and induces phosphorylation of the receptor, associated

Figure 3 Signaling pathways that mediate activation of the PRL receptor. Jak2 binds to box 1 within the intracellular domain of the receptor. The Jak2/Stat5 pathway (1) is considered the main pathway, but phosphatidylinositol-3-kinase (2) and mitogen-activated protein kinase (3) pathways are also stimulated by ligand binding to the PRLR in a cell-specific manner. Phosphorylation is designated by circled P's.

kinases, and Stat proteins. Of the seven known Stat proteins, Stats 5a and 5b serve as the primary mediators of PRL action. Upon phosphorylation, Stat proteins dimerize and translocate to the nucleus, where they bind to consensus elements on target genes. Milk proteins are the best-characterized PRL-R-regulated genes involving the Jak/Stat pathway.

The Ras/Raf/MAPK pathway is also activated by PRL (Figure 3). Phosphorylated Jak2 recruits adaptor proteins such as Ras and Raf which then activate the MAP kinase pathway. Activation of PRL-R also facilitates docking of Src family kinases and activation of the phosphatidylinositol 3 kinase/Akt pathway. Both the strength and the duration of the PRL-induced signaling are regulated by suppressors of cytokine signaling (SOCS) proteins, whose expression is rapidly induced upon receptor activation. The SOCS proteins interact with the PRL-R or with Jak2 and inhibit further signaling. In summary, signal transduction activated by the PRL-R does not represent a linear progression but involves interacting pathways which differ in predominance among the various PRL-R-expressing cells.

Comparative Physiology of Prolactin

Rodents

PRL is a modulating/adaptor hormone which has assumed multiple functions throughout evolution. Consequently, its overall regulation and the dynamics of its secretion vary among species. In rodents, PRL is essential for the maintenance of the corpus luteum (luteotropic activity), and its release is altered during the reproductive cycle and pregnancy by an interplay between dopamine-releasing hormones, ovarian steroids, and placental lactogens. Concomitant with the preovulatory surge of luteinizing hormone (LH) during late proestrous in rats, serum PRL levels also surge by an estrogen-dependent mechanism. The preovulatory PRL surge is nonsymmetrical but has a prolonged plateau phase which subsides toward estrous. If mating occurs, the corpus luteum is rescued from disintegration by two daily PRL surges whose timing is controlled by the superchiasmatic nucleus. In the case of a nonfertile mating (pseudopregnancy), the PRL surges persist for 12 days, followed by resumption of cyclicity. In the case of pregnancy, the daily PRL surges terminate on day 10 in response to the rising levels of placental lactogens. During mid- to late pregnancy, serum PRL is low, until a large surge occurs just before parturition.

Suckling during lactation initiates a classical neuroendocrine reflex and is the most potent physiological stimulus for PRL release. Within minutes of the initiation of suckling, and in direct proportion to the intensity of the stimulus, PRL release increases manifold and is sustained as long as nursing endures. Cessation of suckling rapidly terminates PRL release, with the decline in its serum levels determined by the metabolic clearance rate. The control of the suckling-induced PRL release is complex, involving a coordinated action of several PRL-releasing factors from both the hypothalamus and the posterior pituitary, superimposed on a markedly reduced dopaminergic activity.

Humans

The physiology of PRL in humans differs in many respects from that in rodents. During development, fetal plasma PRL levels are low between 10 and 20 weeks and increase progressively to peak levels before birth. Another increase occurs immediately after birth and persists for several days. Fetal PRL is regulated independent of the mother and may respond to dopaminergic inhibition. PRL in the maternal circulation also increases gradually toward term, reaching seven- to tenfold higher levels than in nonpregnant women. Elevated PRL is essential for preparation of the breasts for lactation, which is prevented during pregnancy by high progesterone levels. Pregnancy also causes pituitary enlargement due to lactotroph hypertrophy and hyperplasia. Labor activates cervical neural signals that trigger a PRL surge which does not occur during cesarean delivery.

During pregnancy, large amounts of PRL are independently produced by the decidua. Neither dopamine nor estrogen affects decidual PRL release. Decidual PRL is secreted into the amniotic fluid, where its concentrations peak between 18 and 23 weeks of gestation, attaining 50- to 100-fold higher levels than in either the fetal or the maternal circulation. Basal PRL levels remain elevated during the first 2 or 3 weeks postpartum in women who do not breastfeed, and then they decline. Similar to rodents, suckling is the most potent stimulus for PRL release. The magnitude of the suckling-induced PRL increase is robust during early lactation but wanes thereafter. Tactile stimuli of the breast can increase serum PRL in nonlactating women. Coitus for both men and women also causes an increase in serum PRL levels.

During childhood, there are no sex differences in serum PRL levels, with PRL becoming twice as high in women than men after puberty. In contrast to rats, estrogens have little effect on acute PRL release in humans. Indeed, circulating PRL levels are largely unchanged throughout the menstrual cycle and do not increase during the preovulatory LH surge. Although estradiol increases PRL release from dispersed adult human pituitary cells, it does not reverse the dopamine-mediated inhibition, indicating that it may be effective when dopaminergic inhibition is absent or reduced. Stress from anesthesia, surgery, strenuous exercise, and insulin-induced hypoglycemia also stimulates PRL release in both men and women. Small increases in PRL also occur in response to high-protein meals. When sampled at high frequency, serum PRL levels display an episodic release pattern whose amplitude increases after the onset of sleep. The nocturnal increase in PRL release is seen in both sexes and is sleep induced rather than driven by an intrinsic diurnal rhythm.

Hypothalamic Dopaminergic Systems

Anatomy and Relative Contribution to Prolactin Release

Studies using rats identify two main hypothalamic dopaminergic systems that regulate PRL: the tuberoinfundibular (TIDA) and the tuberohypophysial (THDA). The perikarya of TIDA neurons are located in the arcuate nucleus and send short axons that terminate in the external zone of the median eminence. These do not form synapses and function as

true neurosecretory neurons whose product is released into perivascular spaces and carried by portal blood to the anterior pituitary. THDA neurons from the rostral arcuate nucleus send axons that course through the pituitary stalk and terminate in the neural (NL) and intermediate (IL) lobes of the pituitary. They are joined by the periventricular hypothalamic neurons with perikarya in the periventricular nucleus and terminals in the IL lobe. The NL terminals are neurosecretory, whereas those in the IL synapse on melanotrophs. Short portal vessels connect the NL and anterior lobe (AL) and provide a vascular route for dopamine delivery to the lactotrophs. Of the three systems, the TIDA plays the predominant inhibitory role in PRL release. However, a reciprocal relationship between TIDA activity and PRL release is not always apparent since it is often masked by other PRL regulatory factors.

Regulation of Hypothalamic Dopamine by Prolactin and Estrogen

In the absence of target gland hormones to provide feedback control over PRL release, PRL is used as the primary regulator of the dopaminergic systems via a short loop negative feedback mechanism (Figure 4). TIDA neurons are activated by both acute and chronic elevations in PRL, with few exceptions. These include pregnancy, lactation, and prolactinomas, when the dopaminergic neurons become refractory to the elevated PRL, enabling the maintenance of physiological or pathological hyperprolactinemia. The rat brain expresses both the long and short PRL-R isoforms, and their expression is altered under various endocrine conditions. After the choroid plexus, the hypothalamus contains the highest density of the PRL-R within the brain. The PRL-R often co-localizes with neurons expressing tyrosine hydroxylase (TH), the rate-limiting enzyme in dopamine synthesis. Similar to peripheral tissues, binding of PRL to hypothalamic neurons activates the Jak2/STAT signaling pathway. PRL reaches the arcuate nuclei via the cerebrospinal fluid following receptor-mediated uptake at the choroid plexus.

Estrogens affect PRL homeostasis at several sites, including the hypothalamus, posterior pituitary, and anterior pituitary (Figure 4). The action of estrogen is mediated by two receptors, ERα and ERβ, that are the translation products of different genes. Both have a similar modular structure of five functional domains, with high homology in the DNA- and ligand-binding domains but distinct regulatory domains. They bind estradiol with similar affinity, and after homo- or heterodimerization they activate an estrogen response element located in the regulatory region of estrogen-responsive genes. Many of the TH-positive

Figure 4 Model of the regulation of lactotroph function by hypothalamic, peripheral, and paracrine/autocrine factors. Dopamine from the TIDA and THDA neurons reaches the anterior pituitary (AP) via the long and short portal vessels, respectively, and serves as the primary PRL inhibiting factor. Compounds that inhibit dopamine cause stimulation of PRL release, whereas those that stimulate dopamine result in its inhibition. Direct stimulators of the lactotrophs are designated as PRFs (PRL releasing factors) and originate either from hypothalamic peptidergic neurons (PN) or from the neurointermediate lobe (NIL). D2R and P-R designate dopamine type 2 receptors and peptidergic receptors, respectively. Estrogen (E2) affects PRL directly or indirectly by modulating the dopaminergic neurons. Local peptides and growth factors are produced by neighboring AP cells, folliculostellate cells, or the lactotrophs.

neurons in the arcuate nucleus express ERα, whose expression changes during the estrous cycle. The importance of estrogen in the regulation of TIDA neurons is underscored by the higher basal TIDA activity in females than in males, the suppression of their activity by ovariectomy, and their reversal by estrogen.

Interactions of the Dopaminergic Neurons with Neuropeptides and Neurotransmitters

Opioids are the best-established neuropeptides that stimulate PRL release by inhibiting the TIDA neurons (Figure 4). The hypothalamus contains perikarya of the three opioid classes – that is, proopiomelanocortin (POMC), endorphins, and enkephalins. Although the arcuate nucleus contains POMC-positive cells, only a few TIDA perikarya receive contacts from β-endorphin terminals, with most interactions occurring at their median eminence terminals. In contrast,

most TIDA neurons make synaptic contacts with dynorphin terminals, with proenkephalin- and prodynorphin-related peptides acting as paracrine regulators of TIDA neurons via κ- and μ-opioid receptors. Interactions between opioid peptides and TIDA neurons are especially extensive during the proestrus PRL surge, its nocturnal rise in pregnant rats, and during suckling, indicating that they comprise an integral component of the PRL regulatory system. Several neuropeptides, including neuropeptide Y, neurotensin, angiotensin II, calcitonin, bombesin-like peptides, and atrial natriuretic peptides, decrease PRL release by stimulating the dopaminergic systems (Figure 4).

Among neurotransmitters, the stimulatory effect of serotonin on PRL release is well recognized (Figure 4). Serotonergic neurons from the raphe nucleus terminate in the superchiasmatic and arcuate nuclei. Drugs that impair serotonergic neurotransmission or lesions of the raphe nucleus prevent PRL increases in response to stress and suckling. However, a consistent effect of serotonin agonists on TIDA neuronal activity has not been observed and serotonin may affect PRL secretion primarily by stimulating the release of PRF. γ-Aminobutyric acid (GABA) has a dual effect on PRL release: a direct inhibitory action at the level of the anterior pituitary and a central stimulation. There is also an endogenous rhythm of cholinergic neurons which appears to contribute to the circadian changes of TIDA neuronal activity.

Mechanism of Action of Dopamine

Dopamine exerts its action on the lactotrophs by binding to dopamine D_2 receptor, a seven domain G-protein-coupled receptor. Based on sequence and structural similarities, the five dopamine receptors are subdivided into two groups. The D1-like receptors (D1 and D5) increase adenylyl cyclase activity in response to dopamine, whereas the D2-like receptors (D2–D4) inhibit adenylyl cyclase. Alternative splicing of the D2 receptor yields two isoforms, long (D_2L) and short (D_2S). The short isoform has a 29-amino-acid deletion in the third intracytoplasmic domain, where interactions with G_0/G_i proteins occur. The long isoform is predominant in the pituitary and its expression is regulated by sex steroids. Despite a similar binding affinity to dopamine, the two isoforms differ in their coupling to second messengers and account for the different responsiveness of lactotroph subpopulations to dopamine.

The diverse effects of dopamine on the lactotrophs are best exemplified by temporal events. Within seconds, dopamine increases potassium conductance and inactivates voltage-sensitive calcium channels. This results in membrane hyperpolarization, reduced intracellular calcium, and inhibition of PRL release. Since PRL release from storage granules is coupled to calcium availability, the relatively high intracellular calcium accounts for the high basal release of PRL typical of cultured lactotrophs in the absence of dopamine and the immediate suppression of PRL release upon exposure to dopamine. Within minutes to hours, dopamine suppresses adenylyl cyclase activity as well as inositol phosphate metabolism and arachidonic acid release, followed by downregulation of the PRL gene. Within days, dopamine suppresses lactotroph proliferation.

Prolactin Releasing/Regulating Factors

Thyrotropin-Releasing Hormone, Vasoactive Intestinal Peptide, and Prolactin-Releasing Peptides

In addition to compounds that affect PRL release by altering the dopaminergic system, several peptides affect PRL gene expression/release by acting directly on the lactotrophs (Figure 4). Following the discovery of the hypothalamic releasing/inhibiting factors, strict criteria have been established for this class of compounds. These include localization in the hypophysiotropic area of the hypothalamus, the presence in portal blood, binding to specific receptors on lactotrophs, and alterations in their expression/release that reflect changes in PRL secretion. Because many of these compounds were later found to also be produced within the pituitary, broadening of the criteria for PRL regulating factors became necessary.

Thyrotropin-releasing hormone (TRH) was initially defined by its ability to regulate thyrotropin-stimulating factor, but it is also an effective stimulator of PRL secretion. TRH is a tripeptide with a C-terminal amide and a pyro-Glu residue at the N-terminus. The prohormone is cleaved by prohormone convertases to yield five copies of TRH. TRH-producing neurons are located in the paraventricular nuclei and have terminals in the median eminence, where their product is secreted into portal blood. TRH binds to membrane receptors, present on both thyrotrophs and lactotrophs, that belong to the family of seven domain G-protein-coupled receptors. TRH stimulates PRL release both *in vivo* and *in vitro*, especially when the dopaminergic input is absent or reduced. It induces a rapid, biphasic increase in intracellular free calcium, leading to increased PRL release. TRH also induces the PRL gene via protein kinase C- and calcium-dependent activation of MAP kinase pathways. Although TRH is an important modulator of PRL release, it is not considered the primary PRF. A TRH stimulation test is used by clinicians to distinguish prolactinomas from other causes of hyperprolactinemia in patients.

Vasoactive intestinal peptide (VIP) is a 28-amino-acid peptide present at high concentrations in the superchiasmatic and paraventricular nuclei and in hypophysial portal blood. VIP and related peptides, peptide histidine–isoleucine and pituitary adenylate cyclase-activating polypeptide, stimulate PRL release both *in vivo* and *in vitro*. This is supported by passive immunization studies and the increase in hypothalamic VIP during sexual maturation, lactation, and following estradiol treatment. Hyperprolactinemia causes a reduction in VIP concentrations in portal blood, suggesting negative feedback by PRL. VIP is also produced by anterior pituitary cells, including the lactotrophs, suggesting that it also acts as a paracrine/autocrine agent that maintains elevated basal PRL release. VIP binds to two subclasses of G-protein-coupled receptors named VIP-R1 and VIP-R2. Despite their high homology, each subtype is coupled to specific signaling pathways and its expression is tissue- and cell-specific. VIP acts by increasing the production of cyclic AMP, followed by activation of protein kinase A. On a molar basis, VIP is more sluggish and less potent than TRH as a PRL secretagogue. Similar to TRH, VIP stimulates PRL gene expression, but it also enhances PRL mRNA stability.

Two peptides, consisting of 20 and 31 amino acids, were named PRL-releasing peptides (PrRP20 and PrRP31) based on their ability to increase PRL release *in vitro*. Both peptides originate from a larger precursor molecule by proteolytic cleavage and have amidated C-terminals. It is currently debated whether they truly deserve their assigned name. Upon incubation with rat pituitary cells, only PRL release was increased, whereas other pituitary hormones were unchanged. However, this required pharmacological rather than physiological doses. In addition, peptide expression is highest in the nucleus of the solitary tract and the adrenal medulla, with low to undetectable levels in the ventral hypothalamus or median eminence, raising the question of how they can reach the pituitary gland. Since both the peptides and their receptors are abundant in rat and human pituitaries, one possibility is that they regulate PRL release in an autocrine/paracrine manner. If so, they do not differ from several locally produced peptides/growth factors capable of stimulating PRL secretion but are not classified as hypothalamic releasing factors.

Prolactin Regulators within the Pituitary

The posterior pituitary in most species is composed of two adjacent tissues, the NL and IL, which differ in embryonic origin, innervation, vascularization, cell types, and hormonal products. The NL extends from the median eminence and is composed of nerve endings and pituicytes, or astroglial cells. The IL shares its origin and many features with the glandular AL. The main cell type within the IL is the POMC-producing melanotroph. The short portal vessels that connect the NL and AL lobes do not penetrate the IL, and this layer of cells is practically avascular. Two compounds, oxytocin from the NL and an unidentified substance from the IL, act as PRFs (**Figure 4**).

Oxytocin is a nonapeptide produced by the magnocellular neurons of the paraventricular and supraoptic nuclei. Posttranslational processing of prooxytocin occurs inside secretory granules during their axonal transport to the NL. Both oxytocin and its carrier protein, neurophysin I, are stored in nerve terminals in the NL and are released in equimolar amounts in response to action potentials which originate in the hypothalamic perikarya. Oxytocin can reach the AL either from the median eminence via the long portal vessels or from the NL via the short portal vessels, and it binds to receptors present on lactotrophs and other cell types. Oxytocin is released at times of elevated PRL secretion, such as during suckling, the afternoon of proestrus, following estradiol administration, and during immobilization stress. Since oxytocin and PRL have different thresholds of activation and dissimilar kinetics, their co-release may be coincidental or functionally related. The consensus is that oxytocin is not a major physiological PRF. Relative to TRH, the potency of oxytocin is much lower, but it is much more abundant and thus it can serve as a modulator of PRL release under some conditions.

Another PRF was serendipitously discovered in the posterior pituitary when posterior pituitary lobectomized (LOBEX) rats were used to examine the role of THDA neurons in the suckling-induced PRL rise. Basal PRL release was elevated in LOBEX lactating rats, confirming that dopamine from THDA neurons contributes to the tonic inhibition of PRL release. However, suckling, with or without oxytocin administration, failed to increase plasma PRL levels, indicating the presence of PRF. Additional studies have shown that this PRF participates in the generation of the proestrus PRL surge, mediates the acute estradiol-induced increase in PRL, contributes to the nocturnal increase in PRL during early pregnancy, but is not involved in the stress-induced PRL release. This PRF activity is localized in the IL but not in the NL, hypothalamus, or cerebral cortex. Posterior pituitary extracts stimulated PRL release in a rapid, dose-dependent and hormone-specific manner both *in vivo* and *in vitro*. Co-culturing posterior pituitary cells and lactotrophs resulted in a dramatic increase in PRL mRNA levels. Attempts to isolate this PRF from posterior pituitaries from several species were unsuccessful.

Many locally produced peptides and growth factors affect PRL production/release as well as lactotroph proliferation (Figure 4). Unlike the classical releasing/inhibiting factors characterized by a very rapid action on PRL release, local factors primarily affect the PRL gene with a subsequent effect on PRL release. The intrapituitary regulatory system involves not only hormone-producing cells, such as lactotrophs and gonadotrophs, but also folliculostellate cells. The latter form an intricate cellular network via slender processes and are involved in the coordination and synchronization of neighboring cells. Local PRL regulatory factors include epidermal growth factor, basic fibroblast growth factor, transforming growth factor-α (TGF-α), TGF-β, calcitonin, and galanin. The role of TGF-β is particularly intriguing since TGF-β_1 and TGF-β_3, two isoforms encoded by different genes, stimulate and inhibit PRL expression and lactotroph proliferation, respectively. Most of the local factors also interact with dopamine and/or estrogen by affecting their receptors or signaling pathways.

Prolactin-Releasing Peptide

Introduction

The human genome project was completed in 2003, and the draft of human genome sequences was published. One of the most surprising findings of the human genome sequences was the existence of a large number of G-protein-coupled receptor (GPCR) candidates in the genome. Most of these receptors are classified as odor receptors; however, about 170 GPCRs were considered orphan receptors, and their natural ligands were not known. Therefore, many studies have sought to discover the endogenous ligands for these orphan receptors. Prolactin-releasing peptide (PrRP) was found by a reverse pharmacological search for an endogenous ligand of an orphan receptor (hGR3/UHR-1/GPR10) highly expressed in the anterior pituitary gland. PrRP was first reported as a good candidate for prolactin-releasing hypophysiotropic factor; however, much recent research suggests that besides prolactin (PRL) release, PrRP has a wide range of functions in the central nervous system, such as metabolic homeostasis, stress responses, cardiovascular regulation, gonadotropin secretion, growth hormone (GH) secretion, and sleep regulation.

Chemical Structure of PrRP and Its Receptor

PrRP has two isoforms, PrRP31 and PrRP20, which are composed of 31 and 20 amino acid residues and have molecular weights of 3.6 and 2.2 kDa, respectively. Bovine PrRP complementary DNA (cDNA) isolated from hypothalamus was found to encode a precursor protein with 98 amino acid residues. This protein has a typical N-terminal secretory signal sequence of 22 amino acid residues. PrRP31 starts from Ser-23 just after the signal sequence, whereas PrRP20 starts from Thr-34. PrRP has turned out to be RFamide peptide, which contains the RF (Y) amide motif in its C terminal. PrRP also undergoes some enzymatic processes to be amidated like other RFamide peptides. First, signal peptide is removed from the bovine PrRP precursor protein, followed by cleavage in the basic amino acid of Arg-55, Arg-56, and Arg-57. After these basic amino acids are removed, Phe-53 at the C-terminus of the mature PrRP is amidated by reacting with Gly-54 as an amide donor. Human and rat PrRP precursor proteins, with amino acid lengths of 87 and 83, respectively, have essentially the same structure as the bovine precursor protein and have sequence similarity of 90% and 83%, respectively, with bovine PrRP31 (Figure 1).

PrRP receptor is a seven-transmembrane-domain receptor, that span the cell membrane seven times. PrRP is coupled to guanine nucleotide-binding protein (G-protein), a heterotrimer consisting of α, β, and γ subunits as machinery to transduce intracellular signals, and the result is called G-protein-coupled receptor. In GH_3 rat pituitary tumor cells and primary cultures of rat anterior pituitary cells, PrRP rapidly and transiently activated extracellular signal-regulated protein kinase (ERK). This PrRP-induced ERK activation was completely blocked by pertussis toxin, which inactivates G_i/G_o proteins. This finding suggests that the PrRP receptor couples to either of the G-proteins.

Distribution of PrRP

Among the variety of tissues studied, however, major PrRP distribution was noted in the brain. An *in situ* hybridization study has shown PrRP messenger RNA (mRNA) to be localized in the caudal portion of the dorsomedial nucleus of hypothalamus (DMH), nucleus of the tractus solitarius (NTS), and ventral and lateral reticular nucleus (VLRN) in the brain, with the strongest PrRP mRNA detected in the NTS area. PrRP mRNA has also been detected in some peripheral tissues of the adrenal gland, pancreas, testis, and placenta. Immunohistochemical assay has shown that PrRP-producing cells/PrRP-cells are located in the NTS, VLRN, and DMH in the brain. PrRP-producing cells have also appeared in the area postrema (AP) of adrenalectomized rats.

In contrast, PrRP fibers have been detected in a wide range of the brain, such as the paraventricular hypothalamic nucleus (PVN), basolateral amygdaloid nucleus, bed nucleus of the stria terminalis, supraoptic nucleus, and paratenial thalamic nucleus. However, the external region of the median eminence, site of the classical hypophysiotropic hormones, was devoid of immunopositive PrRP fibers. This distribution profile indicates that PrRP may have a wide range of biological functions.

Distribution of PrRP Receptor

To elucidate the specific sites of action of PrRP, one should know the distribution of its receptor. Various advanced molecular techniques, that is, *in situ* hybridization, polymerase chain reaction (PCR), reverse transcription PCR (RT-PCR), Northern blotting, and autoradiography, have made it possible to know

Figure 1 Amino acid sequence of PrRP20 and PrRP31. The numbers and arrows indicate the position of amino acid from N terminal in the mature peptide. Here we additionally represent the human PrRP sequence to compare with other two species' PrRP (similarity and dissimilarity). Red letters show the amino acids different from bovine PrRP.

the tissue distribution of PrRP receptor and PrRP receptor mRNA. Both RT-PCR and *in situ* hybridization have confirmed a dense expression of PrRP receptor mRNA in rat pituitary gland, indicating that this gland is the major site for PRL secretion in the body. High expression of human PrRP receptor mRNA in the pituitary gland, among the tissue examined by Northern blot analysis, has strengthened this concept. *In situ* hybridization has also found PrRP receptor mRNA expressed in the brain (Figure 2). This receptor is expressed abundantly in the reticular thalamic nucleus, periventricular hypothalamus, dorsomedial hypothalamus, NTS, AP, and adrenal medulla. These areas of the brain are important for the control of neuroendocrine and autonomic functions such as cardiovascular regulation, homeostasis, gonadotropin secretion, and stress, which suggests the involvement of PrRP in the mediation of these functions.

Functions of PrRP

PRL Secretion of PrRP

As for biological activities, PrRP was first reported to stimulate PRL secretion from rat pituitary adenoma-derived cell line RC-4B/C in a dose-dependent manner and from dispersed rat anterior pituitary cells. In addition, PrRP31 was not found to promote the secretion of the other anterior pituitary hormones, such as GH, follicle-stimulating hormone (FSH), luteinizing hormone (LH), thyroid-stimulating hormone, or adrenocorticotropin (ACTH), but PrRP31 immediately promoted the secretion of PRL from rat anterior pituitary cells, indicating that PrRP might directly stimulate lactotroph cells to secrete PRL. As revealed from other studies, however, the stimulating effect of PrRP on PRL release is less than that of thyrotropin- releasing hormone, which has been shown to have more potential in inducing PRL secretion. More interesting, a quite opposite result has been reported, that is, that PrRP had no direct stimulating effect on PRL secretion from the dispersed pituitary cells. It has also been reported that PrRP has a much weaker effect on PRL secretion in rats in stress or suckling conditions.

On the other hand, following PrRP injection, PRL secretion has been found to vary according to gender, estrous cycle, and dose. A relatively high dose (500 nmol PrRP31 kg^{-1} IV) was found to be effective for a significant increase in plasma PRL level in male rat whereas only 50 nmol PrRPkg^{-1} IV enhanced the plasma PRL level in female rat within 25 min. Female rat, especially at the proestrous and estrous stage, proved more sensitive than male rat to PrRP-induced PRL secretion. In addition, because PRL release is regulated by estrogen, dopamine, and several other hypothalamic factors, these factors might have some influencing effects on PrRP.

By immunocytochemical study, it has been found that immunoreactive PrRP fibers project only onto the internal layer of median eminence, whereas other classical hypophysiotropic hormone-producing cells project onto the external layer of median eminence. These results suggest that the mechanism and pathway for PrRP's action on the anterior pituitary differ from those of the classic hypophysiotropic peptides regulating the secretion of pituitary hormones. Actually, this stimulating mechanism is not straightforward. Pharmacologically, PrRP is shown to stimulate PRL secretion, but it has no physiological basis; physiological investigation is needed. The PRL secretion-stimulation mechanism is described on the basis of two possible assumptions. On the one hand, the dense existence of PrRP receptor in the anterior pituitary gland suggests that PrRP stimulates PRL release in an autocrine fashion. On the other hand, PrRP is transported to the posterior pituitary gland through the blood vessel between the hypothalamus and posterior pituitary gland. This PrRP from the posterior pituitary gland might be transported via the short loop portal vein system into the anterior pituitary, where lactotroph cells exist. However, this seems rather unlikely, and additional research is required to resolve this discrepancy.

Stress Responses of PrRP

These investigations demonstrate that PrRP fibers and cells are widely distributed throughout the brain. Actually, this distribution pattern of PrRP has broadened the way for scientists studying whether PrRP stimulates the stress mechanism in animals. Initially, it was found that PrRP-like immunoreactivity (PrRP-LI) colocalized with tyrosine hydroxylase-like immunoreactivity (TH-LI) in A1 (VLRN) and A2 (NTS)

noradrenergic neurons of the rat caudal medulla. However, some of the TH-LI neurons appeared to be PrRP-negative in the A2 region. Noradrenergic neurons in A1 and A2 cell groups appear to send their axons to innervate various regions of the rat hypothalamus, including median eminence, arcuate, dorsomedial, ventromedial, periventricular, and paraventricular nuclei. Also, PrRP neuron cells in NTS and VLRN project

their fibers/axons to corticotropin-releasing hormone (CRH)-positive parvocellular neurosecretory cells in the PVN and then make synapselike contact with CRH cell bodies. This suggests that PrRP might have some effect on CRH secretion. In addition, plasma ACTH level has been found to increase dramatically after intracerebroventricular (icv) administration of PrRP. On the other hand, animals pretreated with a potent CRH antagonist (α-helical CRH) showed attenuated plasma ACTH levels after icv PrRP31 application. These results strongly suggest that PrRP affects the hypothalamic–pituitary–adrenal (HPA) axis as a potent stimulator of CRH neurons in the PVN. Furthermore, colocalized stay with a marker enzyme (tyrosine hydroxylase) of catecholaminergic neurons is strong evidence for PrRP in stress-responsive signal transduction through the HPA axis. In any case, activation of the HPA axis results in the secretion of CRH from the CRH cells located in hypothalamic PVN, which in turn enhances ACTH secretion from the pituitary gland (Figure 3).

Regulation of PrRP cell function is important for understanding the physiological response of PrRP cells. It has been reported that nicotine stimulates PrRP cells. In addition, c-Fos expression in the A2 PrRP neurons is a marker of neural activation and c-Fos-positive cells in the PrRP neurons have been found to be lowest in estrus. Investigators have also found that estrogen receptor α is positive in A2 PrRP neurons, which suggests that PrRP cells may regulate with estrogen. In addition, they studied the effect of estrogen on the stress response of A2 PrRP neurons and found that stress responses of PrRP cells are suppressed by estrogen.

Earlier studies revealed that different types of stressors (e.g., water-immersion, foot shock, hemorrhage, and conditioned fear) activate PrRP/TH double positive cells/neurons in the A1 and A2 regions of medulla oblongata, resulting in the elevation of ACTH in plasma, which in turn stimulates the release of glucocorticoids and catecholamines from the adrenal glands.

Also, synapic contact of PrRP neurons with oxytocin cell bodies in the hypothalamus has been demonstrated by means of double immunohistochemical study. It has also been reported that icv administration of PrRP stimulates oxytocin release from the pituitary. PrRP-producing neurons in the medulla oblongata are known to produce both PrRP and noradrenaline simultaneously. These morphological features of PrRP neuron suggest that PrRP and noradrenaline might synergistically affect the CRH neurons in the secretion of ACTH. On this point, it has been reported that icv administration of low doses of PrRP (1 nmol per rat) and noradrenaline (0.1 nmol per rat) could not significantly stimulate ACTH secretion through CRH, and vice versa. On the other hand, simultaneous administration of these subactive doses of PrRP and noradrenaline markedly stimulated ACTH secretion. This result suggests that the combined effect of PrRP and noradrenaline, even at a subactive dose, is stronger than that of a separate single dose, either high or low, in stimulating secretion of ACTH.

Food Intake Regulation of PrRP

PrRP mRNA is expressed in three regions of brain: DMH, NTS, and VLRN. These regions are also implicated in appetite control and autonomic regulation. Therefore, PrRP might have some role in the regulation of food intake. Previous study has suggested that PrRP may act as a homeostatic regulator of food intake. It has been found that 4 nmol PrRP significantly reduces the initial refeeding response in fast-induced female rats. This result indicates that PrRP has a physiological role to play in appetite and weight control. This reduction in food intake was not owing to visceral illness or injury after icv injections of PrRP (2–4 nmol). However, water intake was unaffected by the treatment. In animal physiological systems, there are some special types of endogenous, homeostatic satiety factors (cholecystokinin, for instance) that signal to the brain via vagal nerve afferents being released by the gut during a meal. Also, some exogenous, nonhomeostatic factors such as lithium chloride cause visceral illness or injury and reduce food intake thereby. Although these two factors have a different origin, they seem to exert their action on ingestive behavior by the same action pathway, via vagal nerve afferents. Likewise, on satiation, PrRP causes a pattern of brain/neural activation similar to that produced by cholecystokinin. However, PrRP does

not cause conditioned taste aversion but instead enhances the normal behavioral satiety sequence. Moreover, PrRP has been found to activate some additional areas in the brain, such as lateral hypothalamus and hypothalamic PVN. It is interesting that both of these areas of brain have been implicated in appetite regulation. Actually, PrRP inhibits food intake via the DMH because this area of brain contains a high level of neurotensin, a potent food intake inhibitor. It has also been found that PrRP can stimulate the release of neurotensin from hypothalamic explants in a dose-dependent manner. The increase in neurotensin by PrRP could be an important mediator of the anorectic effect of PrRP. In addition, PVN injection of PrRP does not appear to change food intake in male rat.

Coadministration of PrRP and leptin, an anorexigen, resulted in additive reductions in nocturnal food intake and body weight gain and an increase in core body temperature compared with either peptide alone. Using immunohistochemical study, it has been shown that more than 90% of PrRP cells in all regions (DMH, NTS, and VLM) contain leptin receptors. This result suggests that the effect of PrRP on food intake is mediated, at least in part, by leptin.

On the other hand, icv administration of PrRP increases food intake in the chicken. This result is completely opposite to those obtained in mammals. Further extensive research is required in this area.

Other Functions of PrRP

Morphological studies have shown that PrRP fibers are distributed in different parts of the brain. As the brain controls almost all mechanisms in the body, either directly or indirectly, PrRP might have some involvement in those mechanisms. Beyond PRL release, stress response, and food intake inhibitory functions, PrRP is also known to play some important physiological roles in cardiovascular regulation, gonadotropin secretion, growth hormone secretion, sleep regulation, and others. The stress response of PrRP has been reported already. During stress conditions, circulating catecholamine increases the heartbeat, producing high blood pressure. In experiments with rats, arterial blood pressure was significantly increased by the icv administration of PrRP. Elevation of arterial pressure was observed in response to 0.4 and 4 nmol PrRP31. The effect of PrRP continued 15 min following administration of 0.4 nmol and 20 min following administration of 4 nmol PrRP. It is also known that GPR10 and PrRP are associated with blood pressure.

Gonadotropin-releasing hormone (GnRH) neuronal perikarya exist in medial preoptic area (MPOA), and GnRH neuronal fibers terminate in arcuate nucleus (ARC). It has been found that PrRP is released in the MPOA prior to the GnRH release, whereas in the ARC area the release of PrRP is not changed significantly. This suggests that PrRP may play a role in mediating the steroid-induced LH surge by activating GnRH neurons in the MPOA. It has also been reported that plasma LH and FSH were increased on central administration of PrRP in male rat.

PrRP-positive nerve fibers make synapselike contact with somatostatin neurons in the hypothalamic periventricular nucleus (PerVN). Some parts of somatostatin neurons in PerVN express PrRP receptor; therefore, they are considered to be directly regulated by PrRP via PrRP receptor. In addition, icv administration of PrRP decreases plasma GH level, but rat pretreated with somatostatin depleter, cysteamine, does not show any decrease in GH. These results strongly suggest that plasma somatostatin level increases on PrRP administration, which in turn inhibits growth hormone secretion from the anterior pituitary gland.

PrRP increases sleep time in a dose-dependent manner. Low-dose PrRP enhances only rapid eye movement (REM), whereas high-dose PrRP (10 nmol) enhances non-REM sleep with a febrile response. PrRP receptors express prominently in reticular thalamic nucleus (RTN) of brain. This region of brain is critical for sleep regulation. Icv injection of PrRP was found to suppress sleep oscillation in sleeping rats and promote rapid and prolonged awakening. Given the critical role of the RTN neurons in the generation and control of thalamic oscillatory activity, activation of PrRP receptors in this region could be used to influence sleep–wake state and absence seizures.

The endogenous opioid system is an innate pain-relieving system in animals. It produces opioids that diminish pain and produce analgesia. PrRP has been found to destroy these opioids, resulting in increased pain. PrRP receptor knockout mice were found to have higher nociceptive thresholds and stronger stress-induced analgesia than wild-type mice. Icv administration of PrRP in wild-type mice increased hyperalgesia and reversed morphine-induced anti-nociception, whereas PrRP receptor knockout mice did not show any change, suggesting that PrRP is a strong modulator of the opioid system.

Localization of PrRP mRNA in the adrenal gland has also been reported. The function of PrRP cells in the adrenal gland remains to be elucidated.

Conclusion

As implied by its name, PrRP releases PRL; more specifically, it stimulates lactotroph cells to release PRL. However, recent investigations have modified this concept, and its other physiological roles are beginning to receive more emphasis, although even

more is needed. PrRP's broad-spectrum roles in the body include metabolic homeostasis, stress response, cardiovascular regulation, gonadotropin secretion, GH secretion, and sleep regulation. Despite, we think, the presence of its receptors outside the HPA axis, PrRP may have many other functions yet to discover. In fine, PrRP's research horizon is vast.

Proopiomelanocortin

R Day, University of Sherbrooke, Sherbrooke, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

This article is reproduced from the previous edition, © 2004 Elsevier B.V.

Proopiomelanocortin (POMC) is a complex precursor protein that is proteolytically cleaved to a variety of biologically active and important neuroendocrine peptides. These are the highly potent opioid peptide β-endorphin (β-END) and its intermediate β-lipotropin (β-LPH), the stress peptide adrenocorticotropic hormone (ACTH), and various melanotropic peptides including α-, β-, and γ-melanocyte-stimulating hormone (MSH). Other peptides that are produced include corticotropin-like intermediary peptide (CLIP) and joining peptide (JP). The cells which principally express POMC (Figure 1) are the pituitary anterior lobe corticotrophs and intermediate lobe melanotrophs. POMC is highly synthesized in neurons of the arcuate nucleus which project to the median eminence and to a wide spectrum of other brain structures. POMC is also found in neurons of the medullary nucleus tractus solitarius (NTS). In each of these cells, the size and structure of the POMC protein precursor (241 amino acids) and mRNA (1.1 kilobases) are identical; however, a tissue-specific posttranslational processing occurs which results in the formation of a different set of end products by each POMC-producing cell. Therefore, from a single POMC precursor protein, multiple biological activities are obtained depending on which cleavages occur.

Specific enzymes generally known as the prohormone or proprotein convertases (PCs) are responsible for these processing events. Seven such enzymes have been characterized and include PC1 (also known as PC3), PC2, furin, PACE4, PC4, PC5 (also known as PC6), and PC7 (also known as LPC). These enzymes are members of a family of enzymes known as the kexin/subtilisin-like serine proteinases. The PCs specifically cleave only at the C-terminus of single or multiple basic residues, and while POMC is a substrate for the PCs, other proteins can also serve as substrates. The amino acid sequence lysine-arginine (KR) is the most frequently observed cleavage site by the PCs. Other cleavage sites include KK, RR, and RK as well as multiple basic residues. Each PC recognizes basic residue motifs, but cleavage specificity is also determined by the surrounding amino acids. The differential cleavage catalysis by each PC explains how a single precursor such as POMC can be processed into different peptides in different tissues.

The differential processing of POMC has been studied thoroughly in the pituitary. The anterior lobe corticotrophs cleave POMC principally into ACTH and β-LPH. The intermediate lobe melanotrophs also express high levels of POMC, but the main products obtained are α-MSH and β-END. The differences in processing are principally explained by a differential expression of PCs, in particular that of PC1 and PC2 (Figure 2). The anterior lobe corticotrophs express PC1 but rarely express PC2. On the other hand, the intermediate lobe melanotrophs express both PC1 and high levels of PC2. Various experiments, including cellular expression studies and *in vitro* analysis have come to the conclusion that PC1 can only cleave POMC into ACTH and β-LPH (Figure 3). The further processing of these POMC products requires the actions of PC2, which can produce β-END and α-MSH. Since PC2 is generally not expressed in the anterior lobe corticotrophs, ACTH and β-LPH are the major peptides found in these cells. In neuronal POMC-expressing cells, such as those of the ARC, both α-MSH and β-END are observed. Within these POMC ARC neurons, PC1 and PC2 are both co-localized. The role of the other members of the PC family in the processing of POMC is not clear and remains to be investigated.

While it is clear that differential processing of POMC will result in different biological activities, the most striking switching of biological activity of this precursor is observed during anterior pituitary development. Adult anterior lobe corticotrophs normally produce ACTH, but in the first 2 weeks of postnatal development, a large number of these cells produce an α-MSH-like peptide. During this same period, these same corticotrophs also produce high levels of the enzyme PC2, which is important for the production of α-MSH. It is only when the PC2 levels are reduced, after 2 weeks of postnatal development, that MSH-like peptide levels are then reduced, and afterward only occasional MSH cells can be observed. The switching of POMC biological activity (from ACTH to MSH-like peptide) during development may be functionally related to some of the observed effects of melanocortins as growth factors.

The pituitary POMC system is a major component of the physiological stress-regulating circuitry. Anterior lobe corticotrophs release ACTH which acts on the biosynthesis and release of adrenal steroids. Adrenal steroids exert a negative feedback control either directly on the anterior lobe corticotrophs or via the

hypothalamus, through corticotroph-releasing hormone (CRH) cells synthesized in the parvocellular cells of the paraventricular nucleus. CRH neurosecretory neurons project to the median eminence and CRH is released into the portal vessels. Removal of the negative feedback by adrenal steroids can be produced in animals by adrenalectomy, a procedure which stimulates ACTH release and increases anterior lobe POMC mRNA dramatically. Steroid replacement, using dexamethasone or corticosterone, prevents these effects in adrenalectomized animals.

Figure 1 Sagittal diagram describing the location of POMC-synthesizing cells in the brain and pituitary. ARC, arcuate nucleus; IL, pituitary intermediate lobe; AP, pituitary anterior lobe; NTS, nucleus tractus solitarius. Figure outline is based on Swanson LW (1992) *Brain Maps: Structure of the Rat Brain*. Amsterdam: Elsevier.

Glucocorticoids may directly inhibit POMC expression at the level of the corticotroph as well as modulate hypothalamic input to the corticotroph.

In the intermediate lobe, the synthesis and secretion of POMC-derived peptides are tonically inhibited by hypothalamic axons that release dopamine. Adrenocortical steroids from the adrenal gland which feedback and inhibit the anterior lobe corticotrophs do not appear to regulate the POMC cells of the intermediate lobe. The role of the intermediate lobe POMC cells is not clear; however, there is some evidence which suggests that α-MSH secreted from the melanotrophs may act on the neighboring anterior lobe cells to recruit additional lactotrophs to release stored prolactin. It is also noted that β-END produced in the intermediate lobe melanotrophs is mostly acetylated, resulting in poorly opioid receptor active peptides. These weak opioid peptides may be secreted into the blood, but there is no evidence that they exert biological effects in the periphery.

In the brain mainly two cells groups of POMC neurons are observed in the ARC nucleus and the NTS. Both groups of cells have extensive projections in the CNS. The POMC ARC neurons, in the posterior hypothalamus, are homogeneously distributed over the entire rostrocaudal length, with some

Figure 2 Distribution of PC1 and PC2 mRNA in the rat pituitary using *in situ* hybridization histochemistry. (a) PC1 and (b) PC2 mRNA distribution as displayed by silver grains which appear in white in these dark-field low-power photomicrographs. PC1 mRNA is heterogeneously expressed in many anterior lobe (AL) cells but also in all intermediate lobe (IL) melanotrophs which homogeneously express POMC. PC2 mRNA is very highly expressed in the IL, but expressed in fewer AP cells. To better define the sites of PC1 and PC2 expression in AL POMC cells, an mRNA co-localization experiment is shown in (c) and (d). In (c) PC1 mRNA (white grains) is colocalized in AL corticotrophs that also express POMC mRNA (dark staining cells) as indicated by black arrows. In (d) PC2 mRNA is not co-localized (white grains) with POMC mRNA (dark staining cells) as indicated by open arrows.

Figure 3 Differential processing of POMC by proprotein convertase (PC)1 and PC2. PC1 cleaves POMC at basic residues (as indicated by small arrows) to yield adrenocorticotropic hormone (ACTH) and β-lipotropin (β-LPH). PC2 cleaves POMC into α-melanocyte-stimulating hormone (α-MSH) and β-endorphin (β-END). This processing profile correlates with the POMC peptide products found in the pituitary corticotrophs and melanotrophs and the expression of PC1 and PC2 (see also **Figure 2**). JP, joining peptide; CLIP, corticotropin-like intermediary peptide.

scattered cells in the medial basal hypothalamus. Rostral projections pass through periventricular and diencephalic regions and innervate hypothalamic nuclei and limbic structures, including the septum, bed nucleus of the stria terminalis, and the preoptic area. Laterally, POMC fibers extend through the medial basal hypothalamus ventrally and enter the amygdala. Caudal projections course through the dorsal diencephalon into the mesencephalon and brain stem, innervating the periventricular thalamus and the periaqueductal gray, areas associated with nociception and sensory integration. Projections to the brain stem regions include, ventrally, the reticular formation and, dorsally, the nuclei parabrachialis and ambiguus, the NTS, and the regulation of the respiratory and cardiovascular systems. Areas which show no or extremely few POMC-containing fibers are striatum, cortex, and hippocampus.

The second group of POMC neurons is observed in the caudal part of the of the NTS and exhibits more local and caudal projections extending down to the spinal cord. The small POMC cells in the NTS show a more caudal orientation forming a fiber bundle between the NTS and the ventrolateral medulla. The POMC fibers observed in the NTS seem to be of local origin, whereas the catecholamine-containing brain stem nuclei and the baroreceptor areas of the lower brain stem receive a double innervation from the arcuate nucleus and the NTS. POMC fibers observed in the spinal cord originate, at least in part, from the NTS, although the presence of local POMC circuits in the cord cannot be excluded.

While the physiological role of POMC-derived peptides in the pituitary is clearly characterized by its involvement in the stress-regulating circuitry, their functional role in the CNS is less clear. Given the potent analgesic properties of β-END, it is likely to play a role in pain modulation, including phenomena such as stimulation-produced analgesia. Electrical stimulation of the periaqueductal gray, an area rich in POMC fibers, can produce profound behavioral analgesia, while stimulation of the medial thalamus, along the POMC bundle, can relieve pain. In addition, the best sites of stimulation-produced analgesia represent a pattern which coincides almost perfectly with the β-END pathway.

Proprioception

J L Taylor, Prince of Wales Medical Research Institute, Sydney, NSW, Australia

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Bastian, in 1887, described 'kinaesthesia' as "the sense of movement" whereby "we are made acquainted with the position and movements of our limbs, we are enabled to discriminate between different degrees of 'resistance' and 'weight,' and by means of it the brain also derives much unconscious guidance in the performance of movements generally." The term 'proprioception' is used synonymously with kinesthesia. It was first used by Sherrington in 1906 and can be thought of as referring to the sensations of the body. Although proprioception is a sense like vision, hearing, touch, taste, and smell, these more commonly recognized sensory systems give us information about the outside world, whereas proprioceptors are the sensory receptors which tell us what the body itself is doing. As Bastian suggested, kinesthesia encompasses a complex of sensations which include a sense of joint movement, a sense of joint position, a sense of muscle force or tension, and a sense of effort. Sensations derived from the vestibular apparatus are also sometimes included in proprioception, but these signals of the position and movement of the head relative to the external world will not be discussed here.

The sense of joint movement (movement sense) is the process by which we perceive movements of parts of the body relative to one another. It includes detection of movements and perception of their direction, velocity, distance, and timing. Both passive movements, which are imposed by an external force, and active movements, generated by the muscles, are perceived. The sense of joint position (position sense) is the process by which we perceive the current positions of parts of the body relative to one another. Again, relative positions can be perceived when the body parts are at rest and when they are held in position by muscle contraction. The sense of force or tension is the process by which we perceive forces generated through the muscles, whereas the sense of effort gives a perception of the strength of muscle contraction relative to the total strength of the muscle. Both of these signals are used in perception of applied forces, and in judging heaviness. All of these sensations are used separately and together to give knowledge of the body's own actions and its interactions with the environment. Thus, proprioceptive sensations provide feedback of the consequences of motor output and are vital to the control of voluntary movement.

Sensory Receptors Contributing to Proprioception

Sensory receptors in the muscles, joints, and skin are all involved in proprioception. In muscle, the major receptors for proprioception are muscle spindles and Golgi tendon organs. Muscle spindles are complex receptors which lie in parallel with the muscle fibers. They are fluid-filled fusiform (spindle-shaped) capsules of connective tissue with bundles of small (intrafusal) muscle fibers inside them. On the intrafusal fibers are two kinds of sensory nerve endings: the spiral endings of the primary muscle spindle (Ia) afferents and the flower-spray endings of the secondary muscle spindle (II) afferents. Both classes of muscle spindle endings fire with stretch of the muscle and so give a signal of muscle length. The primary ending has the more dynamic response. It fires a burst at the beginning of a stretch and signals velocity and acceleration as well as muscle length. Muscle spindles also have their own motor nerve supply to the intrafusal muscle fibers. As contraction of the intrafusal fibers stretches the sensory endings, muscle spindle firing can result from motor output as well as from muscle stretch. Thus, interpretation of muscle spindle signals during active muscle contractions is complex.

Golgi tendon organs are situated at the musculotendinous junction. They consist of several strands of collagen attached to the tendon at one end and to a number (3–25) of muscle fibers at the other end. The strands of collagen are covered by a connective tissue capsule and are innervated by a Ib sensory neuron. Although tendon organs can fire in response to passive stretch of the whole muscle, they are much more sensitive to active forces generated by the specific muscle fibers that are attached to them.

In the joints, sensory endings are located in the joint capsule and ligaments. Ruffini endings are slowly adapting afferents which are sensitive to stretch of the joint capsule. They fire most at the ends of joint range, but a few afferents can fire across the midrange of joint movement. Larger tendon-organlike receptors are found in the ligaments. These also respond to stretch but have a higher threshold compared to the joint capsule receptors.

In the skin, the receptors most directly associated with proprioception are the slowly adapting type II (SAII) receptors. These fire in response to stretch of the skin in specific directions. They can signal changes

in joint angle when the skin is stretched over one side of a joint and compressed on the other side.

Neural signals from all of these sensory receptors are carried via large-diameter myelinated sensory neurons with cell bodies in the dorsal root ganglia and projections which enter the spinal cord through the dorsal roots. Cutaneous afferents from both the upper and the lower limbs ascend directly to the medulla, where they synapse. Muscle afferents from the upper limb follow the same route whereas those from the lower limb have an intermediary synapse in Clarke's column in the spinal cord. From the medulla, proprioceptive signals cross the midline to the contralateral thalamus and from there project to the cortex.

Sensations of Movement and Position

Position sense and movement sense give perceptions about the relative locations and movements of parts of the body. These can be perceptions of angle or movement at a single joint (e.g., bend of the knee), about many joints (e.g., perception of the distance between the thumb and a fingertip), or even of position or movement that does not involve joints (e.g., of facial expressions or the direction of the eyes). The sense of movement and sense of position can be difficult to separate, as movement is a change of position and each position is reached through movement. However, it is possible to impose movements that are too slow to feel and yet, when displacement is great enough, a new position is perceived. This suggests that there is a sense of position separate from movement.

Testing Movement Sense

The sensitivity of movement sense is often tested by determining the smallest imposed movement that can be detected with the muscles relaxed. The size of this threshold movement depends on velocity, with faster movements detected more easily than slower movements (Figure 1). With velocities of $>1^\circ\,s^{-1}$, very small movements of 0.1–0.5° can be detected at limb joints and for rotation of the neck and trunk. With slower velocities, larger movements of ~1–3° are required. With very slow velocities ($2^\circ\,min^{-1}$), study participants no longer report any sensation of movement. At the interphalangeal joints of the fingers and toes, much larger angular movements are needed for detection. For the big toe, detection thresholds of ~20° at $1^\circ\,s^{-1}$ are reported. It is not clear how active muscle contraction changes the detection of imposed movements, as both impairment and improvement have been reported. The strength of contraction and the task performed may be important.

Perception of the velocity of movement is another facet of movement sense that has been tested. Discrimination between velocities of imposed movement about a joint is better for slower velocities. For movements at $\sim15^\circ\,s^{-1}$, individuals perceive differences of $2–4^\circ\,s^{-1}$, whereas for movements at $\sim50^\circ\,s^{-1}$, differences of $10^\circ\,s^{-1}$ are detected. Individuals can actively match the velocity of an imposed movement to within $\pm5^\circ\,s^{-1}$ over velocities from ~15° to $80^\circ\,s^{-1}$.

Testing Position Sense

Position sense also has a number of facets that can be tested in different ways. As noted, movements can be imposed so slowly that individuals do not

Figure 1 The magnitudes of movement required for detection of movements of different velocities are plotted for joints of the upper limb – shoulder, elbow, distal interphalangeal joint (DIP) and metacarpophalangeal joint (MCP) of the finger – and for joints of the lower limb – hip, knee, ankle, and the interphalangeal joint of the big toe (toe). Movement detection is better at faster velocities. If velocities are slow enough ($0.1^\circ\,s^{-1}$), detection is independent of velocity. Adapted from Refshauge KM, Chan R, Taylor JL, et al. (1995) Detection of movements imposed on human hip, knee, ankle and toe joints. *Journal of Physiology* 488: 231–241, with permission.

perceive them. With these very slow displacements, changes of position of ~2–5° of the ankle, shoulder, and finger are discriminated.

The ability to match joint positions is tested in a variety of ways. The simplest is for the person to move one limb to match the angle of a joint of the contralateral limb which was moved passively and is supported in position. Under such conditions, individuals can match joint angle within 5–10°. Some variants on this test include repositioning the same limb rather than matching with the other limb, using a pointer or indicator rather than using a matching limb, and giving a verbal estimate of angular position. Other variations focus on changes in the limb being matched – for example, varying the time between arrival at the position and matching, having the person move actively to position, or hold the position actively. When muscle activity is used to maintain position, accuracy is improved with errors of ~2°.

Another aspect of position sense is the ability to perceive the instantaneous position of the arm during an ongoing movement. During an imposed movement at the elbow at velocities of 70–200° s^{-1}, individuals can indicate with an accuracy of ±1° when the arm passes through a particular joint angle. This contrasts with the poorer performance in detection of imperceptibly slow movements, and in position-matching tasks.

Evidence for the Mechanisms Underlying Movement and Position Sense

It is generally accepted that sensory inputs from muscle, skin, and joints all contribute to movement and position sense, although belief in the relative importance of each contribution has varied over the past century. The evidence that supports the contribution from each type of afferent includes the findings that (1) the afferents fire in response to joint movement or joint position, (2) activation of the afferents leads to the perception of joint movement or altered joint position, and (3) elimination of the firing of the afferents impairs the ability to perceive joint movement or position.

Joint receptors The activity of joint afferents has been recorded from awake people through microneurography, in which a fine needle can record the activity from single nerve fibers. In general, the afferents tend to fire at the ends of joint range and do not give an unambiguous signal of joint position or the direction of movement. However, occasional afferents do fire throughout the whole range in a way related to position, and this may be sufficient to give a useful signal. With microneurography it is possible to stimulate a single nerve fiber electrically. For ~30% of joint afferents, this stimulation is perceived as small joint movements. With other afferents, individuals report pressure in the joint. When joint afferents are not active, either during testing after total joint replacements or with injection of local anesthetic into the joint, there is little impairment. Thus, although joint afferents contribute to perception of joint movement and position, other inputs can compensate for their loss.

Skin receptors Recording from skin afferents shows that the slowly adapting afferents which respond to stretch of the skin can fire with changes in joint angle. For example, afferents with receptive fields over the back of the hand increase firing with flexion of the metacarpophalangeal joints. Thus, these afferents can signal joint movement and position. Activation of skin afferents can produce perceptions of movement of the fingers and limb joints. If the skin is stretched on one side of a joint by pulling on tape stuck to the skin, many people report feeling movements about the joint. The illusion is enhanced if the skin on the other side of the joint is compressed at the same time. When input from the skin is removed by local anesthetic, perceptions of movement and position are impaired but not abolished at finger joints. However, impairment does not occur with anesthesia of a sleeve of skin around the knee. Thus, sensory input from the skin contributes to movement and position sense. It may be easier to compensate for its loss at the larger limb joints than in the hand.

Muscle spindles The muscle afferents associated with movement and position sense are those from the muscle spindles. These fire when the muscle spindle is stretched during lengthening of the muscle. Recording in humans and in animals shows that muscle spindles can signal joint movement and position during passive movements. The Ia afferents signal velocity (with a position component) whereas the group II afferents primarily signal position. Muscle spindle activity increases with muscle lengthening, but most spindles fall silent during passive shortening of the muscle. Thus, muscles on both sides of a joint are needed to give adequate signals of movement and position. Stimulation of a single muscle spindle afferent causes no sensation, but when a population of muscle spindles is activated by vibration applied over the tendon of the muscle, joint movement and altered joint position are perceived. Illusory movements are felt in the direction consistent with lengthening of the vibrated muscle. Higher frequency vibration (~100 Hz) generates a strong illusion of movement with a velocity related to the frequency of vibration. This illusion is attributed to discharge of Ia afferents. With lower frequency vibration, the

movement illusion is diminished but an illusion of altered position remains. This is attributed to group II afferent activity. The anatomy of muscle attachments to the phalanges allows the muscles to be disengaged functionally from the distal interphalangeal joint of the middle finger by positioning the hand with the middle finger fully flexed at the proximal interphalangeal joint and all the other fingers extended. Because no muscles act at the distal interphalangeal joint in this posture, movement and position sense can be tested without muscle spindle activity. The absence of muscle spindle firing impairs, but does not abolish, detection of joint movement and position.

During active movements, signals from joint and skin afferents are the same as during passive movements. Muscle spindle activity in the antagonist (non-contracting) muscle should also be unchanged. In contrast, the firing of muscle spindles in the active muscle depends on fusimotor drive, in addition to changes in muscle length. In humans, fusimotor drive to the muscle fibers inside the muscle spindles usually occurs concurrently with voluntary activation of the muscle. Therefore, during an isometric contraction, spindle firing increases from fusimotor drive even though the muscle is not stretched. During a shortening contraction, spindles will keep firing if the shortening is slow, but will fall silent if the shortening velocity of the muscle exceeds the ability of the intrafusal fibers to contract quickly. During a lengthening contraction, both fusimotor drive and muscle stretch will add to spindle discharge. It has been postulated that a signal related to fusimotor output must be used by the brain to interpret muscle spindle input in terms of joint movement and position during voluntary contraction.

Corollary discharge A final mechanism that may give rise to sensations of movement or position is a central signal related to motor output. Such a signal is known as a corollary discharge. This idea is well established for the eyes. Because the muscles of the eyes always have to move the same load, a set amount of drive to the muscles should always result in the same eye movement. That is, you should know which way your eyes are pointing because you told them to go there. Individuals' reports that the visual world moves when passive movements are imposed on the eyes are consistent with this proposal. In contrast, there is no fixed relationship between motor command and the resultant movement or position for the limb muscles, because they work under ever-changing loads. However, a recent study, in which individuals experienced illusions of altered joint position when they tried to move a paralyzed and anesthetized hand, suggests that a signal related to motor command may also have a role in position sense in the limbs.

Sensations of Force and Effort

The sense of muscle force or tension and the sense of effort are difficult to separate. One provides a perception of the absolute force being generated by the muscle. The other gives a perception of the proportion of total muscle strength being used. Both contribute to judgments of applied forces and of heaviness. The mechanisms underlying the sensations differ. The sense of muscle force is attributed to sensory input whereas the sense of effort is attributed to a central signal related to motor command.

Testing Force and Effort

Sensations of force are often tested by asking persons to make judgments about the weights of objects. The heavier an object, the more muscle force is required to move or lift it. People can discriminate between weights which differ by about 6%. This ability is independent of the muscle group which is used to support the weight. When individuals give numerical estimates of the magnitude of force or weight, perceived force doubles if exerted force is increased by 50%. However, if they lift a weight with one muscle group and then choose a matching weight with the contralateral muscles, the relationship between the two weights is linear, although lower weights (<40% maximal force) are overestimated and higher ones (>80% maximal force) are underestimated. The linearity of weight-matching suggests that the relationships between force production and perception are similar in the two muscle groups. People can match isometric forces in the same way as weights, with an average error of ~4% of maximal force. People can also scale forces based on their own effort. When individuals produce designated proportions of maximum effort, they produce more force than expected for weak efforts and less for strong efforts. This is consistent with the overestimation and underestimation in matching light and heavy weights.

Evidence for the Mechanisms Underlying Sensations of Force and Effort

The main sensory inputs that underlie the sense of muscle force are the Golgi tendon organs. Because each tendon organ is activated by the contraction of only a few muscle fibers, the firing of single tendon organs does not represent the force generated by the whole muscle. In contrast, the response from a population of tendon organs is a good measure of overall force, although a dynamic component to the

firing accentuates changes in force. It is not clear whether stimulation of tendon organs gives a perception of muscle force, although people do experience sensations of muscle force when muscle contractions are produced by electrical stimulation.

Sensory signals of muscle force and central signals of effort are both directly related to the force generated by a muscle. However, when a muscle becomes fatigued, it cannot produce as much force, and sensations of muscle force and effort are dissociated. It is a common experience to hold an object which gets heavier and heavier as the muscles holding it get tired. The increase in perceived heaviness despite the object's constant weight is an indication that the sensation is not conveyed by the tendon organs, which continue to give a true signal of muscle force. In this situation, progressive fatigue of the muscle fibers means that more of the muscle needs to be recruited to support the object. That is, the motor drive or command to the muscle is increased, and the sense of effort, which is related to the proportion of the muscle that is being used, also increases. Thus, the increase in heaviness of objects during fatigue suggests that the sense of effort has a large influence on perception of weight and force. This is confirmed when individuals match weights lifted by two muscle groups of different strength. Heavier weights lifted with the stronger muscles are matched to lighter weights lifted with the weaker muscles (Figure 2). However, the sense of effort is not the sole contributor to perceptions of heaviness. Although a weight supported by a fatigued muscle feels heavier, the increase in heaviness is not directly proportional to the reduction in force-generating capacity of the muscle. That is, if the maximal force of the muscle is reduced by half, the weight does not feel twice as heavy. This suggests that some other signal, presumably sensory input from tendon organs, also has a role. Similar results are reported when individuals' muscles are weakened by partial curarization.

Finally, in most judgments of force, tactile information is also important. Pressure-sensitive receptors are not truly proprioceptors, because they give information about the body's interaction with the environment rather than conveying sensations about the body itself. However, skin receptors can signal the magnitude and direction of forces. When muscle receptors and central signals of effort cannot contribute, such as when objects are placed on a hand which is resting on a table, people can discriminate changes in weight of ~30%. Although discrimination is improved when the object is supported actively, the elimination of tactile input alters force sensations even during active conditions.

Figure 2 Individuals matched forces produced by elbow flexion (reference) with forces produced by a finger (■) or by a pinch grip of the hand (○). (a) The same force produced by the elbow was matched with a lower force produced by the finger than by the hand. As the finger could produce a lower maximal force, compared to the hand, the difference in matching is consistent with matching effort. (b) The same data as in panel (a) are shown expressed as percentages of maximal voluntary force (MVC). For a force produced by the elbow, individuals matched the same proportion of muscle force for the finger and hand. Note that these weak forces produced by the elbow (~2–8% MVC) were overestimated by both the finger and the hand, which matched with ~5–15% MVC. Interactions of Senses

Some sensations require interactions between the proprioceptive senses. For example, heaviness of an object can only be gauged if the object can be moved. Movement signals the time when the perceived force is a measure of the object's heaviness. The perceptions of qualities such as stiffness, which is a combination of force and distance, and viscosity, which combines force and velocity, need continuous interaction of sensations of movement and force. The senses of movement, position, force, and effort can all contribute to the perception of limb position under different circumstances. If the limb is resting passively, only position sense is available to give a perception of joint angle. In contrast, if the limb is supported against gravity by active muscle contraction, then the muscle force

needed to hold the limb in position will also vary with joint angle. Thus, the sense of effort associated with the level of muscle contraction, as well as signals of muscle force from tendon organs, will be able to contribute (Figure 3). Finally, if the joint position was reached by a movement, then movement sense may also have a role.

Interactions between proprioception and other senses provide orientation in the environment. Perception of where the body is in space relies on the sensations of movement and position of the neck, trunk, and limbs, combined with sensory input from the vestibular apparatus, which signals movements of the head in space. If the head rotates 90° to the right, it might mean that the neck has turned, that the trunk has turned or that the whole body has turned. Sensations of movement and position from the neck and trunk allow us to differentiate these conditions which give similar vestibular signals. Sensations of position and movement of the eyes are essential for the perception of the location of visual objects relative to the head, with proprioceptive input from the neck needed to identify the location relative to the body. Similarly, the location of sounds relative to the body requires sensations of movement and position of the head on the neck.

Figure 3 Diagram showing the proprioceptive signals available to contribute to the perception of elbow angle (limb position) while the forearm is supported against gravity by active contraction of biceps brachii. Sensory signals are available from muscle spindles and tendon organs in the agonist (biceps) and antagonist (triceps) muscles. Sensory input is also available from joint receptors and from skin receptors on both sides of the joint. A central signal related to the motor output (corollary discharge) is also available.

The contribution of proprioceptive sensations to awareness of the size and shape of the body is demonstrated by illusions that can be induced by tendon vibration. If vibration is applied to the biceps brachii tendon while a person touches the nose with the finger, the nose feels like it grows. As discussed previously, the vibration activates muscle spindles, which give the illusion that the arm is extending at the elbow (consistent with biceps lengthening). However, tactile sensations insist that the finger is still touching the nose. The brain's resolution to this dilemma is that the nose is getting longer. Thus, proprioceptive signals influence the body image.

Changes in Proprioception with Pathology

Proprioceptive function changes with normal events such as fatigue as well as with injury and disease. As discussed, muscle fatigue alters judgment of force and heaviness. It can also impair the detection of imposed movement and judgment of limb position when the limb is actively held against gravity.

Musculoskeletal injuries such as ankle sprains and knee ligament injuries are associated with impaired movement and position sense at the injured joint. Similarly, impaired proprioception is reported with arthritis and low back pain. Disturbance of proprioceptive input from the neck may lead to the dizziness and impaired balance in patients with whiplash. The mechanism of such impairments is not clear. Possibilities include changes in the periphery, including inflammation or altered tissue compliance, which could change receptor firing, and more central effects, such as interaction between pain and proprioceptive sensations.

Interruption of the neural pathway from the sensory receptors to the brain will also result in impairment of proprioception. This could happen in the periphery through neural injury or neuropathy, in the spinal cord with injury or diseases such as multiple sclerosis, and in the brain stem or at the cortex through injury or stroke. Very rarely, patients who have lost all large myelinated nerve fibers have no sensory input to provide proprioceptive signals and must rely on central signals related to muscle contraction and on vision to perform motor tasks successfully. They are unable to learn new motor skills.

Apart from lesions in the proprioceptive pathway to the cortex, movement disorders (such as Parkinson's disease, focal dystonia, Huntington's chorea) and cerebellar disorders have associated impairments of various proprioceptive sensations. For example, detection of passive movements and joint position is

impaired in Parkinson's disease, whereas in cerebellar disorders, the discrimination of velocity and duration of movements is impaired.

Contribution of Proprioception to Motor Control

Proprioception and motor control are so entwined that it is often impossible to separate where the sensory signals subserve a direct motor function and where the same signals evoke proprioceptive sensations which might then be used in control of movement. Proprioceptive signals contribute to movement at every level. Proprioceptive afferents have roles in reflex responses at the spinal and cortical levels and provide feedback that allows the control of all purposeful movements. We can attend to some of this feedback and report sensations related to it, but we more commonly employ it to guide our actions. Although we usually pay no attention to the current position of a hand before we use it to pick something up, we could, if asked, report the hand's location. Proprioception is essential to motor learning. New patterns of movement, such as driving a car or hitting a ball, cannot be learned in its absence. Without proprioceptive sensations there is no direct link between the motor output and its consequences.

Summary and Conclusions

Proprioception is the sense which allows perception of the location, movement, and action of parts of the body relative to each other. Proprioceptive sensations are derived from combined sensory input from muscle, joint, and skin receptors, plus central signals related to motor output. Sensations of movement and position and force and effort can be tested separately, but are used in conjunction with each other during many perceptual and motor tasks. Proprioception is so closely tied to the control of voluntary movement that impairments are more likely to be noticed as deficits in the performance of motor tasks than as impaired sensations.

Prosopagnosia

D Tranel and N L Denburg, University of Iowa Hospitals and Clinics, Iowa City, IA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Prosopagnosia is a neurological term of Greek origin (Greek *prosop*, face, + a + Greek *gnosis*, to know), used to denote a condition in which patients lose the ability to recognize familiar faces. The disorder is confined to the visual realm, and the affected patient cannot arrive at the meaning of some or all previously known faces, despite normal or near-normal visual perception and intact alertness, attention, intelligence, and language. Most patients manifest a comparable defect in the anterograde compartment; that is, they cannot learn new faces despite adequate exposure. Prosopagnosia is usually caused by cerebrovascular disease, head injury, or cerebral tumors. In some instances, it can occur in the setting of a degenerative condition such as Alzheimer's disease, although in these cases it is usually part of more widespread neuropsychological dilapidation. Finally, prosopagnosia can arise during early childhood, with deficits presumably present from birth.

Prosopagnosia (or face agnosia) is the most frequent and well established of the visual agnosias. The phenomenon has been noted since the nineteenth century, and it has been the focus of considerable scientific inquiry. The fascination with prosopagnosia stems from the oddity of the disorder, along with the opportunity it provides to investigate perception, learning, and recall of complex and unique knowledge. From a clinical standpoint, the condition is also important, and given its devastating effect on its victims, accurate diagnosis and management are essential. Investigation of prosopagnosia has been marked by controversy regarding the relative importance of perceptual versus mnestic factors in the development of the condition and a dispute about whether prosopagnosia requires bilateral lesions or can be caused by unilateral damage.

Neuropsychological and Neuroanatomical Correlates of Prosopagnosia

The face recognition defect in prosopagnosia typically covers both the retrograde and anterograde compartments. Patients can no longer recognize the faces of previously known individuals and are unable to learn new ones. They are unable to recognize the faces of family members, close friends, and in the most paradigmatic instances, even their own face in a mirror. On seeing those faces, the patients experience no sense of familiarity, no inkling that those faces are known to them; that is, they fail to conjure up consciously any pertinent information that would trigger recognition. However, the recognition disorder is confined to the visual modality, and recognition via other modalities (e.g., hearing recognizable voices) is unaffected.

As with other forms of agnosia, prosopagnosia must be distinguished from disorders of naming, that is, it is not an inability to name faces of persons who are otherwise recognized as familiar. There are numerous examples of face naming failure, from both brain-injured populations and the realm of normal everyday experience, but in such instances, the unnamed face is invariably detected as familiar, and the precise identity of the possessor of the face is usually apprehended accurately. In prosopagnosia, however, the defect sets in at the level of recognition. Needless to say, the patients will also manifest a face naming impairment (they will not name faces they cannot recognize), but this is artifactual and not a true naming defect. Several major types of prosopagnosia can be distinguished.

Pure Associative Prosopagnosia

In this variety, the recognition impairment is relatively pure in the sense that it is confined to the visual modality and occurs in the setting of normal or near-normal visual perception. Associative prosopagnosia largely conforms to the strict definition of agnosia, that is, "a normal percept stripped of its meaning" (Teuber's classic definition of agnosia; Teuber, 1968: 274–328). The patients perform normally on standard neuropsychological tests of visuoperceptual discrimination and visuospatial judgment. As noted, recognition via other sensory modalities is unaffected, and on hearing the voices of individuals whose faces go unrecognized, the patients will instantly recognize the identities of those individuals. Even within the visual modality, the defect is highly circumscribed. For instance, patients may be able to recognize individuals on the basis of a distinctive feature (e.g., hairstyle) or gait or posture.

Most patients with pure associative prosopagnosia also have achromatopsia, an acquired impairment of color perception. The combination of the defects is due to the contiguity of the neural processing systems for form and color and their sweeping damage by one lesion. The color perception defect *per se*, however, does not account for the face recognition impairment, and normal individuals can easily recognize faces in black-and-white. The ability to read may or may not

Figure 1 Illustration of the neuroanatomic findings of a patient with pure associative prosopagnosia.

be affected in prosopagnosia patients, depending on the location of the lesion in the left occipital region. When the lesion encompasses both the left occipito-temporal region and the left periventricular region (the white matter beside, beneath, and behind the occipital horn), reading impairment (alexia) coexists with prosopagnosia.

Pure associative prosopagnosia is caused by bilateral damage in inferior occipital and temporal visual association cortices, that is, in the inferior component of cytoarchitectonic areas 18 and 19 and part of the nearby cytoarchitectonic area 37 (see Figures 1 and 2 for an illustration of the neuroanatomic findings in such a patient). Most cases are due to cerebral infarctions caused by occlusion in posterior cerebral artery branches. Head injury and cerebral tumors, especially gliomas originating in one occipital lobe and traversing into the opposite hemisphere via the splenium of the corpus callosum, can also produce prosopagnosia. Prosopagnosia in connection with lesions (bilateral or unilateral) located exclusively above the calcarine fissure, in superior visual association cortices, has never been reported, although there are cases of face agnosia in which on one or both sides, the inferior lesions extend upward above the calcarine fissure.

Apperceptive Prosopagnosia

Face agnosia in the setting of significant visuoperceptual disturbance has been termed 'apperceptive' prosopagnosia. Apperceptive face agnosics have defects in basic visual perception, demonstrable on neuropsychological testing, which compromise abilities such as matching of unfamiliar faces, judgment of line orientations, and mental manipulation of pictures and picture fragments. It should be noted, however, that such defects are not so severe as to compromise most aspects of basic form vision; thus, the condition conforms in a broad sense to the definition of agnosia. As in other forms of recognition, perceptual processes on the one hand and recognition–recall processes on the other cannot be rigidly compartmentalized. Even in 'pure' cases of associative prosopagnosia, there may be fairly subtle, albeit important, disturbances of high-level integrative perceptual abilities which cannot be detected by available probes. Also, any explanation of face agnosia tied to perceptual factors must reconcile the fact that most patients with visual perceptual defects, even severe ones, do not lose their ability to recognize faces. That is, visuoperceptual disturbance as detected by neuropsychological probes does not necessarily cause face agnosia. For these reasons, it is useful to maintain a distinction between associative and apperceptive prosopagnosia because generally it is possible to determine whether the condition is largely due to memory defects (associative) or to high-level perceptual defects (apperceptive).

Apperceptive face agnosia is most often associated with bilateral damage to 'early' visual association cortices or with damage in right visual association cortices within the occipital and parietal regions. It appears that the damage must involve both the inferior and superior components of posterior visual association cortices (areas 18 and 19), mesially and laterally, for severe and lasting face agnosia to develop. In most cases, parts of areas 39 and 37 on the right will also be damaged. Figure 3 illustrates the neuroanatomic findings in such a patient.

Developmental Prosopagnosia

Some individuals never develop a normal capacity for learning faces. They have a lifelong deficiency in learning and recognizing faces that ought to have been readily mastered, and since the problem begins in childhood, it is appropriate to call it 'developmental' prosopagnosia. Developmental prosopagnosia has not been widely reported or studied, but it may be far more frequent than suspected, its apparent rarity being because affected persons tend to conceal their disability. It is probably associated with learning disability for other classes of visual stimuli which, like faces, require individual identification and have many similar exemplars. Neural correlates for this condition are in the early stages of being identified, and the findings point to the potentially important role of the midfusiform gyrus and the inferior occipital gyrus. The youngest documented case of developmental prosopagnosia was recently reported. Briefly, patient AT was studied at approximately 5 years of age. AT has both a negative medical history and a negative MRI of the brain. Intellect falls in the very superior range, and he came to medical attention during preschool because of problems recognizing individuals who were well known to him. AT's difficulties are mainly

Figure 2 Illustration of the neuroanatomic findings of a patient with pure associative prosopagnosia.

Figure 3 Illustration of the neuroanatomic findings of a patient with apperceptive face agnosia.

associative in nature, although he does manifest aspects of apperceptive prosopagnosia, as demonstrated by defects in certain aspects of visuoperception. Interesting parallels with the experimental research in acquired prosopagnosia in adults are evident in this case and are noted in the section titled 'Nonconscious discrimination of familiar faces.'

A recent study identified a subgroup of patients with Asperger's disorder who manifested prosopagnosic-like defects, suggesting the possibility of occipitotemporal dysfunction in patients with social developmental disorders.

Other Aspects of Face Processing

Nature and Extent of the Defect

In prosopagnosia, the recognition impairment occurs at the most subordinate taxonomic level, that is, at

the level of identification of unique faces. Prosopagnosics are fully capable of recognizing faces as faces; that is, performance is normal at the superordinate taxonomic level. Also, most prosopagnosics can recognize facial expressions, and can make accurate determinations of gender and age based on face information. These dissociations highlight the fact that recognizing faces at the level of unique identity is a highly demanding task which requires the brain to distinguish between numerous exemplars that bear a high degree of resemblance to one another.

Although face agnosics recognize any number of visual entities at basic object level, such as cars as cars, buildings as buildings, and dogs as dogs, they often fail to recognize these items at the subordinate level of unique identity. Thus, similar to the problem with faces, they are unable to recognize the specific identity of a particular car or building. These recognition impairments are common in prosopagnosia and underscore the notion that the core defect in face agnosia is the inability to disambiguate fully individual visual stimuli. In fact, cases have been reported in which the most troubling problem for the patient was in classes of visual stimuli other than human faces, such as a farmer who lost his ability to recognize individual dairy (Holstein) cows or a birdwatcher who became unable to tell apart various subtypes of birds.

Prosopagnosic patients can often recognize identity from movement. This means not only that their perception of movement is intact but also that they can evoke appropriate memories from the perception of a unique pattern of movement. Combined with the finding that recovery of identity from motion can be impaired by lesions in superior occipitoparietal regions, these findings underscore the separable functions of the 'dorsal' and 'ventral' visual systems, the dorsal one being specialized for spatial placement, movement, and other 'where' capacities and the ventral one being specialized for form detection, shape recognition, and other 'what' capacities.

Nonconscious Discrimination of Familiar Faces

Some prosopagnosic patients show accurate covert or nonconscious discrimination of familiar faces despite their complete inability to recognize those faces at overt level. For example, it has been shown that prosopagnosics generate large, discriminatory electrodermal responses to familiar faces that are otherwise unrecognized. Preserved covert face discrimination has been demonstrated in other experimental paradigms, such as reaction time tasks and forced choice procedures. In the electrodermal paradigm, covert face discrimination has even been demonstrated for faces from the anterograde compartment, indicating that the brain can continue to learn new visual information even without conscious influence. In the earlier mentioned developmental case, it was found that AT's covert face discrimination based on an autonomic index was normal, suggesting that the brain is capable of acquiring some information about familiar faces, even without conscious recognition.

Recovery

Prosopagnosic patients often become quite adroit at using nonface information to recognize the persons around them. For example, they rely on voice, or gait, or a distinctive visual feature. Regarding the latter, it is often helpful to add a distinctive feature in situations in which recognition is highly demanded but difficult. At a crowded social gathering, for example, the patient's spouse might wear a special hat or other article of clothing, which would facilitate rapid and accurate identification by the patient. There is also evidence to suggest that the prosopagnosic individual may benefit from a local, components-based examination of the face rather than a holistic, configural approach. Generally speaking, though, the earlier in the course of recovery that compensatory strategies such as these can be taught, the better the chances for healthy adaptation to the disability.

Unanswered Questions

An issue which has remained central in the study of prosopagnosia is the mechanism of the defect and in particular, the reason the recognition of faces is affected so much more severely than the recognition of other visual stimuli. It has been proposed that faces, more so than many other types of items, have two important qualities: First, they are highly similar in terms of physical structure, that is, they have high visual resemblance or what can be termed homomorphism. Second, they are numerous, and it is necessary to tell them apart at the unique, individual level. It does not suffice, for example, to recognize a good friend as simply a female person or as a female person who works at the hospital. Rather, recognition must take place at the level of unique identity. Together, these factors make faces a 'visually crowded' category, which may explain the vulnerability of familiar face recognition to acquired brain disease.

Other questions remaining in the study of prosopagnosia concern the reasons some prosopagnosic patients are able to generate covert responses to familiar faces while other patients cannot. A related question concerns the relationship among different indices of covert discrimination – for example, are skin conductance responses, reaction times, and eye movement patterns all tapping into the same discrimination mechanisms?

On another point, much still remains unknown about the neural mechanisms of developmental prosopagnosia. Finally, a recent finding regarding covert discrimination of faces in the setting of 'childhood amnesia' raises many interesting questions. Specifically, it has been shown that when school-age children (e.g., ages 10–15) are shown faces of former classmates who were known only in the early developmental years for which much information is not readily retrievable into declarative memory (especially ages 2–5), the children generate discriminatory skin conductance responses even for faces that are entirely 'forgotten' by overt measures. This finding warrants further investigation.

Proteasome Role in Neurodegeneration

L Korhonen, N Putkonen, and D Lindholm,

Introduction

Recent studies have shown the critical role of the proteasome system in different human neurological disorders. Herein, we review the current knowledge of the role of the proteasome in neuronal and axonal degeneration and discuss different ubiquitin E3 ligases, deubiquitinating enzymes (DUBs), and signaling pathways controlling the activity of the proteasome in these disorders.

The Proteasome

Proteasomes are the main proteolytic machinery in cells and exhibit trypsin-like, chymotrypsin-like, and peptidyl-glutamyl peptide hydrolyzing enzymatic activity. The proteasomes are present as 26S and 20S particles in the cell. The 26S proteasome consists of a catalytic 20S core and two 19S regulatory subunits (19RS) at both ends of the 20S subunit forming a barrel-like structure. The 19RS consists of several proteins that mediate substrate recognition and delivery to the core complex for proteolytic degradation into short peptides. The 19RS also removes ubiquitin from proteins ensuring optimal levels of free ubiquitin in the cell. The 20S proteasome cleaves peptides and unfolded proteins without the regulatory unit. Apart from protein degradation, additional nonproteolytic functions have been ascribed to the proteasome. Thus, it was shown in *Saccharomyces cerevisiae* that the 19RS regulates gene transcription through an interaction with the activator protein, Gal4. In addition, 19RS promotes the Spt-Ada-Gcn5-acetyltransferase (SAGA) histone acetyltransferase complex to target promoters during gene activation.

In neurons as well as in other cells, the proteasomes are present in the nucleus, in the cell soma, as well as in the dendrites and the axons. Proteins destined for proteasomal degradation are marked with a chain of ubiquitin molecules in a three-step reaction catalyzed by the E1, E2, and E3 enzymes (see Figure 1). In mammalian cells, there is one E1 and a couple of E2's, but many more E3 ubiquitin ligases that can be divided into four major classes: the homologous to E6-AP C-terminus (HECT), Really Interesting New Gene (RING), plant-homeodomain (PHD), and UFD2-homology domain (U-box) families. The HECT domain ligases share a conserved C-terminal catalytic domain that forms a thioester bond with ubiquitin during the transfer from E2 to the substrate. The N-terminal regions of HECT domain ligases are involved in substrate specificity and recognition. The RING-finger ubiquitin ligases exist either as multisubunit complexes or as monomers and can interact directly with the E2 and the protein substrate. The PHD and U-box domain containing proteins, as well as the RING-finger E3 ligases, facilitate ubiquitin conjugation by acting as a bridge between the E2's and the protein substrates. In addition to the E3 ligases, the ubiquitin chain elongation factor E4 is involved in the efficient elongation of polyubiquitin chains. These proteins contain a protein motif known as the U-box and may act in concert with the E3 ligases. The C-terminus of Hsc0 interacting protein (CHIP) is a U-box containing protein important for the degradation of misfolded proteins, such as the Pael receptor in PD (see below).

Ubiquitin protein has seven lysine sites to which ubiquitin can be enzymatically linked. Attachment of multiple ubiquitin molecules to lysine 48 (called K48 ubiquitinylation) mediates mainly protein degradation, whereas K63 ubiquitinylation is involved in endocytosis, DNA repair, and in cell signaling. However, proteins can also become monoubiquitinated at different lysine sites as shown, for example, for receptor tyrosine kinases (RTKs), such as the epidermal growth factor receptor (EGFR) (see Figure 1).

The levels of ubiquitin are tightly regulated in the cells, among others by the action of the DUBs that remove and recycle ubiquitin from ubiquitin-conjugated proteins (see Figure 1). There are approximately 80 DUBs in the human genome that can be divided into five classes based on the ubiquitin protease domain: ubiquitin-specific proteases (USPs), ubiquitin C-terminal hydrolases (UCHs), Otubain proteases (OTUs), and Machado–Joseph disease proteases (MJDs) and JAMM (JAB1/MBN/Mov34). The latter is a metalloprotease whereas the others are cysteine proteases.

During neuronal differentiation the levels of ubiquitin and its conjugates, as well as protein ubiquitination and the activity of the proteasome, all increase suggesting an important function of these processes during development. In the mature nervous system, mutations in different components of the ubiquitin–proteasome system have been linked to the process of neurodegeneration, occurring in many human neurological disorders.

Figure 1 Schematic view of the function of the ubiquitin–proteasome system (UPS) in protein turnover. Cellular proteins are ubiquitinated by the action of various enzymes acting in concert to add either poly- or monoubiquitinated species to the substrates. Polyubiquitinated proteins are usually doomed for degradation, while monoubiquitinated ones can have other destinies. The regulation of the UPS is complex and dysfunctions may occur in various human diseases. These aspects of the UPS are covered in great detail in recent reviews. U, ubiquitin; E1, ubiquitin-activating enzyme; E2, ubiquitin-conjugating enzyme; E3, ubiquitin ligase; 20S, catalytic core; 19S, regulatory particle; PS, protein substrate; DUB, deubiquitinating enzyme.

Neuronal Degeneration and the Proteasome

Neurodegenerative diseases, such as Alzheimer's, Parkinson's, and Hungtinton's diseases (AD, PD, and HD), are characterized by the selective loss of neurons in specific brain areas. Distinct insoluble protein aggregates and inclusion bodies are found in the affected brain areas in form of tau-positive neurofibrillary tangles and amyloid β (Aβ) peptide in the plaques in AD, α-synuclein containing Lewy bodies in PD, and intranuclear inclusions of polyQ proteins in HD. The deposits contain misfolded proteins, molecular chaperones, and various components of the ubiquitin–proteasome system, such as ubiquitin, various E3 ligases, the 19RS and the 20S proteasome subunit. The accumulation of misfolded proteins in neurons can disturb cell metabolism in different ways and also cause dysfunction of the proteasome.

Normally in the cell, ubiquitin is generated from the ubiquitin precursor protein consisting of tandem ubiquitin molecules that are cleaved into monomeric ubiquitin by the UCH. However, a mutant form of ubiquitin (Ubiquitin^{+1}) has been identified in some neurodegenerative diseases. The ubiquitin^{+1} is generated by a dinucleotide deletion in the mRNA encoding for the ubiquitin B precursor, resulting in a +1 frame shift in the C-terminus of the first encoded ubiquitin molecule. This molecular misreading leads to a 19-amino-acid-long extension of the protein that is resistant to the cleavage by the UCHL. Ubiquitin^{+1} in high concentrations accumulates in neurons and glial cells and can inhibit the proteasome. Studies with human autopsy material and transgenic *ubiquitin*$^{+1}$ mice crossed with transgenic AD and other mouse models have shown that aberrant ubiquitin^{+1} accumulates in AD and in some polyglutamine diseases. Interestingly, ubiquitin^{+1} is not detected in synucleinopathies, such as in Lewy body disease and in multiple system atrophy.

Decreased proteasome activity has been reported in brain autopsy material from PD, AD, and HD patients. In sporadic PD, the 20S proteasome activity is impaired and various components, such as the 19RS and PA28 protein regulator, are expressed at lower levels compared to the controls. In addition, proteasome activity is decreased in neuronal cells after expression of the mutant forms of α-synuclein and of other disease-causing proteins. Recent developments in fluorescent-based reporter systems monitoring proteasome activity *in vivo* has provided further evidence for an impaired proteasome function in neurodegenerative diseases. Treatment with chemical compounds inhibiting the proteasome have been reported to induce degeneration of dopaminergic neurons and cause PD-like symptoms in rats, as well as decrease the viability of nerve cells expressing the mutant amyloid precursor protein. In contrast, the proteasome inhibitors are shown to be partly neuroprotective in ischemic brain injuries, showing a complex relationship between the control of neuronal death and survival and the function of the proteasome.

Direct evidence for the role of the proteasome in neurodegeneration comes from studies of some familial and genetic forms of diseases. In PD, deletions and point mutations have been found in the protein Parkin in approximately 50% of patients with the autosomal recessive form of PD (AR-JP). Parkin is a 465-amino-acid-long protein with an N-terminal UBL domain and two C-terminal RING motifs that can function as an E3 ligase. Parkin is a component of the SCF-like E3 complex together with the F-box/WD repeats protein hSel-10 and Cullin. Mutations in Parkin are thought to reduce its ability to degrade substrates and decrease the overall proteasome activity in cells. Several substrates have also been identified for Parkin, such as the Parkin-associated endothelial-like (Pael) receptor, synphilin-1, and the Cell Division Control related protein (CDCrel-1). Pael-1 is a putative G-protein-coupled transmembrane polypeptide that can trigger the unfolded protein response in the endoplasmic reticulum, and Parkin can ubiquitinate and promote degradation of the insoluble receptor.

Synphilin-1 has an unknown function but is associated with α-synuclein. CDCrel-1 is a member in the serpin family and has a role in synaptic vesicle dynamics. The mechanism by which loss-of-function of Parkin mutations causes PD is currently under intensive investigation.

Like Parkin, Dorfin is an E3 ligase with the ability to protect motor neurons against degeneration caused by mutant human copper/zinc superoxide dismutase 1 (SOD1) protein in amyotrophic lateral sclerosis (ALS). Dorfin ubiquitinates mutant SOD1 and reduces the occurrence of inclusion bodies of this protein in neurons. Dorfin also interacts with the AAA-ATPase valosine-containing protein (VCP) that can bind both the proteasome and polyubiquitinated proteins. The role of such shuttle proteins in different neurodegenerative diseases warrants more studies. Similarly, the precise role of Dorfin in sporadic ALS that represents the major form of the disease remains to be clarified.

For other diseases, it was shown that the ubiquitin E3 ligase, Ube3A, is mutated in Angelman's syndrome, characterized by mental retardation. Ube3A is crucial for long-term potentiation in mouse hippocampus, suggesting important protein targets in the nerve cells. In addition, it is known that anti-apoptotic proteins, such as the X chromosome-linked inhibitor of apoptosis protein (XIAP), exhibit ubiquitin ligase activity. XIAP is highly expressed in the nervous system and inhibits various caspases and further facilitates ubiquitinylation and degradation of pro-apoptotic proteins, such as Smac/DIABLO and Omi//HrtA2 released from the mitochondria during cell death. XIAP is an important regulator of neuronal cell death as shown in excitotoxicity, ischemia, and after nerve cell axotomy.

Synaptic Dysfunction and the Proteasome

Apart from the ubiquitin E3 ligases, decreased activity of some DUBs has been linked to neuronal dysfunction. Usp14 is a USP acting on ubiquitinated target proteins, and mutations in the *usp14* gene cause ataxia in mice. This is the result of defects in synaptic transmission observed both at the neuromuscular junction and in hippocampal CA3–CA1 synapses, suggesting a presynaptic action of the Usp14 protein. Many of the DUBs are involved in the regulation of protein trafficking and endocytic pathways and are therefore expected to have important roles in vesicle transport and in the control of neuronal viability. The precise functions of the different DUBs in the nervous system and in neurological diseases remain to be studied.

Synapses undergo large structural changes during maturation and in response to neuronal activity. Recent studies have further shown that the proteasome is involved in the degradation of molecules belonging to the postsynaptic densities (PSDs) that contain various receptors and scaffolding proteins. In addition, synaptic activity influences the ubiquitination and turnover of a subset of PSD proteins, important for the control of synapse function, and maintenance. As shown by studies in models, systems such as *Aplysia* and *Drosophila* have shown that protein ubiquitination can influence synaptic development and plasticity. In the fruit fly, mutations in the *fat facets* (*faf*) gene, encoding a DUB enzyme, cause severe presynaptic overgrowth and defects in neurotransmitter release. Faf most probably acts by stabilizing the *liquid facets* (*laf*, *Drosophila* epsin) gene product, thereby influencing endocytosis and cell receptor signaling. Recent studies on the neuromuscular system in *Drosophila* revealed a relatively short time window for the degradation of synaptic proteins by the proteasome. Chemical compounds inhibiting the proteasome, as well as genetic manipulations in the fly, subsequently identified the *Drosophila* UNC protein, DUNC-13, as a selective target for the proteasome in the presynaptic terminal. Data showed that proteasome inhibition locally increases neurotransmitter release and the levels of DUNC-13, and enhances synaptic efficacy. Members of the UNC protein family are involved in synaptic vesicle priming and regulation of neurotransmitter release in different species, suggesting similar mechanism for the control of synaptic activity by the proteasome.

As indicated above, monoubiquitination regulates protein trafficking, involving endosomes and clathrin-mediated endocytosis. RTKs, such as the EGFR, are monoubiquitinated upon ligand binding. This leads to RTK internalization and degradation in lysosomes, thereby preventing receptor recycling to the plasma membrane. Similarly, several other receptors such as the neurotrophic factor receptors, TrkA and TrkB, are ubiquitinylated after receptor activation. Very recently, it was shown that the accumulation of mutant Aβ peptide disturbs multivesicular body sorting by inhibiting the ubiquitin–proteasome system and thereby causes defects in receptor cycling. Current data suggest that receptor activation triggered by ubiquitinylation may serve as an important control step for signals mediating neuronal survival and degeneration.

Apart from this, several signaling pathways in the nervous system are regulated by the proteasome. In this context, the activation of the nuclear factor-kappa B (NF-κB) pathway after proteasome degradation of the inhibitor-κB protein mainly mediates neuronal survival. The nature of specific genes regulated by

the different NF-κB proteins in brain tissue, however, is only partly understood. In addition, the activities of the c-Jun-N-terminal kinase (JNK)-pathway can, depending on the cellular context, either increase nerve cell death or promote survival. The c-Jun-specific E3 ligase, Fbw7, is required for proper degradation of this protein, and mice deficient in Fbw7 exhibit tremor and loss of specific neuronal subtypes in the brain. The precise roles of the proteasome in controlling various signaling proteins and cascades in different neuronal populations afflicted by neurodegeneration need to be studied more in the future.

Axonal Degeneration and the Proteasome

Apart from changes in the cell soma, various neurological diseases are often characterized by early disturbances in neuronal connectivity and in axonal functions. Particularly in AD, in ALS, and in multiple sclerosis, axons degenerate that leads to changes in neuronal signaling and cell communication. The axon and the synapse can also undergo degeneration due to genetic causes or disturbed metabolism by various chemicals and toxins, as well as following different types of nerve injuries. In these conditions, the neuronal soma will ultimately also degenerate by mechanisms involving disturbed axonal transport and signaling leading to a 'dying-back' disorder that follows the degeneration of the axon.

One model to study axonal reactions has been mechanical transections of a peripheral nerve in rodents that leads to a degeneration of the distal nerve stump. In these conditions, characteristic changes occur in the cellular composition and molecular interactions in the nerve following the injury, described under the term Wallerian degeneration. Studies of the mouse mutant (*WLd*^{s}) with a delay in Wallerian degeneration for about 2–3 weeks has helped to identify a gene product on chromosome 4 that is important for preservation of axonal integrity following the injury. The unique 85 kDa fusion protein in the *WLd*^{s} mice is produced by gene rearrangements and consists of 70-amino-acid-long N-terminal portion of the ubiquitination factor E4b (UbE4b) connected by an 18-amino-acid stretch to the full-length nicotinamide mononucleotide adenylyl transferase (NMNAT) gene. Expression of the fusion protein in transgenic mice and using different vectors has been shown to delay axonal degeneration after traumatic and toxic injuries, as well as those due to genetic mutations.

The mechanisms by which WLd^s protein affords neuroprotection and delays axonal degeneration has been intensively studied using both *in vitro* neuronal systems and transgenic mice. The *WLd*^{s} mice protein in fusion gene is involved in the synthesis of nicotinamide adenine dinucletoide (NAD) that takes part in different cellular reactions. Increased levels of NAD have been shown to be neuroprotective acting either locally in the axons or indirectly in the nucleus by enhanced activity of the NAD-dependent deacetylase, SIRT1. SIRT1 in turn may induce transcription of genes involved in neuroprotection that then acts on the axons, and the effect of NAD can be blocked or enhanced using chemical compounds acting on SIRT1. In line with the presumed effect on gene transcription is the observation that the WLd^s fusion protein is abundantly expressed in nuclei. However, studies on SIRT1 gene deleted mice as well as others suggest that other mechanisms and genes may also be activated in the *WLd*^{s} mice.

Recent findings using transgenic mice indicate that apart from the NMNAT gene the N-terminal region in the *WLd*^{s} gene is also important for counteracting axonal degeneration. The truncated UbE4b protein in this region is part of an E4 enzyme that can function in polyubiquitination and proteasome-mediated degradation of proteins. It may be that for full neuroprotection the whole molecule of WLd^s is required. In the future, it is important to define the precise mechanisms and downstream gene products by which the WLd^s protein can counteract axonal degeneration and increase neuronal survival in different systems.

Results obtained with the crush lesions in the optic nerve in rodents and with injured cultured neurons have shown that inhibition of the proteasome can retard the onset of axonal degeneration and specifically inhibit the fragmentation of microtubule that occurred early after the injury. Preserved axonal integrity was also observed after the expression of an ubiquitin protease that can reverse ubiquitination of protein substrates. These studies thus show that the local activity of proteasome is involved in axonal degeneration and certain drugs targeting this complex can inhibit this. Studies on the Gracile axonal dystrophy (*Gad*) mutant mice support further the involvement of the proteasome in axonal degeneration. Dysfunctional UCH-L1 leads to the degeneration of the gracile tract of the spinal cord and this protein can act both as a DUB and as an ubiquitin ligase. The exact mechanism causing axonal degeneration in the *Gad* mice is however so far unknown.

Studies in *Drosophila* have shown that the proteasome activity is involved in axonal degeneration of occurring during development. In axonal pruning, neuronal connections in the nervous system are refined and mature to meet requirements of functional activity. Interestingly, expression of an ubiquitin

protease or a mutant form of the *Drosophila* E1 ubiquitin-activating enzyme, in the mushroom bodies, was found to inhibit pruning in the fly. This was also observed with mutations in two of the subunits in the 19S regulatory particle. These results indicate a crucial role for local proteasome activity in axon pruning and degeneration in *Drosophila*, supporting studies made on Wallerian degeneration in rodents. However, the identity of ubiquitination proteins as targets for the proteasome in the axons and in axonal degeneration remains to be studied.

In conclusion, available data support the view that the mechanisms underlying axonal degeneration and degeneration of the nerve cell body are inherently different. Death of the soma can occur through both caspase-dependent and caspase-independent mechanisms involving the mitochondria, whereas axonal degeneration occur likely via different mechanisms. However, both neuronal and axonal degeneration involves alterations in local activity of the proteasome including changes in ubiquitination of certain target proteins. As discussed above, data on the function of the WLd^s fusion protein have shown that nuclear reactions with change in gene expression cause a delay in axonal degeneration and can contribute to nerve repair. Similar neuroprotective mechanisms with activation of specific gene programs also underlie the action of different neurotrophic factors that counteract neurodegeneration and promote neuronal survival.

Conclusions

Ample evidence suggests that dysregulated proteasome activity can contribute to different neurodegenerative diseases involving both the cell soma and the axons. The discovery of the E3 ligase, Parkin, has given important insights into the role of proteasome in PD, and similar mechanisms or disturbances in protein turnover may prevail in other types of neurological disorders. Studies of the proteasome activity in axonal reactions and in the slow Wallerian degeneration mice (Wlds) have revealed mechanisms governing axonal degeneration and repair. A summary of the current knowledge about the involvement of the proteasome in axonal and nerve cell degeneration is given in Table 1. Increased insights into the function of the proteasome and its disturbances will deepen our understanding about the cellular mechanisms and proteins underlying different neurological disease and help us to design drugs to modify the cellular reactions involved and to counteract disease and axonal degeneration.

Table 1 Summary of the evidence suggesting a role for the proteasome in neuronal and axonal degeneration

Defect in	*Gene*	*Diseases/models*
Ubiquitin gene		
	Ubiquitin^{+1}	AD, HD: accumulation and cell death
Ubiquitination enzymes and related proteins		
E3 ligases	UBE3A	Angelman syndrome
	Parkin	PD
	Dorfin	ALS (mouse model)
Ubiquitin hydrolase	UCH-L1	PD, GAD
Ubiquitin proteases	usp14	Ataxia (mouse model), synaptic defects
Fusion protein	NMNAT	Slow Wallerian degeneration (Wld^s): axonal degeneration
Proteasome inhibition		
Synthetic inhibitors		PD (rat model), cell models: decreased cell viability; axons: decreased axonal degeneration
Decreased proteasomal activity		PD, HD (autopsy material, cell and mouse models)
Aggregates		
PolyQ proteins	Different	HD, SCA, DRPLA, SBMA
Amyloid plaques	Aß	AD
Lewy bodies	α-Synuclein	PD
Bunina bodies	SOD-1	ALS
Others		
Axonal pruning		*Drosophila* models with synthetic proteasome inhibitors
Signaling		NF-κB
Anti-apoptotic proteins	XIAP	Smac/DIABLO
Receptor endocytosis	RTK, Glu6R TrkB, TrkA	Receptor internalization

Protein Folding and the Role of Chaperone Proteins in Neurodegenerative Disease

Introduction

Many neurodegenerative disorders are characterized by the accumulation of misfolded proteins in or adjacent to neurons and glia. Misfolded proteins can adopt distinct conformational states that exert abnormal and even pathological activities. Molecular chaperones are proteins that mediate the proper folding of other proteins and appear to have other important functions in the healthy and diseased brain. One essential function is to ensure that misfolded proteins do not accumulate in the brain. Increased expression of molecular chaperones is protective in numerous animal models of neurodegenerative disease. A small molecule that induces the expression of molecular chaperones is being evaluated in a clinical trial for amyotrophic lateral sclerosis (ALS). The molecular mechanisms that enable molecular chaperones to combat the toxicity of misfolded proteins *in vivo* are not well understood. However, their ability to modulate conformational states of disease-related proteins suggests that they prevent early aberrant protein interactions that trigger pathogenic cascades.

Protein Misfolding, Aggregation, and Molecular Chaperones

The amino acid sequence of a protein contains all of the information necessary for it to fold into a functional, three-dimensional structure *in vitro*. Within cells, however, protein folding occurs in a complex environment. The cellular cytoplasm is chock full of proteins, nucleotides, sugars, lipids, and organelles. As they attempt to fold in this dense milieu, proteins can easily misfold and aggregate.

Because the proper folding (or conformation) of proteins is critical to life, a class of 'helper' proteins called molecular chaperones has evolved. These proteins prevent inappropriate interactions within and between nonnative polypeptides, enhance the efficiency of *de novo* protein folding, and promote the refolding of proteins that have become misfolded as a result of cellular stress. Molecular chaperones function at essentially any cellular location where a folding or unfolding protein chain may interact inappropriately (for example, as a protein chain is translocated into mitochondria). Under certain conditions, chaperones interact with components of the ubiquitin–proteasome pathway and lysosome-mediated autophagy to degrade proteins they cannot refold.

What exactly are molecular chaperones? Many are 'heat shock' proteins (HSPs). When cells are stressed, such as with increased temperature, the transcription of HSPs is quickly induced, while generalized protein synthesis is turned off. HSPs are classified into six main families based on their approximate molecular weight. The number of human diseases linked to mutations in molecular chaperones is large and growing.

Protein Aggregation and Neurodegeneration

Molecular chaperones, together with the ubiquitin–proteasome pathway and lysosome-mediated autophagy, constitute a 'quality control' system that normally prevents the accumulation of misfolded proteins. However, since misfolded proteins are thought to accumulate as a result of normal aging, additional insults, such as mutations, can easily saturate the quality control system. Interestingly, neurons and other postmitotic cells appear to be especially vulnerable to the effects of misfolded proteins. It is now abundantly clear that saturation of the protein quality control machinery is a factor in many neurodegenerative diseases, including Alzheimer's disease (AD), Parkinson's disease (PD), Huntington's disease (HD) and related polyglutamine (polyQ) disorders, ALS, and the prion encephalopathies.

The major pathological feature of neurodegeneration associated with misfolded proteins is the accumulation of aggregated protein in intra- or extracellular deposits, generically referred to as amyloid and known as senile plaques and neurofibrillary tangles in AD, Lewy bodies and neurites in PD, and inclusion bodies in HD and other diseases in which the protein aggregates inside cells. The aggregated proteins are composed of fibrillar material, as shown by electron microscopy, and have similar chemical structures, consisting of β-sheets perpendicular to the fibril axis, that produce a characteristic cross-β X-ray diffraction pattern. They also share biochemical properties, such as insolubility in detergents, resistance to proteases, and the ability to bind lipophilic dyes such as congo red.

Diverse neurodegenerative diseases are characterized by accumulation of amyloid-like fibrils and likely have common pathogenic mechanisms. But are the amyloid fibrils themselves toxic? Increasing evidence suggests that fibrillar aggregates are inert or perhaps

even protective, rather than being directly pathogenic. For example, senile plaques are found in persons without clinical symptoms of AD, and in cases of AD, the severity of dementia does not correlate well with plaque density. In PD, neuropathological analyses show that neurons that contain Lewy bodies are healthier than cells that do not, indicating that inclusion bodies might be protective. In support of this hypothesis, the formation of inclusion bodies by proteins with expanded polyQ repeats is a regulated cellular process that requires an intact microtubule cytoskeleton. This process might have evolved as a protective mechanism to sequester toxic, misfolded protein entities that would otherwise disrupt cellular homeostasis.

If amyloid fibrils do not trigger pathogenic cascades in neurodegenerative diseases, then what is the toxic culprit? In the past decade, detailed structural and biochemical studies of purified proteins have shown that the assembly of aggregating proteins into amyloid fibrils is a complex process, involving a number of different intermediates. Intense research has focused on the pathogenic role of these so-called prefibrillar or protofibrillar amyloid intermediates, also called soluble oligomers or, in the case of AD, amyloid β-peptide (Aβ)-derived diffusible ligands (ADDLs). Atomic force microscopy has been used to characterize several metastable structures, such as spherical oligomers, protofibrils, and porelike annular structures, which might be on a pathway to fibril formation. These small, potentially diffusible assemblies, rather than mature amyloid fibrils, might trigger neuronal dysfunction by initiating a cascade that culminates in neuronal death. For example, injecting soluble oligomers of Aβ into the brain decreases long-term potentiation, and it is thought that the oligomers specifically target proteins localized to synapses. Antibodies have been generated that specifically recognize aggregating proteins solely in their oligomeric forms. Incubation of oligomers with these antibodies blocks their subsequent toxicity to cultured cells, supporting the hypothesis that soluble oligomers are the toxic culprit. However, our understanding of soluble oligomers is largely based on *in vitro* and cell culture studies. Little is known about their *in vivo* role for the simple reason that we lack the tools to visualize their structure *in vivo*. The development of such tools will allow one to carefully characterize from a temporal and spatial perspective the role of oligomers in pathogenesis.

Molecular Chaperones and Neurodegeneration

Since molecular chaperones normally function in protein folding, it is not surprising that they can be found, together with components of the ubiquitin–proteasome system, by immunohistological analysis of sections from diseased brains at sites of aggregate deposition, such as in senile plaques and inclusion bodies. In several studies, sophisticated fluorescence imaging techniques showed that molecular chaperones are not bound irreversibly to intracellular aggregates. Rather, they quickly cycle on and off the aggregates, apparently in an effort to refold the misfolded protein, to transfer it to the ubiquitin–proteasome system, or to help sequester oligomeric intermediates into fibrillar inclusion bodies. Future studies will be required to discriminate among these and other possibilities.

Compelling evidence to support a critical role for chaperones in neurodegenerative diseases comes from recent *in vivo* studies that show that overexpression of the chaperone Hsp70 or Hsp40 suppresses neurodegeneration in fruit fly and transgenic mouse models of HD and PD. While initial studies were based on a candidate gene approach, unbiased genetic screens in *Saccharomyces cerevisiae, Drosophila melanogaster,* and *Caenorhabditis elegans* models of polyQ aggregation have further substantiated the importance of molecular chaperones and protein folding in regulating polyQ aggregation and toxicity. Importantly, overexpression of chaperones also suppresses neurodegeneration *in vivo* in transgenic mouse models of PD and polyQ diseases.

Mechanisms of Chaperone-Mediated Neuroprotection

Although chaperones are clearly protective in animal models of neurodegenerative disease, the mechanisms that underlie protection are unclear. They can directly influence the folding state or conformation of disease-associated proteins that aggregate. They might alter a particular conformational state that is highly toxic, exerting a protective effect simply by decreasing its abundance. Another possibility is that molecular chaperones may cooperate with the ubiquitin–proteasome and lysosome degradation systems to help degrade aggregation-prone proteins; however, experimental evidence in animal models that directly supports this mechanism of action is lacking. The chaperones likely facilitate neuroprotection through mechanisms that are both dependent on, and independent of, their protein folding activity (**Figure 1**). In addition to cooperating with the protein degradation machinery, they can also block apoptotic signaling pathways. Ultimately, the collective effects of multiple direct and indirect chaperone actions might be essential to impede disease pathogenesis.

Figure 1 Direct and indirect effects of molecular chaperones on disease protein toxicity. Molecular chaperones might prevent toxicity by preventing inappropriate protein interactions, by facilitating disease protein degradation/sequestration, and/or by blocking downstream signaling events that lead to neuronal dysfunction and apoptosis. HSP, heat shock protein; LAMP, lysosome-associated membrane protein; ROS, reactive oxygen species; ER, endoplasmic reticulum; ERAD, endoplasmic-reticulum-associated degradation. Reproduced from Muchowski PJ and Wacker JL (2005) Modulation of neurodegeneration by molecular chaperones. *Nature Reviews Neuroscience* 6: 11–22, with permission.

Molecular Chaperones as Potential Drug Targets

It is clear from animal studies that increased expression of molecular chaperones might prove beneficial for the treatment of neurodegenerative diseases. However, finding drugs that increase the expression of proteins in specific cells and tissues will be a major challenge. Furthermore, continuous upregulation of molecular chaperones might cause undesirable side effects, including cancer. Nonetheless, a small molecule that induces expression of HSPs has shown promise in an animal model of ALS and is being evaluated in a phase II clinical trial.

Conclusions

Protein folding in neurons mediated by molecular chaperones plays a critical role in normal brain function and in neurodegenerative diseases. The mechanism by which chaperone activity facilitates neuroprotection is being studied intensively in many laboratories, but deep insights are still lacking. In principle, molecular chaperones are an attractive target for therapeutic intervention in neurodegenerative diseases, because they presumably can act at the earliest change of the disease process, by preventing aggregation-prone proteins from adopting a toxic conformation. Interestingly, most studies of molecular chaperones in animal models have shown that chaperones facilitate neuroprotection in the absence of a visible effect on inclusion-body formation, suggesting that protection might arise from decreasing formation of small, diffusible aggregate assemblies or perhaps of misfolded conformations of monomers.

Psychiatric Disorders Associated with Disturbed Sleep and Circadian Rhythms

E K Simon, Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Sleep disturbance is one of the most common complaints associated with the psychiatric syndromes described in the diagnostic and statistical manual of mental disorder-4th edition-text revision (DSM-IV-TR). The mood disorders, unipolar and bipolar together with anxiety disorders (generalized anxiety disorder (GAD) and posttraumatic stress disorder (PTSD)), have sleep disturbance in their criterion. Schizophrenia is also associated with poor sleep quality. Sleep and circadian disturbances influence the presentation and course of psychiatric illnesses, together with the quality of life, and in many cases help in predicting the outcome. Models developed from studies of sleep and circadian rhythms in psychiatric patients help us gain insight into the disease process itself. Proper diagnosis and treatment with emphasis on sleep and circadian rhythm lead to better understanding of the disorders, as well as an improved outcome.

Mood Disorders

Major Depressive Episode

The diagnostic criteria for major depressive episode (MDE) are shown in Table 1.

Sleep disturbance in MDE MDE is characterized by depressed mood, anhedonia, fatigue, psychomotor retardation or agitation, insomnia or hypersomnia, weight loss, guilt, sense of worthlessness, and suicidal ideations, plans, or acts (Table 1). Insomnia manifests as difficulty in falling asleep or staying asleep or waking up earlier than the usual schedule. Self-reports, questionnaires, and structured interviews from several studies reveal poor sleep quality and impaired daytime functioning in MDE. Hypersomnia is seen primarily in younger patients and in bipolar depressed patients.

According to the (DSM-IV-TR), 90% of inpatients and 40–60% of outpatients with MDE have polysomnography (PSG) abnormalities. They have delayed sleep onset, disturbed sleep continuity, and poor sleep efficiency (Figure 1). Slow-wave sleep (SWS and non-rapid eye movement (NREM) stages 3 and 4) is reduced particularly in the first half of the night. Rapid eye movement (REM) sleep shows decreased REM latency, increased REM density, and increased duration of REM sleep early in the night and increased duration of REM throughout the night.

Quantitative electroencephalography (EEG) shows decreased delta wave power and delta wave counts during sleep. The abnormalities in delta sleep are seen more in men than in women. PSG abnormalities are not prominent in adolescents and prepubertal children. In psychotic depression, the PSG findings are most marked and REM latency is very short. The REM sleep abnormalities are associated more with the first episode of depression, or seen earlier during the course of a depressive episode or in recurrence. The patients with significant life stressors preceding the onset of a depressive episode is less likely to have REM sleep abnormalities compared to patients without stressors. Reduced REM latency is associated with increased response to pharmacotherapy and electroconvulsive therapy (ECT) but not psychotherapy. Response to cognitive behavioral therapy (CBT) or interpersonal therapy (IPT) is significantly reduced in patients with reduced REM latency, increased REM density, and disturbed sleep continuity. Reduced REM latency and reduced SWS are trait markers of depression, as they persist after remission and are seen in twins and first-degree relatives of the patients.

Functional neuroimaging findings in MDE Functional neuroimaging studies of depressed patients during wakefulness show hypometabolism in the dorsolateral prefrontal cortex (DLPFC) and anterior cingulate regions and hypermetabolism in the amygdala, hippocampus, and the orbitofrontal cortex (ventral and medial) (Figure 2). The functional neuroimaging studies during sleep reveal differences between controls and patients during both NREM and REM sleep. An 18-fluorodeoxyglucose positron emission tomography ([^{18}F] FDG PET) study focusing on the first NREM sleep period in MDE showed a higher metabolic rate of glucose globally in comparison to controls. The glucose metabolic rate was high in the posterior cingulate, amygdala, hippocampus, occipital and temporal cortices, and the pons. Reduced glucose metabolism was found in the anterior cingulate, caudate, and medial thalamus compared to controls. Another [^{18}F] FDG PET study examining the transition from wakefulness to NREM sleep in MDE found that the metabolic rate remained relatively elevated in the frontoparietal regions and the thalamus (Figure 2). Examination of the relationship

Table 1 Diagnostic criteria for major depressive episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly due to a general medical condition or mood-incongruent delusions or hallucinations.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). *Note:* In children and adolescents, can be irritable mood.
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others).
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. *Note:* In children, consider failure to make expected weight gains.
4. Insomnia or hypersomnia nearly every day.
5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
6. Fatigue or loss of energy nearly every day.
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms do not meet criteria for a Mixed Episode.

C. The symptoms cause clinically significant distress or impairment in social,occupational, or other important areas of functioning.

D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse or a medication) or a general medical condition (e.g., hypothyroidism).

E. The symptoms are not better accounted for by bereavement (i.e., after the loss of a loved one), the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

between regional cerebral glucose metabolism assessed by [^{18}F] FDG PET and beta EEG power, a marker of arousal, in patients with MDE and controls during NREM sleep showed that beta power is negatively correlated with subjective sleep quality. Both groups showed significant correlation between beta power and regional cerebral glucose metabolism in venteromedial PFC and right lateral inferior occipital cortex. The studies taken together suggest a dysfunction of arousal in the depressed patients.

Functional neuroimaging of REM sleep in the normal subjects show a pattern resembling wakefulness in the cortical metabolism (Figure 3). There is also increased metabolism in the limbic and paralimbic structure during REM sleep. This has been referred to as the anterior paralimbic REM activation axis. In patients with MDE, [^{18}F] FDG PET reveals an activation of the anterior paralimbic structures greater in area, spatially, compared to controls. They also show greater activation in bilateral DLPFC, left premotor, primary sensorimotor, and left parietal cortices, together with midbrain reticular formation. The increased paralimbic activation may be related to affective dysregulation and the increased activation of the DLPFC may be linked to cognitive dysfunction in depressed patients.

Circadian rhythm disturbance in MDE *Methodological issues*. Most of the studies on circadian rhythm in MDE are of patients following a regular diurnal rhythm. Constant routine or other protocols used to avoid masking are seldom used. When employed, sleep deprivation, a necessary part of the procedure, can lead to remission or a switch into hypomania or mania, thus making interpretation difficult. The disorder itself can influence the circadian rhythm and lead to differences between controls and patients. The differences noted may be epiphenomena or they can actually precipitate or perpetuate the depression.

Standardized sleep–wake schedules that are used prior to protocols, such as constant routine, being therapeutic, alter the phenomenology of the illness. Even with these limitations, this strategy can eliminate the possibility that the observed differences are epiphenomena from the influence of the disordered sleep–wake cycle on the patient's circadian rhythms. Most studies recruit patients via ads or from tertiary centers, thereby reducing the generalizability of the findings. There is also the bias of self-selection. Use of a heterogeneous patient population has led to confounding of results in circadian studies (e.g., mixing bipolar and unipolar patients, inpatients and outpatients, melancholic and nonmelancholic patients). Homogenous patient samples, correctly matched for age and sex, with control groups, lead to better understanding of the disease and to valid, reproducible results.

Core body temperature rhythm in MDE. Early studies had reported a phase advance of core body

Figure 1 Sleep profile of a medication-free depressed female patient and a healthy female control. Compared with the healthy subject, the sleep profile of this patient shows many of the typical features of sleep in depression: impaired sleep continuity, disinhibition of REM sleep, and reduction of slow-wave sleep. W, wake; REM, rapid eye movement sleep; S1–4, sleep stages 1–4; MT, movement time; BM, body movement; EM, rapid eye movements. From Berger M, van Calker D, and Riemann D (2003) Sleep and manipulations of the sleep–wake rhythm in depression. *Acta Psychiatrica Scandinavica* 108(supplement 418): 84. Used with permission from Blackwell Munksgaard.

temperature in MDE, but it was not consistently replicated by later studies. The most consistent finding was the reduced amplitude of the core body temperature (Figure 4). This was related to the reduced fall of temperature during sleep. The amplitude was lower among patients with reduced REM latency compared to patients with longer REM latency. The period and amplitude of core body temperature rhythm normalizes while in remission.

Melatonin in MDE. Melatonin exhibits blunted amplitude, as already noted, with temperature. Studies with highly specific assays did not validate the finding already discussed that resulted from older studies. Melatonin is also influenced by light, posture, and medications, factors not taken into account by older studies. Reduced concentration of melatonin in patients with MDE has been reported, but the studies have methodological flaws, such as small sample size, poor matching, and infrequent sampling. At reported temperature, the amplitude of melatonin normalizes with remission. Differing levels of nocturnal melatonin secretion have been observed during two different episodes of depression in the same patient. This finding should serve as a cautionary note while we attempt to interpret cross-sectional studies.

Hormonal rhythms in MDE. Among the rhythms studied, cortisol linked to the circadian rhythm has shown a decrease in amplitude and phase advance. Growth hormone secretion shows a reversal of its usual pattern, leading to more secretion in the day as opposed to the night. Thyroid-stimulating hormone also shows decreased amplitude. To sum up, decreased

Figure 2 Areas of significant reduction in cerebral glucose metabolism from presleep wakefulness to NREM sleep in healthy subjects and depressed patients and between group differences in metabolic change. Region-of-interest analyses with small volume corrections show a reduction in regional cerebral glucose metabolism in the thalamus from presleep wakefulness to NREM sleep in both study groups. A bilateral metabolic decline in the thalamus was seen in the healthy subjects (left thalamus shown in figure; blue lines intersect at Talairach coordinates $x = -4$, $y = -22$, $z = 8$), whereas the metabolic decline was limited to the right thalamus in depressed patients (blue lines intersect at Talairach coordinates $x = 8$, $y = -16$, $z = 8$). Areas where depressed patients exhibited less of a decline in regional cerebral glucose metabolism from presleep to NREM sleep relative to healthy subjects are presented in the bottom image: depressed patients showed less of a metabolic decline in the thalamus relative to healthy subjects (blue lines intersect at Talairach coordinates $x = -2$, $y = -14$, $z = 4$). From Germain A, Nofzinger EA, Kupfer DJ, and Buysee DJ (2004) Neurobiology of non-REM sleep in depression: Further evidence for hypofrontality and thalamic dysregulation. *American Journal of Psychiatry* 161: 1859. Used with permission from American Psychiatric Publishing, Inc.

amplitude of various rhythms appears to be the most consistent observation in depression (Figure 4).

A recent study comparing patients with MDE with and without psychotic features suggests that each subtype is associated with distinct patterns of hypothalamic–pituitary–adrenal (HPA) axis activity. The patients with psychosis had significantly higher evening cortisol levels than healthy controls

Figure 3 Waking to REM sleep activation, comparison between patients with MDE and healthy controls. Waking to REM sleep activations in healthy subjects (column 1), depressed subjects (column 2), and interactions showing regions where the depressed subjects' waking to REM activations are greater than those of healthy subjects (column 3). DLPFC indicates dorsolateral prefrontal cortex; SMA, supplementary motor area; and *x* and *y*, Talairach *x* and *y* coordinates, respectively. From Nofzinger EA, Buysee DJ, and Germain A, et al. (2004) Increased activation of anterior paralimbic and executive cortex from waking to rapid eye movement sleep in depression. *Archives of General Psychiatry* 61: 699. Used with permission from American Medical Association.

or nonpsychotic patients. This is consistent with earlier literature and is thought to be linked to reduced feedback inhibition of HPA axis in psychotic depression.

Figure 4 Comparison of circadian rhythms of temperature, cortisol, norepinephrine (NE), thyroid stimulating hormone (TSH), and melatonin between patients with endogenous depression, recovered patients, and healthy subjects. Circadian profiles approximating that of controls are noted in recovered patients. Adapted from Souetre E, Salvati E, Belugou J-L, et al. (1989) Circadian rhythms in depression and recovery: Evidence for blunted amplitude as the main chronobiological abnormality. *Psychiatry Research* 28: 266. Used with permission from Elsevier Scientific Publishers Ireland, Ltd.

Diurnal variation in MDE. It has been known since antiquity that the symptoms of depression have a distinct diurnal pattern: worse in the morning and improving as the day progresses. This is especially true for the melancholics. Some studies suggest that the diurnal variation is also seen in other types of depression, other psychiatric disorders, and even in healthy subjects. It has been demonstrated that every pattern of diurnal variation can be observed in a population of depressed individuals on long-term follow-up (i.e., morning low, evening low, and indifferent type).

A recent study of patients with MDE compared with controls, matched for age, gender, body mass index (BMI), and menstrual cycle, found significant mean elevation of interleukin-6 (IL-6) in the patient group from 1000 to 1200 h and at 1500 h (**Figure 5**). They also found a 12 h shift in the circadian rhythm of IL-6 but not of cortisol in the MDE patients with the zenith during wake hours and nadir during sleep hours, as opposed to the rhythm in normal subjects (zenith during sleep hours (0100–0500 h) and nadir during morning hours (0800–1000 h)). A striking finding of the study was the significant correlation found between fatigue and poor concentration with IL-6 levels in depressives, which could explain the diurnal variation of symptoms.

Social rhythms in MDE. The social *zietgeber* hypothesis posits that in patients who are vulnerable to affective disorder, changes in social *zeitgebers* can lead to disruption of circadian rhythms and eventually precipitate a mood episode, manic, or depressive (**Figure 6**). The event in question may be a *zeitstorer*, an active disrupter of social and familial life, such as the death of a spouse or the birth of a new baby. The *zeitstorer* leads to lack of regular activity or to uncoupling phenomena, where the regular activity fails to entrain the circadian rhythm and presentation of the disorder.

A recent study found that depressed and control groups were similar in levels of regular daily activity, done alone or with others. The regular pattern of daily activity was entraining the cortisol rhythm of healthy controls but not of the depressed patients,

Figure 5 Mean chronograms of IL-6 (a) and cortisol levels (b) measured over 24 h in patients with MDE and age-, gender- and BMI-matched controls. A significant group-by-time interaction in repeated-measures ANOVA, followed by *post hoc t*-tests at each time point, showed significant IL-6 elevation from 1000–1200 h and at 1500 h, and cortisol decrease from 2230–0030 h and at 0430 h in MDE patients, compared with controls. Results are presented as mean ± SEM in metric units (conversion factors to SI units: IL-6, 0.131; cortisol, 27.5862). *, $P < 0.05$; **, $P < 0.01$. From Alesci S, Martinez PE, Kelkar S, et al. (2005) Major depression is associated with significant diurnal elevations in plasma interlukin-6 levels, a shift of its circadian rhythm, and loss of physiological complexity of its secretion. *Journal of Clinical Endocrinology and Metabolism* 90: 2525. Used with permission from the Endocrine Society.

and the controls had a more normative decline in cortisol rhythm on the days they reported more activities involving others. In depressive patients the daily activity was not entraining the cortisol rhythm

Figure 6 Social *zeitgeber* hypothesis. Adapted from Frank E (2005) *Treating Bipolar Disorder: A Clinician's Guide to Interpersonal and Social Rhythm Therapy*. Used with permission from Guilford Press.

and an uncoupling was observed. It should be noted that the patients were outpatients who had a score of 23 on Beck Depression Inventory without meeting the DSM criteria for MDE.

Psychotherapy helps re-entrain the disrupted rhythm of depressed patients by establishing regular routines and providing exposure to *zeitgebers*, both photic and otherwise. With cognitive behavior therapy, activity scheduling, in which the patient is asked to schedule and engage in preplanned activities, was found to be one of the critical components of the therapeutic action.

Seasonal Affective Disorder

In seasonal affective disorder (SAD), episodes of depression are temporally connected to a particular time of the year (e.g., depression in winter and remission in summer) (Table 2). Winter SAD shows prominent anergy, hypersomnia, overeating, weight gain, and carbohydrate craving. Less common is presentation of depression in the summer; summer SAD presents with insomnia, irritability, loss of appetite, and loss of weight. SAD can be a part of a unipolar or bipolar disease. It is more common in Bipolar II Disorder, in which the summer leads to hypomania. The prevalence of the disease increases with higher latitudes, young are at higher risk, and women comprise 60–90% of patients with SAD.

Self-report questionnaires and prospective sleep diaries show that the symptomatic SAD patients have significant increase in sleep duration and difficulty awakening in winter (Figure 7). Polysomnographic studies of SAD show reduced sleep efficiency, reduced NREM stage 3 and 4, and increased REM density, but less evidence of reduced REM sleep latency (SL). Actigraphic studies have found dimin-

Table 2 Diagnostic criteria for seasonal pattern specifier

Specify if:

With Seasonal Pattern (can be applied to the pattern of Major Depressive Episodes in Bipolar I Disorder, Bipolar II Disorder, or Major Depressive Disorder, Recurrent)

A. There has been a regular temporal relationship between the onset of Major Depressive Episodes in Bipolar I or Bipolar II Disorder or Major Depressive Disorder, Recurrent, and a particular time of the year (e.g., regular appearance of the Major Depressive Episode in the fall or winter). *Note:* Do not include cases in which there is an obvious effect of seasonal-related psychosocial stressors (e.g., regularly being unemployed every winter).

B. Full remissions (or a change from depression to mania or hypomania) also occur at a characteristic time of the year (e.g., depression disappears in the spring).

C. In the last 2 years, two Major Depressive Episodes have occurred that demonstrate the temporal seasonal relationships defined in criteria A and B, and no nonseasonal Major Depressive Episodes have occurred during that same period.

D. Seasonal Major Depressive Episodes (as described above) substantially outnumber the nonseasonal Major Depressive Episodes that may have occurred over the individual's lifetime.

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington, DC: American Psychiatric Association.

Figure 7 Seasonal change in symptoms of SAD ($n = 1042$). Adapted from Modell JG, Rosenthal NE, and Harriet AE et al. (2005) Seasonal affective disorder and its prevention by anticipatory treatment with bupropion XL. *Biological Psychiatry* 58: 663. Used with permission from Society of Biological Psychiatry.

ished levels of activity in both seasonal and nonseasonal depression.

A recent trial of bright light for those with SAD comparing patients who fulfilled the Rosenthal and DSM-IV-TR criteria for SAD with age and sex-matched healthy subjects found that the former had 33% lower total activity and 43% lower daylight activity in week 1 of the trial, as documented by actigraphy. The SAD patients also exhibited attenuation of the amplitude of sleep–wake cycle by 6%, a phase delay of almost 1 h, and lowered sleep efficiency. The bright light by week 4 led to increase in the total and daylight activity in the patients. The reduced amplitude of the circadian rhythm also increased and the delayed circadian rhythm advanced with improved sleep efficiency.

The above view is supported by another study that demonstrated that the prototypical SAD patient is phase delayed (71% in the study) whereas a subgroup may be phase advanced (29% in the study). The same study also found that the phase-delayed patient group responded to low-dose melatonin in the afternoon. The effect was pronounced as the phase angle difference (PAD) between dim light melatonin onset (DLMO) and midsleep approached the ideal of 6 h. The phase-advanced SADs showed a similar antidepressant response to low-dose melatonin when it was administered in the morning.

The treatment for SAD is bright light therapy, at an intensity of up to 10 000 lux, for a period of 30–60 min in the morning. Studies suggest that morning light is superior to evening light. The bright lights used currently are polychromatic. One recent study reports that blue light with short wave length (468 nm) from light-emitting diodes (LED) is comparable in efficacy to bright white light and is better than dim long-wavelength red light.

FDA approved bupropion extended release in 2006 for prevention of SAD. The pivotal studies were three randomized placebo controlled trials of patients ($n = 1042$) who had history of SAD, on average 13 prior episodes, who were treated with Bupropion XL 300 mg day^{-1}, in autumn prior to the onset of depression. At the end of 4–6 months, the treatment groups had 16% patients who had depression as opposed to the 28% in the placebo group. It should be noted that there was a significant placebo response, which was attributed to the close attention the placebo group received during the trial. Historically, the placebo response has been increasing in efficacy trials of depression.

Bipolar Disorder

Bipolar disorder is a severe disorder of mood manifested by recurrent episodes of mania and depression. The mania is characterized by persistently elevated, expansive, or irritable mood, with grandiosity, decreased need for sleep, pressure of speech, distractibility, flight of ideas, and increased involvement in goal-directed or high-risk activity (Table 3). Patients with bipolar disorder exhibit depression that resembles unipolar depression. Bipolar disorder is divided into slow cycling (fewer than four episodes a year) and rapid cycling (more than four episodes) forms. Rapid cycling bipolar disorder (RCBD) tends to be more common in women than in men. Bipolar disorder in which the switch happens multiple times a day has been called ultra rapid cycling.

Table 3 Diagnostic criteria for manic episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 week (or any duration if hospitalization is necessary).

B. During the period of mood disturbance, three (or more) of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity
   2. Decreased need for sleep (e.g., feels rested after only 3 h of sleep)
   3. More talkative than usual or pressure to keep talking
   4. Flight of ideas or a subjective experience that thoughts are racing
   5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
   7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)

C. The symptoms do not meet criteria for a Mixed Episode.

D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

E. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

Note: Manic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, and light therapy) should not count toward a diagnosis of Bipolar I Disorder.

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington DC: American Psychiatric Association.

Sleep disturbance in bipolar depression It has been suggested that bipolar depressed patients have hypersomnia, characterized by increased duration of sleep during the night and excessive daytime somnolence. Studies using measures such as the multiple sleep latency test (MSLT) found no signs of objective hypersomnia in bipolar depression as opposed to hypersomnia in obstructive sleep apnea (OSA) or narcolepsy.

PSG studies of sleep in bipolar depression have generally found results that are no different from those in unipolar depression (Figure 8). A recent review of PSG studies, seven in total, found no difference between unipolar and bipolar participants. The authors went on to reanalyze their own data of unipolar and bipolar patients, exactly matched for age, gender, and severity of depression, and found that bipolar depressed patients had more pronounced sleep abnormalities. They showed significant decrease in sleep efficiency, increase in number of wake periods, longer duration of early morning awakenings, and increased REM density, both in the first REM period and during the total duration of REM.

Sleep disturbances in mania There are few studies of sleep disturbance in manic patients compared to those with depression because of the nature of the disorder, the difficulty in getting consent for a study, and the ethical issues involved in keeping patients unmedicated for the study period. Subjectively, manic patients report reduced need for sleep, with few hours of sleep at night and no deleterious effect on daytime functioning or energy. Some patients have total insomnia during the manic phase.

Studies using PSG in unmedicated patients have found more pronounced sleep continuity disturbances in mania compared to depressives. REM sleep findings were similar to depression, but the SWS was not found to be reduced.

Circadian rhythm disturbances in bipolar disorder Among the different types of bipolar disorder, rapid cycling bipolar disorder (RCBD) has been most associated with abnormality of the circadian rhythm. In patients with RCBD, the decrease in sleep duration heralds the onset of mania or the switch from depression into mania (Figure 9). Decreased sleep duration is more consistently associated with a shift to an earlier wake-up time. Diurnal variation, which is discussed prominently in depression literature, is also seen in RCBD. The patients with RCBD tend to switch up during the day from depression or euthymia into hypomania or mania, and switch down from mania or hypomania into depression or euthymia after overnight sleep. It is also observed in a handful of cases that DLMO is phase delayed early in the course of a depression episode in patients with RCBD. The phase advances slowly as the illness progresses, and the most advanced position is reached prior to a switch to hypomania or mania.

Social rhythm in bipolar disorder The social *zeitgeber* hypothesis mentioned earlier in the case of MDE holds good for bipolar disorder too (Figure 6). It has

Figure 8 Polysomnographically recorded sleep variables in unipolar vs. bipolar depression ($n = 27$ patients per group). (*) $p < 0.10$, * $p < 0.05$. SPT; Sleep period time. From Riemann D, Voderholzer U, and Berger M (2002) Sleep and sleep–wake manipulations in bipolar depression. *Neuropsychobiology* 45(supplement 1): 9. Used with permission from Karger.

Figure 9 (a) Double-plotted actogram (consecutive days next and beneath each other) of a schizophrenic patient (27-year-old man), whose rest–activity patterns reveal extremely delayed rest and activity onsets, reversed day–night activities, and remarkably prolonged activity and rest phases. This person's weekly sleep onset times delayed from 00:00 to 06:40 h between week 1 and week 5, and his wake-up times delayed from 10:38 to 16:52 h. On average, he slept about 8:30 h (SD + 2:43 h) per 24 h, but sleep efficiency was low (75.9%, SD + 12.9%). Light–dark exposure (gray) also coincides with his rest–activity behavior, indicating an irregular light input to the clock. The phase of his melatonin peak (dark gray squares with 95% confidence interval) changes in synchrony with activity. Abscissa 1/4 days of measurements, Ordinate: clock time in hours. (b) Lomb-Scargle periodograms of the above data, detecting the dominant period at 1450 min (24.17 h) for both activity–rest and light–dark cycles. *p*, power; — indicates missing data. Medication: olanzapine, sodium valproate. From Wulff K, Joyce E, Middleton B, Dijk D-J, and Foster RJ (2006) The suitability of actigraphy, diary data, and urinary melatonin profiles for quantitative assessment of sleep disturbances in schizophrenia: A case report. *Chronobiology International* 23: 489. Used with permission from Taylor & Francis.

been noted that disruptive events (*zeitstorer's*) happen more frequently prior to manic or hypomanic episodes when compared with euthymic periods. In RCBD, significantly decreased social rhythm has been reported. Reduced social rhythm has been found in groups of adolescents who were at high risk of developing bipolar disorder in a sample of bipolar II patients compared to a control group. In a recent study conducted in Germany that examined social rhythm instabilities in adolescents and young adults at risk for affective disorders, participants from the bipolar risk group were found to have

reduced social rhythm scores as measured by the Social Rhythm Metric when compared with a control group. The Social Rhythm Metric quantifies the stability of an individual's daily routine and lists activities that are identified as central to everyday life. The group with risk for unipolar depression defined by the high rigidity scores from the rigidity subscale of the Munich Personality Test did not show reduced social rhythm scores.

Schizophrenia

The diagnostic criteria for schizophrenia are shown in Table 4.

Sleep Disturbance in Schizophrenia

Schizophrenia is a chronic psychotic disorder characterized by delusions, hallucinations, disorganized speech, grossly disorganized behavior, and negative symptoms such as affective flattening, alogia, and avolition.

The sleep of the schizophrenic is characterized by increased latency and increased wake time after sleep onset. The latter may be a sign of impending relapse of the psychosis. In a study of 145 patients with schizophrenia, patients who reported poor subjective sleep quality had lower perceived quality of life, more depressive symptoms, more psychological distress, and adverse events to medications. Some schizophrenics complain of total or near total insomnia although PSGs document objective sleep. The subjective perception of insomnia may be incorporated by schizophoenic patients into their delusional belief system.

Patients with schizophrenia show a decrease in continuity of sleep, SWS, REM sleep, and reduced REM latency. A recent review of never-medicated or previously medicated schizophrenics found that the majority of the studies reported reduced SWS and REM latency

Table 4 Diagnostic criteria for schizophrenia

A. *Characteristic symptoms:* Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated):
1. Delusions
2. Hallucinations
3. Disorganized speech (e.g., frequent derailment or incoherence)
4. Grossly disorganized or catatonic behavior
5. Negative symptoms, i.e., affective flattening, alogia, or avolition

Note: Only one criterion A symptom is required if delusions are bizarre or hallucinations consist of a voice keeping up a running commentary on the person's behavior or thoughts, or two or more voices conversing with each other.

B. *Social/occupational dysfunction:* For a significant portion of the time since the onset of the disturbance, one or more major areas of functioning such as work, interpersonal relations, or self-care are markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, failure to achieve expected level of interpersonal, academic, or occupational achievement).

C. *Duration:* Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or two or more symptoms listed in criterion A present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).

D. *Schizoaffective and mood disorder exclusion:* Schizoaffective Disorder and Mood Disorder with Psychotic Features have been ruled out because either (1) no major depressive, manic, or mixed episodes have occurred concurrently with the active-phase symptoms; or (2) if mood episodes have occurred during active-phase symptoms, their total duration has been brief relative to the duration of the active and residual periods.

E. *Substance/general medical condition exclusion:* The disturbance is not due to the direct physiological effects of a substance (e.g., a drug abuse or a medication) or a general medical condition.

F. *Relationship to a pervasive developmental disorder:* If there is a history of Autistic Disorder or another Pervasive Developmental Disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least a month (or less if successfully treated).

Classification of longitudinal course (can be applied only after at least 1 year has elapsed since the initial onset of active-phase symptoms):

Episodic with Interepisode Residual Symptoms (episodes are defined by the reemergence of prominent psychotic symptoms); also specify if with Prominent Negative Symptoms

Episodic with No Interepisode Residual Symptoms

Continuous (prominent psychotic symptoms are present throughout the period of observation); also specify if with Prominent Negative Symptoms

Single Episode in Partial Remission; also specify if with Prominent Negative Symptoms

Single episode in Full Remission

Other or Unspecified Pattern

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington, DC: American Psychiatric Association.

together with unchanged duration of REM sleep. The never-medicated group had increased latency to stage 2, wake time after sleep onset (WASO), and total number of awakenings and reduced total sleep time (TST) and sleep efficiency (SE), with pronounced decrease in REM latency but unchanged REM duration. Similar findings were found for patients in first episode or acute exacerbations. Two studies did not find a decrease in SWS. Findings for chronic schizophrenics were also similar, except for a significant increase in the latency to stage 2 sleep. To sum up, sleep in patients with schizophrenia, irrespective of exposure to psychotropics or clinical course, shows initial and middle insomnia and reduced SWS.

Reduced SWS is consistently seen in studies using quantitative methods of EEG analysis but not always in studies using visual. SWS decrease is associated with the negative symptoms and has been consistently replicated in many studies. It is stable over the course of the disease (1 year follow-up) and predicts poor outcome at years 1 and 2. It also is associated with impaired attention in schizophrenia. The findings regarding REM sleep are harder to interpret, as studies have variously reported an increase, decrease, and no change in the total REM sleep. Only previously treated patients show an increase in total REM, which may be due to the effects of withdrawal from medication or related to the state of the disease (acute exacerbation). Two studies have noted an association between increased REM sleep and suicidality in schizophrenia. The negative symptoms have also been inversely associated with the REM SL.

Methodological Issues

Most studies follow a small number of schizophrenic patients who are heterogeneous regarding the course and subtype of the illness. The control groups include patients with neurological disorders or other medical disorders. The use of differing criteria for diagnosis and lack of clarity regarding the process of diagnosis makes it difficult to compare results across studies. Some studies have not used the latest scoring criteria for sleep, thus putting the validity of findings at risk. The age and gender of the patients also influence the results (increased incidence of OSA or periodic limb movement disorder (PLMD) with age or insomnia in women). Many studies fail to rule out the primary sleep disorder, thereby leading to abnormal findings falsely attributed to schizophrenia. Patients exposed to psychotropics, especially on a chronic basis, have changes in sleep continuity, NREM, and REM sleep that can act as confounding factors. Another factor noted is the first-night effect that reduces the REM and SWS sleep, particularly stage 4, leading to a lack of difference between patient and control group. This is obvious when the values of the control group are compared with similar controls.

Circadian Rhythm Disturbance in Schizophrenia

The studies in this area are few, follow a small number of patients, and have methodological issues as already described in the section on PSG. Studies of schizophrenia have not used techniques such as temporal isolation or constant routine. Body temperature and hormonal rhythms generally show a pattern similar to that of the normal subjects, as opposed to the findings in MDE. The cortisol levels in one study showed higher levels in early sleep but a normal overall pattern. Growth hormone secretion shows inconsistent results across studies, with both normal and decreased values reported.

A recent case report of a 27-year-old man with schizophrenia (monitored by wrist actigraphy, light detection, diary records, and urinary 6-sulfatoxymelatonin (aMT6s) measurements) showed phase shifts, highly delayed sleep-onset and offset, and irregular rest activity phases (Figure 9). The period of the rest activity rhythm, melatonin rhythm, and light–dark (L-D) cycle were longer than 24 h. In another study, the second-generation antipsychotic (SGA), clozapine, led to highly ordered rest–activity cycles, when compared to first-generation antipsychotics (FGA) (e.g., haloperidol; Figure 10). This was the first study that reported the differential effect of FGA and SGA on the circadian rhythm.

Anxiety Disorders

The anxiety disorders that are described in the DSM-IV-TR are panic disorder, phobias (specific and social), obsessive compulsive disorder (OCD), PTSD, and GAD. Among these disturbed sleep is mentioned as a criterion for PTSD and GAD. Epidemiological studies have noted the links between insomnia and anxiety disorders. The treatments, pharmacologic and psychotherapeutic, used for anxiety disorders are also useful for insomnia, thus implying a common basis for these disorders.

Sleep and Circadian Rhythm Disturbance in Panic Disorder

Panic disorder is characterized by recurrent panic attacks and anticipatory anxiety, together with avoidance (Tables 5 and 6). It may present with or without agoraphobia. Sleep is of poor quality, interrupted, or restless as reported in surveys of patients with panic disorder when compared to controls. Among patients with panic disorder, 68% have difficulty falling

Figure 10 Actograms of seven schizophrenia patients on monotherapy for at least a year. All patients were hospitalized except patient 3 (day patient) and patient 4 (ambulatory). Patients 1–4 were treated with classical neuroleptics (haloperidol or flupentixol); patients 5–7 were treated with clozapine. Motor activity is registered in black (1-min bins) and graphed as a double 24 h plot over 48 h (first line, days 1 and 2, second line, days 2 and 3, etc.). Occasional missing data are left blank. From Wirz-Justice A, Haug H-J, and Cajochen C (2001) Disturbed circadian rest–activity cycles in schizophrenia patients: An effect of drugs? *Schizophrenia Bulletin* 27: 499. Used with permission from Oxford University Press.

asleep and 77% have restless sleep. Nocturnal panic attacks are reported by patients (33–71%) that resemble the daytime attacks. Patients report waking up "like a jolt" and experience a full-blown attack. Patients with nocturnal panic have early age of onset, comorbid depression, severe symptomatology, and increased suicidal ideation. It has been noted in case reports that panic disorder is associated with sleep-related breathing disorder.

PSGs show decreased sleep efficiency and total sleep duration. However, studies that excluded patients with comorbid depression did not show these changes. Normal amounts of REM and SWS are seen. The REM latency is reported either as normal or reduced. Increased movement time is also seen with panic disorder. The panic attacks appear while transitioning from stage 2 to SWS in the first half of night. Nocturnal panic attacks can be induced by infusing caffeine during SWS. Two groups have reported cardiopulmonary instability in patients with panic disorder, one by infusing lactate during sleep and the other by demonstrating greater variability in the heart rate during NREM sleep.

There have been few studies regarding panic disorder and circadian rhythm. Circadian rhythms of cortisol and adrenocosticotropin (ACTH) may be abnormal in panic disorder. Elevated nocturnal cortisol secretion has been reported, as well as increased ultradian secretory episodes. The CRF has variable phase and changes in mean level has been noted.

Table 5 Diagnostic criteria for panic attack

Note: A Panic Attack is not a codable disorder. Code the specific diagnosis in which the panic attack occurs (e.g., **300.21** Panic Disorder with Agoraphobia).

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms developed abruptly and reached a peak within 10 min.

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal distress
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
10. Fear of losing control or going crazy
11. Fear of dying
12. Paresthesias (numbness or tingling sensations)
13. Chills or hot flushes

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington, DC: American Psychiatric Association.

Table 6 Diagnostic criteria for panic disorder

Diagnostic criteria for panic disorder without agoraphobia

A. Both (1) and (2):
   1. Recurrent unexpected Panic Attacks.
   2. At least one of the attacks has been followed by 1 month (or more) of one (or more) of the following:
      a. Persistent concern about having additional attacks
      b. Worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, 'going crazy')
      c. A significant change in behavior related to the attacks

B. Absence of Agoraphobia.

C. The Panic Attacks are not due to the direct physiological effects of a substance (e.g., a drug or abuse a medication) or a general medical condition (e.g., hyperthyroidism).

D. The Panic Attacks are not better accounted for by another mental disorder, such as Social Phobia (e.g., occurring on exposure to feared social situations), Specific Phobia (e.g., on exposure to a specific phobic situation), Obsessive–Compulsive Disorder (e.g., on exposure to dirt in someone with an obsession about contamination), Posttraumatic Stress Disorder (e.g., in response to stimuli associated with a severe stressor), or Separation Anxiety Disorder (e.g., in response to being away from home or close relatives).

Diagnostic criteria for panic disorder with agoraphobia

A. Both (1) and (2):
   1. Recurrent unexpected Panic Attacks.
   2. At least one of the attacks has been followed by 1 month (or more) of one (or more) of the following:
      a. Persistent concern about having additional attacks
      b. Worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, and 'going crazy')
      c. A significant change in behavior related to the attacks

B. The presence of Agoraphobia.

C. The Panic Attacks are not due to the direct physiological effects of a substance (e.g., a drug abuse or a medication) or a general medical condition (e.g., hyperthyroidism).

D. The Panic Attacks are not better accounted for by another mental disorder, such as Social Phobia (e.g., occurring on exposure to feared social situations), Specific Phobia (e.g., on exposure to a specific phobic situation), Obsessive–Compulsive Disorder (e.g., on exposure to dirt in someone with an obsession about contamination), Posttraumatic Stress Disorder (e.g., in response to stimuli associated with a severe stressor), or Separation Anxiety Disorder (e.g., in response to being away from home or close relatives).

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington, DC: American Psychiatric Association.

Sleep and Circadian Rhythm Disturbance in Social and Specific Phobia

Social and specific phobia are both characterized by fear and avoidance (Tables 7 and 8). Subjective reports show poor sleep quality, daytime impairment, and increased SL, but these findings were not reported by one study that used PSG. In another study, sleep architecture was no different between patients having MDE with or without phobias. The TST, SL, and SE were similar between patients and controls. The measure of REM SL, density, duration, and distribution was also normal in phobias.

Table 7 Diagnostic criteria for specific phobia (formerly known as simple phobia)

A. Marked and persistent fear that is excessive or unreasonable, cued by the presence or anticipation of a specific object or situation (e.g., flying, heights, animals, receiving an injection, seeing blood).
B. Exposure to the phobic stimulus almost invariably provokes an immediate anxiety response, which may take the form of a situationally bound or situationally predisposed Panic Attack.
Note: In children, the anxiety may be expressed by crying, tantrums, freezing, or clinging.
C. The person recognizes that the fear is excessive or unreasonable.
Note: In children, this feature may be absent.
D. The phobic situation(s) is avoided or else is endured with intense anxiety or distress.
E. The avoidance, anxious anticipation, or distress in the feared situation(s) interferes significantly with the person's normal routine, occupational (or academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.
F. In individuals under age 18 years, the duration is at least 6 months.
G. The anxiety, Panic Attacks, or phobic avoidance associated with the specific object or situation, are not better accounted for by another mental disorder, such as Obsessive–Compulsive Disorder (e.g., fear of dirt in someone with an obsession about contamination), Posttraumatic Stress Disorder (e.g., avoidance of stimuli associated with a severe stressor), Separation Anxiety Disorder (e.g., avoidance of school), Social Phobia (e.g., avoidance of social situations because of fear of embarrassment), Panic Disorder With Agoraphobia, or Agoraphobia without History of Panic Disorder.

Specify type:
Animal Type
Natural Environment Type (e.g., heights, storms, and water)
Blood-Injection-Injury Type
Situational Type (e.g., airplanes, elevators, and enclosed places)
Other Type (e.g., fear of choking, vomiting, or contracting an illness; in children, fear of loud sounds or costumed characters)

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington, DC: American Psychiatric Association.

Table 8 Diagnostic criteria for social phobia (social anxiety disorder)

A. A marked and persistent fear of one or more social or performance situations in which the person is exposed to unfamiliar people or to possible scrutiny by others. The individual fears that he or she will act in a way (or show anxiety symptoms) that will be humiliating or embarrassing. *Note*: In children, there must be evidence of the capacity for age-appropriate social relationships with familiar people and the anxiety must occur in peer settings, not just in interactions with adults.
B. Exposure to the feared social situation almost invariably provokes anxiety, which may take the form of a situationally bound or situationally predisposed Panic Attack. *Note*: In children, the anxiety may be expressed by crying, tantrums, freezing, or shrinking from social situations with unfamiliar people.
C. The person recognizes that the fear is excessive or unreasonable. *Note*: In children, this feature may be absent.
D. The feared social or performance situations are avoided or else are endured with intense anxiety or distress.
E. The avoidance, anxious anticipation, or distress in the feared social or performance situation(s) interferes significantly with the person's normal routine, occupational (academic) functioning, or social activities or relationships, or there is marked distress about having the phobia.
F. In individuals under age 18 years, the duration is at least 6 months.
G. The fear or avoidance is not due to the direct physiological effects of a substance (e.g., a drug abuse or a medication) or a general medical condition and is not better accounted for by another mental disorder (e.g., Panic Disorder with or without Agoraphobia, Separation Anxiety Disorder, Body Dysmorphic Disorder, a Pervasive Developmental Disorder, or Schizoid Personality Disorder).
H. If a general medical condition or another mental disorder is present, the fear in criterion A is unrelated to it, e.g., the fear is not of Stuttering, trembling in Parkinson's disease, or exhibiting abnormal eating behavior in Anorexia Nervosa or Bulimia Nervosa.

Specify if:
Generalized: if the fears include most social situations (also consider the additional diagnosis of Avoidant Personality Disorder)

Source: American Psychiatric Association (2000) *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington, DC: American Psychiatric Association.

Sleep and Circadian Rhythm Disturbance in Generalized Anxiety Disorder

GAD is characterized by excessive worry (Table 9). Patients have sleep disturbance as one of the criterion in the DSM-IV-TR, namely initial or middle insomnia with restless or unsatisfying sleep. The latter occurs in 60–70% of patients. Patients may report a variety of sleep complaints clinically. PSG studies show sleep initiation and maintenance difficulties. NREM stage 2 is increased while SWS is decreased in GAD. GAD patients do not show the decreased REM latency seen in MDE. This may help differentiate one from the other. Patients with GAD have lower levels of activity as documented by SRM (social rhythm metric) in one study.

Table 9 Diagnostic criteria for generalized anxiety disorder (includes overanxious disorder of childhood)

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).
B. The person finds it difficult to control the worry.
C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms present for more days than not for the past 6 months). *Note:* Only one item is required in children.
   1. Restlessness or feeling keyed up or on edge
   2. Being easily fatigued
   3. Difficulty concentrating or mind going blank
   4. Irritability
   5. Muscle tension
   6. Sleep disturbance (difficulty falling or staying asleep, or restless unsatisfying sleep)
D. The focus of the anxiety and worry is not confined to features of an Axis I disorder, e.g., the anxiety or worry is not about having a Panic Attack (as in Panic Disorder), being embarrassed in public (as in Social Phobia), being contaminated (as in Obsessive–Compulsive Disorder), being away from home or close relatives (as in Separation Anxiety Disorder), gaining weight (as in Anorexia Nervosa), having multiple physical complaints (as in Somatization Disorder), or having a serious illness (as in Hypochondriasis), and the anxiety and worry do not occur exclusively during Posttraumatic Stress Disorder.
E. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
F. The disturbance is not due to the direct physiological effects of a substance (e.g., a drug abuse or a medication) or a general medical condition (e.g., hyperthyroidism) and does not occur exclusively during a Mood Disorder, a Psychotic Disorder, or a Pervasive Developmental Disorder.

Source: American Psychiatric Association (2000): *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington DC: American Psychiatric Association.

Table 10 Diagnostic criteria for posttraumatic stress disorder

A. The person has been exposed to a traumatic event in which both of the following were present:
   1. The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
   2. The person's response involved intense fear, helplessness, or horror. *Note:* In children, this may be expressed instead by disorganized or agitated behavior.
B. The traumatic event is persistently reexperienced in one (or more) of the following ways:
   1. Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. *Note:* In young children, repetitive play may occur in which themes or aspects of the trauma are expressed.
   2. Recurrent distressing dreams of the event. *Note:* In children, there may be frightening dreams without recognizable content.
   3. Acting or feeling as though the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur on awakening or when intoxicated). *Note:* In young children, trauma-specific reenactment may occur.
   4. Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
   5. Physiological reactivity on exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
C. Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by three (or more) of the following:
   1. Efforts to avoid thoughts, feelings, or conversations associated with the trauma
   2. Efforts to avoid activities, places, or people that arouse recollections of the trauma
   3. Inability to recall an important aspect of the trauma
   4. Markedly diminished interest or participation in significant activities
   5. Feeling of detachment or estrangement from others
   6. Restricted range of affect (e.g., unable to have loving feelings)
   7. Sense of a foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span)
D. Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following:
   1. Difficulty falling or staying asleep
   2. Irritability or outbursts of anger
   3. Difficulty concentrating
   4. Hypervigilance
   5. Exaggerated startle response
E. Duration of the disturbance (symptoms in criteria B, C, and D) is more than 1 month.
F. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:
Acute: duration of symptoms is less than 3 months
Chronic: duration of symptoms is 3 months or more
Specify if:
With Delayed Onset: onset of symptoms is at least 6 months after the stressor

Source: American Psychiatric Association (2000): *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn., Text Revision. Washington DC: American Psychiatric Association.

Sleep and Circadian Rhythm Disturbance in Posttraumatic Stress Disorder

PTSD is characterized by persistent reexperiencing of the trauma, with avoidance and hyperarousal (Table 10). Nightmares and initial and middle insomnia are reported subjectively. Nightmares are found in 59–68% of patients. There are anxious arousals that occur in relation to both REM and NREM sleep. The arousals lead to excessive motor activity and awakenings. PSG documents decreased sleep efficiency and decreased TST with increased movement time. REM sleep in PTSD is reported as resembling depression in some studies. Reduced or prolonged latency is shown, depending on the studies reviewed, and reduced duration of REM sleep. Comorbid MDE, SRBD (sleep-related breathing disorder), or SUD (substance use disorders) may confound results. Although nightmares are reported in both REM and NREM sleep, the majority of studies support an association with REM sleep. Increased REM density has been described in combat veterans with chronic PTSD.

Patients with PTSD have increased excretion of 24 h catecholamines. The ratio of nocturnal to diurnal urinary catecholamines is increased relative to controls. The hypersecretion of cortisol during the night is not seen in the PTSD, as opposed to patients with depression.

Conclusion

There is strong evidence that disturbances of sleep are central to many psychiatric disorders. The strongest evidence is with mood disorders, both unipolar and bipolar. The REM and SWS abnormalities noted are biologic markers, both state and trait. They are also strong predictors of response to treatment and outcome in MDE. SAD is increasingly being recognized, and the new treatment modalities that are being developed will go a long way in treating and preventing it. Treatments of bipolar disorder, which take into account the circadian component, would bolster the current therapies. Studies of sleep in schizophrenia help us understand the disease and improve the quality of life in patients by managing sleep and circadian rhythms optimally. Anxiety disorders present hand in hand with sleep disturbance, and findings regarding sleep help us delineate anxiety from depression and devise better management strategies.

Psychiatric Disorders: Functional Genomics

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

There are about 30 000 genes in the human genome, approximately 20 000 of which are expressed in the central nervous system and approximately 3000 of which are brain specific. Diseases and disorders of the nervous system, including psychiatric disorders, result from a combination of genetic and environmental effects, so it is reasonable to assume that many of the 20 000 genes expressed in the central nervous system (CNS), and most of the 3000 genes that are not expressed anywhere else, might be functionally linked to important neural processes whose disruption or perturbation could contribute to the disease phenotype or at least to a form of susceptibility when there is a significant environmental component. Furthermore, since the products encoded by these genes will have direct functional roles in the nervous system, it is also likely that many of them would represent useful biomarkers and/or drug targets.

The key to identifying genes involved in human disease, including psychiatric disorders, is to establish each gene's function and show how the disruption of its activity has a pathogenic effect. Through conventional methods, the gene–disease or gene–response relationship has been unraveled for only about 1500 genes, and in each case the path to enlightenment has been slow and laborious. The aim of functional genomics is to determine the functions of genes on a large scale using high-throughput screening technologies. The overall goal is to learn the precise relationships between genes, or more accurately between the proteins they encode, in coordinating the activities of the healthy brain.

Functional Genomics: Major Technology Platforms

Functional genomics is not a specific technique but an umbrella term to describe any approach for large-scale functional annotation of uncharacterized genes. Therefore, many different approaches can be used in functional genomics, ranging from those carried out completely *in silico* to complex, large-scale bench experiments in which many genes are analyzed simultaneously.

In Silico Methods

Computers are an essential component of all functional genomics technology platforms because of the need to handle, analyze, and store large data sets. However, it is possible to find out a large amount of information about the function of a gene without doing any bench experiments, and these bioinformatics-based approaches are usually the best place to start. The computer programs that are used to search for genes in genomic DNA often incorporate algorithms that attempt to find sequences matching known genes by applying the principle of similarity searching. Search algorithms such as BLAST, FASTA, and their derivatives allow new sequences to be compared with all the stored sequences in an attempt to find matches. It is important to note that the sequence databases contain not only sequences but also information that may relate to gene function. If the function of a human gene is unknown, it is often the case that a related gene has been studied in another species and that some information about its function is known. Therefore, the quickest way to establish the function of a new gene is often to search the databases and attempt to find related sequences that have already been annotated.

Functional annotation by sequence comparison can be applied on a whole genome scale, but this is not sufficient to determine the functions of all genes. For example, when the baker's yeast (*Saccharomyces cerevisiae*) genome was sequenced in 1996, 30% of the genes were already known, and functions had been assigned by bench experiments, a further 30% of the predicted genes could be assigned tentative functions on the basis of homology to other genes already in databases, and 10% were regarded as uncertain predictions. This left researchers with no hint as to the likely function of 30% of the genes, nearly 2000 in total. The functional annotation of the human genome is complicated by the greater difficulty in predicting genes accurately, and the proportion of uncharacterized genes in the human genome is therefore even higher, 40%. Based on the numbers cited at the beginning of the article, this would approximate to about 8000 genes expressed in the CNS and 1200 genes expressed solely in the brain. Many of these genes are likely to underpin susceptibility to diseases of the nervous system, including psychiatric disorders.

Standard search algorithms such as BLAST and FASTA can reliably detect protein sequences that are >30% identical, but below this level are many relationships that are not found. More-sophisticated search techniques based on patterns and profiles compiled from large protein families can help in some circumstances, but these methods are not always reliable. A relatively new approach is to use protein structures rather than sequences for functional annotation.

Protein structures are much more highly conserved than sequences, and it is possible to match protein structures showing less than 10% identity at the primary sequence level by the use of structural comparison algorithms such as DALI, VAST, and COMPARER. As for sequences, primary databases of protein structures have been solved by X-ray crystallography and/or nuclear magnetic resonance spectroscopy. Several international collaborative efforts are ongoing to solve protein structures in a systematic and high-throughput manner so that examples of every protein family in existence may be stored in the databases. In the future, it may be possible to identify the functions of uncharacterized genes by expressing the proteins, solving the protein structures, and comparing these to structures in the databases.

Another sequence-based method for functional annotation is comparative genomics. The principle of comparative genomics is that similarities between species extend far beyond the level of individual genes and include whole genomes. In closely related species (e.g., mouse and human), comparative genomics can help identify genes and their regulatory elements since only sequences with an evolutionarily conserved function would be found in both genomes whereas others would have diverged significantly. There is also a surprising degree of conservation at the level of whole molecular pathways and networks, even between distantly related organisms. An example is the extraordinary degree of conservation in hormone and neurotransmitter signaling pathways and the general processes involved in the development of the nervous system between mammals and invertebrate animals such as the nematode *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster*, which are much more amenable to large-scale experiments. Indeed, nearly 60% of known human disease genes have counterparts in the worm and/or the fruit fly, and 30% of them have counterparts in yeast.

Expression Profiling

Many diseases are characterized by the dysregulation of gene expression. Traditional methods that look at the expression of single genes in an attempt to identify disease biomarkers are now being replaced with global profiling strategies which look at all genes simultaneously. In the context of functional genomics, expression profiling can help to determine a gene's function through the principle of guilt by association. If a gene is switched on in response to neurotransmitter release, then it is likely that the function of that gene has something to do with the generation, detection, propagation, or downstream impact of that neurotransmitter, and thus without any other information, it is possible to imply that the gene is involved in one of those functions. By studying all genes simultaneously and identifying those whose expression is modulated, it becomes possible to select them for further, more detailed experiments. In the case of psychiatric disorders, as with any other disturbance to the normal function of the body, useful information can be obtained by comparing the expression profiles of hundreds or thousands of genes in the disease state and the unaffected state, that is, by searching for differential expression specific for the disease.

Two major technologies are used in expression profiling, one based on the high-throughput sampling of complementary DNA (cDNA) sequences and one based on miniature devices called microarrays, which allow messenger RNA (mRNA) levels to be measured by hybridization. Sequence sampling is based on the principle that a strongly expressed gene will be abundantly represented in the mRNA population of a particular cell or tissue and will be similarly represented in an unbiased cDNA library or sequence database derived from that population. Therefore, random sampling will tend to pull out clones or sequences of strongly expressed genes much more frequently than those of poorly expressed genes. Relative expression levels can be determined simply by counting the score for each sequence pulled out during sampling, and because these data are in the form of real numbers, they are digital. A method called serial analysis of gene expression accelerates the sampling process by reducing each cDNA to a short tag 9–15 bp in length and allowing up to 200 such tags to be concatemerized prior to sequencing. Microarrays are miniature devices comprising a collection of immobilized DNA sequences arranged in a grid. Each address on the grid corresponds to a unique gene, or at least to a unique mRNA if the gene undergoes alternative splicing. These arrayed targets are hybridized (interrogated) with a complex mRNA or cDNA probe, that is, a probe comprising many different sequences representing the entire population of mRNAs from the cell or tissue under investigation. In this case, quantitative data are obtained, not by counting, but by measuring the strength of the hybridization signal at each address. If the source mRNA/cDNA probe is universally labeled, the most abundant mRNA/cDNA molecules in the population will generate quantitatively stronger signals on the array, as long as hybridization does not reach saturation. Both sequence sampling and microarrays can be used for comparative expression profiling, in one case by comparing the representation of different sequences in two different tissues (e.g., prefrontal cortex from normal brain and schizophrenic brain) and in the

other case by using two complex probes, labeled with different fluorophores, and comparing the signal intensity of each fluorophore for each gene.

Expression profiling is also possible at the protein level, although the procedure is more complex because proteins have a wider range of physicochemical properties than do DNA and RNA. Although all mRNA/cDNA molecules will hybridize to a microarray under the same conditions, it is more difficult to establish conditions in which all proteins in a sample will bind uniformly to, for example, an array of antibodies or other capture agents. Therefore, while protein microarrays have been developed, the more widely used technology is the display of proteins on two-dimensional (2D) gels. The proteome of a typical human cell is extremely complex, containing up to 100 000 different protein molecules (this takes into account the many different forms of posttranslational modification) differing in abundance over four or five orders of magnitude. Since there is no procedure for amplifying rare proteins equivalent to the polymerase chain reaction (PCR), expression profiling at the protein level will always lack sensitivity compared with mRNA profiling, a particular disappointment because the interesting proteins (regulators, signaling components) are often those that are least abundant, sometimes only a few molecules per cell. Because the proteome is so complex, a separation process based on one property (e.g., size, charge, solubility) would not provide sufficient resolution. The advantage of 2D gel electrophoresis is that proteins are separated orthogonally, that is, in one dimension on the basis of charge and then in the second dimension on the basis of mass. It is possible to run pairs of gels using different samples (e.g., schizophrenia vs. unaffected control) or to use the technique of difference gel electrophoresis, which, analogous to the DNA arrays, involves the use of two protein samples, universally labeled with different fluorophores, and coseparating them, then identifying protein spots where the two fluorophores have different intensities. There are also a number of ways to quantify proteins directly by mass spectrometry, and these can also be used to compare multiple samples. Such methods involve the use of pairs of labels carrying different isotopes that can be distinguished by a mass spectrometer. The heavy and light labels are applied to the different samples (e.g., healthy and schizophrenic brain tissue), and then the samples are mixed prior to protein isolation so that purification losses are equivalent. The proteins are separated by two-dimensional gel electrophoresis (2DGE) or high-performance liquid chromatography (HPLC) and the fractions analyzed by mass spectrometry, with each labeled peptide appearing as a doublet, one carrying each isotope. The relative amounts of the two isotopes are measured in each fraction, and a significant difference indicates that the protein in that fraction is either more abundant or underrepresented in the disease tissue.

Interaction Analysis

Another guilt-by-association method for ascertaining gene functions is to look at protein interactions directly. This can be useful when one gene is known to be involved in a particular psychiatric disorder but nothing is known about the pathway or regulatory hierarchy to which it contributes. The principle is that proteins physically interacting with this initial lead protein are almost certainly involved in the same function. It is also likely that interference with the activity of such interacting proteins may cause a similar spectrum of disease symptoms.

Methods such as affinity chromatography and coimmunoprecipitation have been used for many years to study the interactions of individual proteins. More recently, they have been used more systematically to identify the components of protein complexes, in some cases on a global scale. Complexes are isolated by lysing cells gently and using antibodies that recognize one of the complex's components to pull down the interactors. The complexes may then be analyzed directly by mass spectrometry or may first be separated into individual components by electrophoresis. This approach can define all the proteins that function in a complex and may thus result in the functional annotation of several uncharacterized genes. Furthermore, since many signaling pathways involve the formation of transient complexes, this is an excellent way to probe the roles of different signaling pathways in psychiatric disease.

Interaction screening on an even larger scale can be carried out by the yeast two-hybrid system, an *in vivo* assay in which a bait protein is expressed in yeast as a fusion (a hybrid) with the DNA-binding domain of a transcription factor. All the candidate interactor (prey) proteins are expressed as fusions with the transcription factor's transactivation domain. The bait yeast strain is mated either systematically or randomly to a prey library. The products of the mating are diploid cells containing the bait construct and one of the many prey constructs in the library. If the bait protein happens to interact with the prey, a functional transcription factor is assembled that can activate a test gene which is also introduced into the cell. However, if the bait and prey do not interact, the transcription factor remains as two separate hybrid proteins, and the gene remains inactive. Large-scale interaction screening using the yeast two-hybrid system has been used to study the interactions of many human proteins and has recently been carried out on the entire mouse proteome.

Mutational Genomics

All the functional genomics technologies discussed above help establish molecular/biochemical or cellular functions but do not provide direct links to disease. The direct approach is to mutate genes in model organisms, particularly the mouse, and look for phenotypes that resemble human psychiatric diseases. Disease models can be generated by sporadic mutations and by deliberate gene knockout techniques on individual targets, but more recently there has been increasing interest in carrying out whole-genome mutagenesis programs with the aim of generating comprehensive mutant libraries representing hits in every single gene. These can be used as a central resource so that when researchers find evidence from another experimental approach that a particular gene is involved in a psychiatric disease, the corresponding mutant can be 'ordered' and used to study the molecular pathology of the disease and to develop and test new therapies.

Whole genome mutagenesis (saturation mutagenesis) has been used for many years to recover mutants affecting particular biological processes. The difference in the functional genomics approach is that whereas in the past scientists discarded mutants that did not interest them, now every mutant is interesting. Recent mutagenesis screens in mice using the potent chemical mutagen ethylnitrosourea (ENU) involved the analysis of some 40 000 lines for medically relevant phenotypes, including allergy, immunology, physiology, developmental defects, and behavioral and clinical biochemistry, with the behavioral phenotypes being particularly relevant in terms of psychiatric disorders in humans.

In addition to chemical mutagens, further mouse mutagenesis programs using DNA-based mutagens have been initiated. These are DNA sequences that are introduced into the genome in a deliberate effort to disrupt genes and cause disease-like phenotypes. The advantage of this approach over chemical mutagenesis is that the interrupted gene is tagged with an alien sequence that can be detected by hybridization or PCR, which permits the rapid isolation of the gene and its identification.

One of the most popular current methods for functional analysis in cells and whole organisms is RNA interference (RNAi), in which double-stranded RNA is expressed in or introduced into a cell and processed into short interfering fragments that induce the rapid degradation of any mRNA with the same sequence. This method has been used to inactivate nearly 95% of the genes in the nematode, which as stated above contains relatives of 60% of the known human disease genes and provides useful models for a number of disorders. RNAi can also be used directly in human cells and indeed represents perhaps the only current method that allows the large-scale and direct analysis of the functions of human genes. Although RNAi has yet to be used specifically to study psychiatric disorders, it has been widely used to study gene function in fundamental neurobiological processes such as intracellular signaling, embryonic development, formation of cellular junctions, cell cycle, programmed cell death, neural plasticity, axon guidance, and membrane trafficking, all of which may contribute in some small way to the disease phenotype.

Case Studies

Expression Profiling

Expression profiling using sequence sampling and microarrays has been applied to the study of several psychiatric disorders, with particularly promising results from the analysis of schizophrenia, bipolar disorder, and manic depressive disorder (MDD).

In MDD, expression profiling has shown that levels of mRNA encoding neuropeptide Y (*NPY* mRNA) and mRNA encoding thyrotropin-releasing hormone (*TRH* mRNA) fall, but that the levels rise again in response to electroconvulsive therapy, correlating with the antidepressant effects of NPY and TRH injections in the forced-swim model.

Several common themes have been identified in schizophrenia, including the dysregulation of genes involved in energy metabolism, oligodendrocyte function, and the development and maintenance of synapses. The general downregulation of mitochondrial genes encoding enzymes and structural components of the respiratory chain has been replicated in several studies, but similar trends are seen in other disorders, including Alzheimer's disease and multiple sclerosis, indicating that reduced energy metabolism in schizophrenia may be secondary to another, primary defect.

The dysregulation of critical oligodendrocyte development and maturation genes is seen in the prefrontal cortex and other brain areas, which supports evidence from magnetic resonance imaging studies showing reduction in white matter volume and decreased oligodendrocyte density in schizophrenic patients. Another common feature of schizophrenia expression profiling studies is the dysregulation of genes with roles in the presynaptic release machinery in the prefrontal cortex. It is interesting that while many of the same transcripts have been identified in independent studies, it has been shown that the pattern of affected transcripts differed from individual to individual, suggesting diversity at the molecular level, which might underpin the similarly diverse spectrum of disease symptoms. It is also notable that many of

the transcripts underrepresented in disease tissue have been shown to increase in abundance in response to haloperidol or clozapine, drugs that are used to treat schizophrenia.

Protein expression profiling has also identified several genes involved in psychiatric disorders. Brain proteome analysis of mice selectively bred for either high or low anxiety-related behavior revealed quantitative and qualitative protein expression differences, with the enzyme glyoxalase-I consistently expressed to a higher extent in several brain areas in low-anxiety mice. Additionally, enolase phosphatase displayed a different mobility in 2D gel electrophoresis, probably reflecting different degrees or forms of posttranslational modification in the different samples. The presence of these protein markers in red and white blood cells, respectively, should allow anxiety to be diagnosed by blood screening.

Protein Interactions

The yeast two-hybrid system has been employed successfully to find interaction partners for a protein named Disrupted-In-Schizophrenia 1 (DISC1), which has been identified as a susceptibility factor in schizophrenia. The first such protein to be identified was fasciculation and elongation protein zeta-1 (FEZ1) which plays a role in the control of axonal outgrowth and fasciculation. The two proteins were subsequently shown to be co-localized in the growth cones of hippocampal axons, and evidence suggests that the interaction is required for neurite outgrowth. Follow-on studies identified additional binding partners Kendrin and DISC1-binding zinc-finger protein, the latter of which was shown to be expressed strongly in the hippocampus, olfactory tubercle, cerebral cortex, and striatum. This pattern was similar to that of pituitary adenylate cyclase, suggesting a role for the pituitary adenylate cyclase-activating polypeptide (PACAP) pathway in providing further insight into the basis of psychiatric disorders.

Mutational Genomics and RNAi

Mouse genetic models have played an important role in the analysis of psychiatric disorders since candidate human susceptibility genes can be evaluated through the behavioral analysis of mice carrying mutations in orthologous genes. Recently, the use of large-scale ENU mutagenesis followed by phenotypic analysis for mutants with anomalies in anxiety behavior, rest–activity patterns, sensorimotor gating, and learning and memory has considerably expanded the potential for functional annotation of human genes associated with psychiatric disorders. The identification of behavioral phenotypes is more challenging than are mutations affecting visible or physiological traits, which can be measured directly, and as in human populations, an additional layer of complexity is introduced by the variable genetic background and environmental effects. Even so, the strategy has been successful in identifying the mouse *Clock* gene, encoding a transcription factor that plays a fundamental role in establishing the circadian rhythm. Since sleep deficit and disrupted circadian rhythms underlie a variety of psychiatric disorders, including bipolar disorder and depression, the identification of the *Clock* gene provides an important example of the use of mutational genomics to identify and characterize genes involved in psychiatric disorders.

RNAi has also been used to study psychiatric disorders following the development of an osmotic minipump to facilitate widespread siRNA vector infusion into the brain. Silencing has been achieved for several genes, including *DAT* (encoding the dopamine transporter) and *SERT* (encoding the serotonin transporter). DAT controls the temporal and spatial activity of dopamine by allowing reuptake into presynaptic terminals, thus regulating dopamine actions on emotion, reward, and cognition and playing a role in many neurological diseases, including mood disorders like depression. *DAT* mRNA levels were reduced by more than one-third using a 2-week minipump, resulting in various behavioral phenotypes including hyperlocomotor activity, as seen in *DAT* knockouts. SERT is implicated in the etiology of several psychiatric disorders, including anxiety and depression, and a similar 2-week siRNA infusion into the dorsal third ventricle also reduced mRNA levels by one-third in the dorsal and median raphe nuclei. There was a concomitant reduction in protein levels, and the resulting antidepressant behavior in a forced swim test was very similar to that obtained using a selective SERT inhibitor.

Psychiatric Genomics and Expression Profiling

R M Twyman, University of York, York, UK

© 2009 Published by Elsevier Ltd.

Introduction

Certain aspects of gene function can be determined by the analysis of gene and protein expression. For example, if a gene is expressed specifically in response to growth factor signaling, it is likely the gene's function is in some way linked to the control of cell proliferation. Genes that are expressed in a disease state but not in healthy tissue are likely in some way to reflect the pathogenesis of that disease or the body's response to it. This is one way to identify and characterize genes that are modulated in psychiatric disorders or whose abnormal expression underlies susceptibility to such disorders.

Traditionally, gene expression profiles have been studied individually or in small groups, using techniques such as northern blotting, nuclease protection, or the reverse transcriptase–polymerase chain reaction (RT-PCR). This has provided useful information about specific candidate genes but has limited the scope for functional annotation on a wider scale. In the mid-1990s, however, the first experiments were carried out based on high-throughput expression profiling, in which hundreds or even thousands of gene expression profiles could be studied simultaneously. The ultimate goal of examining the entire transcriptome, that is, the sum of all mRNA molecules synthesized in a cell, tissue, or organism, became possible. Such comprehensive analysis can help identify all the genes involved in any medically relevant process and fill in some of the gaps in our knowledge of signaling pathways and regulatory networks. Already, transcriptome analysis has helped identify new disease markers, drug targets, and potentially therapeutic gene products for psychiatric disorders.

Expression Profiling Technology

Two major strategies have been developed for global gene expression profiling, one based on high-throughput sequencing and the other on miniature devices called microarrays or gene chips. Both methods are quantitative, but one produces digital data and the other analog data which must be converted into a digital readout. It is also important to understand that while the terms transcriptional profiling and expression profiling are widely used to describe these methods, what they really measure is not the amount of transcription or expression that occurs but the steady state mRNA level for each gene. The steady state mRNA level takes into account RNA degradation and turnover as well as transcription, and both processes are highly regulated and differ considerably between gene products. A prodigiously expressed gene whose mRNA is very unstable and breaks down quickly will have the same steady state level as a weakly expressed gene with long-lasting mRNA, the principle being that the actual amount of functional gene product produced (the protein) will depend on the availability of mRNA in the cell for translation, not solely on how quickly it is produced or how long it lasts.

Sequence Sampling

The first large-scale gene expression profiling studies involved the random sampling of sequences from complementary DNA (cDNA) libraries, and later the *in silico* equivalent – unbiased sampling of partial cDNA sequences, known as expressed sequence tags (ESTs), stored in DNA databases. The principle behind such techniques is that a strongly expressed gene will be abundantly represented in a cDNA library or equivalent database as long as it remains unnormalized. Normalization is the process by which redundant sequences are removed so that genes are equally represented. In an unnormalized library or database, then, redundancy remains, and any sampling experiment will tend to pull out clones or sequences of strongly expressed genes much more frequently than those of poorly expressed genes. Relative expression levels can be determined simply by counting the score for each sequence pulled out during sampling, and because these data are in the form of real numbers, they are digital.

Although the sampling of cDNA libraries and EST databases has been used with success, the amount of sequencing required to achieve statistically relevant data is very high, making such experiments lengthy and expensive. An improved method called serial analysis of gene expression (SAGE), developed in 1995, circumvents this problem by using very short tags to represent each gene. The principle is that even in a large genome, it should still be possible to identify each gene uniquely with a short sequence signature of 9–15 nucleotides. SAGE works by joining hundreds of such sequence signatures (SAGE tags) in a concatemer, which can be sequenced in a single reaction. Whereas one sequencing reaction is required to identify one gene in traditional sampling, one sequencing reaction can identify 200–300 genes in SAGE. However, the data are still digital representations of transcript abundance, allowing direct comparison between expression profiling experiments.

A more recent development in this field is massively parallel signature sequencing (MPSS), which replaces the SAGE concatemer with a flow cell full of latex beads, each carrying out an individual sequencing reaction. Although the basis of MPSS is complex, essentially what happens is that restriction enzymes are used to chew away cDNA sequences that are covalently attached to microscopic beads. The enzyme chews away four bases of DNA in each cycle and always leaves a four-base overhang. The 16 possible combinations of four bases can be identified by hybridization with complementary oligonucleotides attached to a unique fluorescent label. Therefore, each sequencing cycle sees four bases exposed on thousands of different cDNA sequences attached to beads and the identification of those bases by a flash of light at a particular wavelength. Since each bead is kept in a unique position, 10–50 bp of sequence can be determined very quickly simply by logging the different flashes of color on each bead as the cDNA is progressively digested away. Just like SAGE, each cDNA sequence is identified and counted, and more abundant mRNA species will be represented by more abundant cDNAs. Just like SAGE, the data are digital scores of sampling, and the advantage is that hundreds or even thousands of sequences can be sampled in one experiment.

Microarrays

Microarrays are miniature devices comprising a collection of immobilized DNA sequences arranged in a grid. Each address on the grid corresponds to a unique gene, or at least to a unique mRNA if the gene undergoes alternative splicing. These arrayed targets are hybridized (interrogated) with a complex mRNA or cDNA probe, that is, a probe comprising many different sequences representing the entire population of mRNAs from the cell or tissue under investigation. In this case, quantitative data are obtained, not by counting, but by measuring the strength of the hybridization signal at each address. If the source mRNA or cDNA probe is universally labeled, the most abundant mRNA/cDNA molecules in the population will generate quantitatively stronger signals on the array as long as hybridization does not reach saturation. Since each individual feature on the array generally comprises 10^6–10^9 identical DNA molecules, only a small proportion are occupied during hybridization even in the case of abundant RNAs. The use of arrays allows simultaneous measurement of the relative levels of thousands of mRNAs, but it should be borne in mind that the information derived from the experiment is restricted by which sequences are represented on the array. If any gene is not represented, then its expression level cannot be measured. This is a disadvantage compared with SAGE, in which the system is completely open and any sequence can be sampled, although this disadvantage can be overcome by using comprehensive arrays uniquely representing every possible transcript.

There are two major types of microarrays used in expression analysis: spotted DNA arrays and printed oligonucleotide chips. They differ in many ways, including the manufacturing process, experimental principles, and data extraction, but they do provide data of approximately equal sensitivity. Spotted arrays are produced by printing DNA samples onto microscope slides treated to facilitate covalent attachment. The features are printed in dense grids (usually about 5000 features per square centimeter) using specially designed arraying robots that can transfer minute amounts of fluid from microtiter dishes onto the array surface. The DNA sequences transferred to the device must therefore be prepared beforehand with the polymerase chain reaction, and they are double-stranded molecules varying in length from 100 to 300 bp.

When using spotted arrays to study psychiatric disorders, samples are obtained from diseased and normal tissue, and the complex probes from each source are extracted and labeled with different fluorophores. They are applied to the array simultaneously to allow the measurement of expression levels in both tissues on the same device. The most common strategy is to use Cy3 and Cy5, which fluoresce at different wavelengths, and then use false color to provide a readout of which genes are differentially expressed and which are expressed at the same level in the two different tissues. If a particular cDNA is present only in the Cy3-labeled population, the spot on the array can be colored to appear red. If another cDNA is present only in the Cy5-labeled population, the spot on the array can be colored to appear green. The cDNAs that are equally represented in both populations contain equivalent proportions of each label and appear yellow.

In contrast to spotted arrays, oligonucleotide chips consist of short single-stranded oligonucleotides (20–70 bases in length) which are manufactured on the chip *in situ*. The procedure involves the attachment of single nucleotides at the correct positions on a hydroxylated and silanized glass or silicon wafer and the obstruction of the 3′-hydroxyl group that accepts the next incoming nucleotide with a photolabile protecting group. A chromium mask is then applied to the surface of the chip and determines which areas are exposed to light. Under illumination, the protecting groups in these areas are destroyed, allowing the addition of a single nucleotide, which is also blocked with a photolabile protecting group. If this process is repeated using a series of different masks and different nucleotides, a precise grid can be generated

containing millions of defined and precisely arrayed oligonucleotides. More recently, alternative technologies have been developed which reduce the capital costs involved in chip manufacture by employing virtual masks, such as miniature arrays of mirrors, to control oligonucleotide synthesis. Oligonucleotide chips are operated similarly to spotted arrays, but dual hybridization is not used. Instead, probes for chip hybridization are made from cleaved, biotinylated RNA, and comparative expression analysis is carried out by hybridization of alternative RNA samples to identical chips, followed by comparison of signal intensities. The specificity of hybridization to spotted DNA arrays is relatively high, due to the length of each target. In contrast, the specificity of short oligonucleotides is lower, and to get round this problem, each gene is represented by up to 20 nonoverlapping oligonucleotides to reduce false positives. Also, the chips are designed to contain both 'perfect match' and 'mismatch' oligonucleotides for each specific target, the former being exactly complementary to the target and the latter containing a central mismatching base to control for cross-hybridization. The signal obtained from the mismatch control is subtracted from that of the corresponding perfect match to reveal the actual level of specific hybridization.

Experimental Design and Data Processing

Expression profiling to study psychiatric disorders necessarily involves the use of postmortem brain material, and one factor that must be considered carefully is the cellular diversity and hence the potential for gene expression heterogeneity in small subpopulations of brain cells. This will affect comparisons of tissue samples from different parts of the same brain, as well as comparisons between different brains. In contrast to cancer profiling, in which it is relatively simple to obtain diseased and healthy tissue from the same individual, the study of psychiatric disorders is complicated by potential variance introduced by the diverse genetic background of different brain tissue samples, the impact of lifestyle and drug treatments on gene expression, diversity introduced by age and race, comorbidity, and the fact that many psychiatric disorders actually represent a spectrum of symptoms rather than a single disease. In addition, since some psychiatric disorders involve the depletion of certain populations of brain cells, differences found in gene expression may reflect the differing populations of particular cells rather than the disease itself.

If all these issues can be addressed using carefully matched postmortem brains, sequence sampling experiments such as SAGE will generate digital data in the form of hits on specific genes that can be counted and converted into percentage scores that can be compared directly between experiments without further standardization or normalization. In contrast, microarrays generate analog data (spots of light at different wavelengths) which must be corrected for background, nonspecific hybridization and spurious signals and then normalized against the expression of housekeeping genes (whose expression should be the same in all samples) before cross-comparisons are possible. This is achieved by converting the signal from each area of the array into a numerical readout by measuring the intensity measurement of each of the microarray pixels and combining these into a single intensity value that corresponds to individual gene targets. Normalization is necessary because the overall microarray signal intensity may vary greatly across arrays within the same experiment, and the manual elimination of spurious signals, such as from dust particles, may also be required. Microarray targets that do not yield a uniform signal are flagged, as are gene targets that do not reach a certain signal-to-background ratio or signal intensity. As a result of this procedure, microarray targets are divided into a group of measurable and nonmeasurable genes. In a typical brain microarray experiment, this approach can reduce the data set to about 50% of the total starting amount.

In most profiling experiments, there is some form of comparative analysis, which means the differentially expressed genes need to be identified, and this is usually the province of specialized data analysis software that calculates the likelihood that observed differences reflect a true difference in gene expression as opposed to natural variation. It is difficult to apply stringent correction methods without limiting the discovery of genuine differential gene expression, so a typical approach is to pick candidate genes showing at least a 20% change in expression level and then use a data set-specific false discovery rate assessment, which involves multiple statistical testing to ensure that differential expression results can be repeated.

To help researchers interpret data from various transcriptional profiling experiments, most peer-reviewed journals have implemented a standardized process for presenting microarray data. This process is based on the Minimum Information about a Microarray Experiment guidelines devised by the Microarray Gene Expression Data Society.

Expression Profiling in Specific Psychiatric Disorders

Anxiety

Although human studies have not been carried out, insight into the changes in gene expression that

accompany human anxiety disorders has been gained by studies in rats. PVG hooded rats and Sprague–Dawley rats react quite differently in response to cats, showing different degrees of anxious behavior. Comparative analysis has revealed significant changes in the abundance of mRNAs for Arc, glyoxalase-I, NGF-I, and PLP, as well as genes involved in the synthesis and transduction of γ-aminobutyric acid (GABA)ergic signals, suggesting these may also be involved in human anxiety.

Autism

Autism was one of the first conditions tested by expression profiling of brain tissue. Using cDNA microarrays and a range of other techniques to compare brains from ten autistic patients and 23 normal individuals, it was established that autism might involve differences in the mRNA levels for certain α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-type glutamate receptors and glutamate transporters in the cerebellum. Another study using cortical tissue from 28 brains suggested that differences in MeCP2 expression could be linked to autism as well as a variety of other neurodevelopmental disorders, such as pervasive developmental disorder, Prader–Willi syndrome, and Angelman syndrome. However, these findings have yet to be repeated.

Bipolar Disorder

Another early study involved the analysis of 1200 genes in the frontal cortices of ten postmortem brains from people with bipolar disorder. This analysis showed clearly increased levels of *CASP8* and *ERBB2* mRNA, whereas the levels of TGFβ1 decreased. TGFβ1 has a neuroprotective role, and it has been suggested that its reduced expression may reflect neurotoxicity. Other studies have shown that bipolar disorder involves significant disruption to transcripts encoding enzymes and other components of mitochondrial energy metabolism, causing downstream deficits in adenosine triphosphate. There are also some common links with schizophrenia, in that studies of both bipolar disorder and schizophrenia show that neuropeptide Y (*NPY*) mRNA levels are lower in the frontal cortex, and there is also downregulation of certain oligodendrocyte and myelination genes, including transcription factors that regulate their expression.

Major Depression Disorder

Few studies have shown reproducible transcriptome data for major depression disorder (MDD), although there have been some interesting findings when therapeutic strategies for treating the disorder have been investigated. Oligonucleotide arrays were used to test dorsolateral prefrontal cortex and anterior cingulate samples from MDD patients and unaffected controls, revealing dysregulation affecting several components of the fibroblast growth factor (FGF) signaling pathway. Among the ligands affected were FGF1, FGF9, and FGF12, and at least two receptors were also involved: FGFR2 and FGFR3. The comparison of 12 patients with MDD and 14 closely matched controls also found evidence that genes involved in cell communication and signal transduction were dysregulated, leading to oligodendroglial abnormalities and loss of synaptic function.

Studies of MDD therapies have pointed to the activation of several signaling pathways by electroconvulsive therapy, which is used to treat drug-resistant MDD patients. Of particular interest was the finding that *NPY* mRNA levels increased, since NPY levels are known to fall in MDD patients and can be increased by antidepressants. Similarly, the level of thyrotropin-releasing hormone (TRH) mRNA was shown to increase in response to therapy, which correlates with the antidepressant effects of intraperitoneal TRH injections in the forced-swim model. Notably, NPY also has antidepressant effects in this model. The data from drug therapy experiments have been less rewarding. For example, only four genes were shown to be downregulated in response to treatment with the antidepressants paroxetine and mirtazapine, and it is not clear how these genes are related, if at all, since two were uncharacterized ESTs, one encoded a ribosomal protein, and the other a conserved gene in the major histocompatibility complex.

Schizophrenia

Schizophrenia has been profiled more than any other psychiatric disorder, but analysis has been complicated by the fact that the disease presents a spectrum of symptoms rather than a single, unique phenotype. Perhaps for this reason, different studies have generated diverse findings, although there have also been some interesting cross-study correlations, particularly focusing on the dysregulation of genes involved in energy metabolism, oligodendrocyte function, the GABA and glutamate systems, and the development and maintenance of synapses.

The impact of energy metabolism on schizophrenia is one of the most clear-cut findings from microarray studies, with one team of investigators showing that the expression of genes related to energy metabolism and oxidative stress differentiated almost 90% of schizophrenia patients from controls, in agreement with proteomic and metabolomic data. The general downregulation of mitochondrial genes encoding

enzymes and structural components of the respiratory chain has been replicated in several studies, along with indications that schizophrenia may also affect the transcarboxylic acid cycle, amino acid metabolism, polyamine metabolism, and ubiquitin metabolism. However, similar trends are seen in other disorders, including Alzheimer's disease and multiple sclerosis, indicating that reduced energy metabolism in schizophrenia may be the secondary consequence of a distinct primary defect.

Another consistent finding across expression profiling studies is the reduction in mRNA levels corresponding to myelination and oligodendrocyte function. In one of the largest such studies, prefrontal cortices from older, hospitalized schizophrenia patients were analyzed against matched controls, with the use of an oligonucleotide chip containing 6000 probe sets. This study revealed 35 genes that were specifically downregulated in schizophrenia, and with these genes alone, it was possible to differentiate 100% of the schizophrenia patients from the controls. The repeated finding of oligodendrocyte and myelination genes in profiling studies using sequence sampling and microarrays has been backed up by other experimental approaches (e.g., differential display PCR, RT-PCR). This provides compelling evidence that the dysregulation of critical oligodendrocyte development and maturation genes is an important component of schizophrenia, not only in the prefrontal cortex but also in other brain areas, such as the temporal gyrus. This is concordant with studies based on magnetic resonance imaging, which show reduction in white matter volume and decreased oligodendrocyte density in schizophrenic patients.

Schizophrenia is also characterized by the loss of presynaptic markers. The first profiling study of human postmortem brain tissue from patients with schizophrenia established that transcripts related to the presynaptic release machinery in the prefrontal cortex were present at lower levels than normal. However, it was found that the pattern of affected transcripts differed from individual to individual, suggesting diversity at the molecular level, which might underpin the spectrum of disease symptoms. In this and subsequent investigations, a large number of underrepresented transcripts have been identified, including those encoding synaptobrevin, synaptogyrin 1, synaptophysin, synaptotagmin I and IV, SNAP23 and SNAP25, *N*-ethylmaleimide-sensitive factor, and various components of the clathrin-dependent endocytosis pathway. While most of the dysregulated transcripts were underrepresented in the disease state, the mRNA for the plasma membrane protein syntaxin was shown to be overexpressed in schizophrenia. It is also notable that many of the transcripts identified above were shown to increase in abundance in response to haloperidol or clozapine, which are used to treat schizophrenia. However, many other genes are also affected, and synaptic genes can be repressed as well as induced by these drugs, so the picture revealed by these studies remains complex.

While many of the genes shown to be modulated in schizophrenia fall into the functional groups discussed above, others have been identified which fall without this classification, and the specific way in which they contribute to the disease remains to be elucidated in detail. Microarray studies support previous findings that schizophrenia may involve alterations to the GABA and glutamate systems. One study showed a reduction in the mRNA for GAD67, an interneuronal enzyme, and in the mRNA for several postsynaptic GABA-A receptor subunits. Other studies have shown reduced expression of AMPA2 receptor mRNA in the temporal cortex of patients with schizophrenia. The mRNA for 14-3-3 protein, a regulatory protein with roles in many signaling pathways, the cell cycle, and neurotransmitter metabolism, is underrepresented in schizophrenics, according to several independent studies, as is the mRNA for the heat shock protein and molecular chaperone HSPA12A and for the signaling regulator RGS4, which has been identified in linkage studies as a susceptibility factor for the disease. Conversely, transcripts for several members of the apolipoprotein L family are upregulated in the prefrontal cortex, and the *chondrex* mRNA, encoding a protein involved in neuronal migration, is upregulated in the hippocampus.

In addition to studies profiling neural tissue, there has been some effort to use the profiling of nonneural tissue for disease diagnosis. In one notable study, the microarray-based analysis of peripheral blood from schizophrenics, individuals with bipolar disorder, and unaffected controls was used successfully to distinguish between the three groups. This effort involved the analysis of linear and nonlinear combinations of eight putative biomarker genes (*ADSS*, *APOBEC3B*, *ATM*, *CLC*, *CTBP1*, *CXCL1*, *DATF1*, and *S100A9*) and achieved an accuracy of more than 95%.

When all the results from the schizophrenia transcriptome studies are combined, it appears to be that the affected transcripts in schizophrenia occur in multiple cell types and involve impairments related to processes of synaptic release, GABA- and glutamate-related neurotransmission, cell signaling, second messenger systems, energy metabolism, protein turnover, and myelination. There is little doubt that these changes are interrelated, although the precise causal relationship among them is poorly understood.

Summary

Expression profiling has been used since 1995 to identify genes whose dysregulation underlies human disease and drug responses. The use of expression profiling to study psychiatric disease is a more recent development, yet already these studies have provided useful data on a range of disorders, particularly schizophrenia. Several principles have already emerged, including the tendency for certain transcriptome disturbances to occur in multiple psychiatric disorders and the tendency for diseases often to reflect a multitude of molecular disturbances with a destabilizing cumulative effect on certain processes (such as oligodendrocyte function in the case of schizophrenia) rather than very clear and definitive disturbances in the expression of individual genes. This fits in well with the spectrum of symptoms seen in many psychiatric diseases. Data from expression profiling have provided a number of new leads in terms of identifying disease susceptibility genes, particularly where changes in expression levels are due to regulatory mutations (i.e., mutations in promoters, enhancers, or *cis*-acting sites required for RNA splicing) and can thus be identified in at-risk populations by scanning for single nucleotide polymorphisms in target genes. The identification and characterization of such mutations may also lead to improved therapies, as drugs can be developed with the specific aim of restoring the expression levels of key genes to normal or of selectively destroying overexpressed transcripts and normalizing the phenotype.

Historical Background

The work of the German philosopher and scientist Wilhelm Wundt (1832–1920) laid the foundation for psycholinguistics, although Wundt did not have the benefit of the linguistic insights that give the modern field its power. At his laboratory in Leipzig, he developed an early theory of speech production, and used reaction time and other experimental measures that are still basic to psycholinguistic research. The premise that underlies the measurement of reaction time is that the time taken to respond to an experimental task reflects the degree of mental complexity involved in processing it. For instance, in some contemporary studies the participants are asked to respond as quickly as possible as to whether a string of letters flashed in front of them on a tachistoscope comprise a real word; these tasks are called lexical decision tasks. Typically, it takes much longer to respond to letters representing rare words than it does to those representing common ones. Thus, it takes much longer to reach a lexical decision about the string of letters 'a w r y' compared to a decision about the string 'n e a t.' This difference in reaction time presumably mirrors the greater amount of cognitive activity required to search through the mental lexicon to find the rarer word, match it to the tachistoscopic stimulus, and decide that the string of letters is, indeed, a word. Studies of this nature have consistently shown that there is a direct relation between the usage frequency of a word and the latency of response to it: the more common the word, the more rapidly it can be accessed.

Until the 1950s most psychologists studying language followed learning theories that emphasized serial patterning in behavior. Psychologists working within the framework of behaviorism, such as Hull, Watson, and Skinner, differed in their specific accounts, but they all viewed language as the product of various forms of learning. For instance, classical conditioning could be invoked to explain the acquisition of meaning. According to this model, an infant learns the meaning of a word such as 'bottle' through repeatedly hearing adults say the word while presenting the actual bottle. Ultimately the word alone evokes a response in the infant that is very similar to the response to the bottle itself. That response (pleasure, anticipatory eating actions, etc.) can be thought of as the meaning of the word. Instrumental learning occurs if parents train infants to speak through shaping and reinforcement of their early vocalizations until the infants' successive approximations of language become closer and closer to actual language. Finally, social learning occurs if children acquire language through imitation of the speech of others. The belief that children acquire language through imitation is widespread, even though psycholinguistic research has challenged this view. Behaviorist accounts of sentence production based on transitional probabilities (or the statistical likelihood that one word is likely to follow another) were advanced by some researchers in the 1960s. In his 1957 book *Verbal Behavior*, Skinner presented a behavioral model of language functioning that became particularly controversial as the revolution in cognitive science began. Within 2 years (in 1959), Chomsky forcefully argued that conditioned stimulus–response associations could not adequately explain the infinite productivity of language, its rapid acquisition by children, and the lack of one-to-one correspondence between the meanings of utterances and their grammatical structure. His work spurred the development of numerous accounts specifying the domain-specific mental representation and acquisition of linguistic rules, including proposals that the mechanisms that enable language development and use were distinct from those used in general learning, and innately enabled by principles of universal grammar. Psycholinguistic experimentation seeking to explore the functional reality of evolving linguistic theories dominated the field until the mid-1980s when an alternative framework, connectionism, emerged to compete with linguistic accounts of language acquisition and use. Connectionism views language knowledge as the product of generalized, rather than domain-specific, patterns of neural network activity that establish and then rely on spreading activation patterns distributed across the network.

The Structure of Language and Its Mental Representation

Every human language is hierarchically organized and can be described in terms of its component subsystems. These systems include phonology, the lexicon, morphology, syntax, and pragmatics and discourse.

Phonology

Phonology includes the significant sounds of the language and the rules for their combination. The words of a language are divisible into sound sequences, and part of language knowledge is an understanding of the particular sounds used in a language, and the rules for how they can be combined and ordered. There are many speech sounds available to the world's languages. Any single language employs a subset of these sounds, typically about 23 consonants and 9 vowels. There is, however, substantial diversity in the world's languages, with numbers of consonants in a given language ranging between 6 and 95, and numbers of vowels ranging between 3 and 46. The distinctive sounds used by a language are its phonemes. Phonemes are contrastive; changing from one to another within a word produces either a change in meaning or a nonword. For example, the /p/ in pit serves to contrast pit from other English words, such as bit, sit, and kit, which are similar in all respects except that they begin with other English phonemes. Psycholinguistic research has shown why speakers often have difficulty trying to learn a second language that has a different phonemic inventory. For example, the initial sound of the English word *this* is rare in the world's languages, and poses particular difficulties for those learning English as a second language, whereas English speakers have difficulty learning sounds not in English, such as the initial sound of the French word *rue*. Research studies using innovative techniques, such as nonnutritive sucking and conditioned head turn responses to stimuli, have shown that human infants can initially discriminate among the sounds of all languages, but around their first birthdays, as they acquire their native language, they begin to lose the ability to make fine distinctions among the phonemes of other languages.

The importance of knowing the rules for the combination of sounds within one's language (phonotactics) becomes apparent in ordinary conversation, because the identity of individual speech sounds is often unclear. Experimental research shows that listeners are often confronted with an auditory puzzle: They hear some sounds, but not all, and must 'fill in the blanks.' The effortless and accurate solution of such puzzles is mediated by adult listeners' knowledge of their phonemic inventory, phonotactic constraints, and lexicon, and also by inferences that can be drawn from the context. In addition, spoken language is characterized by a great deal of acoustic variability in the representation of phonemes, both within and across speakers. Research suggests that speech sound processing is characterized by categorical perception, in which acoustically variant tokens are forced into binary percepts. Infants' abilities to use such skills in segmenting and decoding the ambient speech signal to induce the lexicon and grammar of their language is obviously less apparent, leading to large numbers of current studies and models that seek to understand how they 'bootstrap' and expand early linguistic discoveries.

The phonological system of a language also includes rules for the interpretation of prosody, or intonation and stress patterns. In English, prosodic cues can distinguish between grammatical contrasts, such as the difference between statements and questions (You're going. vs. You're going?). Prosody can also convey emphasis and emotion in language. The status of prosody as a separate system is upheld by the finding that some patients with right hemisphere brain damage lose the ability to distinguish between happy and sad productions of the same sentence. Spoken word recognition is thus enabled by a number of perceptual biases that operate from the bottom up in analyzing the input signal, combined with the use of top-down knowledge of language-specific phonological and prosodic rules, vocabulary, and syntax, along with generalized use of context to derive an appropriate interpretation. Such rapid and complex integration of cues to meaning poses a continuing challenge to the development of computerized spoken word recognition systems that can successfully mimic human speech perception.

The Lexicon

A capable user of a language possesses a vast and complicated mental lexicon, or dictionary, the nature of which is of great interest to psycholinguists. Most adults know the meanings of 60 000–80 000 words in their language, and can readily comprehend or access them for communicative purposes. Psycholinguists investigate both how these words are represented in the mental lexicon as well as how they are rapidly accessed during language production and comprehension.

It is not easy to explain exactly what a word 'means.' How is it that one identifies certain objects as chairs, no matter how they may vary in construction? When does an object deserve the label cup, rather than glass? The difficult problem of explaining how people categorize and name concrete concepts has been the subject of much research. Proposals that the association of names with objects is constrained by innate biases in child language acquisition have been an object of recent psycholinguistic research. There is also clear evidence, through studies in which lexical access is speeded by priming the listener with semantically related items, that meaning is used in the word recognition process. Researchers also

contrast the knowledge of concrete words with abstract notions such as 'friendship' or 'patriotism,' and relative words such as 'good' or 'short.' There is evidence that factors such as abstractness and relativity of meaning increase task difficulty and influence the order in which children acquire the meanings of various classes of words. Some types of Freudian slips, in which the speaker retrieves the opposite of the intended lexical target, also suggest an underlying organization of the mental lexicon along semantic dimensions.

Some words in the language do not easily lend themselves to definition: In the sentence 'John is frustrated by calculus,' what does 'by' mean? In 'John wants to sleep,' what does 'to' mean? Linguists categorize words such as 'John,' 'frustrated,' and 'calculus' differently from words like 'is,' 'by,' and 'to.' Words in the first group are content words and those in the second group are function words. Content words have external referential meaning; function words serve particular functions within the sentence by making the relations between the content words clearer. The distinction between content and function words is psychologically meaningful. It is, among other things, possible for psycholinguists to distinguish between the processes used to retrieve these two types of words in both comprehension and production. The distinction between content and function words in mental representation is further upheld by studies of the language of patients suffering from damage to the language areas of the brain (aphasia). Patients with lesions in Broca's area frequently exhibit agrammatism, a type of aphasia in which content words are easily produced, whereas function words and other grammatical markers, such as plural endings, may be difficult or impossible to produce.

Normal conversational phenomena also provide insight into the possible nature of the mental dictionary. In a 'tip of the tongue state,' when we cannot recall a word, why do we often know what its beginning sound is? Speech production errors (slips and spoonerisms), such as saying 'slickery' rather than 'slippery,' or the Reverend Spooner's, "You have hissed all my mystery lectures. You have tasted the whole worm," are of potential value in psycholinguistic modeling. Such performance errors provide evidence for possible stages in and models of the way we use our mental lexicon in constructing messages. They suggest, among other things, that words may not be stored as wholes, and that to access some words, speakers must retrieve and assemble their components. Some errors suggest that the meanings of words and their phonological representations are stored separately. Moreover, the fact that the vast majority of speech errors result in real, albeit inappropriate, words of the language suggests a prearticulatory stage in speech production in which output is scrutinized for lexical well-formedness, with revision of ill-formed plans as necessary.

Morphology, or Word Formation

In English and other languages, one can readily identify meaningful items that are separable parts of words. In a word like 'cats' we recognize that the final '-s' signifies the notion of plurality; it can thus be appended to other words we wish to pluralize. Other similar word endings in English are -ing, as in 'jumping,' '-s' as in 'boy's', and -ed, as in 'dropped.' These suffixes are grammatical morphemes. A morpheme is the smallest unit of a language that carries definable meaning or grammatical function.

In English, some words consist of only one morpheme. One cannot divide 'table' or 'the' into smaller units that have meaning. Words like 'cats,' however, comprise two separable but unequal notions. Cat can stand by itself in a sentence; '-s' cannot. A free morpheme is one that can stand by itself, whereas a bound morpheme, or affix, cannot stand alone. Affixes serve two distinct functions. Some affixes change a word into a new word with a different meaning or grammatical function; these are called derivational morphemes because they are used to derive a new word. For instance, the affix '-ness' may be added to the adjective 'kind' to derive the noun 'kindness.'

A second type of bound morpheme provides additional information about a word without changing its part of speech or meaning. These are inflectional morphemes; in English they mark number in nouns (cat vs. cats), possession (John vs. John's), verb tense (eat/eating; study/studied), and subject–verb agreement (I/you/we/they understand vs. he/she/it understands).

The distinctions between content and function words and between free and bound morphemes appear psychologically significant when one examines language understanding and production. There is evidence that morphologically complex items are decomposed into their constituent units during the process of lexical access. In addition, slips of the tongue show that these different classes of morphemes are retrieved at different stages of the sentence formulation process during the process of speaking, because they may exchange and have their pronunciation adjusted to their new environments in the errored output (e.g., 'he run outs,' in which the transposed inflection assumes the allophonic realization of /s/ rather than /z/ appropriate to its intended position at the end of the word 'run').

Morphological rule learning is also an intense topic of scrutiny in connectionist accounts of language learning, because connectionist models have been relatively successful in replicating children's patterns of learning and overregularization (e.g., the transient and quite normal use of 'holded' for 'held').

Syntax

Syntax includes rules for combining words into meaningful propositions. Phonological, lexical, and morphological systems are only part of the competent language user's armamentarium. It is important to know how to combine words into sentences that convey meaning, and to be able to interpret the grammar of the language heard.

Young children soon learn the differences signaled by syntax. For example, the sentences 'John loves Mary' and 'Mary loves John' have very different meanings, although the words are the same in the two utterances. Their order differs, and in English these different orders signal major differences in meaning. In English, word order is extremely important: In parsing or processing utterances, we expect the first noun in a sentence to be the subject, and the next to be its object. We also expect subject nouns to be followed closely by verbs. For these reasons, English is called an S–V–O (subject–verb–object) language. Approximately 75% of the world's languages are either S–V–O languages or S–O–V (subject–object–verb) languages.

Word order in English aids in the interpretation of the relationships among words in a sentence. However, not all sentences of English are arranged in S–V–O order. For example, the sentences 'Mary is loved by John' (a passive construction), 'Mary showed John the old man', (a dative construction) and 'The man who lives next to my sister collects antique cars', (a center-embedded relative clause) all violate the typical ordering of subject–verb–object in English. The expectation that words follow a conventional order in English is a processing heuristic that helps a listener arrive at a rapid and accurate interpretation of many sentences. We all use typical word order patterns as a comprehension strategy in English. But if word order deviates from the norm, problems in interpretation can arise; for example, the sentence 'The invasion surprised many people' is easier to process than its synonymous passive 'Many people were surprised by the invasion.' Experimental research with children has also shown that initially children learning English employ a S–V–O word order strategy that leads them to misinterpret passive sentences: Preschoolers, when asked to select from an array of pictures the one called 'The mommy is kissed by the daddy' typically point to a picture showing a woman kissing a man. Sentence processing heuristics vary among languages according to their specific word order typologies. Moreover, the lack of explicit parsing cues in a sentence, such as 'The man felt the dog was poorly trained,' may cause readers expecting subjects, verbs, and, objects to follow each other to initially assume that the subject was touching his pet. It also appears that the mental lexicon assists the language user by setting up syntactic expectations that accompany word meaning. Current theory holds that the mental lexical entry for a verb such as 'greet,' for example, includes information about what greet 'means,' and also specifies the requirement that it be followed by a noun phrase in a sentence. Such a model predicts the psycholinguistic finding that sentences having verbs with a variety of potential arguments appear to be more difficult to process, compared to those with limited options.

Sentence ambiguity is another focus of psycholinguistic research. A sentence such as 'Visiting relatives can be a nuisance' has more than one meaning; a complex interaction of parsing preferences and context appears to aid listeners or readers in selecting the appropriate interpretation. Recent research using functional brain imaging demonstrates that complex and atypical constructions elicit greater cortical activity; additional recent techniques such as eye-tracking and event-related potentials permit psycholinguists to track the parsing strategies used in comprehension and the time course for resolving difficult structures.

It is increasingly clear that language processing is affected by interactions between linguistic systems and the situational context. Work that examines the role of context in interpreting ambiguous speech signals and in making logical assumptions in understanding sentences suggests that many kinds of information contribute to the process of language comprehension. Not all of these sources of information are adequately described by linguistic theory alone.

Pragmatics and Discourse

Language users must evaluate what they hear or read within a context. If we are told by a police officer, for instance, 'This is a no-parking zone,' the message is typically taken as more than a simple comment. It may be a warning or a threat. Language has many uses: It can, among other things, inform, promise, request, query, blame, and even lie. The way language is used in social context is the domain of pragmatics. Pragmatics influences our choice of wording and our interpretation of language within the social context. Just as there are rules for creating grammatical sentences, there are also linguistic conventions for the appropriate use of language in various contexts.

The situational setting or context of spoken messages is often crucial to their successful interpretation.

A woman who says to her friend standing near the window, 'It's hot in here,' is probably asking her friend to open the window. This indirect statement contrasts with the more direct utterance, 'Open the window.' Although it may appear to complicate conversation, indirect phrasing is often used to make requests of others, because it is more deferential or polite. Politeness, like grammar, is a complex and rule-governed linguistic system. However, use and comprehension of such indirect language may pose particular problems for children and adults with language disorders.

Spoken discourse or text comprehension demands more than successful identification and parsing of words and phrases. Every speaker of a language must understand connected discourse and the conventions that relate sentences to one another. Much of our language use involves verbal or written interactions that are longer than a single utterance. Conversation and written text are governed by discourse conventions that dictate the appropriateness of content, structure, and turn-taking. For example, determining the reference for a pronoun (anaphoric reference) may require successful processing and retention of large quantities of prior linguistic information. Conversely, use of a pronoun implies that its antecedent has been previously established. In English, a noun must be specified before a pronoun can be used. Thus, 'I found it!' is a poor opening gambit in conversation with a stranger on a bus, but it makes perfectly good sense if you have just told her that you have lost your ticket. This skill may be difficult for children to master and may result in frustrating conversational gambits for parents (e.g., 'He hit me! Who hit you?'). There is ample evidence that memory for verbal material is rather fleeting; the specific words and sentence structures heard or read decay rather rapidly, leaving only propositional and more general semantic content. Recall of text usually results in substitution of lexical and syntactic paraphrases for the original material. Additionally, much of what we take to be the meaning of text or discourse is inferred rather than explicitly stated (as in mistakenly responding that the phrase 'John used a hammer' was seen in a series of sentences that included the phrase, 'John nailed the boards together').

Successful use of language in social settings also requires appropriate modifications when addressing different types of listeners. Speech styles can vary according to the subject being discussed, the characteristics of the addressee, or the characteristics of the speaker, as well as according to the medium of discourse (written or spoken, telephoned, or face-to-face, etc.). These specially marked ways of speaking are called 'registers.' The way we talk to babies, the language of a sportscaster, and the speech of a minister are examples of different registers. Some registers typify casual interaction, whereas others are more appropriate to formal events. Recent research has shown that the pragmatic system may be less developed than other parts of the language in children suffering from certain types of developmental disabilities, particularly children with autism.

Major Themes in Psycholinguistic Research

Rather than characterizing psycholinguistic inquiry according to the structural properties of language, we can also identify major themes that require integration of linguistic and paralinguistic information across levels of language structure.

How Individuals Understand Spoken and Written Language

The broad area of investigation of understanding language involves scrutiny of the comprehension process at many levels, including investigation of how speech signals are interpreted by listeners (speech perception), how the meanings of words are found (lexical access), how the grammatical structure of sentences is analyzed to obtain larger units of meaning (sentence processing), and how longer conversations or text are appropriately evaluated (discourse). Concerns specifically related to how written language is processed are also in this domain.

Psycholinguistics also explores language processing in a wide variety of disordered populations, including individuals with aphasia, acquired reading disorders and dyslexia/alexia, split-brain functioning, deafness, autism, mental retardation, stuttering, and Williams syndrome. In particular, study of language use following brain damage, and in children with developmental disorders, has the potential to greatly inform and constrain theories and models of normal language functioning.

How Individuals Produce Language: Speech Production

It is easier to evaluate the comprehension process than the production process. We can analyze patterns of accuracy and error, response time, and other behaviors to arrive at a rough estimate of how language stimuli are comprehended by listeners. However, it is more difficult to gain insight into how ideas are put into linguistic form; the process is largely hidden from observation, and speakers' verbal expressions, even in response to controlled eliciting stimuli, vary considerably. Researchers are currently developing complex models of the production process. Typical

models of language production contain multiple stages, beginning with the meaning that is generated; they then proceed to the selection of syntactic structures and intonation contours, the specification of words from the lexicon, and, finally, phonological rules and commands to the motor system for speech. Major sources of information about the probable nature of the speech production process can be found in speakers' speech errors or false starts and in hesitations and pauses that break the rhythm of ongoing speech.

How Language Is Acquired

The major focus in the domain of language acquisition has been on developmental psycholinguistics, or the acquisition of a first language by children. Early findings in developmental psycholinguistics countered behaviorist claims about imitation as a basis for language learning. They showed that young children's language often contains utterances that do not replicate anything the child has heard from adults (e.g., 'I falled down and hurted myself'); in the earliest stages of language development children also do not use articles such as 'a' and 'the', even though these are the most frequent words in English. In an early study (1958) of children's acquisition of the English morphological system, Berko showed that preschool-aged children can correctly form the plurals and past tenses of nonsense words they have never before heard: When shown a picture of a creature called a wug, even very young children could say that two such creatures were wugs. This was strong evidence that children were acquiring a rule-governed internal representation of the language, and not simply imitating the adults around them.

There has been active and enduring controversy over the respective roles of the environment and innate (or inborn) abilities in helping the child master language. Do adults teach language to children by using special kinds of language with them, and providing them with feedback when they have used the language well or poorly? Or do children come into the world with a special, uniquely human talent that enables them to extrapolate the grammar of a language without overt instruction or correction?

Chomsky noted two problems that have spurred enduring controversy in the field of child language development. The first is what has become known as the degeneracy problem: the assumption that the language overheard by young children contains many incomplete and ungrammatical sentences, and that it does not contain the full range of structures used by the language. Thus, there may not be sufficient positive evidence available to the child to allow adequate, competent language development. The second problem relates to negative evidence. This argument holds that children are not taught that some structures are not permissible in the language, either through parental correction of their errors or through literal instruction (e.g., 'You can say X in English, but you can't say Y'). Both the validity and interpretation of such claims are a matter of spirited inquiry and debate within the field of child language acquisition. Many child language researchers have proposed that environmental influences play a substantive role in the acquisition of language by children. The study of language development in children has become a formidably large discipline, with a wide array of journals, texts, and monographs specifically devoted to developmental psycholinguistics.

Psychopharmacology of Reward and Appetite in Rats

E M Bowman, University of St. Andrews, St. Andrews, Fife, UK

Introduction

The order Rodentia includes nearly all of the species of small mammals used in neuroscience, including mice, rats, hamsters, gerbils, and guinea pigs. Considered as a group, rodents are found in a wide variety of ecological niches and are so successful that they are estimated to include more than 40% of mammal species. In this article, the neurobiology of mice and rats will form the core of the material since these two species are studied most frequently in neuroscience and since behavioral studies can take advantage of their dietary and behavioral flexibility.

First, however, it is important to define the terms reward and appetite. In common language, 'reward' is used to indicate pleasure, gratification, or satiation. In this article, the term reward will refer to the hedonic experience an organism feels after fulfilling a biological or social need. Reward is a latent variable that describes a central psychological state that cannot be observed directly but must be inferred from behavior. In this regard, reward is often confounded with reinforcement and motivation. Reinforcement refers to the ability of the outcome of an action to increase the relative frequency of the action. In many circumstances, reward and reinforcement covary, but reinforcement can occur following the avoidance of aversive outcomes; it is possible to disrupt reinforcement without disrupting the emotional experience of reward; and the conditioned behaviors induced by reinforcement can become independent of reward after habit formation.

Reward is also easily confounded with motivation, which for purposes of this article is defined as the desire to obtain a reward. Perhaps the most concise statement regarding the difference between motivation and reward is the distinction between 'wanting' and 'liking' that was drawn by Berridge and Robinson. It is also important to note that reward occurs during a positive behavioral event rather than in anticipation of it.

The measures used to infer reward in rodents are categorized into three classes. First, unconditioned behaviors, such as orofacial reactions to tastes or ultrasonic vocalizations to play, can be quantified. This is perhaps the approach in which reward is least confounded with motivation and reinforcement. Second, the reinforcing efficacy of a putative reward can be used, assuming that varying the magnitude of reward will influence the relative vigor of operant responding in animals. Third, a behavioral economic approach can be taken in which the cost that the organism is willing to pay for a reward is viewed as an indicator of its magnitude. The costs can be quantified by the amount of work required to earn the reward or by the degree of aversive stimulation an animal is willing to endure to obtain it.

'Appetite' in common parlance refers to hunger, although in many scientific contexts appetite also refers to enduring patterns of consumption. Like reward, appetite is a latent psychological variable that is inferred rather than directly measured. In scientific and medical literature, the specificity of the term appetite varies from author to author, with some referring only to hunger and others referring to ingestive behaviors (both thirst and hunger). The focus of this article is on hunger because it has been most thoroughly researched. Short-term measures of appetite include the amount of food ingested, meal duration, and food preference, whereas long-term measures are based mostly on weight changes.

Psychopharmacology of Reward in Rodents

Dopamine: Pleasure Pathway or an Adaptive Foraging System?

Perhaps the first method of studying the neural correlates of pleasure was intracranial self-stimulation (brain stimulation reward). Discovered in 1954 when Olds and Milner were mapping the functions of the rat reticular activating system, the rewarding effects of localized electrical stimulation were first noted as a conditioned place preference for the quadrant of the test chamber in which the stimulation was delivered. Later, the degree of reward was quantified by varying the stimulation parameters and its locus and subsequently measuring the rate at which rats would press a bar to self-administer it. Mapping studies in rats found that among the most effective sites for intracranial self-stimulation is the medial forebrain bundle, which links the dopaminergic tegmentum with the ventral striatum (nucleus accumbens). It is noteworthy that the title of Olds and Milner's paper refers to the stimulation in terms of reinforcement, whereas the discussion describes the effects of the stimulation in terms of reward. The difficulty in distinguishing reinforcement from reward with respect to the functions of the dopamine system persists to this day.

The rat mesolimbic system, which includes the ventral tegmental area and the ventral striatum, responds to a variety of naturally rewarding events, although the functional significance of these responses is still debated. Increases in extracellular dopamine levels in the ventral striatum have been observed after hungry rats consume food. The dopamine response is lessened by conditioned taste aversion, in which rats learn to avoid food that makes them ill, and by sensory-specific satiety, in which rats devalue food that they have eaten to satiety. Neurophysiological responses evoked by food and water have been observed from individual neurons in the rat ventral striatum and ventral tegmental area. Social rewards evoke dopamine release in the ventral striatum as well. In male and female rodents, increases in dopamine levels in the ventral striatum occur during mating behavior. Increases in extracellular levels of dopamine have been also observed in rat dams suckling their pups. The breadth of dopamine responses to biological and social rewards suggests that they do not encode the specific sensory aspects of reward but, rather, its hedonic valence.

The range of natural rewards to which the rat dopamine system responds is matched by its responsiveness to a variety of artificial rewards. Given the research of Olds and Milner, it is not surprising that intracranial self-stimulation of the medial forebrain bundle leads to increases in extracellular dopamine levels in the ventral striatum, increased expression of c-*fos* in the ventral striatum and the ventral tegmental area, and neurophysiological responses of ventral striatal neurons. Additionally, nearly all recreational drugs, including psychostimulants, opiates, cannibinoids, alcohol, and nicotine, cause increases in extracellular dopamine in the ventral striatum, despite the fact the some of these drugs are stimulants, whereas others are depressants. Drug abstinence in rats results in psychological withdrawal and is associated with decreased dopamine levels in the ventral striatum and elevated intracranial self-stimulation thresholds in the medial forebrain bundle. One hypothesis supported by research on artificial reinforcers in rats is that they substitute for natural rewards but do not undergo satiety because of their direct neural effects. As noted by DiChiara, this notion has obvious application to human addiction.

The dopamine responses described previously do not irrefutably link dopamine with reward since the data are correlational. In order to make statements regarding causality, it is necessary to manipulate the dopamine system by administering dopamine antagonists, dopamine agonists, dopamine reuptake blockers, or compounds that alter dopamine synthesis and metabolism. In general, drugs that increase stimulation of dopamine receptors in the striatum are self-administered by rats, and they potentiate self-administration of other drugs. Dopamine antagonists have been used to disrupt the rat mesolimbic system. The results vary by the selectivity for dopamine receptor subtype, dose, route of administration, and behavioral assay of reward. For instance, administration of neuroleptics in rats leads to response reduction in operant tasks in which the reinforcer is food or intracranial self-stimulation. This led Wise to propose that neuroleptics produce anhedonia. This apparent anhedonia is also seen in unconditioned behaviors, as shown by the reduction in rat ultrasonic vocalizations evoked by reward following administration of the dopamine antagonist flupenthixol. However, there are counterexamples. For instance, administration of the D2 antagonist pimozide spares the orofacial reaction of rats to sweet tastes, which Berridge and colleagues used as a measure of the degree to which the rats like the reward. Given the latter results, Robinson and Berridge proposed that dopamine is involved in incentive motivation (wanting, the process whereby stimuli are tagged as those that should be approached) rather than pleasure (liking).

The involvement of the dopamine system in reward-related processes has also been explored through behavioral phenotyping in mice. The results are globally consistent with psychopharmacological studies in rats. Genetic manipulations that interfere with the lifetime expression of dopamine receptors (D1–D3) or of the dopamine transporter alter the reaction of mice to rewarding stimuli, including addictive drugs. However, dopamine-deficit mice retain preferences for sweet tastes, although they do not feed normally unless given L-DOPA. They also form conditioned place preference for morphine, which demonstrates that dopamine is not necessary for behavioral reactions to reward in these animals. It should be noted that generalizing these results to 'normal' outbred mice should be done cautiously since the result of the genetic manipulation can cause compensatory changes in the nervous system. It is likely that the use of acute antisense RNA or interference RNA will minimize such changes in future mouse research on the dopamine system.

In summary, research in rodents has implicated the mesolimbic dopamine system in reward-related processes, but the precise function is controversial. Two hypotheses have been supported by the rodent work: the first is that the mesolimbic dopamine system signals reward (liking), and the second is that it is involved in incentive salience (wanting). However, research in monkeys by Schultz and others has raised the possibility that the dopamine system is involved in

associating sensory stimuli and environmental contexts with reward (learning). Like the neurophysiological work in monkeys, single-neuron recording studies in rats have shown that neurons in the nucleus accumbens and the ventral tegmental area respond not only to primary reward (both ingestive reward and addictive drugs) but also to stimuli that have become associated with reward through Pavlovian (classical) conditioning. Indeed, manipulating the dopamine system in rats changes the degree to which conditioned stimuli act as reinforcers or enhance operant responding for primary rewards. Thus, reward-related processing within the rodent dopamine system displays plasticity based on experience, and it is possible that the system is involved with the adaptive foraging that has made rodents so successful.

Opiates: The Neural Basis of 'Liking'?

The role that opiates play in reward is obvious from the self-administration of these compounds in both humans and animals. The addictive potency of opiate drugs is interpretable in light of the widespread distribution of opiate receptors in heavily interconnected structures in reward-related neural pathways. Opiate receptors in rodents are found in the ventral tegmental area, the striatum, prefrontal cortex, and the ventral pallidum (a target of ventral striatal projections). Considered as a group, there is strong evidence that these structures are involved in opiate self-administration and reinstatement after abstinence. For instance, rats will self-administer morphine directly into the ventral striatum and into the ventral tegmental area. Rats will also administer selective mu and delta opiate agonists into the ventral tegmental area. The mu agonists are far more potent in this regard, and therefore there is evidence that different opiate receptor subtypes are not equally involved in reward-related processes.

Research on opiate self-administration has linked the opiate system to gamma-aminobutyric acid (GABA) and endogenous cannabinoid neurotransmission within 'limbic' striatopallidal pathways. Heroin self-administration is reduced strongly by compounds that elevate GABA levels in the ventral tegmental area and the ventral pallidum. In the ventral striatum, the activation of the cannabinoid receptor CB1 appears to be important for the reinforcing effects of opiates. Mice lacking the CB1 receptor do not form conditioned place preference to heroin, and in rats CB1 receptor antagonists reduce heroin self-administration and lessen the transient decreases in GABA levels in the ventral pallidum that are evoked by morphine. Thus, it appears that opiate self-administration causes a chain of events in which the activation of CB1 receptors reduces the activity of ventral pallidal GABA receptors, thereby disinhibiting neural activity in the ventral pallidum. Opiate antagonism by naloxone also prevents cannabinoid place preference and self-administration in mice. Thus, the opiate and cannabinoid systems are very closely linked, leading some authors to suggest that the point of intersection lies within the ventral striatum, where cannabinoid and mu opiate receptors are closely juxtaposed.

Given the addictive nature of opiates, it is reasonable to ask whether the endogenous opiate system plays any role in the processing of natural rewards. It is well known that opiate agonists increase the intake of palatable foods and antagonists reduce food intake. Microinjection of the opiate mu agonist DAMGO into the ventral striatum nearly quadruples the amount of fat that hungry rats eat and nearly doubles the amount of carbohydrates they ingest. Microinjections in the ventral striatum of the opiate antagonists naltrexone and naloxone reduce the consumption of sucrose solution in satiated rats. These studies suggest that endogenous opiates selectively influence consumption based on palatability rather than hunger. Thus, the most reasonable conclusion at this point is that endogenous opiates within the mesolimbic system are involved in 'liking.'

In summary, evidence is accumulating that endogenous opiates are used in the encoding of the hedonic aspects of reward. This is based on an analysis of the role that activation of opiate receptors plays during self-administration and during consumption of natural ingestive reward. The mu opiate receptor has been confirmed to play a role in reward, but there are reports that other opiate receptor subtypes are also involved.

Acetylcholine: Rapid Sensory Activator of the Dopamine System?

One of the most addictive drugs in humans is tobacco. The self-administration of nicotine by smoking tobacco is based on an activation of endogenous cholinergic systems. Given the role of the dopamine system in reward, research has focused on the anatomical connections between the dopamine and cholinergic systems. One of the problems that arises when attempting this hodological approach is the complicated anatomy of the Ch5 and Ch6 cholinergic cell groups in the pedunculopontine and lateral dorsal tegmentum, in which both cholinergic and noncholinergic neurons are located. However, it is known that cholinergic neurons in Ch5 and Ch6 project to the ventral tegmental area and to the substantia nigra pars compacta. Dopamine neurons in these sites

express both nicotinic and muscarinic receptors, and cholinergic stimulation of dopamine neurons alters their firing rates. Additionally, pontine cholinergic neurons project to thalamic nuclei, including the mediodorsal nucleus, that are allied with the mesolimbic system. Finally, there are cholinergic interneurons within striatum, one of the major targets of midbrain dopamine projections.

Cholinergic responses are seen in a variety of artificial and natural rewards. Substantial acetylcholine release ($\geq$75% of baseline) in the rat ventral tegmental area is evoked by intracranial self-stimulation, feeding during hunger, and drinking during thirst. Changes in acetylcholine levels in the mediodorsal nucleus of a similar magnitude occur when hungry rats eat food or when rats are injected with amphetamine. The concentration of acetylcholine increases in the ventral striatum during cocaine self-administration, and there is a strong correlation ($r^2 > 0.90$) between *fos* expression in ventral striatal cholinergic interneurons and the vigor with which rats self-administer cocaine. Thus, there appear to be at least two cholinergic systems related to reward processing: the ascending Ch5/Ch6 system and the intrinsic striatal system.

Regarding the ascending system, there has been one study in rats in which neurons in the pedunculopontine system were recorded during appetitive Pavlovian conditioning. It was found that the most neurons responded to the onset lights and tones without regard to whether they were paired with reward, although some neurons responded tonically or to the offset of the stimuli. Transient inactivation of the pedunculopontine region eliminated conditioned dopamine responses in midbrain dopamine neurons. This pattern of results implies that the ascending cholinergic system always broadcasts a signal induced by salient sensory stimuli. Given that dopamine neurons selectively respond to conditioned stimuli, it is likely that cholinergic inputs to dopamine neurons are countermanded by other inputs. Thus, the apparent development of conditioned dopamine responses might reflect the removal of inhibitory influences on the dopamine neurons rather than the addition of new excitatory input.

Norepinephrine (Noradrenaline): Attention Signal Related to Reward?

The functions of norepinephrine neurons in the locus coeruleus seem to closely parallel those of dopamine neurons. For instance, both the dopamine and the norepinephrine (NE) systems project to the rat medial prefrontal cortex and parts of the ventral striatum. In the medial prefrontal cortex, both NE and dopamine are released by conditioned stimuli associated with food reward, food itself, and novelty and putative mild stressors such as human handling. Like the dopamine neurons, locus coeruleus neurons may play a role in plasticity. Disruption of prefrontal NE neurotransmission impairs conditioned place preference to morphine, amphetamine, and food. Moreover, rat locus coeruleus neurons respond to conditioned stimuli associated with reward much in the same way that neurons in the ventral tegmental area do. They respond to conditioned stimuli with a shorter latency than neurons in their prefrontal projection areas, and they exhibit plasticity in their conditioned responses earlier in training than prefrontal neurons. Finally, like drugs that enhance dopamine neurotransmission, the adrenergic agonist clonidine supports both self-administration and conditioned place preference in rats.

Research in mice also leads to the conclusion that the NE system interacts with the dopamine system. Depleting prefrontal NE reduces dopamine release evoked by food and cocaine in both the medial prefrontal cortex and the ventral striatum. However, the same depletion also reduces the dopamine response in those two areas evoked by lithium chloride, which causes a highly aversive malaise. It is noteworthy that the NE depletion also blocks the formation of conditioned place aversion evoked by lithium chloride.

Given the close interrelationship between the NE and dopamine systems, it is reasonable to ask whether there are substantive differences in their reward-related processing. There are indications that this is the case. First, sham feeding results in increases in dopamine within the ventral striatum while reducing NE release. Second, although locus coeruleus neurons respond to conditioned stimuli associated with reward, these neurons respond to both paired and unpaired stimuli presented within an aversive conditioning task. It appears that the NE system responds to a wider range of activating stimuli and therefore its functions are likely to be closely related to attentional state. Attention to environmental stimuli is an important determinant of Pavlovian conditioning in learning theory. It is plausible, therefore, that the effects of NE on appetitive processes are related more closely to reinforcement than to pleasure.

Serotonin: A Role in Modulating Reward?

The role of serotonin in reward-related process has been investigated extensively in rodents. Two themes have emerged from this research. First, serotonin modulates the activity of the dopamine system. Second, serotonin is involved when there is a conflict between choosing immediate small reward and choosing delayed large reward. The basis of these serotonergic

effects appears to be changes in processing of both local and extrinsic inputs to midbrain neurons and direct effects in the prefrontal cortex, respectively.

In rats, anatomical studies have localized serotonin receptors on GABA neurons within the ventral tegmental area as well as on dopamine neurons in both the substantia nigra and the ventral tegmental area. Tract-tracing studies in rats have confirmed that afferents to the dopaminergic mesencephalon arise from the raphe nuclei. Moreover, manipulating serotonin alters the efficacy of dopamine neurotransmission in the ventral striatum and the prefrontal cortex, and it changes baseline neural activity within the ventral tegmental area. Since the nucleus accumbens and prefrontal cortex project to the ventral tegmental area, it is possible that serotonin modulates the dopamine system indirectly as well as directly.

Reward-related effects of serotonergic compounds are numerous. It is difficult to formulate generalizations given the number of serotonin receptor subtypes and the varying degrees to which these subtypes can be selectively manipulated by drugs. One obvious connection between serotonin and reward is the use of serotonin reuptake inhibitors (SSRIs) in depression, a central diagnostic feature of which is anhedonia. The clinical use of SSRIs is matched by the finding that long-term SSRI administration in rats lowers thresholds for intracranial self-administration. In another condition affecting global serotonin function, mice lacking the serotonin reuptake transporter (SERT) exhibit less operant responding for food than control mice. Similar findings have been found using drug manipulations that are selective for specific serotonin receptor subtypes: in both rats and mice, serotonin 5HT-1B receptors are important for modulating the reinforcing effects of cocaine and amphetamine. In rats, 5HT-2C agonists reduce operant responding for both food and intravenous nicotine. Antagonism of the 5HT-3 receptor in rats does not affect operant responses for conditioned stimuli (conditioned reinforcers) that have been paired with reward, but mice overexpressing the 5HT-3 receptor gene show reduced conditioned place preference for contexts associated with cocaine, and they exhibit a lower preference for ethanol than control mice.

Serotonin appears to play a role in decision-making processes when different action–reward possibilities confront rats. Typically in these tasks, animals are confronted with delayed large reward and immediate small reward. Both animals and humans discount the delayed reward, resulting in a pattern of choices that is suboptimum. In rats, serotonin is released in the medial prefrontal cortex in such tasks. Serotonergic lesions of the dorsal raphe increase impulsive choices for the immediate small reward under some conditions, as does systemic administration of a partial 5HT-1A agonist. Since serotonin is released when rats are forced to choose between the two alternatives rather than when rats experience a yoked procedure in which the same pattern of reinforcement is given, it has been proposed that serotonin is not involved in the direct valuation of the rewards but, rather, in the neural estimate of elapsed time.

Psychopharmacology of Appetite in Rodents

In rodents, the homeostatic regulation of nutrients is essential. As might be expected from the complexity of digestion and metabolism, the biological processes that determine how much rodents eat are numerous. It simplifies matters to broadly categorize these processes into stages: monitoring of metabolic and digestive state, triggering of appetitive approach behavior, initiation of feeding, and termination of meals due to satiety.

In terms of behavioral measures, the vigor of approach behavior, the amount of food eaten per unit time, the length of meals, and changes in weight all have been used to quantify changes in appetite. Although these measures relate directly to appetite under normal conditions, confounding processes can come into play when psychopharmacological manipulations are undertaken. For instance, a drug that appears to stimulate satiety might actually produce malaise, whereas a drug that appears to stimulate hunger might do so indirectly by altering energy consumption through psychomotor stimulation.

Research on homeostatic monitoring of nutrients in rodents has revealed several peripheral and central mechanisms. Sensory information regarding the taste and quantity of food ingested is sent from the periphery to an ascending central system that includes the nucleus of the solitary tract and the parabrachial nucleus. Additionally, several neuropeptides act as messenger molecules from the body to the brain. Among the most well known are insulin, leptin, cholecystokinin, and ghrelin. Finally, within the hypothalamus there are glucose-sensing neurons in the arcuate nucleus that project to the other hypothalamic nuclei involved in feeding: the paraventricular, dorsomedial, lateral, and ventromedial nuclei.

Neuropeptides appear to control when rodents eat. It has been hypothesized that ghrelin increases appetite, whereas leptin lowers it. Ghrelin is released by enteroendocrine cells in the stomach, subsequently crossing the blood–brain barrier and strongly activating neurons in the arcuate nucleus. Ghrelin also causes arcuate projection neurons to increase production of neuropeptide Y (NPY) and agouti-related peptide (AGRP). It is believed that release of NPY

and AGRP within the lateral and paraventricular hypothalamus stimulates the onset of eating. In most reviews of appetite, leptin is viewed as part of a negative feedback loop that limits the actions of ghrelin. The gene for leptin was discovered following investigation of mutant *ob/ob* mice, which are hyperphagic and develop severe obesity. Mice and rats that have mutations for the leptin receptor are similarly affected. Leptin is released by adipose tissue and causes the production of cocaine and amphetamine regulated transcript (CART) and pro-opiomelanocortin (POMC). CART and POMC, in turn, counteract the effects of ghrelin, NPY, and AGRP. Thus, the balance between leptin and ghrelin can be viewed as a mechanism that influences the set point for appetite and weight.

It should be noted that the neural control of appetite is far too complex to summarize fully here. Many aspects of appetite control have been left out, including multiple metabolic effects of the neuropeptides listed previously, the appetite-enhancing and -suppressing actions of dozens of neurotransmitters and hormones, the coordination of brain stem and hypothalamic structures with the forebrain, the role of the hypothalamus in influencing diverse feeding-related psychological functions, and the complexity of peripheral mechanisms that sense metabolic states. However, it is clear that considerable progress has been made during the past few years and that modern molecular and biochemical techniques have enabled a renaissance of research on feeding control.

Psychophysics of Attention

Introduction

The amount of information available to our senses greatly exceeds the information processing capacity of our brains. How we deal with the overload is the topic of this article – attention. More specifically, this article focuses on the study of visual attention. The purpose of the article is not to summarize the neuroscience of attention, but to introduce the basic behavioral findings that have motivated interest in the concept.

Perhaps the most fundamental points about attention are that it is limited, and that it is selective. It allows an organism to select the information that is most relevant to its current goals. With attention we are not simply passive recipients of stimuli; instead, we play an active role in our interactions with the environment.

Before proceeding, it is worth making an important philosophical point. When we say something like "it allows an organism to select…" there is a real danger that we may reify the 'it.' We should remember that there is not a homunculus directing traffic in our heads; referring to attention as an active 'it' is a convenient verbal simplification. In fact, the selectivity of attention may be better thought of as an emergent property of our nervous system. In this brief overview of the field of attention we will touch on (1) evidence of limited capacity and (2) the nature of attentional selectivity.

Attention Is Limited

Enumeration

Some of the earliest experiments in psychology amounted to demonstrations of the limits of attention. For example, Jevons, a nineteenth-century researcher, picked up handfuls of beans and threw them into a box, and after glancing at them briefly, attempted to say how many there were. He found that he was essentially perfect when there were up to four beans, but beyond four made progressively more errors. Many variations of this experiment have been carried out. When reaction time is measured, the time required to respond increases only slightly from one to about four, and increases more steeply thereafter. The ability to enumerate small numbers of items quickly and accurately has been referred to as 'subitizing.' The widely, but not universally, accepted explanation is that a few items (up to about four to six, depending on the methodology) can be apprehended simultaneously; beyond that elements are presumably enumerated one at a time, or, if there is time pressure, their numerosity may be estimated.

Multiple-Item Tracking

Imagine an array of, say, ten gray disks appearing on a computer screen. They are all moving in erratic, random trajectories. One of them is marked as a target by blinking several times, but it then reverts to gray and keeps moving along with the other nine disks. Your task is to follow it for, say, 12 s. At that time the disks stop moving and a probe (a small box) appears around one of the gray disks. Your task is to indicate whether or not the probed item was the one that had been marked by flashing. Could you do it? Yes, indeed. This is a trivial task. Now imagine a trial on which not one but two of the ten disks are marked by flashing, and then after 12 s a single disk is probed and you are asked if this is one of the two that had been marked by flashing. Could you do this? Yes; this is a bit more difficult, but not much. However, as the number of marked disks increases there comes a point at which you simply cannot keep track of additional elements. That point varies across observers, but is approximately three to five disks.

Span of Immediate Memory

In a classic experiment by Sperling, when individuals were shown a 3×4 matrix of letters (four letters in three rows) briefly (say for about 0.1 s) and were asked to report as many as possible, they typically reported only four to five letters. In another condition, individuals were presented with a high-, medium-, or low-frequency tone, the tone indicating which one row (top, middle, or bottom) of the matrix they were to report. In this case they were able to report all four letters in a row when the tone came before or very shortly after the visual display. As the tone was selected randomly on each trial, this means that individuals briefly had access to all twelve letters in the display. However as the tone was delayed, performance declined, until, after as little as a 0.25 s delay, performance reached the same level as the whole report technique (i.e., about four or five letters). Thus, this research provides evidence of a high-capacity short-lived sensory memory (often referred to as iconic memory), followed by a small-capacity short-term memory store.

Psychologists have wondered whether the numerical similarity of the capacity limits (three to four items) shown in the these kinds of studies (enumeration, multiple-item tracking, and immediate-memory span) is evidence of a common limitation, or is just a coincidence. A strong case has been made for a common limit, due ultimately to the ability of attention to hold just three to four items at once. However, the issue is not yet settled. A related point is whether the limitation is properly described in terms of a fixed number of 'slots,' with one 'item' assigned to each slot. This is far from a trivial issue, as the definition of an item is by no means straightforward. For example, is the word 'attention' a single visual object, or are the nine letters composing it the proper units of analysis, or are the line segments composing those letters the proper units?

Visual Search

A popular method of studying perceptual processes is to have an individual look for a designated target item in a display that contains several distractors. Typically, the number of distractors is varied, although the number of targets has also been manipulated. Performance is assessed by measuring reaction time and/or accuracy of performance. Visual search provides a remarkably versatile tool for exploring many aspects of perception and attention with a task that has considerable ecological validity, as it is ubiquitous in everyday life.

One important characteristic of visual search is its efficiency, where by efficiency we refer to the slope relating total search time to the number of stimuli in the display. When search requires a simple discrimination, such as a circle among triangles, a 4 among Cs, or a red item among blue items, the process is highly efficient; the slope of the search function is often near zero. As adding additional items does not incur a cost in search time, such a result implies parallel processing of all elements in the display. Although a search based on a simple feature such as color or line orientation can be done in parallel, when a search target is defined as a conjunction of features (e.g., the target is a red horizontal line segment and distractors are a mixture of black horizontals and red verticals), then search time is often found to increase linearly with the number of stimuli in the display. One interpretation of such results is that efficient 'feature' searches are performed by preattentive mechanisms that can analyze the entire display at once. Searches for conjunctively defined targets, however, require sequential inspection of items, as attention is responsible for conjoining the separate features that constitute a visual object. (Although it is common to take linearly increasing reaction time functions to imply that processing is serial, it has been known for many years that this is not necessarily a safe assumption.)

The feature-integration theory of attention has been very influential. One appealing aspect of this theory is that it is based on known functions of the brain. It seems to suggest that elementary features detectable by early visual processing areas of the brain can be processed over the entire visual field at once, whereas dealing with combinations of elementary features, which presumably requires higher level cortical processing, must be done one item at a time, to avoid a 'combinatorial explosion.' However, over time, some problems with the theory have appeared. One difficulty is that several studies have demonstrated that there are feature combinations that can be processed in parallel. For example, efficient search has been found for brick-shaped objects drawn in such a way that their apparent orientation depended solely on their shading (i.e., which surface looked like it was directly illuminated). That is, a misoriented brick could be found in a background of uniformly oriented distractor bricks independent of the number of those distractors. It is possible to consider such demonstrations as either embarrassments to feature-integration theory or as discoveries of surprising new elementary features (although that claim seems inelegant and unparsimonious, as the number of such new 'features' has become substantial). Worse yet for the theory, there is clear evidence that a feature/shape conjunction can be processed in parallel. There is now even some doubt about the idea that simple features are processed preattentively; this is covered in the next section, in the discussion of the attentional blink. Finally, there are also some interesting effects of familiarity that seem inconsistent with the theory. For example, individuals have been asked to search for a single backward N among several normal Ns or a single normal N among several backward Ns. The latter search was fast and parallel, while the former search was slower and serial. The physical features of the targets and nontargets in these two searches were essentially identical; it is not obvious how the theory can account for the results. Indeed, these data suggest that familiarity itself may be serving as a feature. Could familiarity be detected by early visual areas? There is functional magnetic resonance imaging (fMRI) evidence of widespread reorganization of activity in the visual pathway after extensive training on a perceptual task. Retinotopic cortex is involved, although this is presumably activated in a top-down fashion.

As a result of these problems, several competing interpretations have been proposed. For example, in the 'guided search' model, attention is guided by

preattentive processes to the location of likely target items. The ultimate identification of an item as the target or not requires attentive scrutiny of the item. The efficiency of a search depends on the amount of preattentive information available to guide search. This varies from the great efficiency of searching for a red patch in an array of green patches, through conjunction search, to the extremely inefficient search that occurs when the target and distractors share the same features (e.g., looking for a randomly rotated L among several randomly rotated Ts).

Doing Two Things at Once

In the preceding examples individuals may have had to deal with multiple stimuli, but the task in each case was in some sense unitary (count the objects, repeat back all of the letters, etc.) There has also been a great deal of research in which quite different tasks have been combined; what has been at issue is the extent to which tasks can be performed without mutual interference. The general expectation based on everyday experience is that it is difficult to do several things at once (e.g., pay attention to two simultaneous conversations). In contrast, multitasking is possible in some cases (e.g., driving while listening to the radio). Thus the research effort has largely been directed at finding out just which tasks are difficult to combine, and why. One part of this effort has been a search for special conditions in which tasks might be combined without loss, as such conditions might have implications for real-world scenarios, such as using a cell phone while driving.

Some early research with continuous tasks suggested that even fairly complex pairs of tasks that initially interfered with one another – such as typing visually presented text and shadowing (i.e., repeating back) a message played through earphones – could, after sufficient practice, be done as well together as separately. However, with complex continuous tasks it is often possible to interleave components of the tasks so as to minimize or even eliminate the amount of temporal overlap between components of the two tasks. (An extreme example: a centerfielder could probably read a book during the 'slack time' when he is not actively engaged in the game.) Scientists wishing to achieve a more fine-grained analysis of dual-task performance have used simplified tasks to permit a closer analysis of stimulus–response relations. Perhaps the most well-developed analyses come from the psychological refractory period paradigm. In this paradigm two stimuli are presented, S1 and S2, with a variable stimulus-onset asynchrony (SOA). Typically, study participants are instructed to respond as quickly as possible to each stimulus with the appropriate response, R1 and R2, respectively. When the two tasks are widely separated in time there should be no interference between them and we can obtain baseline reaction times (RTs). As the stimuli are presented closer together in time, the reaction time to the second stimulus (RT2) will tend to increase. Most strikingly, in some cases, as the time between stimuli becomes less than about 300 ms, RT2 increases about 1 ms for each millisecond that the SOA is decreased. It is this kind of result, suggesting a clear inability to produce R2 at the same time as R1, that led to the nomenclature of a refractory period, by analogy to the refractory period of neurons.

Another example of the difficulty of responding to two stimuli presented close together in time is known as the attentional blink (AB). In a typical AB task, a rapid series of stimuli (e.g., digits or letters) is presented at fixation, typically at a rate around 10 items per second, and either one or two targets can appear within the stream. The AB refers to a decrement in the detection or identification of the second target (T2) when it occurs soon after the presentation of the first target (T1), to which a response is required. Early models of the attentional blink assumed that T2 processing is impaired because attention is temporarily fully occupied by processing of T1.

In an instructive example, a stream of letters was presented at fixation. There were two targets. The first was a green letter; all of the other letters in the stream were black. The green letter was followed after a variable delay (the lag) by the second target, which was a ring of Gabor patches (a Gabor patch is, essentially, a small patch of parallel stripes) in the periphery surrounding one of the later letters in the stream. Participants had to name the colored letter and also indicate if all of the Gabor patches were oriented in the same direction or if one was misoriented by 90°. In a control condition, individuals could ignore the stream of letters and just indicate if the ring of Gabor patches contained an orientation oddball. Performance in the control condition was about 90% correct and did not vary with the lag between the green letter and the Gabor patches. In the experimental condition, performance was poor (about 60% correct) when the Gabor patches were simultaneous with the green target letter, and improved to nearly 90% correct when the lag between the green letter and the Gabor patches was 700 ms.

What makes these results interesting are the implications they may have for the study of visual processing. The detection of a Gabor patch differing by 90° in orientation from an otherwise uniformly oriented set of patches should be handled preattentively according to feature-integration theory, and, indeed, the reaction time to detect a Gabor patch

misoriented by 90° is independent of the number of other patches – which is precisely the diagnostic that has been taken to indicate preattentive processing in discussions of feature-integration theory. Why then should there be a large dual-task decrement? One possible answer is that it takes a really difficult competing task, such as is presumably provided by the attentional blink paradigm, to show that orientation discrimination, while easy, is not completely attention free. However, it is also possible that the deficit is not due to T1 stressing attentional capacity for feature processing; it may be that the attentional blink reflects difficulty with one or more higher level functions, such as maintaining executive control of a task set in the face of a fast-moving sequence of targets and nontargets. The attentional demands of various kinds of perceptual discriminations remain a topic of great interest and the final word has not yet been written.

Attention Is Selective

The preceding evidence points to a variety of limitations on attentional capacity. It is clear that we cannot process everything, at least not at once. What is it that determines just what it is that we do process? William James distinguished between passive and active attention. Today, the corresponding terms for passive attention are usually 'bottom-up,' 'stimulus-driven,' or 'exogenous,' while corresponding terms for active attention are 'top-down,' 'goal-directed,' or 'endogenous.' What we attend to is determined both by properties of the stimulus array (e.g., a sudden loud sound, or a movement in the periphery) and by our goals and intentions. Much research has examined the nature of the interaction between, and relative importance of, stimulus-driven and goal-directed sources of control.

The brute fact of selectivity has been demonstrated many times. In the technique known as shadowing, used in studies of dichotic listening, different messages are played to individuals over left and right earphones. Study participants are instructed to repeat back the message played to one ear. They are able to do this quite well. What is especially interesting is the analysis of what information individuals extract incidentally from the unattended message in such circumstances. They can report a change from speech to a pure tone, or a change from a male to a female voice. However very few persons notice a change from English to German or a change from normal to reversed speech when these changes were in the same voice. Most important is the near-total lack of comprehension of the message in the unattended ear. Related experiments have been performed in vision. Participants were shown two episodes on optically superimposed video screens. One was a ballgame and one was a handgame. Participants counted unpredictable events (e.g., the number of times the ball was passed from one player to another). In some conditions individuals were instructed to attend to just one of the episodes; in some conditions they were asked to attend to both. One finding concerned capacity; participants were reasonably accurate when they had to monitor one episode, but they could not deal with both simultaneously. The other finding concerned selectivity. The episodes occasionally contained distinctly odd events (e.g., a woman carrying an umbrella walking through the ballgame). After seeing the episodes, participants were asked about these odd events; they were often entirely unaware of those that occurred in the unattended episode. This kind of result has since been dubbed inattentional blindness and has been the subject of several more analytic studies.

The interaction of stimulus-driven and goal-directed attention is illustrated in a series of studies concerned with the capture of attention by featural singletons (e.g., the lone red element in a display of green elements) or by sudden onsets of a new stimulus object in a field of persisting objects. In one experiment participants searched for a target letter in an array of three or six other letters. This is a demanding search task in which reaction time increases with the number of letters in the display. Stimuli started out as placeholders (like the figure 8 of a digital clock), and at a certain point in time selected segments were deleted, revealing letters. In some conditions a new object was added to the display at the moment when the letters were being revealed (i.e., a letter was displayed in a location that had not contained a placeholder). Importantly, the location of the sudden onset was in no way predictive of the location of the target. This new object attracted attention; if it was the specified target character, reaction times were fast and independent of display numerosity, but if it was not the target, reaction times increased with display numerosity. Thus the sudden onset of a new object appears to capture attention in a stimulus-driven fashion. A follow-up experiment was conducted to determine if there is something special about sudden onsets. In this case the displays contained a single character that was unique with respect to color or brightness (e.g., a red element when other elements were green). Strikingly, reaction time was the same whether or not the display contained a singleton. In other words, unlike a sudden onset, color and brightness singletons did not automatically attract attention. This study raised at least two questions that

have been the subject of further investigation: (1) Is it really the case that feature singletons do not capture attention? (2) Is the sudden onset of a new object really different from other kinds of featural singletons with respect to its ability to capture attention?

Do Feature Singletons Automatically Capture Attention?

In some studies, performance on displays containing an irrelevant singleton is compared to performance when displays contain no irrelevant singleton. For example, in one study participants were presented with displays consisting of colored circles or diamonds arranged around an imaginary circle. A line segment of a variable orientation appeared inside each shape; the task was to determine the orientation of the line segment within a target item. The target item was defined as the unique green diamond among green circles. Search was parallel – that is, independent of display size – but was significantly slower when one of the circles was red than when all elements were green. When the color singleton was made less salient than the shape singleton by changing the colors in the display, the color singleton no longer slowed search for the shape singleton; indeed when the roles of the original color and shape dimensions were reversed (color target and shape distractor), the more salient shape singleton now slowed search for the color target. Note that the color singleton provided no information about the target. This study was interpreted as showing that attention is captured automatically by the most salient element in the display.

An alternative to this analysis is that what an individual first attends to depends not just on the salience of stimuli, but also on the individual's task set. It has been suggested, for example, that salient stimuli may only attract attention when individuals adopt the strategy of searching for a feature discontinuity (singleton-detection mode). When individuals adopt the strategy of searching for a specific, known-to-be-relevant, feature (feature-search mode), bottom-up capture can be overridden. In tasks where both strategies are available to the individual (e.g., where the target is a specific feature and also a singleton, such as a green circle among green triangles), both search strategies are available. Therefore, an irrelevant singleton may or may not cause interference, depending on which strategy the individual adopts. In support of this claim it has been shown that when singleton-detection mode is discouraged, and individuals are forced to resort to feature-search mode, a salient distractor no longer interferes with search.

There has been an ongoing debate about the extent to which the most salient item captures attention automatically, as opposed to capturing attention only when an appropriate strategy has been selected. Be that as it may, the consideration of search strategies has led to new findings. For example, circumstances can be arranged to force individuals to search in time rather than in space. Individuals viewed a central rapid serial visual presentation stream (just as in the attentional blink paradigm) in which a target letter was defined by being a particular color (e.g., red). On critical trials, an irrelevant color stimulus could appear in the periphery during one frame of the stream. Interestingly, the irrelevant stimulus reduced the probability of an individual identifying the target letter, when that irrelevant stimulus preceded the target by 200 ms. That is, even though the peripheral stimulus was irrelevant and did not have to be responded to, it had the same effect as a first target in the attentional blink paradigm. That sounds like automatic capture by the irrelevant stimulus, but there is a critical additional finding: the existence of this interference effect was dependent on whether the individual was in singleton-detection mode or feature-search mode. In one experiment, to induce singleton-detection mode, the letters were all gray except for one that was red. (In fact, half the individuals were tested with red, half with green.) Note that when there is just one colored character in a stream of otherwise all gray characters, either feature search or singleton detection could have been applied. In this experiment, regardless of whether an individual was in the search-for-red or search-for-green group, both red and green peripheral distractors produced substantial, and equal, interference with target detection. In a second experiment, multiple colors were used in constructing the letter stream. Again the target was either red or green (different groups of individuals), but now the individuals had to look for a particular color, whereas in the first experiment they could have searched for 'anything chromatic.' Now, individuals who searched for a red target only suffered interference when the distractor was red, and individuals who searched for a green target only suffered interference when the distractor was green. Follow-up experiments established that the interference was due to a spatial capture of attention.

Are Sudden Onsets Special?

An influential account of how performance in search tasks might be affected by nominally irrelevant singletons is that participants in search experiments always adopt one or another sort of attentional control setting that determines what will be selected. (We have already come across this notion; singleton detection and feature search can be considered specific examples of attentional control settings.) To test this

idea, participants searched for a target character that could be either a color or an onset singleton across blocks. Immediately preceding each search display another display appeared that contained a cue that was itself either a color or an onset singleton in one of the (four) potential target locations. It was explained to the participants that the location of the cue was independent of the location of the target. The chief result was that target reaction times were strongly dependent on the cue location, but only when the cue matched the target dimension. For example, if the task was to identify a color singleton, then reaction time was faster when the target was in the same location that the cue had occupied than when it was in another location. However, when participants had to identify a color singleton, the location of an onset cue had no effect on reaction time. This finding is contrary to the notion that the sudden onset of a new object is unique in that it captures attention automatically (i.e., in a stimulus-driven fashion). The possibly special status of sudden onsets is controversial and remains a topic of lively current interest.

Conclusion

The study of attention has been of keen interest to psychologists for over a century. A great deal of progress has been made in understanding the limitations of our perceptual and cognitive processes, and the selectivity these limitations force on us. Most of this research has used psychophysical methods solidly within the behavioral tradition. However over the past 20–30 years the conceptual and methodological armamentarium available to study attention has been expanded in scope by the growth of the neurosciences.

Psychotherapeutic Approaches to Psychiatric Disorders

G O Gabbard and E Poa, Baylor College of Medicine, Houston, TX, USA

Introduction and Definitions

Despite impressive advances in the neurosciences and psychopharmacology over the last several decades, psychotherapy continues to be a major treatment modality in the field of psychiatry. A growing body of efficacy research demonstrates that psychotherapeutic interventions can produce substantial improvements in a great many psychiatric disorders. Psychotherapy can be conducted in a one-to-one context (i.e., individual psychotherapy), or it may occur with one or two therapists in the room with a family, a couple, or a group of unrelated individuals. Many schools of psychotherapy are practiced. In this overview, we focus on those that are most commonly used and for which a greater research base has been established.

Psychodynamic or psychoanalytic psychotherapy is the grandfather of all psychotherapies. Growing out of Freud's development of psychoanalysis as a treatment, this form of therapy is based on a set of fundamental principles. These include the notion that much of mental life is unconscious and that the psychotherapist helps patients gradually accept how unconscious influences affect their experiences of themselves and others. Psychodynamic therapists view the patient's transference to the therapist as a primary source of understanding. In other words, a patient repeatedly attributes qualities, thoughts, and feelings to the therapist that actually are connected with figures from the patient's past. Analogously, psychodynamic therapists also focus on their own emotional reactions to the patient – the so-called countertransference – as another important tool in understanding the patient and the process. A key conceptual point in dynamic therapy is that patients construct a set of psychological defense mechanisms early in life to avoid the experience of emotional pain. These defenses emerge as resistances to the psychotherapy process when the patient enters treatment. Hence, a succinct definition of psychodynamic therapy is a process that involves careful attention to the therapist–patient interaction with carefully timed interpretation of transference and resistance embedded in a sophisticated appreciation of the therapist's contribution to the two-person field.

Cognitive behavioral therapy (CBT) is the psychotherapy with the largest empirical base to support its efficacy. It is based on two core principles: (1) the way people act or behave strongly influences their feelings and thoughts, and (2) cognitions themselves exert a powerful influence on behavior and feelings. Cognitive therapists look at levels of cognitive processing and devote a great deal of their attention to identifying automatic thoughts and schemas. They commonly assign homework for their patients. CBT may also involve a daily log of thoughts or prescribed exposure to feared situations. Cognitive therapists frequently use Socratic questioning to stimulate inquisitiveness and curiosity in the patient.

Interpersonal psychotherapy (IPT) was developed as a treatment for depression, but it has since been expanded to other conditions. At its basic level, IPT was targeted to improve the quality of a depressed patient's interpersonal world. In other words, IPT therapists help patients clarify and understand the common interpersonal themes that are involved in the onset or maintenance of a depressive disorder. Four common theme areas that are the focus of IPT are unresolved grief, social role disputes, social role transitions, and interpersonal deficits. Direct interventions are identified based on which of the four themes is most prominent in a particular patient's situation. This therapy is also reeducative in the sense that it explains diagnosis and treatment to the patient. Based on this explanation, the therapist collaborates with the patient on a plan that addresses the interpersonal issues that are pivotal in the pathogenesis of the disorder.

Supportive psychotherapy (SP) is a widely practiced treatment modality that often lacks systematic rigor. SP is not simply offering the patient support in the way that a friend might help someone who is suffering. It is a treatment that involves a careful assessment of the patient's strengths and weaknesses and the use of direct measures to restore or improve self-esteem, ameliorate symptoms, and improve adaptive functioning. Defense mechanisms are questioned only when they are maladaptive, in contrast to the more exploratory version of psychodynamic therapy, where defenses are understood and confronted. Transference phenomena are generally not discussed but simply noted silently by the therapist. A great deal of attention is placed on establishing a solid therapeutic alliance so that the patient trusts the therapist and feels helped. In addition, the therapist tries to reinforce sensible thinking and behavior, and to praise, reassure, encourage, refrain, and advise. An important subcomponent of SP is psychoeducational therapy, which employs education of the patient and family as a major thrust.

These definitions have considerable overlap. Many practitioners use combinations of techniques geared to the patient's specific individual needs. Psychotherapy

research has demonstrated that the therapeutic relationship, particularly when the therapist is flexible and responsive, accounts for most of the outcome variance. Technique probably accounts for only 12–15% of the variance across different kinds of therapies. Nevertheless, for purposes of discussion we consider these therapies separately and examine the research base that supports them. We also present some preliminary research in the area of how psychotherapy may affect the brain.

Efficacy and Indications

In this section, we examine the efficacy data and indications for each of the major therapeutic modalities. Although we focus on randomized controlled trials (RCTs), we also acknowledge that there is considerable controversy regarding whether psychotherapy as a practice is well suited to RCTs. Because of the requirements for manualization and standardization, the treatments delivered in psychotherapy studies often do not reflect clinical practice. Similarly, the patient sample selected for such studies is often unrepresentative of the patients seen by clinicians in community practice settings. Because of the cost of psychotherapy research, most of the treatments delivered in RCTs are unrepresentatively brief. Research also has demonstrated that the researcher's allegiance to one brand of treatment or another is probably the best predictor of outcome. The evidence-based approach used in the rest of psychiatry is problematic because it does not take into account individual differences among therapists. Finally, the studies seeking to prove the efficacy of a particular psychotherapeutic approach are almost always disorder-based, even though may patients wish to discuss problems of living that are inextricably intermingled with specific disorders.

Psychodynamic Psychotherapy

Short-term psychodynamic therapy

Individual therapy. Although psychodynamic therapists have been slow to build a research base, a growing number of RCTs now document the efficacy of short-term psychodynamic psychotherapy (STPP), usually defined as lasting no more than 6 months or 24 sessions, in the treatment of axis I psychiatric disorders. Four RCTs examined the use of STPP in major depression, finding it to be effective for depressive symptoms, general psychiatric symptoms, and impaired social functioning. Combined treatment studies examining the addition of psychodynamic psychotherapy to medication regimens for depression have revealed greater improvement as well as decreased dropout rates, an effect which increases with time.

One study has shown STPP to be useful in decreasing trauma-related symptoms in posttraumatic stress disorder (PTSD), with continued improvement at the 3-month follow-up. Research evidence also supports the use of STPP in eating disorders, with two studies showing significant and lasting improvements in bulimia nervosa and one study demonstrating increases in weight and body mass index changes in anorexia nervosa.

Another area in which STPP has been used to advantage is in substance-use disorders. In one study, STPP was effective in measures of drug-related and psychiatric symptoms among opiate-dependent subjects. In a second study, this modality led to significant declines in alcohol abuse, which remained at the 15-month follow-up.

Group therapy. STPP delivered in a group setting has also shown significant benefits in borderline personality disorder. One RCT showed that this treatment reduced the ratings of borderline symptomatology while also demonstrating improvements in general psychiatric and depression symptoms.

Long-term therapy

Individual therapy. Evidence also exists for the use of long-term psychodynamic psychotherapy (LTPP) in both axis I and II disorders. One RCT showed LTPP to be efficacious in treating generalized social phobia. LTPP has also yielded significant symptomatic improvements in both bulimia nervosa and anorexia nervosa. The value of LTPP in substance-use disorders was confirmed in one study, which showed it to be significantly superior to drug counseling in opiate dependence.

One area in which LTPP has been highly beneficial is in the treatment of personality disorders. In one study, a psychoanalytically oriented partial hospitalization program for borderline personality disorder lasting 18 months led to dramatic decreases in self-harm behavior, suicide attempts, inpatient days, medication use, and self-reported psychiatric symptoms. The main difference between the treatment as usual control group and the experimental group was that the patients in the latter group received individual and group psychotherapy of a psychoanalytic nature. The benefits of the treatment were clear at 6 months and continued to accrue up to the time of termination. In fact, compared to the controls, the patients in the experimental group showed continued improvement during the postdischarge period. In another study, psychodynamic psychotherapy was compared to SP and dialectical behavior therapy (DBT) in a 12-month randomized controlled trial of borderline personality disorder treatment. All three treatments were equally effective, although the dynamic

treatment made statistically significant gains in increasing mentalization compared to the other two.

Evidence also exists for the efficacy of psychodynamic therapy for cluster C personality disorders. In a Norwegian study, patients with these conditions were randomly assigned to 40 weeks of either dynamic or cognitive therapy. Both groups showed significant improvements that remained stable at a 24-month follow-up, and those who received dynamic therapy demonstrated continued posttreatment improvement at a 2-year follow-up.

Group therapy. There has also been some limited evidence for the use of STPP in the treatment of alcoholism; fewer people completed the psychodynamic therapy compared to a behavioral group therapy, but of those who did, a greater number were abstinent than those who completed the behavioral process.

Meta-analyses Two recent meta-analyses have looked at psychodynamic psychotherapy. One meta-analysis of 14 studies of STPP and LTPP in personality disorders showed significant effect sizes in both self- and observer-rated measures. Included were two RCTs that also exhibited significant effectiveness over control conditions. In these studies, there appeared to be a correlation between treatment duration and effect size.

Another meta-analysis evaluated the efficacy of psychodynamic psychotherapy, with durations ranging from 7 to 40 sessions. This investigation examined its use in psychiatric disorders in general, due to an inadequate number of studies focused on individual disorders for the meta-analysis. Overall, it was shown that psychodynamic therapy led to significant improvements in target problems, general psychiatric symptoms, and social functioning. A summary of evidence-based indications for psychodynamic psychotherapy is in Table 1.

Table 1 Evidence-based indications for psychodynamic psychotherapy

Therapy	*Indications*
Short-term	Major depression
	Posttraumatic stress disorder
	Bulimia nervosa
	Anorexia nervosa
	Substance-use disorders
	Borderline personality disorder
Long-term	Social phobia
	Bulimia nervosa
	Anorexia nervosa
	Substance-use disorders
	Borderline personality disorder
	Cluster C personality disorders

Cognitive Behavioral Therapy

Individual therapy CBT lends itself to manualized treatments, so there has been an abundance of experimental data. Extensive evidence supports the use of CBT in axis I disorders.

In depression, CBT has been shown to be effective in nonpsychotic, unipolar depression and in decreasing rates of relapse. These findings are particularly robust in mild to moderate major depression. It has also demonstrated some benefit in patients with a poor response to medication intervention. Some studies have indicated that the combination of CBT and medications may provide a benefit surpassing that of CBT or medications alone, especially when the rates of relapse are examined. A limited number of studies, including both psychotic and nonpsychotic depressed patients, showed considerable benefit from the addition of CBT to medications.

Studies have shown CBT to be effective for panic and anxiety symptoms, indicating that it may be more effective than medications in some instances. In studies of panic disorder, CBT has proven to be more effective than both placebo and medication in terms of symptom reduction as well as tolerability. The use of behavioral therapy in obsessive–compulsive disorder (OCD) has been widely accepted in the form of exposure and ritual prevention (ERP), and has shown significant benefit both for symptom relief and for relapse prevention, even in comparison to medication treatment. Evidence also exists for its use in social phobia. A recent meta-analysis of CBT for generalized anxiety disorder shows this treatment to be highly effective and better tolerated than medications.

CBT has also been effective in the treatment of another anxiety disorder, PTSD. One meta-analysis of CBT found that a brief course produced substantial improvement, with a 56% recovery rate for those entering the studies. Moreover, 67% of those completing the protocol no longer met the criteria for PTSD.

Multiple studies have shown significant benefits from CBT in acute and chronic schizophrenia. These improvements were noted in overall symptomatology as well as in positive and negative symptoms. On follow-up, these gains were sustained across studies. Investigators have noted that the use of CBT may also be able to decrease the likelihood of schizophrenia progressing in patients with prodromal symptoms.

A growing area of research in the use of CBT is in the treatment of personality disorders. As previously noted, CBT appears to be efficacious with cluster C patients. One particular outgrowth of CBT has been DBT, originally designed for borderline personality disorder. This approach, consisting of one weekly individual session and one skills group per

week, has been shown to decrease suicidal behaviors, self-harm, substance abuse, and binge eating. Moreover, greater numbers of patients tend to remain in treatment, and those that do require less inpatient treatment. Studies have also shown promising benefits for borderline patients with comorbid substance abuse.

A smaller body of research suggests that CBT is useful for other conditions as well. CBT has significant evidence supporting it as perhaps the most effective treatment for bulimia nervosa. Finally, CBT has shown benefits for alcohol and cocaine abuse.

Although CBT has proven its utility as a primary treatment, researchers have also examined its use in promoting treatment compliance. Patients suffering from bipolar disorder have greater medication compliance and decreased relapses/hospitalizations when a short course of CBT is added to their medications. CBT also increases adherence to medication when used in patients with schizophrenia.

Group/family therapy The use of CBT-oriented family therapy has proven to be a helpful adjunct in the treatment of disorders with traditionally high relapse rates. This applies to schizophrenia, in which certain types of family involvement with a patient who has schizophrenia has led to decreased rates of relapse in the identified patient. These same findings hold true for patients with comorbid schizophrenia and substance-use disorders. In addition to a decline in relapse, there was a decrease in overall symptoms. Similar results have been found with bipolar disorder.

Patients with alcohol abuse found CBT-oriented groups useful in decreasing alcohol consumption. CBT groups have been effective in the treatment of marijuana abuse as well. Patients with both bipolar disorder and substance-use disorders have gained benefits, as shown in measures of addiction severity and increased rates of abstinence. Behaviorally oriented couples and family therapy have also been effective in the treatment of substance abuse. Finally, marital therapy using behavioral interventions has shown benefit for a variety of marital problems. A summary of the indications for CBT is in Table 2.

Table 2 Evidence-based indications for cognitive behavioral therapy

Therapy	*Indications*
Individual	Major depression
	Bipolar disorder
	Schizophrenia
	Panic disorder
	Obsessive–compulsive disorder
	Social phobia
	Generalized anxiety disorder
	Posttraumatic stress disorder
	Bulimia nervosa
	Substance-use disorders
	Borderline personality disorder
	Treatment compliance problems
Group/family	Schizophrenia
	Bipolar disorder
	Substance-use disorders
	Marital conflict

Interpersonal Therapy

Individual therapy IPT is effective for a number of different psychiatric illnesses. The majority of the studies have examined IPT in affective disorders. These have shown clearly that IPT is efficacious in major depression and may be as effective as medication treatment in some forms of mild to moderate depression. In addition to reducing overall depression ratings, it has been particularly beneficial in increasing self-esteem, social functioning, and overall functioning. Research with IPT targeting elderly patients suggests that it improves treatment response to pharmacotherapy. When that same population enters remission, findings indicate that it is also effective as a maintenance therapy.

IPT has also been applied to bipolar disorder. This research has shown that IPT patients are more likely to remain in a euthymic state, compared to those receiving standard clinical management. In addition, IPT has also been effective when applied to bulimia nervosa.

Group/family therapy Less research has accrued on IPT applied in group and family therapies, but a small body of findings shows promise. IPT-based family therapy demonstrated benefit when treating younger patients with recent onset of anorexia nervosa. Group therapy based on IPT was successful in decreasing bulimic symptoms in individuals suffering from non-purging bulimia nervosa.

IPT focused groups have been used for the treatment of adult victims of childhood sexual abuse as well. In this population, it has led to a decrease in depression, anxiety, trauma-related symptoms and a decrease in the global severity of psychiatric symptoms, as well as an increase in social adjustment.

Pilot studies show that IPT-based couples therapy improves marital satisfaction and decreases depression. Another study combined IPT and supportive interventions in a group of heroin-dependent mothers, leading to decreased opioid use and child maltreatment as well as increased parent–child interaction and overall adjustment. Table 3 summarizes the indications for IPT.

Table 3 Evidence-based indications for interpersonal therapy

Therapy	*Indications*
Individual	Major depression
	Bipolar disorder
	Bulimia nervosa
Group/family	Anorexia nervosa
	Bulimia nervosa
	Substance-use disorders
	Childhood sexual trauma
	Marital conflict

Individual	Schizophrenia
	Bipolar disorder
	Borderline personality disorder
Group/family	Schizophrenia
	Bipolar disorder
	Substance-use disorders

Supportive and Psychoeducational Therapy

Individual interventions SP has often been denigrated by psychiatrists and other mental health professionals, but recent empirical research suggests that it is a modality that is of substantial benefit in psychiatric illness. In schizophrenia, for example, psychoeducational strategies have led to increased patient knowledge and medication compliance. SP has also been shown to increase occupational functioning in this same group. Vocational rehabilitation has displayed consistent results in improving rates of competitive employment, which is often a source of considerable gratification to the patient.

In a recent RCT involving SP, DBT and psychodynamic therapy for borderline personality disorder, SP did just as well as the other two modalities on most measures. In addition, psychoeducation has proven to be useful in improving social and occupational functioning in patients with bipolar disorder, as well as increasing the time before a subsequent manic episode.

Group/family interventions SP family and group interventions are highly useful in the overall treatment of schizophrenia. Especially in families with high expressed emotion, psychoeducational family therapy helps to decrease psychotic symptoms, prevent relapse, and improve social and vocational functioning in the person with schizophrenia. Levels of expressed emotion are also decreased. A majority of studies looking at the use of assertive community treatment programs using intensive and proactive case management in schizophrenia have shown a decreased need for inpatient hospitalization, as well as beneficial effects in symptomatology, housing stability, and subjective quality of life. Social skills training groups have led to improved behavioral social skills, but have not necessarily translated to better functioning overall in patients with schizophrenia.

Family psychoeducational therapy for patients with bipolar disorder has led to decreased relapse rates in multiple studies. It also provided a higher quality of family life in one study, whereas another investigation showed decreased symptoms and improved global functioning, particularly in female patients. Similarly, marital psychoeducation showed substantial gains in medication compliance and global assessment scales for individuals with bipolar illness.

SP group interventions may be extremely useful in problems of substance abuse. They have been shown to be efficacious in smoking cessation. Social skills training groups for alcoholics have led to a decrease in alcohol consumption and an increase in the number of abstinent days. Table 4 summarizes the indications for SP.

The Impact of Psychotherapy on the Brain

The therapeutic action of psychotherapy is now being investigated with the overarching assumption that successful psychotherapy must work by changing the brain. Kandel has demonstrated how synaptic connections can be permanently altered and strengthened through the regulation of gene expression based on learning from the environment. Neurobiological studies of the sea slug *Aplysia* have shown that the number of synapses double or triple as a result of learning. Kandel postulates that psychotherapy should be considered a form of learning about oneself and one's relationship to others. The learning process that occurs in psychotherapy may produce alterations of gene expression and thereby alter the strength of synaptic connections. Kandel clarifies that the sequence of a gene (the template function) cannot be affected by environmental experience but that the ability of the gene to direct the manufacture of specific proteins (the transcriptional function) is quite responsive to environmental factors and regulated by these influences.

Neural imaging studies have allowed investigators to document structures and functions within the brain that are affected by psychotherapy. One investigation of patients with OCD showed that both behavior therapy and fluoxetine appear to produce similar decreases in cerebral metabolic rates in the head of the right caudate nucleus. Another study compared

24 subjects with major depression who received either paroxetine or IPT. At baseline, subjects had higher normalized metabolism than normal controls in the prefrontal cortex, caudate, and thalamus and lower metabolism in the temporal lobe. After treatment with either paroxetine or IPT, positron emission tomography (PET) scans showed that the subjects had metabolic changes in the direction of normalization in these regions. Regional metabolic changes appeared similar in the two forms of treatment.

In other studies, medication and psychotherapy appear to have separate and distinct influences on the brain. Goldapple and her colleagues scanned 17 unmedicated, unipolar depressed patients before and after a 15–20-session course of CBT using PET. They compared the findings to a separate group of 13 depressed patients who responded to paroxetine. The psychotherapy appeared to alter brain regions that medication did not touch. The psychotherapy was associated with increases in metabolic activity in the anterior cingulate and the hippocampus, with decreases in metabolic activity in the dorsal, ventral, and medial-frontal cortices. By contrast, paroxetine showed increases in metabolic activity in the prefrontal cortex and decreases in the brain stem and subgenual cingulate. In brief, therapy seemed to work in a top-down manner, whereas medication worked in a bottom-up manner.

Cognitive therapy appears to influence thyroid hormone levels in those who suffer from major depression. In one study, patients who responded to CBT showed striking decreases in their levels of thyroxin (T_4), whereas nonresponders showed increases in T_4. In another study of depressed patients, CBT seemed to affect the biology of sleep. In fact, the biological changes in sleep architecture were identical to those produced by antidepressant medication.

Psychotherapy may also make modifications in procedural memory. What unfolds in the relationship with the therapist is the patient's stereotyped, automatic, habitual mode of relatedness shaped by attachment relationships in the first years of life. These relational configurations become encoded in procedural memory and operate outside conscious awareness. Psychotherapy may provide a new attachment relationship that is able to restructure attachment-related, implicit procedural memory. Stored prototypes of self and other representations encoded in implicit procedural memory may be modified by new interactions with the therapist that are internalized by the patient. In other words, old neural networks of self and other from childhood may be progressively weakened in psychotherapy while new neural networks of self and other representations are simultaneously strengthened.

Freud's dream was that the changes brought about by psychoanalytic treatment could ultimately be understood in terms of the neurobiological substrate of the brain. Although a great deal of research is needed to clarify the exact nature of these changes, we now stand on the threshold of an era when the technology is available to fulfill Freud's dream.

Pulsatility in Neuroendocrine Systems

G Leng, N Sabatier, and C Caquineau,
The University of Edinburgh College of Medicine and Veterinary Sciences, Edinburgh, UK

Introduction

A major role of the neuroendocrine hypothalamus is to generate pulsatile patterns of activity that are appropriate for the secretion of each of the pituitary hormones and to regulate these patterns according to specific physiological requirements. How the hypothalamus generates the various patterns varies from system to system; there is no common 'pulse generator' into which different systems can tap to generate their individual rhythms. However, what has been learned of the three best studied systems – oxytocin, the gonadotrophins, and growth hormone (GH) – indicates that there are commonalities as well as differences in the underlying mechanisms.

Oxytocin and vasopressin are secreted from the posterior pituitary as a direct result of the electrical activity of the hypothalamic magnocellular neurons that produce these hormones; thus, pulsatile secretion of oxytocin reflects synchronized burst activation of the oxytocin neurons. However, the process is more complex for the hormones secreted from the anterior pituitary gland. GH, prolactin, thyroid-stimulating hormone, ACTH, follicle-stimulating hormone (FSH), and leutinizing hormone (LH) are all secreted in a markedly pulsatile manner, in at least some physiological circumstances. For the most part, their secretion is regulated by releasing factors and release-inhibiting factors. These factors are released into the hypothalamo-hypophysial portal circulation from the nerve terminals of hypothalamic neuroendocrine neurons that project to the median eminence. In general, the secretion of a pulse of a hormone from the anterior pituitary gland follows release of a pulse of a releasing factor into the portal circulation, and it can be inferred that the pulse of releasing factor release in turn reflects synchronized pulsatile activation of the neurons that make the releasing factor. However, this inference has not been demonstrated directly; the only identified neuroendocrine neurons in which synchronized electrical activation has been directly observed during reflex hormone secretion are the magnocellular oxytocin neurons. These play a key role in forming the paradigm by which we understand the origins and significance of pulsatile hormone secretion.

Oxytocin

In a lactating rat, oxytocin is secreted into the blood in short-lived pulses while the mother is being suckled by the young. These pulses are the result of a brief, synchronized burst discharge of all the magnocellular neurosecretory oxytocin neurons in the supraoptic and paraventricular nucleus of the hypothalamus. Each burst lasts 1–3 s, and during a burst the firing rate of the neurons can exceed 100 action potential/s. The normal spontaneous firing rate of these neurons between bursts is just 1–3 action potential/s. These 'milk ejection' bursts occur at intervals of typically 3–5 min while the young are suckling. The fact that the milk ejection reflex involves intermittent pulsatile response to a continuous suckling stimulus appears to be a general feature in mammals, including humans (Figure 1).

In the rat, each milk ejection burst releases approximately 1 mU of oxytocin into the blood from the neurosecretory nerve terminals in the posterior pituitary gland. The released hormone initially travels as a bolus in the blood, and it disperses quickly as it is mixed with the total blood volume. The disappearance rate of the bolus is just a few seconds, much less than the half-life of oxytocin in the blood. This fast disappearance rate makes it very difficult to 'catch' the pulses for measurement by radioimmunoassay of blood samples, but the pulses can readily be detected by online bioassay – measurement of intramammary pressure changes by cannulation of the mammary gland.

The burst discharge of oxytocin cells is still not fully understood. Between bursts, the neurons show little, if any, sign of coordination in their spontaneous activity. However, oxytocin, acting within the hypothalamus, plays a key role in the burst behavior. Oxytocin that is secreted into the blood does not reenter the brain in significant amounts because of the blood–brain barrier, and oxytocin injected peripherally has no effect on the activity of oxytocin neurons, but very large amounts of oxytocin are released from the dendrites of the oxytocin neurons. This dendritic release is regulated semi-independently of peripheral, axonal secretion; dendritic release can be triggered, for instance, by peptides that act on oxytocin neurons to mobilize intracellular calcium stores. Oxytocin injected in small amounts into the brain facilitates the suckling-induced reflex, whereas oxytocin antagonists injected into the brain block it.

Oxytocin is released from the dendrites in response to suckling before any burst discharge is seen. The oxytocin neurons have oxytocin receptors, and activation of these induces calcium mobilization and

Figure 1 The milk ejection reflex. At the posterior pituitary gland, oxytocin is released from the neurosecretory nerve terminals of magnocellular neurosecretory neurons whose cell bodies are in the supraoptic and paraventricular nuclei of the hypothalamus. When young suckle at the nipples of a lactating mother, the sensory signals travel via the spinal cord and brain stem, resulting in synchronized bursting of the oxytocin neurons. This behavior, first observed by Jonathan Wakerley and Dennis Lincoln in the 1970s, leads to a brief pulse of oxytocin which triggers milk let-down and a transient increase in intramammary pressure. The inset shows the burst from one oxytocin cell preceding an intramammary pressure rise. See Lincoln DW, and Wakerley JB (1974) Electrophysiological evidences for the activation of supraoptic neurones during the release of oxytocin. *Journal of Physiology* 242: 533–554; Wakerley JB and Lincoln DW (1973) The milk-ejection reflex the rat: A 20- to 40-fold acceleration in the firing of paraventricular neurones during oxytocin release. *Journal of Endocrinology* 51: 477–493.

further oxytocin release; thus, there is a positive feedback loop. Oxytocin affects the electrical activity of oxytocin neurons in several ways: It suppresses afferent input to the oxytocin neurons, tending to reduce their spontaneous activity, but it also has a slight direct depolarizing action. In addition, oxytocin can 'prime' dendritic stores of oxytocin, making them more available for subsequent activity-dependent release. The consequence of these factors appears to be that during suckling, oxytocin cells become less responsive to external inputs but increasingly capable of mutual excitation.

The amount of oxytocin secreted as a result of a burst is very large even considering the high rate of spike activity. This is because the nerve terminals in the posterior pituitary show a marked 'frequency facilitation' of stimulus-secretion coupling. An action potential within a burst triggers approximately 100 times as much oxytocin secretion as an action potential that arises spontaneously between bursts. The frequency facilitation is a result in part of the nonlinear effects on exocytosis of the summation of calcium entry through voltage-dependent calcium channels opened by the depolarizing effects of action potentials at nerve terminals. In addition, action potential propagation in the axonal fields in the neural lobe is more efficient in axons that are partly depolarized as a result of potassium efflux from neighboring depolarized axons; thus, action potentials within a burst are less likely to 'fail' at branch points, and they therefore invade more of the neurosecretory terminals.

Synchronized bursting is thus a very efficient way of secreting a large bolus in a brief time. The resulting pulsatile hormone signal is also very efficient for stimulating milk let-down at the mammary gland. When exposed to continuous high concentrations of oxytocin, the myoepithelial cells of the mammary gland on

which oxytocin acts desensitize rapidly and become refractory. Accordingly, pulsatile secretion is necessary for the biological efficacy of oxytocin at this site.

Oxytocin is also secreted in pulses during parturition in the rat and other mammals, including humans. Oxytocin is not essential for normal delivery in rodents because transgenic mice without oxytocin can deliver young normally. However, in the rat, the progress of parturition can be interrupted by giving oxytocin antagonists or by pharmacologically blocking oxytocin secretion. In the rat, pulsatile secretion is important for the efficient progress of delivery of the young; when endogenous oxytocin secretion is blocked, parturition is interrupted, but it can be restored by giving exogenous oxytocin. This is achieved much more efficiently by delivering oxytocin in pulses rather than by continuous infusion.

In humans, the role of oxytocin in normal delivery is less clear. In pregnancy, an enzyme that degrades oxytocin, human pregnancy oxytocinase, is highly expressed. When first appreciated, this fact was taken as evidence that oxytocin plays no physiological role in parturition in humans, although its pharmacological potency in inducing uterine contractions has long been known. However, this view has undergone some reappraisal as the importance of pulsatile patterning of secretion has become recognized; the presence of oxytocinase effectively reduces the half-life of a secreted bolus with little effect on its amplitude, and thus oxytocinase might enhance pulsatile patterning of oxytocin rather than eliminate oxytocin completely.

Although pulsatile secretion of oxytocin appears to be very important in lactation and during parturition, there are other circumstances in which oxytocin is secreted continuously. In the rat, oxytocin is secreted continuously when the plasma concentration sodium is high, and the significance of this appears to be that in the rat (but not in all mammals) oxytocin promotes sodium excretion both by a direct action at the kidney and indirectly by activating the secretion of atrial natriuretic factor from the heart. Interestingly, pulsatile oxytocin secretion is an ineffective trigger for natriuresis, apparently because this reflex requires sustained activation of the receptors. Accordingly, continuous secretion of oxytocin and pulsatile secretion of oxytocin can fulfill independent physiological roles – roles that can be combined without conflict.

Vasopressin

Vasopressin neurons, although similar in many respects to oxytocin neurons, do not generate pulsatile vasopressin release in the rat. However, they do generate bursts of activity. These 'phasic bursts' are longer, slower, and more frequent than the bursts of oxytocin cells but are not synchronized among the vasopressin cells and so give rise to continuous secretion rather than intermittent secretion of vasopressin from the posterior pituitary. The significance of the bursting appears to be that it optimizes the efficiency of vasopressin secretion from the nerve terminals of individual vasopressin neurons. Generally, in mammals, vasopressin is a cofactor regulating the secretion of ACTH (acting synergistically with corticotropin-releasing factor), but in most species this regulation is achieved by parvocellular vasopressin neurons of the paraventricular nucleus that project to the median eminence. These parvocellular neurosecretory neurons are functionally independent of the magnocellular vasopressin neurons that project to the posterior pituitary gland, and in most species the concentration of vasopressin secreted from the pituitary is too low for significant action at corticotrophs. However, in some species, notably the horse, vasopressin can be released in large pulses from the posterior pituitary, and these large pulses have an important role in regulating ACTH secretion.

Gonadotrophic Hormones

LH and FSH, coproduced in pituitary gonadotrophs, are secreted in a prominent pulsatile manner in both males and females in response to stimulation by luteinizing hormone-releasing hormone (LHRH), which is released from neurosecretory neurons that project to the median eminence. Whereas magnocellular oxytocin cells are compactly localized in the supraoptic and paraventricular nuclei, the LHRH neurons, of which there are only approximately 1000, are widely dispersed through the preopic/septal area. Nevertheless, these dispersed LHRH neurons are in direct contact with each other via contacts between their dendrites, which in the rat can extend for more than 1 mm. Just as the oxytocin cell dendrites are packed with neurosecretory vesicles, so are those of LHRH neurons, which also express LHRH receptors. Thus, it seems that, as for the oxytocin cells, the pulsatile release of LHRH is a result in part of mutual excitatory interactions between LHRH cells mediated by dendritic release of LHRH.

Again, as for the oxytocin cells, although a basic mechanism for synchronization and pulse generation resides within the LHRH network, afferent inputs to the LHRH cells determine the amplitude and frequency of the LHRH pulses. The gonadal steroids – estrogen and progesterone in the female and testosterone in the male – are powerful modulators of the patterning. The varying steroid environment of the cycling female means that the pattern of

LHRH secretion and hence LH and FSH secretion is different at different stages of the ovarian cycle. The ovarian steroids mediate negative feedback as a result of the gonadotrophic effects of LH and FSH. These negative feedback actions are exerted in the brain but apparently not on the LHRH cells; the LHRH cells express estrogen receptor-β but not estrogen receptor-α (at least not in abundance), but the inhibitory effects of estrogen appear to be mediated mainly by local GABA interneurons and by adrenergic inputs from the brain stem. These two inputs are strongly modulated by direct actions of steroids and are critically important in pulse generation (Figure 2).

The LHRH pulses are not transformed 'passively' into LH and FSH pulses by the pituitary gonadotrophs. First, the response of the pituitary gonadotrophs to LHRH is nonlinear: below a critical amplitude, fluctuations in LHRH release will thus be filtered out, whereas above that threshold the dose–response relationship is steep, so the pituitary will thus tend to 'digitize' the LHRH signal. Second, the synthesis of LH and FSH is regulated differentially by the pattern

Figure 2 Pulsatile gonadotrophin secretion. (a) The pattern of LH and FSH secretion in mammals varies at different developmental stages, and in women it also varies during the ovarian cycle. (b) LHRH neurons are interconnected via their dendrites and are directly regulated by local GABA neurons, which are targets for estrogen actions. This hypothalamic mini-network is modulated by adrenergic inputs from the brain stem (among others). The resulting LHRH output is filtered and amplified by the pituitary gonadotrophs.

of stimulation by LHRH, so the relative proportions in which these two hormones are secreted will depend on the pattern of LHRH stimulation. Third, estrogen, for example, also has effects at the pituitary; it both stimulates the synthesis of LH and alters how the gonadotrophs respond to a pulsatile LHRH signal. After prolonged exposure to high concentrations of estrogen, the effects of LHRH on LH secretion display 'self-priming'; this has close parallels to the priming of oxytocin cells by oxytocin, which potentiates activity-dependent oxytocin release from the dendrites of oxytocin cells. In both cases, this priming involves a delayed and long-lasting recruitment of neurosecretory vesicles into sites from which their release by exocytosis can be readily evoked. Self-priming in estrogen-primed gonadotrophs means that successive pulses of LHRH can lead to progressively larger pulses of LH secretion, culminating in a dramatic surge release of LH at proestrous. This surge is a prerequisite for ovulation in mammals.

Pulsatile secretion of LH and FSH is essential for normal gonadal function in both males and females. The actions of LH in particular require pulsatile delivery to avoid desensitization of the peripheral targets. Thus, continuous administration of an LHRH agonist results in a functional castration, and this is exploited both for prolonged male contraception and for androgen-deprivation therapy as an adjunct to treatment of prostate cancer.

Growth Hormone

In the male rat, GH secretion from the somatotroph cells of the pituitary gland is dominated by large, 3 h pulses separated by 'troughs' of very low levels of secretion. GH is secreted in a similar pulsatile pattern in most mammals, including humans. In rats and mice, this pulsatile pattern is important for the efficiency of its growth-promoting effects; the sexual dimorphism in body size in rats is largely accounted for by a sexually dimorphic pattern of GH secretion. In the female rat, GH pulses are smaller and more frequent than in the male and the trough levels are higher, so the pulsatile pattern is less marked (Figure 3).

GH secretion is controlled by two hypothalamic peptides: growth hormone-releasing factor (GRF), produced by neurosecretory neurons of the arcuate nucleus, and somatostatin, produced by neurosecretory neurons of the periventricular nucleus. It is thought that the underlying pattern of GRF activity is similar in males and females, with the sexually differentiated patterns being produced by different patterns of somatostatin release. Estrogen influences somatostatin neurons, although probably not directly because somatostatin neurons do not express estrogen receptor-α.

Our understanding of pulsatile GH secretion has been limited by the paucity of information about the electrophysiological properties of these hypothalamic neurons and especially about their behavior *in vivo*. In part this is because pulsatile GH secretion does not persist under general anesthesia, which might allow the underlying processes to be observed more directly. However, it is possible to measure GRF and somatostatin release into portal blood and correlate this with GH secretion. These are invasive procedures with limited time resolution, but information from such studies, especially in sheep, has been important in supporting our understanding of GH secretion. However, our understanding mostly comes from measurements of GH concentrations in blood after experimental interventions that affect the release or actions of GRF, somatostatin, and other regulatory factors, including GH, which has negative feedback actions on the hypothalamus.

Much is known about the pituitary somatotrophs and how they respond to somatostatin, GHRH, and ghrelin, which plays an important role in regulating GH secretion by actions at both the hypothalamus and the pituitary. GRF stimulates GH secretion via G-protein-coupled receptors; the transduction pathway involves activation of adenylate cyclase and protein kinase A, elevated levels of cAMP, Ca^{2+} entry through voltage-gated channels, and Ca^{2+}-dependent exocytosis. Somatostatin inhibits GH secretion directly, but it is also a functional GRF antagonist; when somatostatin is present, GRF is less potent at stimulating GH secretion. Somatostatin acts (at separate G-protein-coupled receptors) to oppose the actions of GRF; it reduces the intracellular concentration of cAMP and hyperpolarizes the somatotrophs by increasing potassium conductance. In male rats, GRF and somatostatin are released cyclically and reciprocally to produce the peaks and troughs of GH secretion.

The following features of the pituitary response to GRF and somatostatin are particularly relevant to understanding pulsatile secretion of GH:

- GRF stimulates dose-dependent GH secretion. The sigmoidal nature of this dose–response relationship means that the pituitary acts as a 'band pass filter' for the hypothalamic signal. Small fluctuations of GRF around a low average concentration will be filtered out as below the threshold for activating GH secretion, whereas high concentrations will tend to produce an all-or-nothing secretory response.
- GH secretion in response to GRF desensitizes in a dose-dependent manner. This means that sustained high concentrations of GRF will tend to produce a transient GH response.

Figure 3 Pulsatile GH secretion. In humans, large pulses of GH are secreted at 3 h intervals. The magnitude of these pulses is maximal at puberty and declines slowly but progressively with age, often leading in old age to increased adiposity, bone frailty, and muscle weakening. The pulsatile pattern of GH secretion is important for its biological efficacy, and it arises as a result of a reciprocal interaction between neurosecretory somatostatin and GRF neurons, regulated by negative feedback from GH and somatomedins (particularly insulin-like growth factor 1 (IGF-I)). (a) The behavior of a computational model of the GH system. Adapted from Macgregor DJ and Leng G (2005) Modelling the hypothalamic control of growth hormone secretion. *Journal of Neuroendocrinology* 17: 788–803. (b) The typical GH profile of an adult man with 3 h pulses and a conspicuously large nocturnal pulse.

- Somatostatin inhibits GH secretion in a dose-dependent manner and can prevent desensitization to GRF; rapid removal of somatostatin causes a GRF-dependent rebound secretion of GH. This means secretion of somotostatin will tend to eliminate low levels of GH secretion and prepare the pituitary to respond to a subsequent GRF pulse.

Thus, GH secretion *in vivo* reflects the activity of hypothalamic neuroendocrine systems, acting via the pituitary, which integrates and filters these signals. These two hypothalamic systems interact; exogenous somatostatin inhibits GRF mRNA expression, and somatostatin has a fast inhibitory effect on GRF neuronal activity and release. Therefore, it seems that

GRF neurons are inhibited following increased activity in somatostatin neurons, and there might also be a complementary influence of GRF on somatostatin neurons.

In addition, GH and somatomedins feed back on the hypothalamus to inhibit the GRF neurons. Administration of GH *in vivo* inhibits GH secretion; this effect develops over approximately 1 h, and it takes another 1 or 2 h for normal secretion to recover. GH suppresses GH secretion in both male and female rats, but females continue to respond to GRF after GH injection, whereas males are unresponsive. This suggests that GH induces a prolonged, delayed release of somatostatin in the male rat but suppresses GH secretion through a different mechanism in the female. Males normally show a more variable response to GRF injections than females that is apparently related to more variable somatostatin release generally.

There is evidence that these negative feedback actions of GH are mediated by effects of GH on the somatostatin neurons; GH appears to trigger a prolonged release of somatostatin, lasting much longer than the original GH challenge. This is also a delayed effect; up to 1 h is required before GH stimulates an increase in somatostatin release. This delay seems too short to reflect changes in synthesis but too long to reflect classic electrophysiological mechanisms.

There are two other documented examples of delayed activation in peptide systems. The first is the self-priming action of LHRH at pituitary gonadotrophs, whereby LHRH potentiates its subsequent effectiveness in estrogen-primed pituitaries, and this involves a delayed mobilization of the secretory pool of LH. The second example is the priming effect of oxytocin on dendritic oxytocin release. There is no direct evidence for priming in somatostatin neurons. However, for both oxytocin neurons and gonadotrophs, priming is a delayed, long-lasting effect that is apparently mediated by mobilization of releasable pools of one peptide in response to the actions of another. A similar effect might underlie the delayed, long-lasting potentiation of somatostatin release by GH.

Synthetic GH secretagogues (GHS), like GH-releasing peptide, also promote GH secretion as GRF does but via different receptors. There are GHS receptors both on somatotrophs and in the hypothalamus, where their actions include activation of the GRF neurons. *In vivo*, GRF and GHS act synergistically; GH secretion is greater when GRF and GHS are applied together than when applied separately. The endogenous ligand for the GHS receptor, ghrelin, is secreted mainly from the stomach and is present in the circulation at high concentrations. Ghrelin is also expressed in a subpopulation of arcuate neurons. The physiological role of ghrelin in regulating GH secretion is unclear, but the potential value of GHS in promoting pulsatile GH secretion has been noted.

Conclusions

Although neuronal networks in the hypothalamus can function as pattern generators, the anterior pituitary gland also plays a major role in filtering, amplifying, and modulating the resulting pattern of hormone secretion. It is increasingly recognized that pulsatile patterns of hormone secretion are near ubiquitous, and even hormones once considered classic endocrine hormones with little neural regulation also display biologically significant pulsatile secretion. Also, underlying the generation of these patterns are mechanisms that appear to be very similar to those which govern pituitary hormone release. The biological importance of pulsatile hormone signals has many implications, including for therapeutic interventions in conditions of hormonal insufficiency. It is difficult, if not impossible, to reproduce a complex pattern of hormonal delivery by exogenous administration. In some cases, drugs that act in the central nervous system show promise for their ability to boost the function of hypothalamic pulse generator systems to 'rejuvenate' dysfunctional systems. Other approaches include developing controlled means of intermittent drug release.

Pulvinar Structure and Circuitry in Primates

Pulvinar Structure and Circuitry

The term pulvinar derives from the Latin word for a cushion. Being the thalamic nucleus situated adjacent to the lateral geniculate ('knee-like') nucleus (LGN), the term is quite apt, although the humor may not have been intentional. The LGN and pulvinar constitute the twin thalamic elements of the visual system, but they differ significantly in structure and connectivity. The LGN has significant connections external to its primary cortical target (area V1), but the scope of pulvinocortical circuitry is far more extensive. In fact, there is no known region of ipsilateral visual cortex that fails to interact with the pulvinar, and parts of somatosensory, auditory, cingulate, and frontal cortices are also connected to it. Also unlike the LGN, the pulvinar receives only a very sparse retinal input and lacks the layered structure associated with segregated ocular inputs and monocular response properties. Instead, it appears that a specific subset of cortical inputs to the pulvinar mimics the role of retinal afferents to the LGN – both are known as 'primary afferents.' On this basis, the pulvinar is classified as a higher-order thalamic relay (and the LGN is termed a first-order relay). It therefore follows that the prime purpose of the pulvinar is to operate a set of corticothalamocortical (CTC) loops because the pulvinar has no anatomical output other than its return projections to the cortex.

Clearly, in order to probe the functional role of such a CTC loop, it is helpful to have a clear picture of the detailed anatomical organization of pulvinocortical circuitry: Which cortical areas are interconnected through which zones of the pulvinar? Although we have a workable system of cortical parcellation, a suitable reference system for the pulvinar is not well established. Indeed, the traditional morphological subdivisions found in standard brain atlases are nothing but a hindrance. By analogy, it is like trying to devise a chart of international flight routes indexed to river basins; the task may not be impossible, but hydrology is hardly the natural frame of reference for airborne transport. The following section outlines the basis of the traditional subdivisions and a more satisfactory alternative parcellation based on chemoarchitecture. However, the simplest means to analyze patterns of connectivity within the pulvinar is to allow those patterns to set their own boundaries. This can be achieved by carefully mapping the topography of pulvinocortical connections and using reversals or other forms of topographic discontinuity to establish structural subunits. The exercise is facilitated by reference to visual maps (in ventral pulvinar) which obey similar principles.

The final element for discussion is to consider the neural elements of pulvinocortical circuitry because different subpopulations of neurons may participate in circuits with similar topography while performing different functional roles. At the cellular level, synaptic contacts may be driving or modulatory in effect. It is not clear how these properties are integrated at a systems level, but a hypothetical, hierarchical model for pulvinocortical interaction provides a useful means of organizing existing observations and a source of hypotheses for experimental investigation.

Pulvinar Architecture

Myeloarchitecture and Cytoarchitecture

The traditional subunits of the pulvinar are its medial, lateral, and inferior nuclei, defined on the basis of cell and fiber stains in the 1930s. A fourth nucleus, the oral pulvinar, lying anterior to the other three, was added in 1952. With such methods, some boundaries are more cleanly observed than others, and the pulvinar is no exception. There is little to distinguish the lateral pulvinar nucleus from the neighboring lateral posterior nucleus, for instance. The inferior pulvinar is the most morphologically distinct subunit since it is isolated from the main body of the pulvinar by a substantial fiber tract known as the brachium of the superior colliculus. Many of these fibers are collaterals branching from the optic tract, bound for the superior colliculus, and they course through the gray matter of the pulvinar without making any functional contribution to it. The lateral pulvinar is distinguished from the medial pulvinar by the presence of numerous fiber bundles that perforate its lateral surface, adopting a roughly parallel arrangement within a coronal plane of section. The medial pulvinar nucleus is held to commence at the point where these bundles eventually end, approximately halfway to the medial limit of the pulvinar, but the transition between the two zones is not especially abrupt. Having staked out these zones, there are some corroboratory differences in cellular architecture to be observed, but given the nature of the morphological criteria, it should not come as a surprise if the traditional nuclei bear an arbitrary relationship to the functional substructure of the pulvinar.

Chemoarchitecture

The alternative to traditional cell and fiber stains is a variety of histological treatments that can be collectivized under the term chemoarchitecture. These reveal the distribution of various enzymes or other protein molecules that regulate cell physiology, or transmitter neurochemistry. For instance, fluctuations in the density of stains for the mitochondrial enzyme cytochrome oxidase, and the neurotransmitter degradation enzyme acetylcholinesterase, are often highly correlated. So too is the pattern revealed by an antibody to the calcium-binding protein calbindin, except that this is the complementary pattern – light where the acetylcholinesterase stain is dark and vice versa. Figure 1 contrasts the traditional substructure of the pulvinar with a more recent scheme based on

Figure 1 Comparison of traditional morphological and neurochemical subdivisions of the pulvinar, depicted in a coronal plane of section (top) and in a photograph of a horizontal section stained for cytochrome oxidase (bottom). Architectural subunits (a) are the inferior, lateral, and medial nuclei (PI, PL, and PM, respectively); as coded red, green, and violet in the (miniature) horizontal section, the inferior nucleus is sharply demarcated from the lateral and medial nuclei, whose subdivision is structurally more arbitrary. Neurochemical subunits (b) are the concentrically arranged posterior, medial, central, lateral, and lateral shell divisions of an enlarged inferior pulvinar (PI_P, PI_M, PI_C, PI_L, and PI_{LS}, respectively), and three subdivisions of the dorsal pulvinar that, aiming to retain continuity with the traditional terminology, were named the dorsal division of lateral pulvinar (PL_d) and lateral and medial subdivisions of medial pulvinar (PM_l and PM_m, respectively). The shading in (b) represents relative density of staining for acetylcholinesterase. Borders of the neurochemical subunits of PI indicated on the horizontal cytochrome oxidase section are as inferred from diagrams such as (b), with limited correspondence to the intrinsic staining pattern. Each plane of section (coronal/horizontal) carries an indication of the approximate level of the other; mediolateral, dorsoventral, and rostrocaudal anatomic axes are indicated by the two dials.

chemoarchitecture. The newer scheme retains elements of the older terminology, although none of its subregions are exact equivalents (Figure 1). For instance, the chemoarchitectonic inferior pulvinar (PI) is enlarged to include the ventral half of the traditional lateral pulvinar. It is subdivided into several segments – posterior, medial, central, lateral, and lateral shell (PI_P, PI_M, PI_C, PI_L, and PI_{LS}, respectively; Figure 1) – based on a pattern of alternating densities in calbindin and acetylcholinesterase stains (Figure 2). The dorsal border of PI is placed where this alternation in density subsides, just above the level of the brachium of the superior colliculus. The remainder of the pulvinar, termed the dorsal pulvinar, is also subdivided according to gradations in staining density, with the terminology PL_d, PM_l, and PM_m reflecting approximate correspondence to the traditional lateral and medial nuclei (Figure 1).

Figure 2 A pair of coronal sections through macaque thalamus, stained for acetylcholinesterase, showing subdivisions of inferior pulvinar. The lower section is taken from a level just caudal to the posterior inferior pulvinar (PI_P). PI_M, medial inferior pulvinar; PI_C, central inferior pulvinar; PI_L, lateral inferior pulvinar; PI_{LS}, lateral shell of an inferior pulvinar. Reproduced from Cola MG, Gray DG, Seltzer B, and Cusick CG (1999) Human thalamus: Neurochemical mapping of inferior pulvinar complex. *Neuroreport* 10(18): 3733–3738, with permission.

Having a basis in cellular physiology, it is more realistic that chemoarchitectural zones should reflect functional differentiation within the pulvinar, for example, by demarcating some specific input/output pathways. The functional correspondence of chemoarchitecture is not well understood theoretically, but some empirical correlation with afferent pathways has emerged. For instance, the subunit PI_M (also known as the calbindin 'hole' due to its pale appearance in calbindin-stained tissue) is the main site of retinal terminations. By contrast, an indirect source of retinal input, relayed by the superficial layers of the superior colliculus, avoids PI_M but terminates most densely in the neighboring subunits PI_P and PI_C. PI_M is also the prime focus for reciprocal connections with cortical area V5/MT. Differential relationships with a number of other cortical areas are known to exist in a variety of primate species, but it is also clear that the (known) chemoarchitectural plan is not the sole agent configuring the pattern of corticothalamic connectivity. It is therefore useful to examine a complementary system of codifying the pattern of cortical connections.

Topology and Topography of Cortical Connectivity

Global Organization of Connectivity

As illustrated in many textbooks, there is a topographic relationship between the thalamus as a whole and the cortex of the same hemisphere. To envision this, imagine an image of a flattened cortical sheet being mirror reversed, rotated 90°, and shrink-wrapped around the thalamic ovoid. Figure 3 illustrates, in principle, that the same overall relationship holds for the topography of cortical connectivity within the pulvinar. In the ventral pulvinar, an occipitotemporal cortical gradient is expressed along a rostrolateral–caudomedial axis. Along roughly the same axis, in dorsal pulvinar, there is a parietotemporal cortical gradient. This is consistent, in schematic terms, with a mirror image of the cortical sheet being shrink-wrapped around the posterior surface of the pulvinar (i.e., around the posterior pole of the thalamus); in general, the visual cortex (or the ventral visual pathway) is mapped into the ventral pulvinar and the dorsal visual pathway into the dorsal pulvinar. Neighboring regions of visuosomatic and visuoauditory association cortex are mapped into rostral sectors of the pulvinar, including the anterior pulvinar nucleus and part of the medial pulvinar nucleus.

The 'shrink-map' model is simply a first approximation because there are many topographic irregularities

Figure 3 Topographic relationships between the cortical sheet and the pulvinar. Two principal vectors, parietal–superotemporal (P-ST; red) and occipito-inferotemporal (O-IT; gray) are shown on a whole brain view and on the flattened cortical sheet taken from the same right hemisphere (top left). The constituent individual areas are represented by blue-green and orange-violet color gradients, respectively. In the bottom panel, the same two vectors are marked on a perspectively viewed pair of horizontal sections through the dorsal and ventral pulvinar of the right hemisphere, in which they follow roughly parallel rostrolateral to caudomedial trajectories. The additional red vectors in the cortical sheet represent topographic gradients in cingulate and frontal cortex that are expressed in parallel to P-ST in dorsal pulvinar. The gray arrow is shown with dual components in the cortical sheet to reflect the discontinuity (or tear) which is made in the calarine region of V1 to facilitate flattening without distortion. The form of the cortical sheet is reproduced as a 'compass' (top right) showing cortical axes O-F (occipitofrontal) and C-T (cingulotemporal). The compass in perspective view (bottom left) has been mirror reflected and rotated by 90°. It is now topographically consistent with the P-ST and O-IT vectors marked on the pulvinar sections. Mediolateral and rostrocaudal anatomic axes through the pulvinar are shown on the blue dial.

that it fails to recognize, including superimpositions, duplications, and topological reversals. Furthermore, topography can only be used to rationalize two dimensions of organization within the three-dimensional volume of the pulvinar; there are numerous instances of local inhomogeneities and mosaic or patchy connectivities that could be considered part of a 'third dimension' of pulvinar organization.

Ventral Pulvinar

Ventral pulvinar is territorially equivalent to the expanded, histochemically defined PI and can be subdivided, on topographic criteria, into three subzones termed VP1–VP3 (these terms are adapted from P1 to P3, which were originally used to describe the topography of connections with cortical area V5/MT alone). VP1 are VP2 are coregistered with a pair of visual retinotopic maps, whereas VP3 is much less retinotopic.

Visual topography in VP1 and VP2 The organization of the visual maps of the ventral pulvinar is analogous to the visual topography expressed by cortical areas V1 and V2 in several respects: (1) the 2° map is a mirror image of the 1° map and surrounds it concentrically; (2) the border is formed by a common representation of the vertical meridian; (3) the 2° map has a split representation of the horizontal meridian from 3° eccentricity onward, such that the inferior field quadrant is found dorsally and the superior quadrant ventrally (Figure 4). The 1° and 2° pulvinar maps were originally named the inferior map and the lateral map because they respectively occupy much of the traditional inferior and lateral subnuclei. However, the visual maps do not exactly respect the architectural divisions since part of the 1° map invades lateral pulvinar, and the 2° map only occupies the remaining sector of the ventral half of the lateral pulvinar.

Figure 4 Schematic illustration of the 1° and 2° visual maps in VP1 and VP2 subdivisions of ventral pulvinar. The three-dimensional mapping volume (translucent blue) is superimposed on a perspective view of a horizontal slice through the right pulvinar (at approximately the same level illustrated in Figure 1). The dial in the slice indicates rostrocaudal and mediolateral anatomic axes. (Inset) The same slice in normal view showing how the border between the 1° and 2° maps intersects the anatomical border between the traditional inferior and lateral pulvinar (PI and PL, respectively). (Far left) A left visual hemifield map, as imaged on the retina (i.e., with inversion of superior and inferior quadrants). (Middle left) Transformed 1° and 2° maps (labeled VP1 and VP2), as found in any slice through the mapping volume made in a plane perpendicular to the axis of isorepresentation.

Again, this confirms the functional irrelevance of the traditional subnuclei.

To form a two-dimensional visual map in a three-dimensional body, there has to be one dimension along which the same point in space is continually re-represented. This dimension is well known to be perpendicular to the intrinsic lamination in structures such as visual cortex and the LGN, and it is known as the axis of isorepresentation (AIR). The alignment of the AIR in the pulvinar is approximately rostrolateral–caudomedial (Figure 4). Importantly, the axes of cortical topography and of visual isorepresentation are coincident. The alignment of the AIR can be directly visualized in horizontal sections through ventral pulvinar showing the connections made by focal injections of tracer into cortical areas with good visual topography (e.g., V1–V4), as illustrated in Figure 5. The characteristic product is a column of labeled neurons and/or axon terminals within ventral pulvinar, tracing out the line of the AIR. If the tracer is deposited sufficiently far from the vertical meridian in the visual map of the target cortical area, there are two such columns. One, in VP1, is oriented roughly perpendicular to the planar interface of the inferior pulvinar with the adjacent part of the LGN; the other is within VP2, and it adopts a roughly parallel trajectory. Such anatomical experiments therefore demonstrate that cortical areas link to the pulvinar maps in a point-to-point fashion, and thus that the cortical topographies of VP1 and VP2 have the same mirror relationship to each other as the underlying visual maps. There is no known direct reciprocal connection between VP1 and VP2.

In essence, the connection zones of successive cortical areas along the occipitotemporal gradient within ventral pulvinar constitute a set of parallel slabs, all containing co-registered visual maps. These slabs, or connection zones, are heavily overlapping such that the 1° and 2° pulvinar maps can be considered as global composite maps that emerge from the superimposed cortical (and collicular) inputs. The degree of retinotopic order diminishes along the AIR as the source of cortical input is derived from areas toward the temporal pole of the occipitotemporal gradient, such as TEO and TE, which are known from cortical recording studies to possess large receptive fields and little inherent visual topography. Consequently, the distinction between VP1 and VP2 is more provisional approaching the caudomedial pole of the AIR. However, given the connectional continuity, there is little reason to regard the caudomedial pole of ventral pulvinar as a functionally discrete region.

VP3 The third subunit of ventral pulvinar, VP3, adjoins VP1 on its rostromedial boundary. In contrast to the topological distinction between VP1 and VP2 (i.e., the mirror relationship of visual and cortical topographies), the boundary with VP3 may be recognized as a topographical discontinuity. VP3 is also roughly (perhaps precisely) coincident with the PI_P, PI_M, and PI_C zones of the histochemical scheme. A major source of input to VP3 is the cortical motion area, V5/MT. Connections with this cortical area are focused on PI_M but also invade PI_P and PI_C. The adjacent part of VP1 is connected to area V4, but the connection zones of these two areas (V4 and V5) display little, if any, direct overlap, despite the fact that they are near neighbors in visual cortex; this observation contrasts readily with the high degree of overlap that exists between the connection zones of V4 and other cortical neighbors, such as areas V3 and TEO. Hence, the 'fault line' between the V5 and V4 zones is a topographic discontinuity that defines the boundary of VP1 with VP3. Finally, in both physiological and anatomical studies, VP3 has little visuotopic organization (although there are some indications that the central field is mapped

Figure 5 Anatomical demonstration of the axis of isorepresentation (a. i.-r.) as observed in horizontal sections through macaque pulvinar, demonstrating patterns of connection from occipital visual areas. (a) Connections from a site straddling the V1/V2 border. In visual terms, this was a locus on the inferior vertical meridian, predicting a single column of connections at the representation of this meridian in the pulvinar, coincident with the border between VP1 and VP2. A bidirectional neural tracer was used, demonstrating retrogradely filled cell bodies and orthogradely filled axon terminals in the pulvinar. (b) Orthograde projections from area V4, at a locus in the inferior contralateral visual quadrant. Note the presence of two parallel columns of axon terminals at mirror locations in the respective 1° and 2° visual maps of VP1 and VP2. (c, d) Connections with area V3 from a similar visual locus to that in V4. The two columns of label occur at different levels, with the main part of the 1° column being located more ventral (d). Note that section d also shows connections between area V3 and pulvinar zone VP3. All images show sections stained for cytochrome oxidase with neural connections from adjacent sections superimposed or artificially rendered with graphics software tools.

caudally in VP3). Overall, VP3 may be recognized as a zone distinct from VP1 by a combination of several histochemical and topographic criteria.

Further correspondence (or not) of histochemical and topographic subunits of ventral pulvinar The subdivision between VP1 and VP2 has no known histochemical correlate. This is not necessarily a surprise, since the cortical and subcortical territories connected to VP1 and VP2 are, in general, highly similar. The most prominent difference concerns input from cortical area V1, which distributes throughout VP1 but only within the central 7° of VP2. Hence, VP1 and VP2 together correspond to the outer two histochemical zones PI_L and PI_{LS}. The latter of these (the outermost or 'shell' region) occupies the lateral margin of the ventral pulvinar and has a number of unique characteristics. In calbindin-stained tissue, PI_{LS} is distinguished from PI_L by mildly darker neuropil and sporadic intensely calbindin-positive neurons with extensive dendritic fields. Golgi studies have also described a unique type of relay cell in this region, with an elongated bipolar dendritic field, aligned in parallel with the lateral margin. Two specific

projections are also known to concentrate at the lateral margin of the pulvinar, as if coextensive with the shell region. One of these derives from the superficial layers of the superior colliculus, and the other one derives from V5/MT.

The second V5 zone is similar to the one in VP3 in that both are reciprocally connected to V5. However, the shell zone is much more topographic and, because it receives collicular input (unlike PI_M within VP3), can presumably relay retinotopic collicular signals to V5. Pulvinocortical axons from this region terminate in V5 with remarkably small arbors (0.1–0.2 mm diameter) – approximately half the size of arbors with similar origin observed in V2 and V3 and an order of magnitude smaller than observed within V4.

The shell V5 zone is also a topographic anomaly in that it is inserted at the very rostrolateral pole of the occipitotemporal cortical gradient within VP1 and VP2. In other words, the shell V5 connection zone overlaps inputs from V1 (and V2 and V3) but is of narrower width. A related observation is that it abuts with virtually zero overlap against the V4 connection zone, which fails to extend as far as the lateral margin of ventral pulvinar. It is noteworthy, therefore, that the V4 connection zone within VP1 and VP2 appears to be segregated from the V5 connection zones investing its medial and rostrolateral boundaries, both of which have candidate but dissimilar histochemical correlates. Figure 6 shows a schematic illustration of the geometry of these various relationships; the precise three-dimensional configuration has yet to be fully established.

Figure 6 A model of the relationship between cortical connection topography, visual topography, and histochemical zones in ventral pulvinar. (Top) The two V5 connection zones and the single V4 zone are tinted blue and green, respectively. The subdivision into VP1 and VP2 is dictated by visual mapping (as described in the text and the legend to Figure 4). The border between VP1 and VP3 is demarcated by the transition between the two connection zones. The blue zone within VP1 and VP2 is approximately equivalent to histochemical zone PI_{LS} and the green zone (plus the adjacent untinted region) to PI_L. VP3 corresponds to the sum of PI_C, PI_M, and PI_P. (Bottom) A three-dimensional visual map in VP1 is superimposed on the same slice. The half-cylinder shape is purely schematic to illustrate the principle that the offset between cortical zones is aligned with the visual axis of isorepresentation, and hence that adjacent cortical connection zones can have registered visual maps. Although the V4 zone is separate from that of V5, it overlaps caudomedially with the connection zones of subsequent areas in the occipitotemporal gradient, namely areas TEO and TE. Similarly, the V4 zone overlaps rostrolaterally with the zones of V1–V3 (not shown). The true shape of the mapping volume is closer to that illustrated in Figure 4; clearly, it must be confined within the anatomical body of the ventral pulvinar and in some way distorted by the exclusion of VP3.

Dorsal Pulvinar

There are a number of topographic features by which the dorsal pulvinar is distinguished from the ventral pulvinar. Most obviously, it connects with a separate set of areas, expressing a cortical topography from superior parietal to superior temporal along a rostrolateral–caudomedial axis. Experiments which have simultaneously traced connections from parietal and inferotemporal locations in the same hemisphere have accordingly found a dorsoventral separation of the respective pulvinar connection zones. What overlap, or proximity, does exist is due to the presence of small foci of inferotemporal connections within the territory of dorsal pulvinar. Many of the cortical areas linked to dorsal pulvinar are visual but poorly retinotopic. Consequently, there is little evident influence of visual topography in dorsal pulvinar, and nothing comparable to the topological duplication and mirror inversion shown by VP1 and VP2. Another major difference is the presence of superimposed cortical gradients in dorsal pulvinar. As indicated in Figure 3, the rostrolateral–caudomedial axis also expresses a caudorostral sequence of cingulate cortex connections and perhaps two separate gradients within frontal cortex. There are also connections with the amygdala. The strength of these additional connections is not as great as the primary, parietotemporal gradient; however, their presence implies that a small locale in dorsal pulvinar can connect to widely separate parts of the cortex (i.e., different lobes), unlike anything known for ventral pulvinar.

Although the identification of an overall gradient helps to present a global picture of pulvinocortical connections, it is hardly a full description. Anatomical experiments reveal that the connection zones of

individual areas are broadly overlapping and frequently broken up into separate patches, columns, or disclike aggregates of labeled neurons. One detailed study has also demonstrated that the topographic relationship is not perfectly reciprocal in that a proportion of relay cells whose axons terminate at a particular point within area 7a (i.e., the site of injection of a neural tracer) appear to lie outside the terminal field of corticopulvinar axons emanating from that site. There is also an uncertain relationship vis-á-vis topography and the histochemical substructure of dorsal pulvinar. The neurochemical axis (i.e., a line perpendicular to the three identified subunits shown in Figure 1) is similar but not necessarily identical to the primary topographic axis.

The Replication Principle

What factors influence the organization of CTC loops and their topographic precision? It is worth noting that if the topography of thalamocortical circuitry were perfectly precise, there would be little or no scope for CTC loops to achieve transcortical communication (there would be a set of pinpoint reciprocal connections, with the thalamus acting as a kind of seventh cortical layer). Clearly, an imprecise topography is the signature of the fact that cortical areas do communicate via the thalamus. The 'replication principle' refers to the generalization that indirect CTC circuits tend to replicate direct corticocortical circuits. In other words, if two cortical areas are interconnected, they are likely to have overlapping, or at least partially overlapping, thalamic connection zones, whereas a pair of unconnected cortical areas will maintain segregated thalamic connection zones. Depending on the areas in question, the segregated zones might be totally separate, or interdigitating.

A cortical area forms most of its connections with nearby areas. Hence, a simple blurring of cortical topography in the thalamus will serve to replicate this network of connections. The connections of the ventral visual pathway with VP1 are a suitable example: neighboring areas, such as V4 and TEO, are heavily interconnected by direct and indirect (i.e., CTC) circuits, whereas the areas at opposite poles of the pathway, V1 and TE, do not connect directly and do not overlap in their connection zones. Longer-range cortical networks are replicated by superimposed cortical gradients; for example, the convergent cortical gradients in the dorsal pulvinar (as described previously) replicate the triangular network formed by inferior parietal, frontal, and posterior cingulate cortices. Also notable are reverse examples of the replication principle – that is, instances in which the mutual exclusion of connection zones appears to sculpt the local pattern of connections. An example described previously concerns areas V5 and V4, whose segregated connection zones in ventral pulvinar are matched by a low level of transcortical interconnectivity, in comparison to other areas in their neighborhood. A similar example in dorsal pulvinar concerns areas 7A and LIP, whose thalamic connections are mediated by separated, sandwiched clusters of cells.

Perhaps the largest-scale organization of the visual system is its bifurcation into dorsal and ventral subsystems. The two are certainly not separate but are known to operate semiautonomously (e.g., maintaining parallel representations of object size and shape). Does the replication principle extend to this level of organization? As already mentioned, the ventral visual pathway is represented intact by VP1 and VP2, but the dorsal sequence – for example, V1–V2–V3–V5 leading to parietal and superior temporal cortex – is not so easily recognized. It could exist, however, in a gradient leading from VP3 into dorsal pulvinar. There appears to be topographic continuity between VP3 and dorsal pulvinar, mediated by the connections of areas MST and FST. The connection zones of this pair of areas (both cortical neighbors of V5) overlap the V5 zone in VP3 but also extend more dorsally into dorsal pulvinar. Crucially, VP3 also receives input from V1 and V3. Although the relationships of the V1, V3, and V5 connection zones in VP3 have yet to be established, existing knowledge of pulvinar topography is reasonably consistent with a faithful 'replication' of dorsal and ventral visual subsystems.

Elements of Pulvinar Circuitry

The pulvinar, like other thalamic nuclei, consists of relay cells with cortical projections and also GABAergic (i.e., inhibitory) interneurons. There are two main classes of relay cells: core relay cells, whose axons terminate in the middle cortical layers (layers 3 and 4), and matrix relay cells, whose axons terminate superficially. The two types are distinguished histochemically by being positive for calcium-binding proteins parvalbumin and calbindin, respectively. Matrix relay cells are slightly smaller and are so named because they are relatively evenly distributed throughout the thalamus. Core cells are typically more aggregated. In the LGN, for instance, core relay cells are represented by the well-formed magno- and parvocellular layers, and matrix cells are represented by the koniocellular cells that are distributed within and between these layers. Golgi studies of pulvinar (and of thalamus in general) have identified several subtypes of interneurons with different dendritic characteristics. Interneuron cell bodies are

smaller than relay cells, but the dimensions of the dendritic field can be just as large (150–600 μm). Corticothalamic afferent axons originate from either layer 5 or layer 6 and have several distinguishing characteristics. As visualized in Golgi-stained tissue, or by using an orthograde tracer such as the *Phaseolus vulgaris* lectin, R-type afferents have large, beaded terminals within a rounded, discrete arbor; E-type afferents are finer in caliber, with spinous terminations over a more elongated zone. It is generally accepted (although yet to be directly demonstrated) that E afferents derive from layer 6 corticothalamic neurons, and R afferents derive from sparser, larger layer 6 corticothalamic neurons. R axons have collaterals directed toward typical targets of layer 5, such as the superior colliculus. Both R and E axons may give off collateral branches as they pass through the inhibitory thalamic reticular nucleus ensheathing the thalamus.

The synaptic terminals of R and E axons can also be distinguished at the ultrastructural level. RL and RS terminals, formed by R and E axons, respectively, are both asymmetric, and both contain round synaptic vesicles (the well-established ultrastructural characteristic of excitatory terminals). However, RL terminals are larger, and they contact larger caliber relay cell dendrites than the RS terminals. RL terminals are also observed to form synaptic complexes including dual pre- and postsynaptic elements of interneuron dendrites. A summary diagram of synaptic connectivity is shown in Figure 7.

Figure 7 Synaptic circuitry in ventral pulvinar, as inferred from ultrastructural examination. RS and RL are terminals of corticothalamic axons (blue and green). Both contain round vesicles and make asymmetric contacts, which are hallmarks of excitatory transmission. RL terminals contact larger caliber dendrites (i.e., proximal dendrites), frequently taking part in synaptic complexes. Some RLs (yellow) were thought to be of collicular origin, but this was not directly ascertained. RS terminals are more numerous, contacting finer dendrites, but rarely taking part in synaptic complexes. RS terminals also synapse upon dendritic shafts of inhibitory interneurons. The terminal appendages of interneuron dendrites form synaptic complexes in which they are postsynaptic to an RL terminal and presynaptic to a relay neuron dendrite. The latter synapses are symmetric in form and contain pleomorphic vesicles (hallmarks of inhibitory transmission). Interneurons also occasionally contact other interneurons (not shown). Are Corticothalamic Circuits Organized According to Hierarchical Principles?

The morphological characteristics of R axons and RL terminals are similar to those of retinal afferents within the LGN. Despite forming less than 10% of all afferents to the LGN, retinal afferents drive the response of LGN relay cells and confer the receptive field properties. Other afferents (e.g., from layer 6 of V1) modulate the responsiveness of LGN relay cells, acting through metabotropic as well as ionotropic synaptic receptors. The physiology of pulvinar synaptology is much less studied, but by analogy it is reasonable to assume that layer 5 and layer 6 afferents adopt equivalent driving and modulatory roles. It is because the excitatory drive to pulvinar derives from cortex, rather than from the sensory periphery, that the pulvinar is classified as a higher order (or associative) nucleus. Driving and modulatory roles in corticocortical interactions are associated with ascending and descending pathways within a hierarchical scheme of area relationships. However, ascending and descending connections are more rigorously defined anatomically with respect to their differing layers of origin and termination. It is therefore possible to outline a provisional scheme for hierarchical relationships between visual cortex and pulvinar involving eight identified anatomical characteristics (Table 1).

The core and matrix relay cells are the putative drivers and modulators of the pulvinocortical pathways by virtue of the layers of their cortical terminations. Rather like cortical feedback (descending) connections, the matrix relay cells terminate diffusely within layer 1, in contrast to the more focal

Table 1 Anatomical elements of an integrated corticothalamic hierarchy

		Corticothalamic	*Thalamocortical*
Forward or driving	Source	Layer 5	Core relay neurons; parvalbumin positive
	Termination	R-type axons; RL terminals	Layers 3 and 4
Feedback or modulatory	Source	Layer 6	Matrix relay neurons; calbindin positive
	Termination	E-type axons; RS terminals	Layers 1 and 2

terminations of the core relay cells within the middle cortical layers that resemble ascending cortical projections.

The guiding principle of a notional, integrated corticothalamic hierarchy is that any reciprocal connection between specific cortical and pulvinar locations should be driving in one direction and modulatory in the other. In other words, a direct reciprocal loop should not be formed by driving connections in both directions (known as the 'no strong loops' hypothesis). Figure 8 depicts a hypothetical scheme in which the ventral pulvinar is subdivided into a hierarchical sequence of discrete zones, modeled on its topographic relationship with the hierarchical ventral visual pathway. The model makes certain predictions for the topography of the elements listed in Table 1 that can be tested against observational data.

Notably, the anatomical relationship with area V1 is entirely consistent with such a scheme since the corticopulvinar output from V1 is formed largely by layer 5 efferents, and the return projection is to layer 1 (presumed to arise from matrix relay cells). Hence, V1, at the base of the hierarchy, can be interpreted to provide a driving output to pulvinar, reciprocated by modulatory feedback. In the model, this is stage 'a' in the pulvinar, which in turn provides driving outputs to extrastriate cortex. The model envisions that a second pulvinar stage ('b') is driven by low-order extrastriate cortex (e.g., V2) and provides a driving output to higher-order extrastriate cortex (e.g., V4).

If organized in this fashion, anatomical tract-tracing experiments should have predictable outcomes. For instance, if tracer were placed in zone b of the pulvinar, there should be a signature pattern of cortical labeling, with back-labeled cells present in layer 5 of V2, and layer 6 of V4; orthograde tracer should reveal projections to layer 1 of V2 and layers 3 and 4 of V4. Such a result, with clear offsets in the zones of labeling of different layers, has never been reported. One good reason is undoubtedly that the deposits of tracer in the pulvinar are frequently large, potentially covering two or more zones (a, b, c, etc.) in the pulvinar. In this case, regions of driving and modulatory connection with the cortex would be expected to overlap, perhaps extensively. However, the hierarchical model would still predict particular

Figure 8 A hypothetical scheme for an integrated corticothalamic hierarchy. There are two kinds of corticothalamic loops. (Black) Core relay cells (parvalbumin positive) provide driving output to cortical layer 4, with modulatory feedback from layer 6. (Red) Layer 5 cortical neurons provide driving outputs to the pulvinar, reciprocated by modulatory feedback from matrix relay cells (calbindin positive) to superficial cortical layers. The physiological basis for this scheme relies on an analogy with the LGN (in which, for instance, the primary retinal afferents are isomorphic to the layer 5 afferents to pulvinar). The division of the pulvinar into discrete zones ('a,' 'b,' etc.) coordinated with hierarchical levels in the cortex (V2, V4, etc.) is purely conjectural.

laminar patterns at the fringes of the cortical region demonstrating tracer-labeled cell bodies and axon terminals – specifically, a fringe area toward the lowest tier in the cortical hierarchy with cells in layer 5 and terminals in layer 1, alone, and a fringe area toward the highest tier in the cortical hierarchy with cells in layer 6 and terminals in layer 4, alone. It is due to a lack of any such observational details in the literature that the model, as shown in Figure 8, is not well supported by experimental data.

A similar case could (in principle) be made by considering the results of anatomical experiments tracing the distribution of R and E axons from identified extrastriate visual areas. One crucial fact is that V1 is not the only source of R-type afferents: all areas so far examined (V2, V4, V5/MT, TEO, and TE) provide both R and E afferents, although V1 is the only known area whose corticopulvinar output is predominantly R type. R and E afferents from the same site of origin (i.e., the few cubic millimeters where tracer was deposited in cortex) may terminate separately or in overlapping fields. A systematic pattern with strictly segregated terminal zones, as envisaged

by the model in Figure 8, is not in evidence. Perhaps, if there is an integrated thalamocortical hierarchy, it might not require such regular stratified zones in the pulvinar; a mosaic organization would provide an alternative, in which the formation of strong loops is avoided by patchy local arrangements of driving and modulatory circuitry. A final avenue of study would be to chart the distribution of core and matrix relay cells projecting to the same site in cortex, but this has yet to be performed for visual cortex and pulvinar.

What Are the Functions of Corticopulvinocortical Circuitry?

Theoretical ideas relating to the function of second-order thalamic nuclei are sketchy at best. A recurring notion in regard of the pulvinar is that it is in some way associated with attentional processes. Typically, such ideas address the medial pulvinar in relation to its involvement with frontoparietal cortical circuits known to mediate attention. However, adopting an anatomical approach, it is equally possible to apply this idea to the entire pulvinar. In a neural context, attention must address the means by which brain areas interact cooperatively to select certain forms of processing over others, as dictated by the current behavioral goal. In vision, for example, this may require scrutinizing one particular object. The pulvinar, with its extensive links to the entire visual cortex, is well equipped to take part in this process. The logic of the replication principle may be that the pulvinar acts to facilitate or regulate transmission within existing cortical networks – a kind of remote hub for controlling network activity. The quandary, therefore, is how information transmitted via a corticopulvinocortical (CPC) loop differs in nature from that passing over the equivalent direct corticocortical pathway. The remainder of the article offers a couple of general formulations.

The Pulvinar as a Salience System

Neural models of attention frequently invoke competition. Attending to one object in a busy scene is a process whereby neurons representing that object outcompete other neurons representing rival objects. Because any object is multiply represented across several different visual areas (with each area emphasizing a different kind of feature), there are several simultaneous competitions. An integrated competition model proposes a mechanism to ensure that the same object wins out in all areas. Anatomically, CPC circuitry is an attractive candidate: The winning location emerges from a pooling of all relevant information within the visual map(s) of the pulvinar and is rebroadcast back to the relevant location in each cortical map. In this scheme, pulvinar activity is related to the salience of each object. Salience is a composite signal, having a basis in the raw, visual conspicuity of each object but also modified by behavioral contingency (if bananas are the object of search, anything yellow and/or crescent shaped has enhanced salience). It is also possible to attend relatively featureless locations in space, and such a spatial attentional bias signal could be injected into pulvinar from frontoparietal cortex, either directly or by means of a reentrant pathway via the superior colliculus. Several features of pulvinar physiology are compatible with this concept, such as the lack of feature selectivity in comparison to cortical neurons. In addition, the characteristic bursting property of thalamic relay cells, when they are reactivated from a quiescent state, is a mechanism that lends itself to signaling the salience of a freshly significant location. In summary, the concept of salience illustrates how CPC circuitry might replicate the pattern of cortical circuitry without necessarily duplicating it in function.

The salience model derives from topographic considerations and is rather less informed by knowledge of the local circuitry. A key prediction is that the pulvinar is itself a site of neural competition (e.g., a winner-take-all salience map as envisaged by some models). The architecture of its intrinsic inhibitory circuits is unknown, but the prediction is that there should be long-range lateral inhibition within the plane of mapping (i.e., the plane perpendicular to the AIR) and facilitation (perhaps disinhibition) along the AIR in order to propagate a winning location across the connection zones of different cortical areas. Either process might be augmented by recurrent connections with the TRN. The primary source of activity for the representation of each object within a salience map would be driving (R-type) input from V1. Reentrant collicular afferents might also require a driving action if they are expected to influence activity at a featureless location. The shape of subsequent interactions with higher visual areas is only poorly constrained by existing details of driving and modulatory circuits.

The Pulvinar as a Switchable Central Processor

Another feature associated with the operation of the CTC loop is the generation of rhythmic activity, in which corticothalamic inputs have been demonstrated to exert a synchronizing role. The matrix relay cells, with their diffuse anatomical connectivity, are thought to be an important means by which coherent activity broadens its distribution. Synchronized activity in the cortex, although broadly distributed across areas, is also locally restricted (e.g., to particular columns). The binding-by-synchrony theory posits that rival objects may be represented by distributed cortical networks,

each united by synchronized activity but distinguished by phase. Hence, phase of synchronicity is an alternative (perhaps complementary) domain for hosting an attention-related competition. The crux of the idea is that an incipient transcortical network requires thalamic access in order to grow and distribute across multiple areas, and that networks representing rival objects would compete to recruit pulvinar circuits that, lacking feature selectivity, have no initial affiliation. In this scenario, there is less requirement for competition within the pulvinar. Once the pulvinar, or much of it, has been entrained to the same phase, this phase can be rebroadcast to a wider expanse of cortex. These pulvinocortical signals would not necessarily carry stimulus-specific information but can be expected to sensitize their recipients to corticocortical signals of the same phase, emitted by an increasingly dominant, object-specific network. Acting in this way, CPC circuitry would be (one) anatomical analog for the limited-capacity but task-switchable processing machinery typically envisaged by cognitive accounts of attention.

Purinergic Receptors

Introduction

Receptors for adenine nucleosides and nucleotides have been divided into P1 (those responsive to adenosine and AMP) and P2 (those responsive to purine and pyrimidine di- and triphosphates). P2 receptors are further divided into P2X (ligand-gated cation channels) and P2Y (G-protein-coupled) receptors. There are four subtypes of adenosine receptor – A_1, A_{2A}, A_{2B}, and A_3 receptors – and all members are G-protein-coupled receptors. A_1 and A_3 receptors mediate inhibition of adenylate cyclase, whereas A_{2A} and A_{2B} receptors stimulate this enzyme. To date, the P2X receptor family has seven members ($P2X_{1–7}$) and the P2Y family has eight ($P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{11}$, $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$). The structure, molecular biology, and second messenger signaling of these receptors have been discussed in detail in some excellent reviews.

This article is concerned with the distribution and function of these receptors on autonomic neurons and neuroeffector cells. However, considering the ubiquitous nature of purines and pyrimidines as signaling molecules, the diversity of receptor subtypes, and the fact that in almost all systems of the body ATP, ADP, and/or adenosine are signaling molecules, this article is not able to provide a comprehensive review.

Nervous System

The nervous system expresses multiple P1 and P2 receptor subtypes (Table 1). Peripheral sympathetic neurons have been extensively investigated and shown to express all the P2X receptor subtypes, although functionally the responses of sympathetic neurons can be accounted for by the presence of $P2X_2$ and $P2X_3$ subunits in varying proportions of homomeric and heteromeric receptors, in addition to $P2X_1$ and $P2X_5$ receptors. The dominant P2Y receptors expressed by sympathetic neurons appear to be $P2Y_1$, $P2Y_2$, $P2Y_4$, and $P2Y_6$ receptors. The predominant adenosine receptor is of the A_1 subtype. In contrast, there have been fewer studies of the expression of P1 and P2 receptors on parasympathetic neurons. To date, $P2X_2$, $P2X_4$, $P2Y_2$, and $P2Y_4$ receptor subunits have been identified, although functional responses of parasympathetic neurons are mediated by $P2X_2$ and $P2X_3$ subunits in varying proportions of homomeric and heteromeric receptors and by $P2Y_1$, $P2Y_2$, and $P2Y_{11}$ receptors. As with sympathetic neurons, A_1 receptors are the predominant subtype of adenosine receptor expressed by parasympathetic neurons.

Peripheral sensory neurons have been shown to also express all the P2X receptor subtypes, and $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptors have been identified. Functional responses of sensory neurons are a mixture of $P2X_2$ and $P2X_3$ subunits as homomeric and heteromeric receptors and also $P2Y_1$ and $P2Y_2$ receptors. The principal adenosine receptor expressed by sensory neurons is of the A_{2A} subtype.

Enteric neurons express multiple P2X and P2Y receptor subtypes, with $P2X_3$, $P2X_4$, $P2X_7$, $P2Y_1$, $P2Y_6$, and $P2Y_{12}$ subtypes being abundant, and although there are multiple functional P2X receptors, the $P2Y_1$ receptor is the dominant functional P2Y subtype. With respect to adenosine receptors, A_1, A_{2A}, and A_{2B} receptors have been identified.

Musculoskeletal System

Skeletal Muscle

All of the P2X receptor subtypes are expressed by skeletal muscle; although the functional receptor has not been fully characterized for developing and young animals, there is evidence for the involvement of the $P2X_2$ receptor in the development of the neuromuscular junction. In contrast, in the adult, $P2X_1$, $P2X_3$, and $P2X_5$ receptors have been described. ATP, in both early development and adults, has a role in the upregulation of acetylcholine receptors and inhibition of acetylcholine release. Mammalian motor nerve terminals have been shown to express $P2X_7$ receptors. Developing skeletal muscle expresses $P2Y_1$ receptors, as does the neuromuscular junction, whereas in adults the dominant receptors expressed are the $P2Y_2$ and A_{2A} subtypes.

Bone and Cartilage

Multiple P2X and P2Y receptor subtypes are expressed in osteoblasts, although functionally the dominant receptors are $P2X_7$, $P2Y_1$, and $P2Y_2$, which regulate bone formation (Table 2). Osteoclasts have been found to express a similar distribution of P2X and P2Y receptors, with the addition of a functional $P2X_4$ receptor. Adenosine receptors are also expressed by osteoblast-like cells, inducing proliferation, although

Table 1 Principal P1 and P2 receptors expressed by excitable tissues

Neuronal	
Sympathetic neurons	$P2X_{1-7}$, $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, A_1
Parasympathetic neurons	$P2X_2$, $P2X_3$, $P2X_4$, $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_{11}$, A_1
Sensory neurons	$P2X_{1-7}$, $P2Y_1$, $P2Y_2$, $P2Y_4$, A_{2A}
Enteric neurons	$P2X_3$, $P2X_4$, $P2X_7$, $P2Y_1$, $P2Y_6$, $P2Y_{12}$, A_1, A_{2A}, A_{2B}
Muscle cells	
Smooth muscle	$P2X_{1-7}$, $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, A_1, A_{2A}, A_{2B}, A_3
Skeletal muscle	
Developing	$P2X_2$, $P2X_5$, $P2X_6$, $P2Y_1$, $P2Y_2$
Adult	$P2X_{1-7}$, $P2Y_2$, A_{2A}
Cardiac muscle	$P2X_{1-6}$, $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, A_1, A_3

Table 2 Principal P1 and P2 receptors expressed by nonneuronal cells

Osteoblasts	$P2X_7$, $P2Y_1$, $P2Y_2$
Cartilage	$P2X_2$, $P2Y_1$, $P2Y_2$, A_{2A}, A_{2B}
Keratinocytes	$P2X_5$, $P2X_2$, $P2X_3$, $P2X_7$, $P2Y_1$, $P2Y_2$, $P2Y_4$, A_{2B}
Fibroblasts	$P2X_7$, $P2Y_1$, $P2Y_2$, A_{2A}
Adipocytes	$P2X_1$, $P2Y_1$, $P2Y_2$, $P2Y_4$, A_1
Epithelial cells	$P2X_5$, $P2X_6$, $P2X_4$, $P2X_7$, $P2Y_1$, $P2Y_2$, $P2Y_{11}$, A_1, A_{2A}, A_3
Hepatocytes	$P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{13}$, A_{2A}, A_3
Glial cells	$P2X_{1-7}$, $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{11}$, $P2Y_{12}$, $P2Y_{13}$, A_1, A_2
Sperm	$P2X_2$, $P2X_7$, $P2Y_2$, A_1
Endothelial cells	$P2X_1$, $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, A_1, A_{2A}
Erythrocytes	$P2X_2$, $P2X_4$, $P2X_7$, $P2Y_1$
Platelets	$P2X_1$, $P2Y_1$, $P2Y_{12}$, A_{2A}
Immune cells	$P2X_4$, $P2X_7$, $P2Y_1$, $P2Y_2$, A_{2A}, A_3
Exocrine secretary cells	$P2X_1$, $P2X_4$, $P2X_7$, $P2Y_1$, $P2Y_2$, $P2Y_4$, A_1, A_{2A}
Endocrine secretory cells	$P2X_{1-7}$, $P2Y_2$, $P2Y_4$, A_1, A_{2A}, A_{2B}, A_3
Special senses	
Inner ear	$P2X_1$, $P2X_2$, $P2X_3$, $P2X_7$, $P2Y_2$, $P2Y_4$, A_1
Eye	$P2X_2$, $P2X_7$, $P2Y_2$, A_1, A_2, A_3
Tongue	$P2X_2$, $P2X_3$, $P2Y_1$, A_1
Olfactory organ	$P2X_2$, $P2X_4$, $P2Y_1$, $P2Y_2$, A_{2A}, A_3

the subtype has not been fully characterized. All four adenosine subtypes are expressed by the human osteoprogenitor cell line HCC1.

The dominant P2X receptor expressed by cartilage is the $P2X_2$ subtype, whereas the dominant P2Y receptors are $P2Y_1$ and $P2Y_2$. A_{2A} and A_{2B} receptors have been shown to be expressed by human articular chondrocytes.

Skin

Mammalian keratinocytes express $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptors, and both $P2Y_1$ and $P2Y_2$ receptors have been identified functionally, mediating proliferation. In addition, $P2X_5$ receptors mediating differentiation and $P2X_7$ receptors, involved in cell death, are expressed. $P2X_2$ and $P2X_3$ receptors are also expressed by keratinocytes. Epidermal Langerhans cells express $P2X_7$ receptors, which are believed to have a role in the skin immune response. Adenosine has been shown to enhance the growth of a keratinocyte cell line via an A_{2B} receptor.

Connective Tissue

Fibroblasts express predominately $P2X_7$ receptors, involved in cell death, in addition to $P2Y_1$ and $P2Y_2$ receptors, shown to be involved in the control of proliferation. Fibroblasts express all of the adenosine receptor subtypes; in particular, the A_{2A} receptor has been shown to be involved in stimulating wound healing.

Brown adipocytes express multiple P2X and P2Y receptors, although the dominant functional receptors belong to the $P2Y_1$ and $P2Y_2$ or $P2Y_4$ subtypes. Although a functional P2Y receptor has been described in white adipocytes, it has yet to be characterized. A_1 receptors have been shown to be expressed by both brown and white adipocytes.

Gastrointestinal and Related Systems

Gastrointestinal System

The dominant P2 receptors expressed by intestinal smooth muscle are $P2X_1$, $P2X_2$, $P2X_7$, and $P2Y_1$ and $P2Y_2$ receptors. The P2X receptor subtypes mediate contraction of intestinal smooth muscle and the P2Y receptor subtypes mediate relaxation. In addition, adenosine A_1, A_{2A}, and A_{2B} receptors have been shown to be expressed (Table 2).

Epithelial cells of the intestine express multiple P2X and P2Y receptors, but the dominant receptor subtypes are $P2X_5$, $P2X_7$, $P2Y_1$, and $P2Y_2$ receptors, in addition to adenosine A_{2B} receptors. Interstitial cells of Cajal express $P2X_2$ and $P2X_5$ receptors, and it is thought that ATP may provide a feedback mechanism for pacemaker activity.

Liver and Biliary System

Multiple P2Y receptor subtypes are expressed by hepatocytes and cholangiocytes, the two principal liver epithelial cell types, and functional $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptors have been identified. ATP has a role in regulating hepatocyte gluconeogenesis and mediating bile release from cholangiocytes. Similarly, $P2Y_2$, $P2Y_4$, and $P2Y_6$ receptors expressed by bile duct epithelial cells also modulate bile release. In rat liver, all four adenosine receptor subtypes are

expressed, although the dominant receptor is the A_3 subtype, which is involved in glucose release, particularly following ischemia. Adenosine A_{2A} receptors are expressed in rat and human hepatic stellate cell lines.

Enteric Glial Cells

There are few studies of the expression of P1 and P2 receptors on enteric glial cells, and only $P2X_7$ and $P2Y_2$ or $P2Y_4$ receptors have been shown to be expressed. No evidence for the expression of P1 receptors has been put forward.

Respiratory System

Lung

$P2Y_2$, $P2Y_4$, and $P2Y_6$ receptor subtypes are the predominant receptor subtypes expressed by airway smooth muscle and epithelial cells. In addition, the dominant functional P2X receptor subtypes are of the $P2X_4$ and $P2X_5$ subtypes, where ATP is involved in mucociliary clearance and surfactant release. All of the P1 receptor subtypes are expressed by the lungs. A_1, A_{2B}, and A_3 receptors are involved in adenosine-induced bronchoconstriction, whereas A_{2A} receptors are involved in bronchodilation.

Trachea

The dominant receptors expressed by tracheal smooth muscle and epithelial cells are of the $P2Y_1$ and $P2Y_2$ subtypes. Functional $P2X_1$ receptors are also expressed by smooth muscle mediating contraction, and $P2X_4$ and $P2X_7$ receptors by epithelium activating ciliary function and increasing $[Ca^{2+}]_i$, respectively.

Neuroepithelial Bodies

Only $P2X_3$ and $P2X_2$ receptors have been identified on neuroepithelial bodies, and it has been suggested that the functional receptor is a $P2X_{2/3}$ heteromeric receptor, possibly involved in ATP mechanosensory transduction and O_2 sensing.

Nasal Respiratory Epithelium

$P2X_3$ receptors are expressed by primary olfactory neurons located both in the olfactory epithelium and on subepithelial nerve fibers in the respiratory region. $P2X_5$ and $P2X_7$ receptors are expressed by epithelial cells of the rat nasal mucosa. $P2Y_1$, $P2Y_2$, $P2Y_6$, and $P2Y_{11}$ receptors are found to be expressed by respiratory epithelium. Although adenosine receptors are known to be expressed by apical epithelial cells, they have only been characterized as A_2 receptors.

Urinogenital System

Bladder and Urethra

The expression of all of the known P2X receptor subtypes has been shown in smooth muscle and urothelium of the bladder, although functionally the $P2X_1$ receptor, mediating detrusor contractility, is dominant. The bladder smooth muscle also contains a functional P2Y receptor mediating detrusor relaxation, although this has not been fully characterized, whereas the urothelium has been shown to express $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptors. All four adenosine receptors are expressed in the urothelium. A_1 receptors are prominently localized to the apical membrane of the umbrella cell layer, whereas A_{2A}, A_{2B}, and A_3 receptors are localized intracellularly or on the basolateral membrane of umbrella cells and the plasma membrane of the underlying cell layers. One function of these receptors is thought to be the modulation of exocytosis in umbrella cells.

Urethral smooth muscle cells have been shown to express $P2Y_1$, $P2Y_2$, $P2Y_4$, and $P2Y_6$ receptors, and functional $P2Y_1$ and $P2Y_2$ receptors have been identified mediating relaxation, together with a P2Y subtype responsive to α,β-methylene ATP and an uncharacterized P1 receptor. Urethral epithelial cells are known to express $P2X_5$, $P2X_6$, and $P2X_7$ receptors, with the $P2X_5$ receptor being involved in differentiation of stratified squamous epithelial cells of the terminal urethra.

Ureter

Multiple P2X receptor subtypes are expressed by the ureter, where ATP is involved in smooth muscle contraction and also nociception, following release of ATP in response to distension. A_{2B} receptors have been shown to be expressed in pig intravesical ureter.

Kidney

P2 receptors are widely expressed in the kidney, including most of the P2X and P2Y receptor subtypes currently known. Structures within the glomerulus, including mesangial cells, podocytes, and glomerular endothelial and epithelial cells, express predominantly $P2X_4$, $P2X_5$, $P2X_6$, $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptors. The descending and ascending limbs of the loop of Henle express predominantly $P2Y_1$, $P2Y_2$, and $P2Y_6$, whereas collecting ducts express multiple P2X and P2Y receptor subtypes.

All adenosine receptor subtypes are expressed in the cortex and medulla of the kidney to varying degrees, with differential expression on apical and basolateral surfaces such that proximal tubule

membranes express A_1, A_{2A}, and A_3 receptors, whereas basolateral membranes express A_1 and A_{2A} receptors.

Male Genital System

Functional $P2Y_1$ and $P2Y_2$ receptors have been shown to be present on penile corpus cavernosum, with ATP mediating relaxation of the cavernosum. $P2X_1$, $P2X_2$, and A_{2A} receptors are also expressed, which are believed to be involved in detumescence. Endothelial cells lining the lacunar space express $P2Y_1$ receptors.

In the excretory ducts (ductus epididymidis) of the testis, the dominant P2 receptors are $P2X_1$ and $P2X_2$ subtypes, expressed predominantly in the membranes of the smooth muscle layer, suggesting that these receptors are involved in the process of sperm transport and ejaculation. Sertoli cells express $P2X_4$, $P2X_7$, $P2Y_1$, and $P2Y_2$ receptors. The testes express high levels of A_3 receptors, and adenosine is thought to play an important role in regulating male reproduction. Seminiferous tubule myoid cells express multiple P2X receptor subtypes and $P2Y_2$ receptors. Similarly, multiple P2X receptor subtypes and A_1 receptors have been identified on sperm, and although functional P2X and P2Y receptors have been demonstrated, these remain uncharacterized.

Multiple P2X receptor subtypes are expressed in vas deferens smooth muscle, particularly $P2X_1$, $P2X_2$, $P2X_4$, and $P2X_7$, although functionally the smooth muscle receptor has been identified as being the $P2X_1$ subtype, mediating contraction of the vas deferens smooth muscle. The presence of a P2Y receptors, most likely of the $P2Y_2$ subtype, has also been suggested, although there is evidence for the presence of $P2Y_{12}$ and/or $P2Y_{13}$ receptors. Whereas A_1 receptors are expressed along the whole length of the rat vas deferens, the expression of A_2 receptors differs according to the portion of the vas deferens, with A_{2B} receptors being expressed by the prostatic portion and A_{2A} receptors by the epididymal portion.

In the epididymal epithelium and smooth muscle, $P2X_1$, $P2X_2$, $P2X_4$, $P2X_7$, $P2Y_1$, and $P2Y_2$ receptors are expressed. Functional A_{2A} receptors have been identified, but functional P2X and P2Y receptors are uncharacterized.

Smooth muscle $P2X_1$ and $P2Y_1$ receptors have been identified in the prostate, and $P2X_7$ receptors are expressed by prostate epithelial cells. The expression of $P2X_3$ receptors in interstitial connective tissue has been shown, probably associated with sensory nerves. Prejunctional A_1 receptors have been identified on prostatic smooth muscle, and A_1 and A_{2A} receptors have been identified on prostatic cell lines.

Female Genital System

Uterine smooth muscle expresses predominantly $P2X_2$ receptors when in a nonpregnant state, whereas both $P2X_1$ and $P2X_2$ receptors are expressed in pregnancy. In contrast, multiple P2X and P2Y receptors are expressed by both nonpregnant and pregnant uterine epithelium, particularly $P2Y_4$. Strong A_{2B} receptor expression has also been observed in the myometrium.

Axons in the cervix express $P2X_3$ receptors, presumed to be associated with sensory neurons, whereas cervical epithelium expresses $P2X_4$, $P2X_7$, and $P2Y_2$ receptors. Vaginal smooth muscle expresses $P2X_2$ and A_{2A} receptors, and vaginal epithelial cells, in common with cervical epithelium, express $P2Y_2$ receptors in addition to $P2X_5$ and $P2X_7$ receptors.

The ovary expresses $P2X_1$, $P2X_2$, and $P2Y_1$ receptor subtypes, with $P2X_2$ receptors being dominant in the nonpregnant state, switching to $P2X_1$ receptors during pregnancy. A_2 receptors have been identified in the ovary, but the subtype has not been fully characterized. Oviduct and fallopian tube epithelial cells have functional $P2Y_2$ receptors, and adenosine is known to inhibit noradrenaline release in human fallopian tubes, but the receptor subtype has not been characterized.

The placenta has a functional $P2Y_2$ receptor, although $P2Y_6$ and $P2Y_{11}$ receptors are also expressed. Multiple P2X receptor subtypes are expressed, but the $P2X_7$ receptor is dominant functionally. High- and low-affinity adenosine receptors have been described in the placenta, although these have not been fully characterized.

Cardiovascular System

Vascular Smooth Muscle

Vascular smooth muscle expresses multiple P2X and P2Y receptor subtypes, and this is true for both arteries and veins (Table 1). Although functionally the $P2X_1$ receptor subtype involved in vascular smooth muscle contraction is dominant, $P2Y_1$, $P2Y_2$, or $P2Y_4$ and $P2Y_6$ receptors have been shown to be functional. All the adenosine receptor subtypes are expressed and have functional effects, including prejunctional inhibition of neurotransmission via A_1 receptors on perivascular sympathetic nerves and vasodilatation via A_{2A} and A_{2B} receptors.

Vascular Endothelium

Similar to vascular smooth muscle, the endothelium expresses multiple P2X and P2Y receptor subtypes in addition to functional $P2Y_1$, $P2Y_2$ or $P2Y_4$, and $P2Y_6$

receptors. ATP and UTP are important vasodilators, but they also have roles in endothelial cell proliferation. Adenosine A_1 and A_{2A} receptors are expressed by endothelia cells mediating vasodilatation.

Heart

Expression of all of the P2X and P2Y receptor subtypes has been shown in the heart, although functionally $P2X_1$ and $P2Y_2$ receptors are dominant. In addition to the expression of adenosine receptors on the cardiac vasculature, all the adenosine receptor subtypes have been shown to be expressed in the heart, with functional effects ranging from cardioprotection to cardiac remodeling. In particular, A_1 receptors mediate cardiac depression, and A_1 and A_3 receptors have also been reported to mediate the protective effects of adenosine in preconditioning and during ischemia or reperfusion injury.

Erythrocytes

Erythrocytes express predominantly $P2X_7$ receptors and, at a much lower intensity, $P2X_2$ receptors, whereas erythroid progenitor cells also express $P2X_4$ and $P2Y_1$ receptors. From a functional standpoint, $P2X_7$ and $P2Y_2$ receptors are dominant.

Platelets and Megakaryocytes

Platelets express $P2X_1$ receptors, which are important in platelet activation, and $P2Y_1$ and $P2Y_{12}$ receptors, which are involved in ADP-induced platelet aggregation. In contrast, adenosine inhibits platelet aggregation via A_{2A} receptors.

Megakaryocytes express functional $P2X_1$, $P2Y_1$, $P2Y_2$, and $P2Y_{12}$ receptors. In contrast, megakaryocyte cell lines express multiple P2X and P2Y receptor subtypes, although only $P2Y_1$, $P2Y_2$, $P2Y_{11}$, and $P2Y_{12}$ subtypes have been found to be functional in addition to A_{2A} receptors.

Immune System

Immune Cells

Although multiple P2X and P2Y receptor subtypes are expressed in macrophages, neutrophils, eosinophils, dendritic cells, monocytes, lymphocytes, and hematopoietic cells, the dominant functional subtypes are $P2X_7$ receptors, involved in the formation of pores and cell death, and $P2Y_2$ receptors, involved in the release of inflammatory mediators. Similarly, all four adenosine receptor subtypes are expressed by immune cells, with the A_{2A} receptor being abundantly expressed; the A_3 receptor of eosinophils is thought to be involved in apoptosis.

Thymus

Multiple P2X receptor subtypes have been found to be expressed by both thymocytes and epithelial cells, but the $P2X_1$, $P2X_2$, and $P2X_7$ receptors are dominant, in addition to $P2Y_2$ receptors. Adenosine has been shown to induce apoptosis in immature thymocytes via adenosine A_{2A} receptors.

Spleen

The dominant P2 receptor subtypes expressed by the spleen are $P2X_1$, $P2Y_1$, $P2Y_2$, and $P2Y_{13}$, although functionally the dominant subtypes are $P2X_1$ and $P2Y_1$ receptors, in addition to A_1 and A_{2A} receptors.

Exocrine Glands

Pancreatic ducts express $P2X_1$, $P2X_4$, and $P2X_7$ receptors as well as $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptor subtypes. The dominant P2 receptor expressed by pancreatic epithelial and acini cells is of the $P2Y_2$ subtype, although functional A_{2A} receptors have also been shown. Eccrine sweat glands have functional $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptors, whereas the dominant receptors expressed by salivary glands are A_1, $P2X_4$, $P2X_7$, $P2Y_1$, and $P2Y_2$ receptors. The $P2X_7$ receptor is located on the luminal membrane, and the $P2Y_2$ receptor is typically situated on the basolateral membrane. Only the $P2Y_2$ receptor has been found to be expressed by lachrymal gland acinar cells.

Endocrine Glands

Endocrine Pancreas

Various P2 receptors have been found to be expressed in the pancreas, including $P2X_1$, $P2X_2$, $P2X_7$, $P2Y_1$, $P2Y_2$, and $P2Y_4$ subtypes, whereas functionally, $P2X_7$ and $P2Y_4$ are dominant on α cells, and $P2X_1$, $P2Y_1$, and $P2Y_2$ receptors are dominant on β cells. Adenosine acts on β cells to inhibit insulin secretion via an action on A_1 receptors.

Functional $P2Y_2$ receptors have been demonstrated on pancreatic epithelial cells, although $P2Y_1$ and $P2Y_4$ receptors are also expressed, in addition to $P2X_1$, $P2X_4$, and $P2X_7$ subtypes.

Adrenal Gland

All of the P2X receptor subtypes are expressed in adrenal tissues, although the dominant functional receptor is of the $P2X_2$ subtype, which modulates catecholamine and aldosterone secretion. The dominant functional P2Y receptor linked to steroidogenesis in bovine adrenocortical fasciculata cells is of the

$P2Y_2$ subtype. Bovine adrenal zona reticularis cells express at least three adenosine receptor subtypes – A_1, A_{2A}, and A_3 receptors – involved in the coordination of stress-induced secretion of corticosteroids and catecholamines from the adrenal gland.

Thyroid Gland

Thyroid follicle cells (cuboid epithelia) and thyroid epithelial cell lines express all of the P2X receptor subtypes with the exception of $P2X_1$ and $P2X_2$. $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, and $P2Y_{11}$ receptor subtypes are also expressed by thyrocytes, although $P2Y_2$ receptors are dominant functionally, involved in the modulation of cytokine release. Adenosine A_1 receptors have been found to be expressed by the thyroid cell line FRTL-5, which is believed to be involved in a regulatory feedback mechanism with thyroid-stimulating hormone receptors.

Pituitary Gland and Pineal Gland

The anterior pituitary expresses multiple P2X receptor subtypes, and this is reflected in the presence of multiple functional P2X receptors, with $P2X_2$ and $P2X_7$ receptors being dominant. In contrast, the $P2Y_2$ receptor is the only subtype identified, and it is involved in the release of luteinizing hormone. The posterior pituitary expresses $P2X_2$ and $P2X_6$ receptors, with the $P2X_2$ receptor being dominant functionally. The presence of functional A_1 and A_{2B} receptors in primary anterior pituitary cell cultures and in pituitary folliculostellate cell lines has been demonstrated, with the A_{2B} receptor being functionally dominant in the anterior pituitary. A_{2A} receptor gene expression has been reported to occur transiently during the embryological development of the anterior and intermediate lobes of the pituitary gland.

Only limited studies of the expression of P2 receptors have been carried out on the pineal gland, and only the expression of $P2Y_1$, $P2Y_2$, and $P2Y_4$ receptors has been demonstrated. It has been suggested that $P2Y_1$ receptors present in rat pinealocytes mediate the potentiation of noradrenaline-induced *N′*-acetyl-5-hydroxytryptamine production (the precursor of melatonin), whereas one of the functions of $P2Y_2$ receptors on the pineal gland is the selective inhibition of β-adrenergic receptor-mediated signaling pathways. ATP is thought to be a cotransmitter with noradrenaline, acting on an uncharacterized P2X receptor (although probably $P2X_1$) to stimulate *N′*-acetyl-5-hydroxytryptamine and melatonin release. In contrast, all of the adenosine receptor subtypes have been identified in pinealocytes, and a role for adenosine in the regulation of melatonin synthesis has been postulated, with the A_{2B} receptor being dominant.

Endocrine Ovary

Granulosa–luteal cells express functional $P2Y_2$ receptors, whereas granulosa cells express functional $P2Y_1$ and $P2Y_2$ receptors. There is no evidence for the expression of P2X receptors. Adenosine has been shown to enhance gonadotropin stimulation in granulosa and luteal cells; this effect has been found to be via an A_2 receptor, although the exact subtype has not been identified.

Special Senses

Inner Ear

Structures within the inner ear express multiple P2X receptor subtypes. The cochlear hair cells express $P2X_1$, $P2X_2$, $P2X_3$, and $P2X_7$ receptors, with the $P2X_2$ receptor being dominant functionally. However, $P2X_3$ receptors are believed to be important in cochlear synaptic reorganization and establishment of neurotransmission, which occurs just prior to the onset of hearing function.

The dominant receptor subtypes expressed by epithelial cells of the inner ear are of the $P2X_2$ subtype, whereas for vestibular dark cells, the dominant receptors are $P2Y_2$ and $P2Y_4$ receptors. Both Hensen and Deiters' cells of the organ of Corti express $P2X_2$ receptors involved in the regulation of ion and H_2O balance of cochlear fluid and purinergic modulation of cochlear micromechanisms, respectively.

A_1 receptors have been identified in the cochlear, where they are thought to have a protective effect.

Eye

Structures within the retina have been shown to express multiple P2X and P2Y receptor subtypes, although little is known about the functional role of these receptors in retinal signaling. $P2X_7$ receptors expressed by the inner and outer plexiform layers have been shown to have a significant role in neurotransmission within the retina and may modulate both photoreceptor and rod bipolar cell responses. $P2X_2$ receptors expressed by large ganglion cells as well as in a subset of amacrine cells may be involved in neuronal signaling in the retina, particularly within cone pathways. Activation of $P2Y_2$ receptors stimulates retinal pigment epithelium active transport. $P2Y_2$ receptors are dominant in the ciliary body, where they are involved in the regulation of aqueous humour secretion. Adenosine receptors are also expressed by structures of the eye. Adenosine, via A_1 receptors, has been shown to protect cultured retinal neurons against *N*-methyl-D-aspartate-induced cell death. Photoreceptors express a functional A_2-like

adenosine receptor, involved in the inhibition of L-glutamate release from rod photoreceptors. Ganglion cells have been shown to express A_1 and A_3 receptors, which are believed to be involved in protection from ischemic injury.

Tongue

The expression of $P2X_2$ and $P2X_3$ receptor subtypes has been shown on the nerve fibers innervating taste buds. The $P2X_2$ receptor is probably associated with taste sensation, whereas the $P2X_3$ receptor may play a role in nociception. $P2Y_1$ receptor expression has been detected in a subset of taste bud cells, where they may play a role in ATP-mediated signal transduction between taste bud cells and afferent taste fibers. The presence of an A_1 adenosine receptor has been suggested, which is believed to be important in the modulation of taste perception.

Olfactory Organ

The dominant P2 receptors expressed by the olfactory bulb are $P2X_2$, $P2X_4$, $P2Y_1$, and $P2Y_2$ receptors. Although functional P2X and P2Y receptors have been identified in olfactory receptor neurons, the subtypes have not been characterized. Adenosine A_{2A} and A_3 receptors have been identified in the olfactory bulb, but their exact roles in olfaction are unknown.

Conclusion

This article provided an overview of the distribution of P1 and P2 receptors on autonomic neurons and neuroeffector cells. It should be stressed that this distribution is extensive, with most systems in the body expressing multiple receptor subtypes, having diverse effects such as vasoconstriction, platelet aggregation, nociception, and apoptosis. This article concentrated on the distribution of P1 and P2 receptors in mammalian tissues; however, there is increasing evidence that purinergic signaling is a very primitive system. Evidence has shown that receptors for ATP and adenosine are expressed in animals from primitive phyla such as protozoa (in which ATP inhibits amoeboid movement), mollusks (in which adenosine modulates an excitatory acetylcholine response of *Helix aspersa* subesophageal neurons), and insects (in which ATP stimulates the gorging response of mosquitoes) to lower vertebrates (in which ATP constricts and adenosine dilates the frog aorta). Although there are similarities between these more primitive receptors and those of mammalian receptors, there are many differences, and until these primitive receptors are cloned, a full characterization remains difficult. The first such cloning and characterization of a nonvertebrate ATP-gated ion channel has been carried out for the parasitic blood fluke *Schistosoma mansoni*, which has been characterized as $P2X_4$-like. The field is wide open to the characterization of many more nonmammalian receptors.

A final feature of purinergic signaling that should be noted is the expression of multiple receptor subtypes on single cells. Why are so many different receptor subtypes necessary? A review has attempted to put forward a theory as to why multiple P2 receptors are expressed by cells. It suggests that P2 receptor signaling is an example of increased receptor complexity, either because newly synthesized P2 receptor proteins are casually located on the cell surface or because distinct subunits are expressed by different cell phenotypes determined by genetic control and/or there is selective recruitment under pathophysiological conditions. The idea behind this concept is that the presence of multiple receptor subtypes allows a 'fine-tuning' of the response. Although this idea requires further investigation, it does open a new area of research into purinergic signaling.

Early Studies

A seminal paper describing the potent actions of adenine compounds was published by Drury and Szent-Györgyi in 1929. Many years later, ATP was proposed as the transmitter responsible for nonadrenergic, noncholinergic transmission in the gut and bladder, and the term 'purinergic' was introduced by Burnstock in 1972. Early resistance to this concept appeared to stem from the fact that ATP was recognized first for its important intracellular roles in many biochemical processes, and the intuitive feeling was that such a ubiquitous and simple compound was unlikely to be utilized as an extracellular messenger, although powerful extracellular enzymes involved in its breakdown were known to be present.

Implicit in the concept of purinergic neurotransmission was the existence of postjunctional purinergic receptors, and the potent actions of extracellular ATP on many different cell types also implicated membrane receptors. Purinergic receptors were first defined in 1976, and 2 years later a basis for distinguishing two types of purinoceptor, identified as P1 and P2 (for adenosine and ATP/ADP, respectively), was proposed. At about the same time, two subtypes of the P1 (adenosine) receptor were recognized, but it was not until 1985 that a pharmacological basis for distinguishing two types of P2 receptor (P2X and P2Y) was made. In 1993, the first G-protein-coupled P2 receptors were cloned and a year later two ion-gated receptors were cloned, and in 1994 Abbracchio and Burnstock, on the basis of molecular structure and transduction mechanisms, proposed that purinoceptors should belong to two major families: a P2X family of ligand-gated ion channel receptors and a P2Y family of G-protein-coupled purinoceptors. This nomenclature has been widely adopted and currently seven P2X subtypes and eight P2Y receptor subtypes are recognized, including receptors that are sensitive to pyrimidines as well as purines.

It is widely recognized that purinergic signaling is a primitive system involved in many nonneuronal as well as neuronal mechanisms, including exocrine and endocrine secretion, immune responses, inflammation, pain, platelet aggregation, and endothelial-mediated vasodilatation. Cell proliferation, differentiation, and death that occur in development and regeneration are also mediated by purinergic receptors.

P1 Receptors

Four different P1 receptor subtypes, A_1, A_{2A}, A_{2B}, and A_3, have been cloned. All are G-protein-coupled receptors (GPCRs). At 318 amino acids in length, the A_3 subtype is the shortest, while A_{2A} is the longest (412 residues). Their N-termini are relatively short (7–13 residues in length), as are their C-termini (32–120 residues). In the transmembrane domains (TMI–TMVII), human adenosine receptors share 39–61% sequence identity with each other and 11–18% identity with P2Y receptors. Each of the four human P1 receptor genes contains an intron within the coding region, located immediately after the end of the third transmembrane domain (see Figure 1(a)).

P1 receptors couple principally to adenylate cyclase. A_1 and A_3 are negatively coupled to adenylate cyclase through the $G_{i/o}$ protein α subunits, whereas A_{2A} and A_{2B} are positively coupled to adenylate cyclase through G_s. The human A_{2B} receptor has also been observed to couple through $G_{q/11}$ to regulate phospholipase C activity, and the A_3 receptor may interact directly with G_s.

A number of P1 subtype-selective agonists and antagonists have been identified (see Table 1). Alteration or opening of the ribose ring drastically reduces affinity. The hydroxyl group at the 2′ position is needed for both affinity and activity. The most selective agonist for the A_1 subtype is 2-chloro-N^6-cyclopentyladenosine (CCPA). CGS 21680 is the most selective A_{2A} agonist; NECA is the most potent A_{2B} receptor agonist. 2-Cl-IB-MECA is 11-fold selective for the human A_3 receptor and about 1400-fold selective for the rat A_3 receptor. In general, methylxanthines such as caffeine and theophylline are weak P1 receptor antagonists. DPCPX (8-cyclopentyl-1,3-dipropylxanthine) is an A_1 receptor antagonist with subnanomolar affinity. The most selective A_{2B} receptor antagonist is MRS1754. MRE3008-F20 is the most selective human A_3 receptor antagonist. The diverse physiological effects mediated by the different P1 receptor subtypes, particularly modulation of the cardiovascular, immune, and central nervous systems, have been confirmed by transgenic knockout mice for A_1, A_{2A}, and A_3 receptors. In contrast to knockout studies, overexpression of either A_1 or A_3 subtypes in transgenic mice has a cardioprotective effect.

Figure 1 Membrane receptors for extracellular ATP and adenosine. The P1 family of receptors for extracellular adenosine comprises G-protein-coupled receptors signaling by inhibiting or activating adenylate cyclase (a). The P2 family of receptors binds extracellular ATP or ADP, and comprises two types of receptors (P2X and P2Y). The P2X family receptors are ligand-gated ion channels (b), and the P2Y family members are GPCRs (c). P2X Receptors

Molecular Structure

The first cDNAs encoding P2X receptor subunits were isolated in 1994. Members of the family of ionotropic $P2X_{1-7}$ receptors show a subunit topology of intracellular N- and C-termini possessing consensus binding motifs for protein kinases; two transmembrane-spanning regions (TM1 and TM2), the first involved with channel gating and the second lining the ion pore; a large extracellular loop, with ten conserved cysteine residues forming a series of disulfide bridges; a hydrophobic H5 region close to the pore vestibule, for possible receptor/channel modulation by cations; and an ATP-binding site, which may involve regions of the extracellular loop adjacent

Table 1 Characteristics of purine-mediated receptors

Receptor	*Main distribution*	*Agonists*	*Antagonists*	*Transduction mechanisms*
P1 (adenosine)				
A_1	Brain, spinal cord, testis, heart, autonomic nerve terminals	CCPA, CPA, S-ENBA	DPCPX, N-0840, MRS1754	$G_{i/o}$ ↓cAMP
A_{2A}	Brain, heart, lungs, spleen	CGS 21680, HENECA	KF17837, SCH58261, ZM241385	G_S ↑cAMP
A_{2B}	Large intestine, bladder	NECA (nonselective)	Enprofylline, MRE2029-F20, MRS1754, MRS1706	G_S ↑cAMP
A_3	Lung, liver, brain, testis, heart	IB-MECA, 2-Cl-IB-MECA, DBXRM, VT160	MRS1220, L-268605, MRS1191, MRS1523, VUF8504	$G_{i/o}$ $G_{q/11}$ ↓cAMP ↑IP_3
P2X				
$P2X_1$	Smooth muscle, platelets, cerebellum, dorsal horn spinal neurons	α,β-meATP = ATP = 2-MeSATP (rapid desensitization), L-β,γ-meATP	TNP-ATP, IP_5I, NF023, NF449	Intrinsic cation channel (Ca^{2+} and Na^+)
$P2X_2$	Smooth muscle, CNS, retina, chromaffin cells, autonomic and sensory ganglia	ATP ≥ ATPγS ≥ 2-MeSATP ≫ α,β-meATP (pH + zinc sensitive)	Suramin, isoPPADS, RB2, NF770	Intrinsic ion channel (particularly Ca^{2+})
$P2X_3$	Sensory neurons, NTS, some sympathetic neurons	2-MeSATP ≥ ATP ≥ α,β-meATP ≥ Ap_4A (rapid desensitization)	TNP-ATP, PPADS, A317491, NF110	Intrinsic cation channel
$P2X_4$	CNS, testis, colon	ATP ≫ α,β-meATP, CTP, ivermectin	TNP-ATP (weak), BBG (weak)	Intrinsic ion channel (especially Ca^{2+})
$P2X_5$	Proliferating cells in skin, gut, bladder, thymus, spinal cord	ATP ≫ α,β-meATP, ATPγS	Suramin, PPADS, BBG	Intrinsic ion channel
$P2X_6$	CNS, motor neurons in spinal cord	(Does not function as homomultimer)		Intrinsic ion channel
$P2X_7$	Apoptotic cells in, for example, immune cells, pancreas, skin	BzATP > ATP ≥ 2-MeSATP ≫ α,β-meATP	KN62, KN04, MRS2427, Coomassie brilliant blue G	Intrinsic cation channel and a large pore with prolonged activation
P2Y				
$P2Y_1$	Epithelial and endothelial cells, platelets, immune cells, osteoclasts	2-MeSADP = ADPβS > 2-MeSATP = ADP > ATP, MRS2365	MRS2179, MRS2500, MRS2279, PIT	G_q/G_{11}; PLC-β activation
$P2Y_2$	Immune cells, epithelial and endothelial cells, kidney tubules, osteoblasts	UTP = ATP, UTPγS, INS37217	Suramin > RB2, AR-C126313	G_q/G_{11} and possibly G_i; PLC-β activation
$P2Y_4$	Endothelial cells	UTP ≥ ATP, UTPγS	RB2 > suramin	G_q/G_{11} and possibly G_i; PLC-β activation
$P2Y_6$	Some epithelial cells, placenta, T cells, thymus	UDP > UTP ≫ ATP, UDPβS	MRS2578	G_q/G_{11}; PLC-β activation
$P2Y_{11}$	Spleen, intestine, granulocytes	AR-C67085MX > BzATP ≥ ATPγS > ATP	Suramin > RB2, NF157, 5′-AMPS	G_q/G_{11} and G_S; PLC-β activation
$P2Y_{12}$	Platelets, glial cells	2-MeSADP ≥ ADP ≫ ATP	CT50547, AR-C69931MX, INS49266, AZD6140, PSB0413, ARL66096, 2-MeSAMP	$G_{i/o}$; inhibition of adenylate cyclase
$P2Y_{13}$	Spleen, brain, lymph nodes, bone marrow	ADP = 2-MeSADP ≫ ATP and 2-MeSATP	MRS2211, 2-MeSAMP	$G_{i/o}$
$P2Y_{14}$	Placenta, adipose tissue, stomach, intestine, discrete brain regions	UDP glucose = UDP-galactose		G_q/G_{11}

BBG, brilliant blue green; BzATP, 2′- and 3′-*O*-(4-benzoyl-benzoyl)-ATP; cAMP, cyclic AMP; CCPA, chlorocyclopentyl adenosine; CPA, cyclopentyl adenosine; CTP, cytosine triphosphate; IP_3, inosine triphosphate; IP_5I, diinosine pentaphosphate; 2-MeSADP, 2-methylthio-ADP; 2-MeSATP, 2-methylthio-ATP; NECA, 5'-*N*-ethylcarboxamido adenosine; NTS, nucleus tractus solitarius; PLC, phospholipase C; RB2, reactive blue 2.

P2X$_3$			+		+		
P2X$_4$				+	+	+	
P2X$_5$					+	+	
P2X$_6$							
P2X$_7$							+

[a]P2X receptor subunits carrying either one of two epitope tag units were expressed in pairs of HEK293 cells. +, Subunits immunoprecipitated with antibody to one epitope could be detected with an antibody to the second epitope.
Reproduced from Torres GE, Egan TM, and Voigt MM (1999) Hetero-oligomeric assembly of P2X receptor subunits. Specificities exist with regard to possible partners. *Journal of Biological Chemistry* 274: 6653–6659, with permission from the American Society for Biochemistry and Molecular Biology.

Table 3 Chromosomal localization of human P2X receptors[a]

Subunit	*Chromosome*	*Accession number*
P2X$_1$	17p13.2	X83688
P2X$_2$		AF190826
P2X$_3$	11q12	Y07683
P2X$_4$	12q24.31	Y07684
P2X$_5$	17p13.3	AF016709
P2X$_6$	22q11	AB002059
P2X$_7$	12q24.31	Y09561

[a]Accession numbers are those for the original submission of cDNA sequences. Chromosomal localizations are from human genome databases. P2X$_2$ chromosomal location is not yet determined. The mouse gene is located on chromosome 5, in a region that is syntenic with the extreme end of the long arm of human chromosome 12 (some 6 MB from the P2X$_4$ and P2X$_7$ genes).
Reproduced from North RA (2002) Molecular physiology of P2X receptors. *Physiological Reviews* 82: 1013–1067, with permission from the American Physiological Society.

to TM1 and TM2 (see Figure 1(b)). The P2X$_{1-7}$ receptors show 30–50% sequence identity at the peptide level. The stoichiometry of P2X$_{1-7}$ receptors is thought to involve three subunits, which form a stretched trimer or a hexamer of conjoined trimers. All of the P2X receptor subunits have consensus sequences for N-linked glycosylation.

The pharmacology of the recombinant P2X receptor subtypes expressed in oocytes or other cell types is often different from the pharmacology of P2X-mediated responses in naturally occurring sites. Several contributing factors may account for these differences. First, heteromultimers as well as homomultimers are involved in forming the trimer ion pore. P2X$_{2/3}$, P2X$_{1/2}$, P2X$_{1/5}$, P2X$_{2/6}$, P2X$_{4/6}$, and P2X$_{1/4}$ receptor heteromultimers have been identified (Table 2). P2X$_7$ does not form heteromultimers, and P2X$_6$ will not form a functional homomultimer. Second, spliced variants of P2X receptor subtypes might play a part.

There are seven genes for P2X receptor subunits. P2X$_4$ and P2X$_7$ subunit genes are located close to the tip of the long arm of chromosome 12. P2X$_4$ and P2X$_7$ subunits are among the most closely related pairs in amino acid sequences. P2X$_1$ and P2X$_5$ genes are also very close together on the short arm of chromosome 13. The remaining genes are on different chromosomes (Table 3). The genes vary considerably in size (e.g., mP2X$_3$ = 40 kb; hP2X$_6$ = 12 kb). The full-length forms have 11–13 exons, and all share a common structure, with well-conserved intron/exon boundaries. Many spliced forms of the receptor subunits (or fragments) have been described. Several full-length nonmammalian vertebrate sequences have been identified. There are no reports of homologous sequences from invertebrate species, although there is considerable functional evidence that extracellular ATP and other nucleotides can directly gate ion channels in invertebrates.

Recent advances have been made by the preparation of knockout mice for P2X$_1$, P2X$_2$, P2X$_3$, P2X$_4$, and P2X$_7$ receptors, and transgenic mice that overexpress the P2X$_1$ receptor.

P2X Receptor Subtypes

P2X$_1$ receptors A cDNA encoding the P2X$_1$ receptor was isolated by direct expression in *Xenopus* oocytes, beginning with a cDNA library made from rat vas deferens. Human and mouse cDNAs have also been cloned and expressed. The homomeric P2X$_1$ receptor is a cation-selective channel that shows little selectivity for sodium over potassium. It has a relatively high permeability to calcium.

A major property of the P2X$_1$ receptor is the mimicry of the agonist actions of ATP by α,β-methylene ATP (α,β-meATP), which distinguishes P2X$_1$ and P2X$_3$ receptors from the other homomeric forms. 2′,3′-O-(benzoyl-4-benzoyl)-ATP (BzATP) is also an effective agonist. P2X$_1$ receptors are blocked by suramin and pyridoxal-phosphate-6-azophenyl-2′,4′-disulfonic acid (PPADS), but there are newer antagonists that are more P2X$_1$-selective (see Table 1). A valuable antagonist at P2X$_1$ receptors is 2′,3′-O-(2,4,6-trinitrophenyl)-ATP (TNP-ATP), which has an IC$_{50}$ of about 1 nM.

Desensitization means the decline in the current elicited by ATP during the continued presence of ATP. In some P2X receptors this decline occurs in milliseconds (fast desensitization: P2X$_1$, P2X$_3$), and in others it occurs 100–1000 times more slowly (slow desensitization: P2X$_2$, P2X$_4$). Recovery from desensitization is extremely slow. Treatment with

apyrase allows $P2X_1$ receptors to recover from desensitization. Adenoviral expression of a $P2X_1$ receptor–green fluorescent protein construct in vas deferens shows the receptor to be localized in clusters, with larger ones apposing nerve varicosities.

$P2X_2$ receptors The rat $P2X_2$ receptor cDNA was isolated from a library constructed from nerve growth factor (NGF)-differentiated PC12 cells by testing pools for functional expression in *Xenopus* oocytes. The human receptor cDNA was amplified from pituitary gland. There are no agonists currently known that are selective for $P2X_2$ receptors. However, $P2X_2$ receptors are potentiated by protons and by low concentrations of zinc and copper. There are no selective antagonists for $P2X_2$ receptors. The $P2X_2$ receptor is generally described as nondesensitizing, compared with the $P2X_1$ and $P2X_3$ receptors.

When oocytes are injected with RNAs encoding $P2X_2$ receptors, and also the $\alpha3$ and $\beta4$ subunits of nicotinic receptors, they show responses to both ATP and acetylcholine; these can be selectively antagonized with appropriate receptor blockers. However, with concomitant application of both agonists, the resultant current is less than the expected sum of the two independent currents, indicating an interaction between the two receptors.

Heteromeric $P2X_{1/2}$ receptors $P2X_1$ and $P2X_2$ receptor subunits have been co-expressed in defolliculated *Xenopus* oocytes and the resultant receptors were studied under voltage clamp conditions. Co-expression yielded a mixed population of homomeric and heteromeric receptors, with a subpopulation of novel pH-sensitive P2X receptors showing identifiably unique properties that indicate the formation of heteromeric $P2X_{1/2}$ ion channels. It has been claimed that trimeric $P2X_{1/2}$ receptors incorporate one $P2X_1$ and two $P2X_2$ subunits.

$P2X_3$ receptors $P2X_3$ receptor subunit cDNAs were isolated from rat dorsal root ganglion cDNA libraries, from a human heart cDNA library, and from a zebra fish library. The mimicry of ATP by α,β-meATP makes these receptors similar to $P2X_1$ and distinct from the other homomeric forms. 2-MethylthioATP is as potent as or more potent than ATP at $P2X_3$ receptors. The antagonists suramin, PPADS, and TNP-ATP do not readily distinguish between $P2X_1$ and $P2X_3$ receptors, but NF023 is about 20 times less effective at $P2X_3$ than at $P2X_1$ receptors. Similar to $P2X_1$ receptors, desensitization is fast and recovery is very slow. $P2X_3$ receptors are prominently expressed on nociceptive sensory neurons.

Heteromeric $P2X_{2/3}$ receptors Direct association between $P2X_2$ and $P2X_3$ receptor subunits has been shown by co-immunoprecipitation. $P2X_{2/3}$ heteromeric channels can be defined on the basis of a sustained current elicited by α,β-meATP. $P2X_{2/3}$ receptor channels and, like homomeric $P2X_2$ receptors, are potentiated by low pH, and do not desensitize rapidly. The $P2X_{2/3}$ heteromer, like the homomeric $P2X_3$ receptor, is blocked by TNP-ATP, as well as PPADS and suramin. IP_5I is much more potent for blocking $P2X_1$ and $P2X_3$ homomers than for blocking the $P2X_{2/3}$ heteromers and is therefore useful to distinguish between $P2X_3$ and $P2X_{2/3}$ receptors. $P2X_{2/3}$ receptors have been identified in subpopulations of sensory neurons, sympathetic ganglion cells, and brain neurons.

$P2X_4$ receptors cDNAs for the rat $P2X_4$ receptor were isolated independently from superior cervical ganglion, brain, hippocampus, and pancreatic islet cells. Human, mouse, chick, and *Xenopus* cDNAs have also been isolated. Homomeric $P2X_4$ receptors are activated by ATP, but not by α,β-meATP. The most useful distinguishing feature of ATP-evoked currents at $P2X_4$ receptors is their potentiation by ivermectin.

When the application of ATP is of short duration, $P2X_4$ receptors operate as cation-selective channels; the calcium permeability is relatively high. When the application of ATP is continued for several seconds, the $P2X_4$ receptor channel becomes increasingly permeable to larger organic cations such as *N*-methyl-D-glucamine (NMDG). Desensitization at $P2X_4$ receptors is intermediate between that observed at $P2X_1$ and $P2X_2$.

The rat $P2X_4$ receptor is unusual among the P2X receptors in its relative insensitivity to blockade by the conventional antagonists suramin and PPADS. Currents evoked by ATP at the mouse $P2X_4$ receptor are actually increased by PPADS and suramin, probably because of their ectonucleotidase inhibitory activity.

Heteromeric $P2X_{1/4}$ receptors Co-injection of $P2X_1$ and $P2X_4$ subunits into *Xenopus* oocytes showed that both subunits were present in trimeric complexes of the same size. Voltage clamp experiments revealed functional P2X receptors with kinetic properties resembling those of homomeric $P2X_4$ receptors and a pharmacological profile similar to that of homomeric $P2X_1$ receptors. Preliminary results show that the $P2X_1$ receptor from the vas deferens and the $P2X_4$ receptor from salivary gland form complexes of the same size as the recombinant trimeric complexes expressed in oocytes.

$P2X_5$ receptors The $P2X_5$ receptor cDNA was first isolated from cDNA libraries constructed from rat celiac ganglion and heart. A P2X receptor was also cloned from embryonic chick skeletal muscle. The only human cDNAs reported are missing exon 10 ($hP2X_{5a}$) or exons 3 and 10 ($hP2X_{5b}$).

A feature of the currents elicited by ATP in cells expressing the rat $P2X_5$ receptor is their small amplitude, compared with the currents observed with $P2X_1$, $P2X_2$, $P2X_3$, or $P2X_4$ receptors expressed under similar conditions. The currents otherwise resemble those seen at $P2X_2$ receptors: they show little desensitization, are not activated by α,β-meATP, and are blocked by suramin and PPADS. $P2X_5$ mRNA is highly expressed in developing skeletal muscle.

Heteromeric $P2X_{1/5}$ receptors $P2X_1$ and $P2X_5$ subunits can be co-immunoprecipitated and the defining phenotype of this heteromer is a sustained current evoked by α,β-meATP, which is not seen for either of the homomers when expressed separately. Cells expressing the heteromeric receptor are very sensitive to ATP, concentrations as low as 3 or 10 nM evoking measurable currents. The sensitivity to the antagonist TNP-ATP is intermediate between the sensitive homomeric $P2X_1$ receptor and the insensitive homomeric $P2X_5$ receptor.

$P2X_6$ receptors The rat $P2X_6$ receptor was cloned from superior cervical ganglion cDNA and from rat brain. The human equivalent was isolated from peripheral lymphocytes as a p53-inducible gene. This was originally designated P2XM to reflect its abundance in human and mouse skeletal muscle. The $P2X_6$ receptor appears to be a 'silent' subunit, in the sense that no currents are evoked by ATP when it is expressed as a homomultimer in oocytes or HEK293 cells. It appears that the $P2X_6$ subunit is only functionally expressed as a heteromultimer.

Heteromeric $P2X_{2/6}$ receptors $P2X_2$ and $P2X_6$ receptors have been found to co-immunoprecipitate after expression in HEK293 cells. Oocytes expressing this combination have subtly different responses to ATP as compared to oocytes expressing only $P2X_2$ receptors. The most convincing of these differences is the fact that at pH 6.5 the inhibition of the current by suramin is clearly biphasic; one component has the high sensitivity of homomeric $P2X_2$ receptors, whereas the other component is less sensitive. $P2X_{2/6}$ receptors are prominently expressed by respiratory neurons in the brain stem.

Heteromeric $P2X_{4/6}$ receptors $P2X_4$ and $P2X_6$ receptors form a heteromeric channel when co-expressed in oocytes. The subunits can be co-immunoprecipitated from oocytes and HEK293 cells. The principal functional evidence for co-expression is that currents elicited by ATP are larger in oocytes 5 days after injection of mRNAs for $P2X_4$ and $P2X_6$ than after injection of $P2X_4$ alone. However, the phenotype of the heteromer differs only in minor respects from that of $P2X_4$ homomers. $P2X_{4/6}$ receptors are prominent in adult trigeminal mesencephalic nucleus and in hippocampal CA1 neurons.

$P2X_7$ receptors A chimeric cDNA encoding the rat $P2X_7$ receptor was first constructed from overlapping fragments isolated from superior cervical ganglion and medial habenula; full-length cDNAs were subsequently isolated from a rat brain cDNA library. Human and mouse cDNAs were cloned from monocyte and microglial cells, respectively. The main feature of the $P2X_7$ receptor is that in addition to the usual rapid opening of the cation-selective ion channel, with prolonged exposure to high concentrations of ATP it becomes permeable to larger cations (e.g., NMDG) and later undergoes a channel-to-pore conversion to allow the passage of large dye molecules such as ethidium and YO-PRO-1, and this usually leads to cell death. Evidence for $P2X_7$ receptor activation includes inward currents and increase in $[Ca^{2+}]_i$; other end points involve uptake of YO-PRO-1 or similar fluorescent dyes which bind to nucleic acid, and structural changes in the cell, such as membrane blebbing.

BzATP is a potent agonist at the $P2X_7$ receptor. There are five main types of blockers (see Table 1): ions (calcium, magnesium, zinc, copper, and protons), the suramin analog NF279, Coomassie brilliant blue G (which is most effective at rat $P2X_7$ receptors), oxidized ATP, and KN62, which is selective for the human $P2X_7$ receptor.

ATP or BzATP induces remarkable changes in the appearance of HEK293 cells transfected with the rat $P2X_7$ receptor. After continuous application of BzATP (30 μM) for about 30 s, the plasma membrane begins to develop large blebs, and after 1 or 2 min, these become multiple and sometimes coalesce. Blebs are usually preceded by the appearance of smaller vesicles (<1 μm in diameter), which are shed from the cell and appear to release inflammatory cytokines.

P2Y Receptors

Molecular Structure

The first P2Y receptors were cloned in 1993. Since then several other subtypes have been isolated by homology cloning and are assigned a subscript on the basis of cloning chronology ($P2Y_4$, $P2Y_6$, $P2Y_{11}$). The long-awaited G_i-coupled ADP receptor ($P2Y_{12}$) of platelets was finally isolated by expression

cloning in 2001, while $P2Y_{13}$ and $P2Y_{14}$ receptors were characterized later during a systematic study of orphan receptors. At present, there are eight accepted human P2Y receptors: $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{11}$, $P2Y_{12}$, $P2Y_{13}$, and $P2Y_{14}$ (see Table 1). The missing numbers represent either nonmammalian orthologs, or receptors having some sequence homology to P2Y receptors, but for which there is no functional evidence of responsiveness to nucleotides. p2y3 may be a chicken ortholog of $P2Y_6$, while p2y8 and tp2y could be the *Xenopus* and turkey orthologs of $P2Y_4$, respectively. p2y7 is a leukotriene B4 receptor. p2y5 and p2y10 are considered as orphan receptors. A p2y8 receptor cloned from the frog embryo appears to be involved in the development of the neural plate. p2y9 was reported to be a novel receptor for lysophosphatidic acid, distant from the Edg family. $P2Y_{15}$ was recently introduced to designate the orphan receptor GPR80/GPR99 on the basis that it would be a receptor for adenosine 5′-monophospahte (AMP), but it is now firmly established that it is not a P2Y receptor, but rather a receptor for α-ketoglutarate, as recently underlined in a report by the International Union of Basic and Clinical Pharmacology (IUPHAR) P2Y Subcommittee.

In contrast to P2X receptors, P2Y receptor genes do not contain introns in the coding sequence, except for the $P2Y_{11}$ receptor. Site-directed mutagenesis of the $P2Y_1$ and $P2Y_2$ receptors has shown that some positively charged residues in TM3, TM6, and TM7 (see Figure 1(c)) are crucial for receptor activation by nucleotides. From a phylogenetic and structural (i.e., protein sequence) point of view, two distinct P2Y receptor subgroups characterized by a relatively high level of sequence divergence have been identified. The first subgroup includes $P2Y_{1,2,4,6,11}$ subtypes and the second subgroup encompasses the $P2Y_{12,13,14}$ subtypes (see dendrogram in Figure 2).

Most of the P2Y receptor subtypes are still lacking potent and selective synthetic agonists and antagonists. However, ADPβS is a potent agonist of $P2Y_1$, $P2Y_{12}$, and $P2Y_{13}$ receptors. 2-Methylthio-ADP (2-MeSADP) is a potent agonist (EC_{50}, in nM) at $P2Y_1$, $P2Y_{12}$, and $P2Y_{13}$ receptors. Selective antagonists have been identified for some P2Y receptor subtypes (see Table 1). P2Y receptor-mediated responses occur in nonneuronal and nonmuscular cell types, as well as in the nervous system, involved in both short- and long-term signaling.

Second Messenger Systems and Ion Channels

$P2Y_1$, $P2Y_2$, $P2Y_4$, and $P2Y_6$ receptors couple to G-proteins to increase inositol trisphosphate (IP_3) and cytosolic calcium. Activation of the $P2Y_{11}$ receptor by ATP leads to a rise in both cAMP and in IP_3, whereas activation by uridine 5′-triphosphate (UTP) produces calcium mobilization without IP_3 or cAMP increase. The $P2Y_{13}$ receptor can simultaneously couple to G_{16}, G_i, and, at high concentrations of ADP, G_s. The activation of several P2Y receptors is commonly associated with the stimulation of several mitogen-activated protein (MAP) kinases, in particular extracellular signal-regulated protein kinase-1/2.

In recent years, GPCRs in neurons and other excitable cells have been found to modulate the activity of voltage-gated ion channels in the cell membrane through certain actions of activated G-proteins. Such actions are now well established in closing (or, in certain cases, in opening or potentiating) various classes of K^+ channels and voltage-gated Ca^{2+} channels. ATP (or UTP, or their products ADP or UDP) present at synapses, plus ATP diffusing from astrocytes, activates P2Y receptors on distinct subsets of brain neurons, regulating their activities by the coupling of those receptors to specific ion channels. While ion channel couplings of P2Y receptors are primarily of importance in neurons, they have in a few cases been detected also in various other tissues (e.g., in cardiac muscle cells). Among the channels with which the superior cervical ganglion cell membrane is well endowed are two types of voltage-gated channels, which are important in receptor-based regulation of neuronal activity, the Ca^{2+} channel of the N-type and the M-current K^+ channel.

P2Y Receptor Subtypes

$P2Y_1$ receptors Human, rat, mouse, cow, chick, turkey, and *Xenopus* $P2Y_1$ receptors have been cloned and characterized. In most species, ADP is a more potent agonist than ATP is and their 2-methylthio derivatives are even more potent. UTP, UDP, CTP, and GTP are inactive. At present, the most potent and selective agonist known is the *N*-methanocarba analog of 2-MeSADP, MRS2365 (EC_{50} of 0.4 nM). The most effective antagonists to display selectivity for the $P2Y_1$ receptor are MRS2179, MRS2279, and MRS2500 (see Table 1).

Site-directed mutagenesis studies on the human $P2Y_1$ receptor have shown that amino acid residues in TM3, TM6, and TM7 are critical determinants in the binding of ATP. Four cysteine residues in the extracellular loops, which are conserved in P2Y receptors, are essential for proper trafficking of the human $P2Y_1$ receptor to the cell surface. $P2Y_1$ mRNA expression is highest in various regions of the brain, prostate gland, and placenta, and has also been detected at varying levels in other organs.

$P2Y_1$ receptor knockout mice have been generated. These mice are viable with no apparent abnormalities affecting their development, survival, and reproduction. Platelet counts are normal, but shape change is abolished. Transgenic mice overexpressing the $P2Y_1$

Figure 2 (a) Dendrogram to show relatedness of 29 P2X receptor subunits. Full-length amino acid sequences were aligned with Clustal W software using default parameters. The dendrogram was constructed with Tree View. h, human (*Homo sapiens*); r, rat (*Rattus norvegicus*); m, mouse (*Mus musculus*); gp, guinea pig (*Cavia porcellus*); c, chicken (*Gallus gallus*); zf, zebra fish (*Danio rerio*); f, fugu (*Takifugu rubripes*). The ovals indicate the apparent clustering by relatedness into subfamilies. (b) A phylogenetic tree (dendrogram) showing the relationships among the current members of the P2Y receptor family (human $P2Y_1$, $P2Y_2$, $P2Y_4$, $P2Y_6$, $P2Y_{11}$, $P2Y_{12}$, and $P2Y_{13}$ receptors) and the human UDP-glucose receptor (here indicated as the $P2Y_{14}$ receptor). The P2Y receptors can be divided into two subgroups, shown with blue and purple backgrounds. Sequences were aligned using Clustal X and the tree was built using the Tree View software. (b) Reproduced from Abbracchio MP, Boeynaems J-M, Barnard EA, et al. (2003) Characterization of the UDP-glucose receptor (re-named here the $P2Y_{14}$ receptor) adds diversity to the P2Y receptor family. *Trends in Pharmacological Sciences* 24: 52–55, with permission from Elsevier.

receptor specifically in the megakaryocytic/platelet lineage have also been generated.

$P2Y_2$ receptors $P2Y_2$ receptors have been cloned and pharmacologically characterized from human, rat, mouse, canine, and porcine cells or tissues. $P2Y_2$ receptors are fully activated by ATP and UTP, whereas ADP and UDP are much less effective agonists. The γ-thiophosphate, UTPγS, has been shown to be a potent hydrolysis-resistant agonist of $P2Y_2$

receptors, as is the recently developed $P2Y_2$ receptor agonist, INS37217 (Up_4dC). Suramin acts as a weak competitive antagonist of human and rat $P2Y_2$ receptors. AR-C126313 and the related aminotetrazole derivative AR-C118925, flavanoids, and tangeretin have been claimed recently to be effective antagonists.

$P2Y_2$ receptors can directly couple to $PLC\beta_1$ via $G_{\alpha q/11}$ protein to mediate the production of IP_3 and diacylglycerol, which are second messengers for calcium release from intracellular stores and protein kinase C (PKC) activation, respectively.

Expression of $P2Y_2$ receptor mRNA and protein has been detected in many tissues. $P2Y_2$ receptor activation increases the synthesis and/or release of arachidonic acid, prostaglandins, and nitric oxide. $P2Y_2$ receptor expression in smooth muscle cells is upregulated by agents that mediate inflammation. $P2Y_2$ receptors have been shown to play a role in the wound healing process. $P2Y_2$ receptor activation increases Cl^- secretion and inhibits Na^+ absorption in epithelial cells. A $P2Y_2$ receptor knockout mouse has been produced that is defective in nucleotide-stimulated ion secretion in airway epithelial cells. $P2Y_2$ receptors have been shown to inhibit bone formation by osteoblasts, and N-type calcium currents in neurons.

$P2Y_4$ receptors Human, rat, and mouse $P2Y_4$ receptors have been cloned and characterized. UTP is the most potent activator of the recombinant human $P2Y_4$ receptor. In contrast, the recombinant rat and mouse $P2Y_4$ receptors are activated equipotently by ATP and UTP. Up_4U (INS365) and dCp_4U (INS37217) are agonists of the human $P2Y_4$ receptor. Reactive blue 2 effectively blocks rat $P2Y_4$ receptors, but only partially blocks human $P2Y_4$ receptors. Suramin is a weak antagonist at the $P2Y_4$ receptor. The structural determinants of agonism versus antagonism by ATP are located in the N-terminal domain and the second extracellular loop.

In the human and the mouse, $P2Y_4$ mRNA and protein was most abundant in the intestine, but was also detected in other organs. $P2Y_4$-null mice have apparently normal behavior, growth, and reproduction, but the chloride secretory response of the jejunal epithelium to apical UTP and ATP is abolished.

$P2Y_6$ receptors The mouse, rat, and human $P2Y_6$ receptors are UDP receptors. The uridine β-thiodiphosphate, $UDP\beta S$, and Up_3U are selective agonists of the $P2Y_6$ receptor and are more stable to degradation. INS48823 is also a potent $P2Y_6$ agonist. A 1,4-di-(phenylthioureido)butane derivative (MRS2578) has recently been shown to selectively inhibit UDP-induced PLC activity. A unique feature of the $P2Y_6$ receptor is its slow desensitization and internalization. A wide tissue distribution of $P2Y_6$ mRNA and protein has been demonstrated, with the highest expression in spleen, intestine, liver, brain, and pituitary.

$P2Y_{11}$ receptors Among P2Y receptors, the human $P2Y_{11}$ receptor has a unique profile. Its gene is the only P2Y receptor gene that contains an intron in the coding sequence. The potency of its natural agonist ATP is relatively low and it is dually coupled to PLC and adenylyl cyclase upon stimulation. $ATP\gamma S$ is a more potent agonist than ATP is. The $P2Y_{12}$ antagonist AR-C67085MX acts as a potent agonist at the $P2Y_{11}$ receptor. Suramin behaves as a competitive antagonist of the $hP2Y_{11}$ receptor.

$P2Y_{12}$ receptors The human, rat, and mouse $P2Y_{12}$ receptors have been identified and characterized. ADP is the natural agonist of this receptor. The $P2Y_{12}$ receptor is heavily expressed in platelets, where it is the molecular target of the active metabolite of the antiplatelet drug clopidogrel. Potent direct competitive $P2Y_{12}$ antagonists are also available, including the 5′-triphosphate derivative AR-C69931MX compound, named cangrelor. The $P2Y_{12}$ receptor has also been shown to be expressed in subregions of the brain, glial cells, brain capillary endothelial cells, smooth muscle cells, and chromaffin cells. The $P2Y_{12}$ knockout mice that have been generated display the phenotype of clopidogrel-treated animals.

$P2Y_{13}$ receptors The human, mouse, and rat $P2Y_{13}$ receptors have been identified and characterized. ADP and Ap_3A are naturally occurring agonists of the $P2Y_{13}$ receptor. The $P2Y_{13}$ receptor is primarily coupled to a $G_{i/o}$ protein. However, cangrelor, which is an antagonist of the $hP2Y_{12}$ receptor, is also an antagonist of the human and rat $P2Y_{13}$ receptors. Recently MRS2211, a derivative of PPADS, was shown to selectively antagonize the human $P2Y_{13}$ receptor. The $P2Y_{13}$ receptor is strongly expressed in the spleen, followed by placenta, liver, heart, bone marrow, monocytes, T cells, lung, and various brain regions. $P2Y_{13}$-null mice have been generated recently, but no phenotype has been characterized to date.

$P2Y_{14}$ receptors From a phylogenetic and structural point of view, the $P2Y_{14}$ receptor (previously known as GPR105 or UDP-glucose receptor) is 47% identical to the $P2Y_{12}$ and $P2Y_{13}$ receptors. The gene for this receptor has been found in human chromosome 3q24-3q25, where a cluster of other related GPCRs, consisting of $P2Y_1$, $P2Y_{12}$, and $P2Y_{13}$ receptors and the orphan receptors GPR87, GPR91, and H963, have been found. The $P2Y_{14}$ receptor couples to the $G_{i/o}$ family of G-proteins and is activated by

UDP-glucose as well as UDP-galactose, UDP-glucuronic acid, and UDP-*N*-acetylglucosamine. At present, no selective antagonists are available. $P2Y_{14}$ mRNA is widely distributed in the human body. Both chemoattractant and neuroimmune functions have been claimed for the $P2Y_{14}$ receptor.

Receptor Dimerization and Cross-Talk

It is now recognized that interactions between GPCRs can take place through the formation of oligomers, or downstream of the receptor through the action of second messengers. The former process is commonly referred to as receptor dimerization. The latter process is known as receptor cross-talk.

There is evidence that the human $P2Y_2$ receptor forms homodimers. An example of dimerization involving P2Y receptors with non-P2Y receptors is rat $P2Y_1$ and adenosine A_1 receptors co-expressed in HEK293 cells. It has also been shown that the $P2Y_1$ and A_1 receptors are co-localized in neurons of the rat cortex, hippocampus, and cerebellum. The formation of oligomers by P2Y receptors is likely to be widespread and to greatly increase the diversity of purinergic signaling. P2X receptors and P2Y receptors are often expressed in the same cells. Thus, there is the possibility of bidirectional cross-talk between these two families of nucleotide-sensitive receptors. For example, the $P2X_1$ receptor may have a priming role in activation of $P2Y_1$ receptors during platelet stimulation.

Pursuit Eye Movements

U J Ilg, University of Tübingen, Tübingen, Germany

© 2009 Elsevier Ltd. All rights reserved.

General Properties of the Pursuit System

Compared to a modern digital camera, the human eye has a surprisingly low number of pixels, only approximately 1 million axons of ganglion cells transmit the information from the retina to the brain. This low number of pixels follows from a restriction of the high spatial resolution to the foveal field of vision. We are able to see up to 60 lines per 1° of visual angle in the fovea, and this resolution drops massively with eccentricity. The size of our visual field is approximately 90° in temporal direction and, due to our nose, approximately 60° in nasal direction. The advantage of the reduced amount of transmitted data is bought by the necessity of a very precisely acting oculomotor apparatus. We need to direct our gaze toward an important detail in our environment which requires vision at very high spatial resolution. If this detail moves, there is need for an eye movement command that maintains the image of this detail on, or at least close to, the fovea. In addition, retinal image motion introduces substantial image blur; movement of only $1^\circ\,s^{-1}$ results in image blur equivalent to myopia of 2 diopters. To sum up, smooth pursuit eye movements (SPEMs) are necessary for two reasons: (1) they keep the image of an important moving object on or close to the fovea, and (2) they prevent motion blur of this object. SPEMs warrant the high fidelity of the visual input necessary for higher cognitive processing such as face recognition or the recognition of the emotional state of another person. A hallmark of SPEMs is the excellent adjustment of eye speed to target speed. This can be easily demonstrated. Just move a pencil in front of a friend's face and ask him or her to track the tip of the moving pencil. The eyes move as though they are physically connected to the pencil.

Traditionally, pursuit is modeled as a negative feedback loop minimizing retinal image motion. More precisely, position, velocity, and acceleration of the retinal image of the pursued target are determined and transformed with different weights into an eye movement command. With this in mind, we might ask whether fixation of a stationary target is equivalent to pursuit of a target moving at zero velocity. There are two observations that point out the difference between fixation and pursuit. First, only during the execution of pursuit does the connection between the motion processor and the oculomotor control run at a high sensitivity state. Imagine a small perturbation in target position over time, a sine wave at a periodicity of 100 ms. In the case of a stationary fixation target, no response in the oculomotor behavior of a subject can be elicited by this stimulus. In contrast, if the target is moving, a huge oculomotor response is elicited by exactly the same perturbation. The neuronal substrate of this sensitivity boost is most likely a subarea of the frontal eye field (FEF), the frontal pursuit area (FPA). Electrical microstimulation of this area in rhesus monkeys results in a boost of the motion sensitivity similar to the engagement of the pursuit system. Second, many single-unit studies in rhesus monkeys revealed that different neurons are activated during the execution of fixation or pursuit.

During testing, everybody can imagine a moving target. As easy this is, it is surprisingly impossible to generate SPEMs in this condition. Even highly trained subjects are able to generate only a sequence of small saccades. In other words, we cannot produce SPEMs voluntarily. This inability emphasizes the negative feedback loop that operates on retinal image motion signals during the execution of SPEMs. However, it must be added that we are able to track a nonvisual moving target. If we close our eyes and move our left index finger on our right forearm, we can track this somatosensory perception smoothly. Even if another person touches our forearm, we can track touch in total darkness. Finally, if a sound source moves in darkness, we can track it also. Although there are no retinal slip signals available in these conditions, these situations have in common that there is a moving target. In contrast, if the target is only imagined, we cannot move our eyes smoothly.

Independently of the nature of the tracked target, SPEMs can be separated into two different temporal phases: pursuit initiation (open-loop), followed by steady-state pursuit (closed-loop). In the first phase, the eyes are initially stationary and retinal image movement of the target is directly related to target movement in space. In the second phase, target movement in space has to be computed by adding retinal image motion, eye speed, and, if applicable, head and body velocity. These two phases of SPEMs also differ with respect to their sensitivity for moving distractors. During pursuit initiation, vector averaging occurs if two moving targets are presented. In other words, the initial direction of the eye movement is given by the vector average of the target and distractor trajectory. During steady-state pursuit, a winner-takes-all mechanism is active and prevents

the moving distractor from affecting the ongoing pursuit eye movements.

During the execution of steady-state pursuit, two problems related to our subjective motion perception exist which indicate that our motion perception is not exclusively based on the processing of retinal image motion. First, we perceive the target as moving, even in the absence of any retinal image motion signal, as a consequence of perfectly adjusted SPEMs. Second, we do not perceive the stationary background as moving despite its retinal image. Having said this, it must be noted that our perception of a stationary environment is not perfect. If you move a pencil in front of this text, the text will appear to move in opposite direction while you track the pencil. This apparent motion is called Filehne illusion (for the German physiologist Wilhelm Filehne). Note that you are not able to read the text in this tracking condition. If you actually read the text, your eye movements consist in a series of small rightward saccades with intermingled fixations and huge leftward saccades at the end of each line.

As already indicated, a substantial part of our present knowledge of SPEMs results from experiments using rhesus monkeys. It was shown that the SPEMs of monkeys are very similar to those of human subjects. In addition to the analysis of the executed eye movements, single-unit responses from various brain areas were recorded during the execution of pursuit. These responses were used to pinpoint the neuronal substrate of SPEMs.

Initiation of Pursuit Eye Movements

During steady-state pursuit, eye speed is usually very precisely matched to target speed. But how are SPEMs initialized? Due to the latency of the visual system, the moving target inevitably leaves the foveal field of vision before the eyes could possibly move. Figure 1 shows the stereotypical buildup and maintenance of SPEMs in a human subject. There is a presaccadic initiation during which the eyes start to move. However, due to the latency, the eyes are lagging the target. This position error is compensated by the initial saccade. After the end of this saccade, steady-state pursuit is executed. Having said this, it is clear that pursuit initiation has a shorter latency than saccades.

It was shown that the initial acceleration of the eye is proportional to target speed and inversely proportional to target eccentricity. However, eye velocity is clearly below target velocity just before the initial saccade, and it is quite precisely matched to target velocity immediately after the initial saccade. Note that due to the high speed during saccades, the retinal image velocity of the target during the saccade cannot be used to adjust postsaccadic eye velocity. This

Figure 1 Typical smooth pursuit eye movements of a human subject. A subject was asked to track a moving (11° s^{-1}) target as precisely as possible. Target position is given by the oblique gray line, its width corresponding to the actual size of the target. Note that the eye-position traces of every single trial are very similar. The resulting median eye velocity is given by the red profile. The vertical light gray bar gives the time interval in which all initial saccades occurred.

boost in eye velocity before and after the initial saccade was named postsaccadic enhancement. At the onset of the saccade, the system has already decoded successfully target velocity and now uses this information to compute saccade amplitude adjusted to the target velocity. The saccade terminates exactly at the target's momentary position. These additional computations might explain why saccades directed to moving targets have longer latencies than saccades directed toward stationary targets.

Presaccadic acceleration of the eye can be an example of motor learning or adaptation. In the learning paradigm, the target starts to move at a given velocity and changes its velocity after approximately 100 ms (i.e., the pursuit latency). At the beginning, the initial acceleration of the eye is adjusted to the initial velocity of the target. Consequently, this maneuver produces a severe position error that needs to be corrected by an additional saccade. After close to 100 repetitions of this procedure, the initial acceleration is adjusted to the final target velocity and the huge position error is avoided.

The initiation phase of SPEMs is characterized by a need-for-speed behavior. It is most important to achieve a coarse estimate of target velocity as soon as possible. Because there is a direct relationship between time and position error, longer latencies yield bigger position errors. Due to this need-for-speed behavior, there are specific shortcomings during pursuit initiation. If subjects are asked to track

a second-order motion stimulus, the eyes initially follow the dot movement. In this experiment, let us say, the second-order motion stimulus consists of a rectangular area in which individual dots are moving to the left. The rectangle itself moves to the right. Later, during steady-state pursuit, the subjects' eyes follow the moving rectangle. Another shortcoming of pursuit initiation can be observed if subjects are asked to track a moving edge. The initial eye movements are always perpendicular to the edge, independent of the actual direction of edge movement. This misdirection of pursuit initiation can be explained by the aperture problem illustrated in Figure 2. Without visible line endings, we are able to perceive only motion perpendicular to a moving edge. After approximately 300 ms, these directional errors are corrected and pursuit at high fidelity is generated in the true direction of target movement. With respect to the moving edge experiment, it was nicely shown that the misdirection in eye movements is accompanied by an initial miscoding in the middle temporal area (MT), a bottleneck in the processing of visual motion. The initial error in the direction of eye movements is observed only if subjects track a real contour. If subjects are asked to track an illusionary contour, as shown in Figure 2, the initial misdirection perpendicular to the contour is absent. Nevertheless, we clearly perceive the illusionary contour. The pursuit onset latency is lengthened in this condition compared to the tracking of a real contour.

Although the execution of pursuit is tightly connected to the processing of retinal image motion, there is also a substantial influence of anticipation or prediction, especially during pursuit initiation. If the target moves consistently in the same direction at the same speed, human subjects and rhesus monkeys display pursuit eye movements due to anticipation, without any physical stimulus. This anticipatory pursuit is specific for direction and speed of the predicted target.

Figure 2 Aperture problem and illusionary contours: (a) the aperture problem; (b–c) two different types of illusory contours. In (a), imagine that the tilted blue bar moves to the right. Thanks to the line endings (marked by red circles), we perceive the horizontal movement as indicated by the black arrows. However, if our vision is restricted to the circular area, the bar seems to move 45° to the right and down, as indicated by the dashed arrow. In (b) and (c), the illusory contours do not produce a directional error during pursuit initiation.

In addition to the benefit of anticipation, there is another possibility for reducing pursuit latencies, similar to the way saccadic latencies are reduced. Initially, subjects have to fixate a stationary target. If this fixation target disappears 200 ms before the pursuit target appears (gap paradigm), pursuit onset latency is reduced. This reduction can be explained by the presence of a fixation system, which might consist of the rostral part of the superior colliculus and cortical areas such as the parietal cortex and the FEF. In case of the gap paradigm, this fixation system is switched off as a consequence of the disappearance of the target. In case of the regular paradigm, the fixation system has to be actively switched off to allow the execution of pursuit or saccade, respectively.

Brief Insights into the Anatomy of the Pursuit System

Because SPEMs can be executed only in the presence of a moving target, there is an ultimate connection between motion processing and the SPEM system. As a consequence, many properties of motion perception are in common with properties of the pursuit system. Various experiments revealed very similar characteristics of oculomotoric and psychometric functions. For instance, expectance influences eye movement control and motion perception in the same way.

The neuronal substrate of SPEMs starts with the processing within the retina and ends with the generation of an eye movement command by the extraocular motor neurons as shown in Figure 3. There is general agreement that motion processing in primates is a cortical function. Primates do not have directionally selective retinal ganglion cells like rabbits, for instance. Directionally selective neurons are primarily found in the hierarchy of visual processing in the primary visual cortex (V1) at an abundance between 10% and 20% of all neurons. There is experimental evidence that these directionally selective neurons exclusively provide direct input to the MT in the superior temporal sulcus (STS). In the MT, almost all neurons respond directionally selectively to visual motion. In turn, the MT provides the input of middle superior temporal area (MST) in the same sulcus. MST consists of two parts: a dorsal (MSTd) and lateral (MSTl) subdivision. Object movement is decoded in MSTl, whereas ego motion is decoded in MSTd. The receptive field size increases parallel to

Figure 3 Schematic presentation of the pathways for pursuit. FEF, frontal eye field; LGN, lateral geniculate nucleus; MST, middle superior temporal area; MT, middle temporal area; NRTP, nucleus reticularis tegmentis ponti; PN, pontine nuclei; SEF, supplementary eye field; V1, primary visual cortex; VIP, ventral intraparietal area.

the cortical processing from the V1 via the MT to the MST. At all stages, neurons with similar response properties are clustered together, and there is a columnar organization perpendicular to the surface of these areas. With respect to the generation of SPEMs, the cortical processing seems to be finished at the level of the MST because a massive projection from the MST to the pontine nuclei (PN) exists. It was earlier thought that this cortical processing is confined to the processing of retinal image motion. Position, velocity, and acceleration of the pursuit target is extracted from the retinal image. Extra-retinal signals are thought to be added in subsequent subcortical stages, mainly at the level of the cerebellum. However, the cortical processing is not at all confined to retinal signals, there is now evidence that cortical neurons combine retinal image motion and eye- and head-movement-related signals to compute target motion in space. Most likely, this information is sent to the brain stem. The PN provide an input to the cerebellum. In turn, the output of the cerebellum is directed to the vestibular and fastigial nuclei, whose neurons are presynaptic to the extra-ocular motor neurons. This cortico-ponto-cerbellar system is the direct path underlying the execution of SPEMs.

In parallel to this direct path, the neuronal substrate of the optokinetic system also contributes to the generation of SPEMs. This substrate consists of the accessory optic system (AOS), the nucleus of the optic tract (NOT) located in the pretectal area, and its projection to the inferior olive, which provides the climbing fiber input to the cerebellum. The AOS in primates also receives its directionally selective input from motion-sensitive areas in STS, different from the AOS of other vertebrates which receives directionally selective input from the retinal ganglion cells.

The function of the FEF and its subarea FPA, as well as the supplementary eye field (SEF), in the generation of SPEMs is not totally clear at present time. Some neurons in these areas respond during the execution of SPEMs. Microstimulation at specific sites in the FPA elicits pursuitlike eye movements. More recently, it was suggested that the main function of FPA might be the boost of motion processing during SPEMs. With respect to the importance of the SEF, it was proposed that neurons from this area provide an anticipatory signal related to the execution of predictive pursuit. The frontals areas project to the nucleus reticularis tegmentis ponti (NRTP), which provides another input to the cerebellum.

Finally, it was shown that some neurons in the ventral intraparietal area (VIP) respond directionally selectively during the execution of SPEMs. Because VIP contains a representation of near space, these neurons display a preference for targets moving at high velocity.

How to Differentiate between Retinal and Extra-Retinal Signals

The sensory–motor borderline underlying SPEMs is still a matter of debate. Because it is impossible to execute pursuit without a moving target, there is no easy way to disentangle sensory and motor processing. So far, two attempts have been made to solve this problem. The first attempt consists of a brief temporal removal of pursuit target for on the order of 100–200 ms. Human subjects reported that these brief disappearances of the target yield the perception that the target has briefly moved into the screen, like a toy train moves into a tunnel. Contrary to the assumption that pursuit would continue, eye speed was substantially decreased, even during short tunnel intervals. If the subjects received feedback about the velocity of the executed eye movement (for instance, by a change in the pitch of a sound), the drop in eye speed was less pronounced. A second attempt to disentangle visual and extra-retinal signals consisted of the use of

Figure 4 Middle superior temporal area (MST) activity in a monkey during the tracking of a target: (a) real target; (b) imaginary target. A monkey was trained to track a moving at 15° s^{-1} in the preferred (red) and nonpreferred (green) direction of the recorded neuron. The activity is shown as raster display and as spike density functions. Mean eye position profiles are displayed together with the resulting standard deviation (ten trials each). Note that the eye movements are very similar for both targets, as are the neuronal responses. The experiment was controlled so the receptive field of this neuron was not stimulated by parts of the imaginary figure; thus, the response in this condition can only be explained by extra-retinal signals related to the executed eye movements.

an imaginary figure, as shown in Figure 4(b). Here, the pursuit target was removed not temporally but spatially. During pursuit of such an imaginary target, no visual stimulation occurred in the part of visual field in which the receptive field of the neuron under study is located.

The results obtained from both attempts are consistent – MT turns out to process exclusively visual signals related to retinal image motion. If the pursuit target is either temporally or spatially removed, MT neurons stop responding. In contrast, MST neurons continue to respond in the absence of stimulation while the monkeys execute SPEMs. In addition, it was shown that MST neurons receive vestibular information related to head movements. Based on these results, a hypothesis was developed that MST neurons combine retinal image motion with extra-retinal signals, such as eye and head movement signals, to generate a signal related to the target movement in space.

The signal of the head velocity originates from the vestibular organ, but what is the origin of the extra-retinal signal related to the ongoing eye movement? This question was answered by experiments in which monkeys were trained to track a moving target either by isolated eye or by combined eye and head movements, as shown in Figure 5.

Because this neuron responds very similarly during both types of pursuit, we can dismiss the hypothesis that the extra-retinal signal is a copy of the motor command from the extra-ocular motor neurons; this command is quite different in both tracking conditions. Based on the result of this experiment and others consisting of a combination of a tracking task and vestibular stimulation, it was concluded that the activity of these neurons in the MST represents the trajectory of a moving target in space.

An important benefit of this finding is that the same representation of target movement can explain action (i.e., the generation of SPEMs) and motion perception. As mentioned earlier, motion perception and execution of pursuit have many properties in common. In addition, the signal related to target movement in space is also important to achieving the perception of a stationary environment despite self-induced retinal image motion.

Finally, the MST is not a motion processor exclusively for the generation of SPEMs. In several studies, it was shown that the neuronal activity in the MST is closely related to the animal's perception of motion. In addition, there is experimental evidence that the MST is also involved in the generation of goal-directed hand movements directed toward a moving visual target. Microstimulation and transient inactivation of this area yield modifications of SPEMs as well as modifications of goal-directed hand movements.

Figure 5 Middle superior temporal area (MST) activity in a monkey: (a) during eye movements; (b) during combined eye–head movements. The left panel represents preferred direction, right panel gives nonpreferred direction. A monkey was trained to track a moving target (10° s^{-1}) with either only eye movements or with combined eye and head movements. The neuronal activity is shown as raster displays and spike-density functions. Although the eye-in-head movements were very different in both conditions, the neuronal responses were very similar. This indicates that the extra-retinal component is not related to the eye-in-head movement (i.e., efference copy of the raw motor command) but, rather, to a signal coding for the movement of the target into an external frame of reference.

Conclusion

The execution of pursuit eye movements is a logical consequence of the restriction of the high spatial resolution to the fovea. These eye movements consist of two phases: the an initial open-loop phase, which is dominated by the fast, in some cases incorrect, processing of retinal image motion; and the subsequent closed-loop phase, which is dominated by the presence of a representation of target movement in space based on the combination of retinal and extra-retinal signals.

Introduction

Rab3A, 3B, 3C, and 3D constitute a subfamily of small guanosine triphosphate (GTP)-binding proteins among the Rab family members. The Rab family is the largest family of small ras-like GTPases. Rab proteins are essential molecular switches in regulating virtually all membrane trafficking steps in eukaryotic cells. Rab proteins bind two operationally defined classes of proteins. The first class, the auxiliary proteins, regulates the Rab cycle and the switching between the active GTP-bound form and the inactive guanosine diphosphate (GDP)-bound form. The second class is defined as the Rab effectors, which specifically interact with the active Rab protein and define the function of the Rab protein in the membrane-trafficking step.

During evolution, the Rab family expanded from 7 or 11 members in yeast to more than 60 members in mammals to account for the special requirements of differentiated tissues in mammalian multiorgan systems. The steps involved in membrane traffic are (1) vesicle budding from the source membrane, (2) cargo transport along the cytoskeletal elements, (3) target membrane recognition and attachment, and (4) fusion with the target membrane. Rab proteins are involved in all these events by controlling the assembly and disassembly of effector complexes involved in these processes.

Rab3 paralogs regulate stimulated secretion, in which the final events of membrane traffic are further subdivided into (4a) vesicle docking (i.e., hooking the vesicle onto the release machinery), (4b) priming (when the vesicle becomes fusion competent for Ca^{2+}-triggered release), and (4c) Ca^{2+}-triggered fusion. In synaptic vesicle fusion, these events are tightly coordinated and account for the fastest membrane-trafficking event in eukaryotic cells; it takes 50 μs to transduce the Ca^{2+} influx after excitation to vesicle fusion, and this is approximately 10 times faster than other regulated fusion events, such as granule fusion in adrenal chromaffin cells.

The efficacy of triggered fusion is dynamic, which results in synaptic plasticity. Changes in synaptic efficacy on a short timescale of milliseconds to minutes are defined as short-term synaptic plasticity, important for shaping the signal flow during trains of action potentials. Conversely, changes on a long timescale of hours and perhaps longer are defined as long-term synaptic plasticity, important for mechanisms of synaptic memory. Synaptic plasticity is regulated both presynaptically, in terms of changes in release probability, and postsynaptically, in terms of strength of the neurotransmitter-triggered receptor response. Rab3 is important for regulating the release probability at some synapses and is essential for at least one form of long-term synaptic plasticity expressed presynaptically.

Cloning and Structure of Rab3

Rab3A (initially named smg p25A) is the most abundant GTP-binding protein in the brain and was first purified and cloned (together with its paralogs Rab3B and -3C) from bovine brain membranes. The nucleotide sequence was independently pulled from a rat cDNA library during a ras GTPase homologs screen. The three Rab3 paralogs 3A, 3B, and 3C are enriched in brain, neuroendocrine, and endocrine tissues, where they localize to synaptic vesicles and secretory granules. Rab3D was later cloned from an adipocyte cell line, in which it associates with insulin-sensitive glucose transporter (GluT4) vesicles. Rab3D was also identified on secretory granules from mast cells in the lung and peritoneum, zymogen granules of the pancreas, and post-*trans*-Golgi network vesicles of osteoclasts.

The amino acid identity within the Rab3 subfamily amounts to 77–85%. This value is in the range of other Rab subfamilies, which averages 78.3% amino acid identity, whereas the Rab family average identity is only around 33%. The highest identity is found in the four Rab subfamily sequence (RabSF) motifs, which are characteristic for each subfamily. Whereas the RabSFs are solely determined from primary sequence comparisons, other characteristic motifs, which specifically interact with an effector protein, were derived from the crystal structure of active Rab3A bound to rabphilin. Three regions, named Rab complementary-determining region (RabCDR), form a binding pocket that specifically interacts with a conserved SGAWF(F/Y) structural element of the Rab3 effectors rabphilin, Rab3-interacting molecule (RIM)1α and 2α, and NOC2. RabSF1, RabSF3, and RabSF4 correspond approximately to RabCDR1, -2, and -3, respectively, indicating that RabSF motifs might build effector interaction surfaces of Rab subfamily members. RabSF2 maps to the first α-helix and loop 2 of Rab3A, which do not interact with rabphilin and might therefore form an additional subfamily-specific surface that could bind unrelated effectors or auxiliary proteins.

A key feature of small GTP-binding proteins is that they bind only in the GTP-bound active conformation to effector proteins and they could be switched off by GTP hydrolysis. The structural correlate for this mechanism in Rab3A is the interactions of the switch I and switch II region with rabphilin. On GTP hydrolysis, these two motifs change their conformation and retract the additional binding interface, loosening the strength of the Rab–effector interaction.

Rab3A is attached to synaptic vesicle membranes by posttranslationally modified C-terminal cysteines, which are isoprenylated by a Rab-specific geranyl–geranyl transferase (GGT) and are, furthermore, carboxy-methylated at the terminal residue. The isoprenylation is a common modification of Rab proteins and enables them to bind to intracellular membrane compartments. The lipid attachment is facilitated by Rab escort protein (REP), which binds to GGT and buries the hydrophobic modification, before Rab proteins are hooked onto membranes or bind to GDP dissociation inhibitor (GDI), an additional Rab auxiliary protein.

Rab3 Cycle and the Role of Auxiliary Proteins

As molecular switches, Rab proteins cycle between GTP-bound (active) and GDP-bound (inactive) forms. Membrane association and dissociation parallel this cycle. These features enable Rab proteins to specifically control single steps in a directed membrane-trafficking pathway. In their active state, they recruit effector proteins (or complexes) to the specific membrane-trafficking step. Afterward they are switched off and released into the cytosol to be reloaded for a new step. The membrane dissociation ensures that the protein does not need to recycle with the membrane it was loaded on; instead, it can take a short cut to be specifically used in its target process again. The Rab cycle requires multiple auxiliary proteins, which assist Rab proteins in membrane targeting, activation, inactivation after its performed task, and retrieval from the membrane. This is a multistep procedure, and the tracks of multiple Rab proteins overlap partially. This allows for a reduced set of auxiliary proteins, which assist multiple Rab proteins. However, compartmentalization, noncomplementary sets of auxiliary proteins, and specific effectors define specificity of the Rab protein function.

At the first step, the solubility of GDP-bound Rab proteins in the cytosol is increased. For this purpose, Rab proteins form a complex with GDI, in which the hydrophobic isoprenyl groups are enveloped in a groove of GDI. Only three GDI paralogs are expressed in mammals. GDIβ is expressed ubiquitously, whereas the other two mammalian paralogs have restricted expression patterns; GDIα is predominantly expressed in brain, whereas GDIδ is expressed specifically in muscle and adipocyte cells.

The mechanisms of the next step, the targeting of Rab proteins to their membrane compartment, is just beginning to evolve. A small family of GDI-displacement factors (GDFs) potentially catalyzes the initial entry of Rab proteins to membranous compartments. The mammalian homologs, prenylated Rab acceptor protein (PRA)1 and -2 bind promiscuously multiple Rab proteins, including Rab3A and, in addition, other prenylated small GTPases. Altogether 14–16 PRA (also named Yip) paralogs exist in mammals, of which most are ubiquitously expressed, indicating that no specific Rab protein is assisted by a single GDF. This is advantageous because increased compartmentalization in eukaryotic cells requires at least two entry points for Rab proteins. Rab3 needs to enter transport vesicles to the synapse after biosynthesis in the neuron soma and later has to reversibly attach to synaptic vesicles or the synaptic vesicle precursors from the endosome compartment. Consistent with this hypothesis, both PRA1, localized in the Golgi/endosome compartment, and PRA2, localized in the endoplasmic reticulum, can bind to Rab3 and might serve as the Rab3 GDFs.

After entering the membrane compartment, Rab3 is activated by a GDP/GTP exchange protein (GEP). It has not been directly shown whether the activation happens immediately after Rab3 enters the membrane or after Rab3 reaches the target membrane. Evidence for the first scenario is provided by the following observations. The synaptic targeting and binding on synaptic vesicles of the Rab3 effector rabphilin is strictly dependent on Rab3, whereas Rab3 synaptic targeting does not require rabphilin. In Rab3A single and Rab3 quadruple knockout mice, rabphilin protein (but not mRNA) levels are decreased and rabphilin accumulates in the neuron soma. This indicates that Rab3 is activated in the neuron soma before it reaches synaptic vesicles. However, during local recycling, Rab3 is also activated in synaptic terminals, either on synaptic vesicles or their precursors.

A cytosolic Rab3 GEP was isolated from rat brain, which is the ortholog of the human DENN/ mitogen-activated protein kinase (MAPK)-activating death domain (MADD) protein involved in blocking stress-induced apoptotic pathways in Alzheimer's and other neurodegenerative diseases. Synaptic targeting of Rab3 is dependent on Rab3 GEP function because in mutants of the *Caenorhabditis elegans* Rab3 GEP ortholog aex-3, Rab3 levels are reduced in synapses. Aex-3 serves as a GEP for an additional

Rab. It also catalyzes the GDP/GTP exchange of Rab27, a synaptic Rab protein in *C. elegans*. In aex-3 mutants, synaptic-rich structures are depleted of both Rab3 and Rab27. In addition to the GDP/GTP exchange, aex-3 has another function, whose connection to Rab function is currently unclear. It interacts with Cab-1, a protein involved in neural cell proliferation and differentiation. These multiple functions of the Rab GEP indicate why, in both *C. elegans* and mice, the phenotype of the Rab3 GEP/aex-3 mutants is more severe than in corresponding Rab3 mutants. Both Rab3 quadruple knockout and Rab3 GEP knockout mice die shortly after birth due to respiratory failure. However, whereas in Rab3-lacking neurons the evoked synaptic transmission is reduced modestly by 30%, synaptic transmission in Rab3 GEP knockouts is reduced by 80%. Furthermore, the size of the synaptic vesicles and shape of the active zone were altered in synapses lacking Rab3 GEP activity, whereas both structures were unchanged in Rab3-lacking neurons. In *C. elegans*, the aex-3 phenotype could be mimicked by combining either the Rab3/Rab27 mutations or the Rab3/Cab-1 mutations because the single Rab27 and Cab-1 mutants have similar phenotypes. After activation, Rab3 binds to specific effectors, which define the function of each individual Rab protein.

To terminate Rab3 function, the Rab3 intrinsic GTPase activity is enhanced by Rab3 GTPase activating protein (GAP), catalyzing the conversion of GTP to GDP. Rab3 GAP is a heteromeric complex consisting of a 130-kDa catalytic subunit and a 150-kDa noncatalytic subunit. The human genome encodes more than 50 putative Rab GAPs, which could indicate a high degree of specificity in the termination of Rab activity. However, the specificity of some GAPs is not restricted to one small GTP-binding protein family and acts on the Rab family and on Rho and other families, so we need more comprehensive data on the specificity of the Rab GAPs to draw general conclusions.

Rab3 GAP is ubiquitously expressed and enriched in the synaptic soluble fraction of the brain. Mutations in p130 have been reported to cause Warburg Micro syndrome, a condition with severe mental retardation, indicating an important function for Rab3 GAP in synaptic function. The function of Rab3 GAP was further tested in p130-deficient mice. From all proteins tested, only the levels of p150 were severely reduced, emphasizing the importance of the complex *in vivo*. Significantly, the fraction of GTP-bound Rab3A was increased, indicating that Rab3 GAP is the predominant *in vivo* GAP for Rab3A. Analysis of the synaptic function revealed that the elevated level of active Rab3A led to an increased paired-pulse ratio of two shortly spaced evoked synaptic responses in hippocampal CA1 pyramidal cells. Changes in the paired-pulse ratio are a sensitive measure of functional presynaptic alteration and are often caused by a decrease in synaptic release probability. However, the results of testing release probability were not conclusive because the use-dependent block of *N*-methyl-D-aspartate (NMDA) receptor responses with MK-801, a measure of synaptic release probability, was not altered in the Rab3 GAP-lacking neurons, whereas potassium-induced glutamate release from synaptosomes was greatly attenuated in the absence of Rab3 GAP. More detailed experiments are required to address the consequences of an increase in active Rab3A on synaptic function.

After synaptic vesicle fusion, Rab3A and -3C and their effector rabphilin dissociate from synaptic vesicles. This dissociation requires both synaptic vesicle fusion and Ca^{2+} entry. Osmotic or α-latratoxin-induced release in the absence of Ca^{2+} prevents Rab3 dissociation. These results indicate that synaptic vesicle fusion and Rab3 dissociation are normally coupled but are independent reactions. A tempting question remains of whether Rab3 GAP activity and GTP hydrolysis are involved in the Ca^{2+}-induced retrieval of Rab3 from synaptic vesicles because for some Rab GTP hydrolysis is not absolutely required for function termination.

To close the Rab3 cycle, brain-specific GDIα retrieves Rab3A from synaptic vesicle membranes using a membrane-associated heat shock protein (Hsp)90 chaperone complex.

Rab3 Function in Membrane Traffic and the Role of the Effectors

In neurons, Rab3 has two classes of effector proteins, rabphilin and Rim1α/2α. Rabphilin binds via Rab3 onto synaptic vesicles, whereas RIM1α and -2α are independent components of the active zone at the synapse. Because RIM resides close to the target membrane of synaptic vesicles, an anticipated function of the Rab3–RIM complex was to regulate the tethering of synaptic vesicles at the active zone; a function multiple Rab proteins have in common. It was surprising that the most abundant Rab protein in the brain, Rab3A, was not essential for the tethering of synaptic vesicles. The distribution of synaptic vesicles at the active zone is not convincingly changed to indicate an essential function for Rab3A in synaptic vesicle tethering. Furthermore, there is no obvious change in the distribution of synaptic vesicles in mice lacking all four Rab3 paralogs or Rim1α, indicating that the Rab3–RIM complex has no essential

function in synaptic vesicle tethering. Interestingly, the number of synaptic vesicles at the neuromuscular junction active zone is reduced in the *C. elegans* Rab3 mutant. However, it is not clear whether this change is due to a defect in synaptic vesicle tethering or results from a defect later in the synaptic vesicle cycle.

Rab3 dissociates from synaptic vesicles after Ca^{2+}-triggered vesicle fusion, indicative of a function after docking. Whereas the size of the readily releasable vesicle pool (primed vesicle pool) is unaltered in Rab3 lacking hippocampal neurons, the evoked synaptic responses are reduced by 30%. This reduction in vesicular release probability could be readily explained by the reduced apparent Ca^{2+} affinity of the release machinery in the Rab3-deficient neurons. However, the key finding explaining how Rab3 is involved in this process was an accelerated repriming rate in the Rab3-deficient neurons. This finding indicates that Rab3 is involved in an additional maturation step of primed synaptic vesicles. Synaptic vesicles in this superprimed state, whose conversion is rate-limiting in the priming reaction, have an elevated release probability and are the ones to be released initially during an action potential train. This has immediate consequences for short-term synaptic plasticity, which was altered in Rab3-deficient neurons to a greater extent, compared to a mean change in release probability across all synaptic vesicles. The importance of the additional maturation step in synaptic vesicle priming, at least in mammals, is demonstrated by the lethal phenotype of the Rab3 quadruple knockout mice.

Consistent with the hypothesis of two vesicle populations with different release probabilities, one study analyzed the retrieval of green fluorescent protein (GFP)-tagged Rab3A from synaptic vesicles during trains of action potential and found that the fluorescence dispersion ends before the vesicle pool turns over.

How do the Rab3 effectors contribute to the maturation step in priming? The synaptic localization of rabphilin relies completely on Rab3. Therefore, Rab3 quadruple knockout mice are also deficient in synaptic rabphilin. Conversely, Rab3A is targeted to synaptic vesicles independent of rabphilin, so the function of rabphilin could be analyzed in rabphilin knockout mice in isolation. Surprisingly, no obvious alterations in synaptic transmission and plasticity were detectable in the hippocampus of rabphilin-deficient mice, whereas rabphilin mutants in *C. elegans* are lethargic. This phenotypic difference could indicate either functional redundancy in mice or additional functions of the *C. elegans* homolog. The latter explanation appears to account for the difference because in *C. elegans* rabphilin interacts with two Rab proteins, Rab3 and Rab27, whereas in mammalian synapses rabphilin is dependent on Rab3 alone, despite interacting with Rab3 and Rab27 *in vitro*. The mammalian effectors of Rab27 have a similar structure compared to rabphilin and belong to the family of synaptotagmin-like proteins (Slps), including granuphilin. In mammals, Rab27 and its effectors are localized primarily on secretory granules. Therefore, *C. elegans* rabphilin might serve a dual function as a Rab3 and Rab27 effector, whereas later in evolution more specialist effectors might have developed.

In an analysis of the function of RIM1α, the only α RIM paralog in mouse hippocampal neurons, significant differences to Rab3 mutants were described. The changes were much more complex, compared to changes in the Rab3-deficient neurons. This is probably due to additional interactions of RIM1α with α-liprin, an essential component for active-zone differentiation; ERC; RIM- and liprin-binding proteins of the active zone; and Munc13–1, an essential priming factor, whose levels are reduced in the RIM1α knockouts but not the Rab3 knockouts. In RIM1α knockout mice, the readily releasable pool was reduced by 50%, which resulted in a similar reduction of evoked synaptic responses. Consistent with this result, in hippocampal slices the synaptic release probability was reduced, whereas the vesicular release probability in hippocampal neurons was unaltered. The synaptic release probability measures whether an action potential at a synapse can elicit neurotransmitter release, whereas the vesicular release probability depends on the number of released vesicles at all synapses. Thus, in RIM1α-deficient neurons, the likelihood is that, after triggering, a vesicle fuse is unchanged, but the number of primed vesicles and therefore fusion events is reduced. Consistent with a sole reduction of fusion-competent vesicles, the apparent Ca^{2+} affinity of the release apparatus and the repriming rate were unchanged. This resulted in a change of paired-pulse ratios similar to changes induced by a mean reduction in release probability. The increase was biggest for short interstimulus intervals, in contrast to the change in Rab3-deficient neurons, in which the increase was biggest for intermediate interstimulus intervals. Altogether, these changes in RIM1α-deficient neurons could best be explained by a reduction in synaptic vesicle priming, supported by the reduction of priming factor Munc13–1 levels in RIM1α-deficient synapses. A similar conclusion was drawn from the analysis of *C. elegans* mutants of the RIM homolog unc-10.

In addition to the priming defect in RIM1α-deficient neurons, the release kinetics of synaptic vesicles are changed. After Ca^{2+} influx, the majority

of synaptic vesicles are released instantaneously (termed synchronous release), whereas release of a small fraction of vesicles is delayed (termed asynchronous release). Surprisingly, in RIM1α-deficient neurons, the asynchronous component was preferentially reduced, indicating that the release properties of the primed vesicles are altered.

RIM1α interacts with both Rab3 and Munc13–1 in a trimeric complex and this complex might regulate synaptic vesicle priming. However, the role in priming of Rab3 and RIM1α appear very separated. Whereas RIM1α controls primarily the number of fusion-competent vesicles, Rab3 controls the release probability of fusion-competent vesicles. Surprisingly, these functions do not appear to be interconnected because the most characteristic changes are not shared in the corresponding knockout mice. The number of fusion-competent vesicles is not changed in Rab3-deficient neurons, and the vesicular release probability and priming rate are unchanged in RIM1α-deficient neurons. The functional analysis of both Rab3 effectors RIM1α and rabphilin indicates that both are not responsible for defining the essential role of Rab3 on synaptic vesicle priming. It is interesting to identify the effector which defines this function.

Despite its independent role on synaptic vesicle priming, RIM1α is the effector of Rab3 mediating its function on hippocampal mossy fiber long-term potentiation. This form of plasticity requires protein kinase A (PKA) activation and is expressed presynaptically. In both Rab3A- and RIM1α-deficient mice, this form of plasticity is absent. Surprisingly the short-term alterations, characteristic of both mutants in CA1 pyramidal cells (previously discussed) were absent in the granule cell CA3 pyramidal cell synapses. It will be important to test whether in the mossy fiber terminals additional RIM and Rab3 paralogs are expressed, which are functionally redundant to mask the functional loss of Rab3A and RIM1α, and whether the mechanisms of priming are different. The mechanism of RIM1α function in long-term plasticity was further analyzed in a similar form of plasticity in cerebellar neurons. It was shown that RIM1α phosphorylation is required for this form of plasticity. Thus, these forms of long-lasting increase in transmitter release require both Rab3A–RIM1α interaction and phosphorylation of RIM1α. Because RIM1α can modulate the number of fusion-competent vesicles, a plausible expression mechanism for this form of plasticity could be a long-lasting increase in the readily releasable vesicle pool.

RIM Genes and Proteins

RIM Discovery and Isoforms

RIM1α is the founding member of the RIM (Rab3-interacting-molecule) protein family. It was first detected as a binding partner of Rab3A in a yeast-two hybrid screening. Rab3A is a small guanosine triphosphatase (GTPase) that is covalently linked to synaptic vesicles via geranylgeranyl moieties. Thus, RIMs are named after this interaction. RIM1α is tightly and selectively associated with the presynaptic active zone, the electrondense material that is attached to the presynaptic membrane opposite postsynaptic densities (Figure 1) and that regulates synaptic vesicle docking and priming.

RIM1α is a large multidomain protein (Figure 2(a)) that consists of an N-terminal zinc finger domain, a relatively large linker sequence that contains a protein kinase A phosphorylation site (serine 413), a central PSD-95/Dlg/ZO-1 (PDZ) homology domain, and two C-terminal C_2domains (called C_2A and C_2B). Between the C_2 domains, there is a relatively long linker region that can be alternatively spliced at two splice sites and that also contains a proline-rich region.

Since the initial identification of RIM1α, investigators have found three additional RIM genes that produce six isoforms and many splice variants (Figures 2(b) and 2(c)) in mammals. The RIM1, -3, and -4 genes each produces only a single protein isoform (RIM1α, RIM3γ, and RIM4γ, respectively). The RIM2 gene encodes a full-length α-isoform, a β-isoform in which the N-terminal zinc finger is replaced by a short β-specific sequence, and a short γ-isoform that consist of only the C-terminal C_2domain with a short N-terminal γ-specific peptide (Figure 2(b)). The RIM1 and RIM2 genes are large genes (Figure 2(c)) of approximately 0.5 Mb. Their chromosomal locations are indicated in Figure 2(c).

In both *Drosophila* and in *Caenorhabditis elegans,* RIM homologs have been identified. Whereas there is no functional data available about the *Drosophila* RIM gene, mutants for the *C. elegans* gene unc-10 that encodes RIM have been analyzed in detail. Although some differences in the molecular and cellular functions of mammalian RIM and *C. elegans* RIM have been suggested, the basic function of RIM as being necessary for the efficient regulation of presynaptic release is conserved between invertebrates and vertebrates.

N-Terminal Zinc Finger Domain

The N-terminal zinc finger domain of α-RIMs is very similar to the zinc finger domain of rabphilin, another Rab3 binding protein that is soluble and bound to synaptic vesicles via Rab3 isoforms. Two elements of the N-terminal zinc finger are important for Rab3 binding: (1) N-terminal of the zinc-binding cysteine residues, α-RIMs and rabphilin contain a long α-helix called α1, and (2) C-terminal of the zinc finger, they include a SGAWFF/Y motif at the end of helix α2. The structures of the complexes of Rab3 with RIM1α or rabphilin have been described in detail based on nuclear magnetic resonance (NMR) analysis and crystallography.

In addition to Rab3s, the RIM N-terminus binds to the active-zone protein Munc13. This interaction occurs between the RIM zinc finger domain and the Munc13–1 C_2A domain. Evidence for this interaction is convincing. First, this binding was characterized by use of glutathione *S*-transferase (GST) pull-down experiments and co-immunprecipitation. Later, it was strongly supported by the fact that brain Munc13–1 levels are reduced by approximately 50% in a mouse line lacking RIM1α. Initially, *in vitro* experiments suggested that the binding of either Rab3A or Munc13 to the N-terminus of RIM1α exclude one another. However, more recent data suggest that RIM, Rab3, and Munc13 form a tripartite complex that is involved in priming synaptic vesicles for release and that potentially modulates synaptic plasticity. Interestingly, the SGAWFF/Y motif that is C-terminal to the Munc13–1 binding site is released from Rab3A when the RIM–Rab3A complex binds to Munc13–1. The RIM1 gene (but not the RIM2 gene) contains an alternatively spliced exon between the Rab3 interacting portion of helix α1 and the zinc finger domain. It has been suggested that alternative splicing at this splice site A (SSA) might regulate the binding of either Rab3s or Munc13s, but the experimental evidence for this is inconclusive.

Zinc Finger/PDZ Domain Linker Sequence

Several putative phosphorylation sites have been identified in the linker sequence between the zinc finger and the PDZ domain, and one – the serine residue 413 (S413) – has been characterized in detail. It is phosphorylated by the cyclic adenosine monophophate

Figure 1 Electron micrograph of a presynaptic terminal (pr) synapsing onto a postsynaptic neuron (po) stained for RIM1α by silver-enhanced immunogold labeling showing that RIM1α is localized at presynaptic active zones in the spinal motor cord neurons. RIM1α signal appears as black deposits found only in presynaptic nerve terminals close to the active zone. Scale bar = 0.2 μm. (cAMP)-dependent protein kinase A (PKA), and phosphorylation of S413 is developmentally regulated. In rats, it is highly phosphorylated at birth, and the percentage of phosphoserine 413 RIM1α slowly decreases to reach a relatively low steady state at around postnatal day 30. *In vitro* experiments have further suggested that the S413-phosphorlylated peptide binds to 14–3–3 adaptor proteins, but there is no *in vivo* data to support such an interaction. This PKA phosphorylation site is also present in RIM2β. The physiological relevance of PKA phosphorylation of S413 is a subject of intense investigation.

PDZ Domain

α- and β-RIMs contain a central PDZ domain with unusual binding specificities. They bind to the C-terminal peptide of a class of proteins called ELKS (for protein rich in E, L, K, and S). These active-zone proteins have also been variously referred to as cytomatrix at the active-zone-related structural protein (CAST), Rab6-interacting molecule 2, and ELKS/Rab6IP2/CAST (ERCs). The hydrophobic C-terminal peptide of ELKS (with the amino acid sequence GIWA) matches the profile of a class II PDZ binding motif, but even conserved mutations in any of the four residues abolish binding. This may be because the RIM PDZ domain has an unusually narrow and deep binding groove. Piccolo, another active zone protein, contains a closely related PDZ domain, but it does not bind to the ELKS C-terminus. The high specificity of this interaction might suggest a role of ELKS in organizing active zones, especially because ELKS proteins interact with several other active zone proteins such as Piccolo and α-liprins via their coiled-coil regions.

C_2 Domains

At the C-terminus, α- and β-RIMs contain two C_2 domains (called C_2A and C_2B), whereas γ-RIMs only contain the C_2B domain. C_2 domains were originally described as Ca^{2+}-dependent phospholipid binding modules. The RIM C_2 domains are atypical because they do not bind to Ca^{2+} and they have not been shown to bind to phospholipids. In fact, their interactions are poorly understood, with little *in vivo* data to support *in vitro* findings. The C_2B domain of RIM binds to α-liprins *in vitro*, a class of proteins which are located at presynaptic active zones and which have been shown to regulate the size and organization of active zones in invertebrates. In addition, it has been suggested that the RIMs bind to synaptosomal-associated protein of 25 kDa (SNAP-25), synaptotagmin 1, and cAMP-guanidine nucleotide exchange factor II (GEFII). While tenuous, these possible interactions with the key effectors of neurotransmitter release provide provocative potential mechanisms for RIM function in modulating release.

The linker region between the C_2 domains contains a relatively large amino acid sequence with two alternative splice sites called SSB and SSC. There is a proline-rich region between these two canonical splice sites that binds to RIM-binding proteins (RIM-BPs), another class of active-zone proteins of unknown function.

The localization and biochemical interactions of RIM directly or indirectly with many additional active-zone and synaptic vesicle proteins puts RIM at the core of neurotransmitter release machinery at the synapse. Thus, RIMs are a central component of a protein scaffold that is involved in the organization of the presynaptic release machinery and that controls the docking and priming of synaptic vesicles (Figure 3). In the next section, we discuss the available functional data that have been obtained from a gene knockout (KO) mouse line for RIM1α, one of the key RIM isoforms.

RIM Function in Synaptic Transmission

To characterize the *in vivo* function of RIM1α, a mouse gene KO line has been generated. This mouse line has delivered key insights into the function of RIMs at a number of central synapses. Investigators found that RIMs are crucial for the normal regulation of neurotransmitter release at central nervous system

Figure 3 Schematic of the presynaptic active zone components that assemble in close proximity to the presynaptic plasma membrane. The available data put RIM in the center of this electrondense protein meshwork in terms of scaffolding structure and of function. RIM proteins form a tripartite complex with Rab3A on the synaptic vesicles and with Munc13–1 at the active zone, potentially coupling synaptic vesicles to the active zone and preparing them for Ca^{2+}-mediated release, a process referred to as priming. In addition, RIMs interact directly or indirectly with all other active zone proteins. synapses. Interestingly, the loss of RIM1α leads to very different phenotypes at different types of synapses.

Excitatory synapses have been analyzed in RIM1α-KO mice with electrophysiological recordings from acute slices and cultured neurons of the hippocampus (Figure 4(a)) and the cerebellum. At different hippocampal synapses, very different phenotypes were observed.

Presynaptically Expressed Forms of Long-Term Potentiation

Some central synapses exhibit a presynaptically expressed, PKA-dependent form of long-term potentiation (LTP). These synapses are hippocampal mossy fiber to the CA1 pyramidal neuron synapses, cerebellar parallel fiber to Purkinje neuron synapses, corticostriatal synapses, and corticothalamic synapses. Both hippocampal mossy fiber LTP (mfLTP) and cerebellar parallel fiber LTP (pfLTP) are deficient in mice that lack RIM1α (Figures 4(d) and 4(e)). mfLTP is also absent in mice lacking the RIM1α-interacting molecule Rab3A. In spite of the lack of presynaptic mfLTP in RIM1α-KO mice, short-term plasticity and forskolin-induced potentiation are normal at these synapses. Interestingly, the RIM1α PKA phosphorylation site, S413, has been implicated in presynaptically expressed pfLTP in the cerebellum. *In vitro* experiments on cultured cerebellar neurons suggest that wild-type RIM1α can rescue the lack of pfLTP, whereas a mutant form of RIM1α lacking the S413 phosphorylation site cannot rescue pfLTP. These experiments suggest that PKA phosphorylation of RIM1α may be involved in presynaptically expressed forms of LTP. However, this observation in cultured cerebellar neurons *in vitro* remains to be validated *in vivo*.

Probability of Release and Short-Term Plasticity

In contrast, other synapses are affected in more basic parameters of neurotransmitter release. In Schaffer collateral to CA1 pyramidal cell synapses, paired pulse ratios, posttetanic potentiation (PTP), and

Figure 4 RIM function in short-term and long-term synaptic plasticity: (a) model of the unidirectional hippocampal pathways which were used to analyze several forms of synaptic plasticity in RIM1α-knockout mice; (b) increased paired pulse facilitation in RIM1α-knockout mice compared to littermate wild-type controls; (c) increased paired pulse depression at inhibitory synapses at short interstimulus intervals when the initial release probability is normal in RIM1α-knockout mice, and decreased facilitation when the initial release probability was reduced by lowering the extracellular calcium concentration (note that this effect is reversed compared to excitatory synapses (b)); (d) long-term potentiation at hippocampal mossy fiber synapses is absent in RIM1α-knockout mice; (e) long-term potentiation at cerebellar parallel fiber to Purkinje cell synapses is significantly decreased when RIM1α is absent. (b, c) Reprinted with permission from Macmillan Publishers Ltd: *Nature,* Schoch S, Castillo PE, Jo T, et al. (2002) RIM1alpha forms a protein scaffold for regulating neurotransmitter release at the active zone. 415: 321–326, copyright 2002. (d, e) Reprinted from Macmillan Publishers Ltd: *Nature,* Castillo PE, Schoch S, Schmitz F, Sudhof TC, and Malenka RC (2002) RIM1alpha is required for presynaptic long-term potentiation. 415: 327–330, copyright 2002.

response to prolonged 14 Hz stimulation are significantly increased when RIM1α is absent (Figure 4(b)). These observations suggest a decrease in release probability (P_r). Indeed P_r at these synapses is decreased by 50% when measured indirectly using the rate of blockade of *N*-methyl-D-aspartate (NMDA) receptor-mediated synaptic responses with successive synaptic activations.

These recordings in acute hippocampal slices from RIM1a-KO mice also demonstrated that the loss of function phenotypes are not simply due to RIM1α's role as a Rab3A effector protein. Rab3A-KO mice show a similar decrease in paired pulse ratios, but no change in posttetanic stimulation, P_r, or in response to 14 Hz stimulation.

A subsequent study of RIM1α-deficient hippocampal autapses in culture revealed that the RIM1α-KO mice exhibit decreased P_r via a decrease in the readily releasable pool of synaptic vesicles. Curiously, the decreased P_r in RIM1α-KO hippocampal autapses is observed only during the initial four to five stimuli during sustained 14 Hz stimulation. Wild-type synapses exhibit a depression of P_r during 14 Hz stimulation, whereas RIM1α-KO synapses do not. Thus, the relationship between P_r and the frequency of synaptic activation in the RIM1α-KO mice is complex.

Long-Term Potentiation at Schaffer Collateral to CA1 Synapses

LTP at the Schaffer collateral to CA1 synapse is NMDA receptor-dependent and expressed in part via postsynaptic mechanisms. The early phase of LTP is normal in both RIM1α- and Rab3A-KO mice. However, more intense LTP induction protocols induce a longer-lasting form of plasticity that is dependent on protein synthesis (called late LTP). This late phase of LTP is deficient in RIM1α- and Rab3A-KO mice, implicating presynaptic expression in this form of LTP. Although the mechanism of this involvement remains a mystery, a requirement for presynaptic PKA activation has been suggested. Further study is warranted to confirm and extend this initial observation.

In summary, the loss of RIM1α at excitatory synapses leads to a relative decrease in neurotransmitter release and alterations in short-term and long-term plasticity. This suggests that RIM1α is a positive regulator of excitatory synaptic transmission and plasticity.

Inhibitory Synaptic Transmission

In contrast to its function at excitatory synapses, RIM1α may lead to a decrease in neurotransmitter release at inhibitory synapses. Inhibitory synapses in the CA1 region of the hippocampus show paired pulse depression (PPD) rather than paired pulse potentiation, putatively due to their high initial P_r. This depression can be reversed to facilitation by decreasing the extracellular Ca^{2+} concentration to lower the P_r. In acute hippocampal slices, the loss of RIM1α causes an increase in PPD at the CA1 inhibitory synapse at short stimulus intervals (Figure 4(c)). When the initial P_r is lowered to a level that is comparable to excitatory Schaffer collateral synapses by lowering extracellular Ca^{2+}, RIM1α-KO mice show a decrease in paired pulse facilitation (PPF), which is the opposite effect of what was observed at excitatory synapses. Thus, RIM1α may act as a negative regulator of inhibitory synaptic transmission and plasticity, and this is in strong contrast to the function of RIM at excitatory synapses.

This dichotomy of RIM function in excitatory and inhibitory synaptic transmission and the divergent functions of RIM molecules in different excitatory synapses present an interesting conundrum that leaves many questions open. What are the fundamental molecular mechanisms of RIM function? Which RIM binding partners are mediating the different effects? Do RIM binding partners differ at individual synapses? In addition, it is critical to address how the various RIM isoforms work together or separately in these functions. Can other RIM isoforms compensate for RIM1α? Do different combinations of RIM isoforms lead to different functional properties? These questions and many others are the subject of intense investigation.

Clearly, RIM1α is critical to normal synaptic function and plasticity. The relevance of these functions to the whole animal has been investigated in behavioral studies of RIM1α-KO mice, considered next.

RIM Proteins Are Critical for Normal Learning and Memory

The abnormalities in both short- and long-term plasticity in RIM1α-KO mice raised the issue of whether RIM1α might play a critical role in learning and memory. A broad behavioral analysis of RIM1α-KO mice revealed abnormalities in learning and memory in both the Morris water maze and fear conditioning. In spite of the various synaptic physiology abnormalities and the widespread expression of RIM1α throughout the brain, RIM1α-KO mice revealed normal motor coordination and anxiety-like behaviors.

The abnormalities in Morris water maze behavior imply that RIM1α function is important for hippocampus-dependent learning. In contrast, Rab3A-KO mice with mfLTP deficits, increased PPF, and abnormal synaptic depression exhibited normal learning and memory in fear conditioning and classic water maze behavior. Thus, altered mfLTP, PPF, and synaptic depression

alone are unlikely to play a role in the severe RIM1α learning and memory deficits. In other studies of Rab3A-KO mice, additional behavioral testing revealed deficits in episodic-like/working memory on a delayed match-to-place version of the water maze (Table 1). It will be of great interest to examine additional mutant mice selectively lacking mfLTP to confirm its role in this form of memory.

Another deficit that seems a likely candidate for the behavioral abnormalities in the RIM1α-KO mice is the decrease in P_r in area CA1. A decrease in P_r in isolation, however, does not necessarily alter learning and memory behavior. Synaptotagmin 1 R233Q point mutant knockin mice have a similar decrease in P_r in CA1 as the RIM1α-KO mice, yet they exhibit normal learning and memory on the same tasks. Regardless of

Table 1 Summary of plasticity and behavioral abnormalities in RIM1α and related mutant mice[a]

	Short-term plasticity	*Long-term plasticity*	*Behavior*	*Sources*[b]
PKA-KO	PPF normal	E-LTP↓, L-LTP normal or ↓, mfLTP ↓, CA1-LTD ↓	Normal fear conditioning Normal spatial memory (water maze and Barnes maze) Normal response to novelty	1, 7, 10
Rab3A-KO	PPF ↑, PTP normal, TS normal, P_r normal	E-LTP normal, L-LTP ↓, mfLTP ↓	Normal fear conditioning Normal spatial memory (water maze) Impaired reversal learning (delayed match to place) Normal response to novelty	2–4, 6, 9, 11
RIM1α-KO	PPF↑, PTP↑, TS ↑, P_r ↓	E-LTP normal, L-LTP ↓, mfLTP ↓, CA1-LTD ↑	Impaired fear conditioning Impaired spatial memory (water maze) Increased locomotor activity in response to novelty	3, 8, 9, 11

any molecular accommodations in the synaptotagmin 1 R233Q-knockin mice, the decreased P_r remains, suggesting that synaptotagmin 1 R233Q-knockin mice can accommodate at the synaptic or circuit level to dramatic alterations in their P_r set point.

Other possibilities remain to explain the behavioral abnormalities in RIM1α-deficient mice. These include increased PTP at excitatory synapses and altered PPD at inhibitory synapses. Furthermore, the decreased P_r in RIM1α-KO mice may differ from that of synaptotagmin 1 R233Q-knockin mice. For example, it is possible that the synaptotagmin 1 mutation affects inhibitory and excitatory synapses equally, whereas the loss of RIM1α may affect excitatory out of proportion to inhibitory synapses. Such differential regulation of neurotransmitter release between excitatory and inhibitory synapses has been described for other presynaptic proteins such as Munc13–1 and Munc13–2. In addition, it may be that the multiple synaptic abnormalities in RIM1α-KO mice interact to lead to the behavioral deficits, although this conclusion requires excluding individual synaptic abnormalities as a cause. Finally, although LTP in area CA1 of the hippocampus was reportedly normal in RIM1α-KO mice, this experiment was performed in the presence of γ-aminobutyric acid (GABA) receptor antagonists using a very strong 3 s 100 Hz LTP induction paradigm. Thus, it will be of interest to examine earlier phases of LTP and long-term depression (LTD) in area CA1 of the hippocampus in RIM1α-KO mice more thoroughly before examining additional possible physiological explanations for the hippocampus-dependent learning deficits.

In fear conditioning, RIM1α-KO mice were abnormal in both context-dependent and cue-dependent fear conditioning. The abnormal cue-dependent fear conditioning implicates RIM1α in the amygdala function in addition to its role in hippocampal learning. Thus, it is of particular interest to examine LTP in the amygdala of the RIM1α-KO mice. This is a particularly interesting proposition in light of recent data suggesting that some forms of heterosynaptic LTP in amygdala are postsynaptically induced and presynaptically expressed. Indeed, the initial studies of cortico-amygdala LTP in RIM1α-KO mice suggested a trend toward decreased LTP expression in these mutants.

The loss of RIM1α leads to learning and memory deficits, and many questions remain. Is RIM1α modulated during learning *in vivo*? Which RIM1α binding proteins might be involved in learning and memory that is mediated by RIM1α? And could their function in learning and memory be controlled by modifications such as phosphorylation? Does the loss of RIM1α in a particular brain region correlate with the learning and memory deficits that we observed in the RIM1α-KO mice? These are questions currently under active investigation.

RIM1α-KO mice also display increased locomotor responses when exposed to a novel environment. Locomotor habituation was normal, suggesting that RIM1α-KO mice are not constitutively hyperactive but that they have abnormal responses to the mild stress of a novel environment. This is a phenotype often observed in rodent models of schizophrenia and may mimic the psychomotor agitation seen in some human schizophrenic patients. Additional behavioral characterization of RIM1α-KO mice in other schizophrenia-relevant behaviors such as sensorimotor gating, response to psychotomimetics, and social interaction are under investigation.

In summary, the behavioral data show that RIM1α is essential for normal learning and memory, but it remains unclear which of the physiological deficits in these mice causes the behavioral abnormalities. To understand RIM function *in vivo*, it will be crucial to understand how the various RIM isoforms work together. Furthermore, it will be important to develop strategies that allow for conditional deletion of RIM molecules in selective brain regions. With the strong deficits in synaptic transmission that are observed when RIM1α is absent, it might be possible in future to use RIMs as a tool to gain further insight into how certain areas of the central nervous system work together and how the performance of the central nervous system is affected when RIM-dependent parameters of neurotransmission fail at specific subclasses of synapses.

Overview

RIM proteins are key presynaptic active zone molecules important for normal synaptic transmission and behavior. Future studies will yield additional insights into how RIM proteins function differently in synaptic transmission and behavior at different synapse types. A more precise understanding of the physiological roles of the various RIM protein interactions as well as the functional redundancy across RIM isoforms is a critical frontier in the study of synaptic function.

Radial Glial Cells: Brain Functions

P Rakic, Yale University School of Medicine, New Haven, CT, USA

© 2009 Published by Elsevier Ltd.

Introduction

Radial glial cells (RGCs) are a morphologically, biochemically, and functionally distinct nonneuronal cell class that, during development, radially spans the entire width of the developing cerebral wall from the ventricular cavity to the pial surface. They play several pivotal roles in the production and placement of neurons during vertebrate brain development. Since the discovery of RGCs in the human fetal cerebral wall, this specialized cellular population has been identified in most regions of the developing vertebrate brain, ranging from the spinal cord to the telencephalon (Figure 1). RGCs have a bipolar shape with oval nuclei and one shorter, inner (apical) process terminating at the ventricular surface and the other, much longer outer (basal) process terminating at the cerebral surface. The phenotypic distinction of RGCs from the more specialized neuronal progenitors in the proliferative zones and from the postmitotic migrating neurons in the intermediate zone was initially based on cytological and ultrastructural analysis of the primate fetal forebrain. This distinction has been supported by comparative studies of their molecular and physiological characteristics in other species. In addition, *in vivo* and *in vitro* approaches revealed that these specialized embryonic cells generate neuronal cell lines that either immediately or after several divisions migrate along radial shaft processes of the mother cells which span the expanding cerebral wall. However, the size, longevity, and significance of RGCs for guiding migrating neurons have increased with the evolutionary expansion of the neocortex, reaching a peak in the size and phenotypic differentiation in the gyrencephalic human forebrain. The stability of the scaffolding of RGCs which contains transiently a subpopulation of nondividing RGCs may be an essential evolutionary adaptation to enable proper allocation of neurons to the expanded and convoluted primate cerebral cortex. In most mammals and, with some exceptions, other vertebrates during the late stages of ontogenetic development, the majority of RGCs disappear by transformation into various forms of astrocytes. A subpopulation of RGCs enter the dormant stage in the subependymal zone and can be activated by various insults to produce reactive gliosis or generate glial brain tumors (glioma). The multiple functions of RGCs and their species-specific adaptations indicate a pivotal role in evolution, development, and pathology of the cerebral neocortex.

History and Definition

RGCs impregnate well with most variants of the Golgi silver impregnation method, leading to their early discovery in the human fetal brain during the late nineteenth century. Although similar cells have been observed in most subdivisions of the vertebrate central nervous system, most attention has been given to the elongated RGCs of the telencephalon. In initial studies of the developing telencephalon in various mammalian species, Ramón y Cajal and his contemporaries recognized the distinct characteristics of these cells, with an apical endfoot firmly embedded at the ventricular surface and basal processes that at later stages become studded with lamellate expansions and terminate with branches into several endfeet, forming the outer, subpial cerebral surface, also called the 'glia limitans.' Because of these morphological characteristics, they were classified as a separate cell class that is different from the 'pyriform' neuroblasts which give rise to bipolar neurons migrating to the cerebral cortex. In addition, Ramón y Cajal suggested that RGCs eventually transform into 'spiderlike' cells that differentiate into fibrillary or protoplasmic types of astrocytes of the white and gray matter of the cerebrum, respectively. The investigators of that era also identified additional subclasses of modified RGCs, such as 'tanycytes,' 'faserglia,' 'Müller cells,' and 'Bergmann glia,' that persist in some regions of the adult brain. Although the methods available at the time were not adequate to suggest a specific function or provide definitive phenotypic classification, based on the morphological criteria, most investigators have considered them as 'primitive ependyma' or embryonic or fetal 'glia,' and this term has endured the test of time.

It is not surprising that the initial discoveries of the RGCs, as well as their classification into the glial phenotype, were made in the embryonic human brain because in primates, these cells have distinct ultrastructural and biochemical properties, including the much earlier expression of glial acidic fibrillary protein (GFAP), compared to rodents (Figure 2). Furthermore, a subset of RGCs in the fetal primate telencephalon do not divide for several months while serving as a guide for the curvilinear migratory pathway in the large, gyrencephalic primate forebrain. Thus, RGCs may have evolved to mature early in order to provide stable scaffolding for the formation of the convoluted primate cortex. Although it may

Figure 1 (a) Primordial epithelium, including spongioblast (radial glial) cells of the spinal cord of the chick embryo on the third day of incubation when, according to Ramón y Cajal, they become stainable by the Golgi method. (b) Epithelial cells (radial glial cells) and displaced astroglial precursors and more mature astrocytes in the spinal cord of the newborn mouse stained by the Golgi method display different phases of morphogenetic transformation of a more differentiated glial cell line. (c) Characteristic lamellate expansion on the radial shafts of epithelial (radial glial). (d) Epithelial (radial glial) and neuroglial cells of the cerebral cortex in neonatal rabbit stained using the Golgi method. Adapted from Ramón y Cajal S (1909) *Histologie du Système Nerveux de l'Homme et des Vertébrés*, vol. 1. Paris: A. Maloine. (Reprinted in 1952 by Consejo Superior de Investigaciones Cientificas, Instituto Ramón y Cajal, Madrid).

seem surprising that nonneuronal cells play such a pivotal role for placing cortical nerve cells into their proper locations, it should be recognized that the vertebrate central nervous system is an elaboration of the ectoderm of the dorsal surface of the embryo that initially consists of the epithelial cells, and only after closure of the neural tube do they transform into neuroepithelial cells lining the ventricular cavity.

The major advance in defining the nature of RGCs came with the introduction of new methods in developmental, cellular, and molecular biology, such as electron microscopy, ^{3}H-thymidine autoradiography, immuncytochemistry, transgenic technology, and retroviral gene transfer methods which provide ever higher resolution of cellular and molecular events, allowing for more reliable identification of cell classes. These studies have confirmed the glial phenotype of RGCs in all vertebrates, including humans and nonhuman primates, by their immunoreactivity to a variety of cell markers, such as GFAP, RC1, RC2, vimentin, Rat 401, and Ran-2.

Radial Glial Cells as Neuronal Stem Cells

Classical histological methods indicated that RGCs which arise from nuroepithelial cells retain their capacity to divide and may serve as precursors that directly or indirectly give origin to all major classes of neurons and astrocytes. Studies using more advanced *in vivo* and *in vitro* methods have shown that RGCs can generate not only neuronal progenitors but also, directly, postmitotic neurons (Figure 3). Modern studies also confirmed the existence of dedicated neuronal progenitors in the ventricular zone (VZ)/subventricular zone (SVZ) that are derived from the parent RGCs and do not inherit the basal fiber that terminates at the pial surface. Use of the retroviral gene transfer method, which enables tracing cell lineages in the developing mammalian telencephalon, shows a complex divergence of basic cell types. The use of specific cellular markers, combined with computer-assisted serial electron microscopy (EM) cell reconstruction, *in utero* electroporation, and time-lapse multiphoton imaging, revealed that the embryonic cerebral wall contains multiple cell classes, including dividing and nondividing RGCs, postmitotic, radially and tangentially migrating cells, and stationary neuronal and glial cells that are organized into transient layers (Figure 3). Various classes of neural stem cells and neuronal and glial progenitors can be isolated from the VZ/SVZ of both the rodent and the human cerebrum, and their migratory pattern and phenotypes can be followed in slice preparations of mouse, monkey, and human fetal tissue as they transform into different classes of projections and local circuit neurons. Eventually, fetal RGCs that remain attached to the ventricular surface transform into ependymal cells, and those which detach become astrocytes and/or glioblasts (Figure 3). Thus, RGCs give rise to both neuron and glial progenitors that can each produce several generations of dedicated progenitors before their terminal differentiation.

Role in Neuronal Migration

Another important role of the RGCs is to provide scaffolding and guides for neurons migrating from the proliferative VZ/SVZ to the increasingly distant cortical plate. Initially, the reconstruction of the relationship of the RGCs and migrating neurons was based on the use of a combination of Golgi impregnation, ^{3}H-thymidine autoradiography, and reconstruction

Figure 2 (a–e) Radial glial (RG) cells in the E70 monkey fetal cerebrum immunostained with the antibodies to GFAP. (a) Photomicrograph of a portion of the fetal cerebral wall exposes the richness of the RG fiber scaffolding at the midpoint of cortical neurogenesis. The radial fibers continue to run from the ventricular zone near the lateral cerebral ventricle (LV) across the intermediate zone (IZ) all the way to the cortical plate (not shown), where many of them terminate with the typical endfeet at the pial surface (inset). (b–d) Verichrome photographs of the GFAP-stained RG fibers taken from the three levels of the cerebral wall, starting from the surface of the lateral ventricle (LV) in (b), across the intermediate zone (c), to the pial surface (d). The GFAP-negative migrating neurons (blue) are distinguishable from the GFAP-positive RG cells (brown). (e) RG fibers impregnated using the Golgi method and viewed with the electron microscope. (f) Numerous elaborate lamellate expansions that become more prominent at later stages of corticogenesis. Adapted in part from Levitt P and Rakic P (1980) Immunoperoxidase localization of glial fibrillary acid protein in radial glial cells and astrocytes of the developing rhesus monkey brain. *Comparative Neurology* 193: 815–840.

from EM serial sections in the macaque cerebrum which revealed that cohorts of bipolar postmitotic cells originating in the same sites within the proliferative mosaic of the VZ follow a radial pathway consisting of single or, more often, multiple RGC fibers. Since newly born neurons migrate along the radial fiber of the mother cell, which remains attached to the ventricular surface, the daughter cells are guided by the radial fibers of their mother's cells to the appropriate location in the developing cortical plate (Figure 4). In the human fetal cerebrum, during midgestation a single RG fiber may simultaneously guide several generations of migrating neurons (Figure 5). Although postmitotic neurons in the large gyrencephalic primate brain may require several weeks to reach their final destinations, clonally related cells that originate at the same area in the VZ/SVZ follow the same guide and eventually settle within the same cortical column. The regularity of the well-defined migratory streams (Figure 4) suggests both the stability of the RGCs and the existence of a differential binding affinity mediated by heterotypic, 'gliophilic' adhesion molecules present on opposing neuronal and RG cell surfaces in contrast to cells which move tangentially along axonal tracts using 'neurophilic' adhesion.

Time-lapse imaging of migrating neurons in slice preparations shows that the leading process extends along the shafts of the RGCs. It was shown that specific and separate sets of molecular classes may be involved in the recognition, selective adhesion, and maintenance of neuron–glial interactions during extension of the leading process. Among the proliferating number of

Figure 3 Schematic diagram of the composition, cellular events, and the relationship in the developing cerebral wall, based on data obtained from species ranging from the mouse to human and nonprimates. Initially, a homogeneous population of neural stem cells (green), which divide symmetrically, transform into radial glial cells (RG), which divide asymmetrically and over time produce migrating neurons (MN; red) and dedicated neuronal progenitors with short processes (red mitotic divisions) that populate the ventricular zone (VZ) and subventricular zone (SVZ) and produce all projection neurons as well as the majority of interneurons in humans and a small fraction in rodents. In addition, a population of tangentially migrating neurons arrives to the dorsal telencephalon from the ganglionic eminence mostly via the SVZ and marginal zone (MZ) to supply the majority of interneurons in rodents and approximately one-third in humans. Eventually, RG undergo apoptosis (AP) or directly or indirectly generate ependymal cells, fibrillary astrocytes (FA), protoplasmic astrocytes (PA), glial progenitors (GP), or astrocytic stem cells that retain a neurogenic potential (NP).

molecules considered to be 'candidate' molecules involved in radial migration are neuregulin, which binds to the glial surface via ErbB2 and -4, and integrins, which provide the optimal level of basic neuron–glial adhesion needed to maintain neuronal migration on the shafts of the RGCs. However, a gliophilic-to-neurophilic switch in preference of adhesive interactions of the developing cortical neurons occurs in the absence of functional α_3 integrins.

Dissolution and Transformation

As originally suggested by Ramon y Cajal, the fetal type of RGCs in most regions of the mammalian brain disappears soon after birth. Studies of GFAP immunohistochemistry in the monkey and human fetal cerebrum confirmed that RGCs become transformed into fibrillary and/or protoplasmic astrocytes. The timetable of the disappearance of RGCs in the primate neocortex, hippocampus, and cerebellum correlates with the emergence of protoplasmic and fibrillary astrocytes (Figure 6). The cellular or molecular events that underlie this transformation are not known. In primary cultures, neuronal cells have been shown to exert an inhibitory effect on glial cell proliferation and, additionally, appear to regulate changes in the astroglial cell shape from epithelial-like to radial or stellate cells. The morphological transformation of GFAP-positive RGCs into classical astrocytic cell forms, as well as alternative forms of RGCs, appears to coincide with the loss of RC1, RC2, and Rat-401 antigens, which are not expressed in adulthood. A correlative analysis of antigenic and morphologic transformation *in vivo* and *in vitro* demonstrates that the morphological transformation of RGCs in rodents occurs concomitantly with a gradual acquisition of GFAP immunoreactivity and with a corresponding loss of RC1 immunoreactivity.

Modified RGCs may be found in some regions of the adult central nervous system where a selective microenvironment may allow for their maintenance. In some structures of the mammalian brain, RGCs adapt to the local functional requirements and spatial conditions and transform into specialized astrocytic cell types (e.g., the Bergmann glial cells of the cerebellum, tanycytes of the hypothalamus, or Müller cells of the retina). These specialized cells retain the basic morphological, immunological, and biochemical features of

Figure 4 Schematic three-dimensional reconstruction of the portion of the medial cerebral wall at the level of the incipient calcarine fissure (CF) in the 80-day-old monkey fetus. The reconstruction illustrates how the corresponding points in the ventricular zone (VZ) are connected by the array of elongated RGC fibers which span the full thickness of the cerebral wall to the increasingly distant cortical plate (CP) situated below the convoluted pial surface. (b) Three-dimensional reconstruction of migrating neurons based on electron micrographs of semi-serial sections of the occipital lobe of the monkey fetus. The reconstruction was made at the midlevel of the 2500 μm-wide intermediate zone. The bottom portion of the diagram contains uniform, parallel axons of the optic radiation (OR), whereas the irregularly disposed fiber systems occupying the top part of the diagram are deleted to expose the RGC fibers (striped vertical shafts RF_{1-6}) and their relations to the migrating neurons A–C and other vertical processes. The soma of migrating cell A, with its nucleus (N) and leading process (LP), is situated within the reconstructed space, except for the terminal part of the attenuated trailing process and the tip of the vertical ascending pseudopodium. The perikaryon of cell B is cut off at the top of the reconstructed space, whereas the leading process of cell C is shown just penetrating between axons of the optic radiation (OR) on its way across the intermediate zone. LE, lamellate expansions; PS, pseudopodia. Reproduced from Rakic P (1978) Neuronal migration and contact guidance in primate telencephalon. *Postgraduate Medical Journal* 54: 25–40, with permission.

RGCs that include expression of GFAP. Thus, they may be considered as genealogical, morphological, and biochemical descendents of the transient fetal RGCs. However, in some nonmammalian vertebrate species, RGCs may persist throughout the adult life span. Thus, the fate of the RGCs depends on the context and functional requirements, which differ between regions and between species.

Remnants of RGCs in the adult rodent forebrain can produce glial cells throughout life as well as specialized neuronal cell lines that migrate into the olfactory bulb and as hippocampal formations where they are capable of transformation into neurons. The gain-of-function approach has revealed that Notch activity may be involved in cell decision making by promoting glial differentiation and/or inhibiting neurogenesis. The available data also indicate that both cell–cell interactions and cell lineages are likely to determine the fate of RGCs, and under certain conditions they can serve as a multipotent neural stem cell. Thus, while during their transient existence, fetal RGCs contribute actively to brain construction, and the remnants of their progeny may be involved in brain functioning in health and disease during the entire life span.

Introduction

Although this article is presented in two main sections – reaching and grasping – this dichotomist organization does not mirror a strict anatomical and functional distinction between reaching and grasping. Early evidence suggested that prehension movements under visual guidance are controlled by two parallel visuomotor channels, one for reaching, the other for grasping. According to this idea, reaching movements entail the medial parietofrontal circuit that comprises the superior parietal lobule (SPL) and the dorsal premotor cortex (PMd), whereas grasping movements entail the lateral parietofrontal circuit involving the inferior parietal lobule (IPL) and the ventral premotor cortex (PMv). Recently, however, this basic dichotomy has been reviewed by several authors. Not only it has been shown that the pathways that link posterior parietal cortex to PMd and PMv partially overlap, but also that both PMd and PMv contain cells encoding the arm direction of movement, as well as proximal and distal representations of the arm. Thus, this new evidence questions the existence of two separate circuits for reaching and grasping and suggests that both circuits are likely to be involved in both actions.

Reaching

Reaching toward objects requires the unraveling of a complex spatial problem, given that different reference systems are involved in the coding of the position of the reaching hand and of the position of the to-be-reached object. In order to perform a successful reaching movement toward an object, signals about limb starting position, eye position, and target location have to be combined and integrated into common, distributed spatial representations. A central role for such integration, played by a neural circuit involving the frontal and the parietal cortex for the control of reaching movements, has been revealed by neurophysiological, neuropsychological, and neuroimaging evidence. This circuit comprises motor areas and regions located in the frontal lobe as well as in posterior parietal regions. The evidence emphasizes the role of the posterior parietal cortex in space perception and guiding actions, indicating that the sensory control of action depends crucially on this region. This fundamental role ascribed to the posterior parietal cortex may be due to its anatomical location. The posterior parietal cortex is localized between the visual cortex in the occipital lobe and the somatosensory cortex in the postcentral gyrus. This makes it very well positioned to receive visual and somatosensory information as well as to send output to premotor and motor areas in the frontal cortex, which is also fundamental for the control of reaching movements.

Reaching in the Monkey

By means of single-unit recording techniques, a number of studies have indicated the presence of fronto-parietal reach-related neurons that have the capacity to integrate different spatial variables relative to the structure of the external world, such as spatial location, distance, physical dimension, and to perform some of the associated visuomotor transformations required to organize successful visually guided movements (Figure 1(a)).

Studies conducted on macaque monkeys have also shown that a number of subareas of the posterior parietal cortex contain neurons that respond during the execution of reaching movements. For instance, activity within a visual area (area V6A; Figure 1(a)) located in the superior parietal lobe of the monkey was found when the animal was instructed to push or pull a lever positioned outside the field of view. Another important finding suggested that eye-position signals influence reaching-related activity not only in parietal areas but also in regions of the frontal cortex such as PMd and PMv, suggesting that frontal areas do contribute to the process leading to target localization in space, and therefore to the transformation from visuospatial to motor coordinates necessary for reaching. In line with this evidence an earlier investigation indicated that frontal and posterior parietal areas share similar functional properties, thus suggesting that the parietal region is not the sole area involved in the generation of motor commands appropriate for carrying the hand to a visual to-be-reached target.

Collectively, results from these studies indicate that coding visually guided reaching requires the integration of multisensory information into common or comparable frames of reference, and that this multimodal fusion relies on the combinatorial properties of parietal and frontal reach neurons.

Another interesting issue that has been taken into account by researchers pertains to the study of the 'early' mechanisms of reaching. Of relevance is the question of at which temporal stage of the

Figure 1 Comparison between neural circuits for reaching and grasping in the macaque monkey and humans. Lateral view of the monkey and human cerebral cortex for both reaching (a and b, respectively) and grasping (c and d, respectively) circuits. (a) Representation of the parietal reach region for reaching as identified in monkeys. (b) Reaching areas in humans as identified by neuroimaging studies. (c) Representation of the visuomotor stream for grasping as identified in monkeys. (d) Grasping areas as identified in humans by neuroimaging studies. Cortical areas that control grasping are also connected with basal ganglia and cerebellar circuits (these circuits, although involved in grasping, are not depicted here). AIP, anterior intraparietal area; CS, central sulcus; FC, frontal cortex; IFG, inferior frontal gyrus; IPL, inferior parietal lobule; IPS, intraparietal sulcus; MIP, medial intraparietal area; PCS, postcentral sulcus; PFC, prefrontal cortex; PreCG, precentral gyrus; PostCG, postcentral gyrus; pIPS, posterior intraparietal sulcus; PMC, premotor cortex; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; PO, parietooccipital; PRR, parietal reach region; SI, primary somatosensory cortex; SMA, supplementary motor area; SPL, superior parietal lobule. information processing flow leading from vision to movements does the convergence of multimodal reach-related signals occur. In a recent study, mechanisms underlying the early formation of motor commands for reaching in the parietal cortex were investigated. Results not only confirmed previous evidence suggesting that neurons within the posterior parietal cortex encode visual and eye-related signals, but also indicated that neuronal activity is modulated by arm-related information at very early stages of the coding of reaching. All in all, these findings suggest that many parameters connected to visually guided reaching, such as visual stimuli, oculomotor behavior, and arm motor behavior, affect neuronal activity at an early stage of the visuomotor processing.

Reaching in Humans

Neuropsychological evidence The role of the posterior parietal cortex in reaching has also been documented by neuropsychological studies conducted on patients suffering from optic ataxia, a specific disruption of visually guided hand movements in which misreaching occurs for targets presented in the peripheral visual field, but not for targets presented in central vision. Nevertheless, these patients are usually able to saccade to targets or to accurately reach toward targets presented on their own bodies, suggesting that optic ataxia is not a sensory or a motor disorder *per se*. The lesions underlying optic ataxia were classically localized within the parietal cortex, in particular along the intraparietal sulcus (IPS) and sometimes extending into the IPL or SPL. A recent neuropsychological study, however, in which parietal lesions of optic ataxic patients were compared with parietal lesions of patients who were not diagnosed with optic ataxia, indicates that specific parietal areas associated with this disorder are the IPS, the medial occipitoparietal junction, the superior occipital gyrus, and the SPL (Figure 1(b)).

Neuroimaging and transcranial magnetic stimulation evidence Various studies designed to examine the neural basis of reaching had participants reaching to touch an object with the index finger, reaching to touch an object with the knuckles, or reaching to grasp an object. On the basis of this variability, it may be hypothesized that these tasks differ in their demands and therefore elicit results that are not directly comparable. Although characterized by these methodological problems, results from human neuroimaging studies appear to nicely fit with the aforementioned reported neurophysiological and neuropsychological results. A number of positron emission tomography (PET) studies reported parietal activation contralateral to the hand used to perform the reaching action.

Functional magnetic resonance imaging (fMRI) studies mainly have focused on pointing rather than reaching, and activation in both the medial intraparietal sulcus and the precuneus has been reported. In one study, participants used a joystick to move a cursor to a visual target; a region of activity was found within the medial intraparietal sulcus. Other work provided evidence in favor of a general functional network shared by pointing actions independently of effector (i.e., hand vs. eye). An fMRI experiment examined both execution and preparation of hand-based pointing movements and eye-based pointing (via saccades) movements. Data indicated that similar left hemisphere intraparietal areas were recruited during movement preparation for both eye- and hand-based cued pointing movements, although this activation was slightly greater for hands as compared to eyes. Other recent studies have instead focused on the role of the medial occipitoparietal junction (Figure 1(b)). For instance, in an experiment, participants were requested to reach toward body parts with their eyes closed. Results showed that the level of activity in the medial occipitoparietal junction was maximum for the first executed movements and decreased for subsequent movements, suggesting that this region not only activates in response to reaching toward visual targets but also toward not-visually-available bodily targets.

A more recent study suggested the existence of distinct neural circuits for central and peripheral reaching. Brain activity was measured while healthy participants were requested to reach toward a central or a peripheral visual target. Results indicated the existence of two systems. The first is specific for reaching in central vision and involves a restricted network, including the medial intraparietal sulcus and the caudal part of the PMd (Figure 2). The second system is specific for reaching in peripheral vision and involves the same network, with the addition of two areas: the parietooccipital junction and the rostral part of the PMd (Figure 2). These results indicate that reaching to the peripheral visual field engages a more extensive cortical network than does reaching to the central visual field, and well explain the deficits of peripheral vision showed by patients with optic ataxia.

Using transcranial magnetic stimulation (TMS), a technique that allows temporary and circumscribed virtual lesions to be induced in healthy humans, to

Figure 3 Example of how the hand preshapes during reaching to the target object.

momentarily disrupt the human posterior parietal cortex, indicated a tendency to reach closer toward fixation and the inability to correct (i.e., to compensate for jumps in target location and to learn new movement trajectories). Again this confirms the prominent role played by the parietal cortex for the planning and execution of reaching.

Grasping

Grasping is coded in terms of changes in grip aperture – the separation between the thumb and the index finger and hand-shaping, or the posture assumed by all digits along the reaching action. During a reach-to-grasp movement, there is first a progressive opening of the grip, with straightening of the fingers, followed by a gradual closure of the grip until it matches the object's size (Figure 3). As discussed in the following sections, a surge in research on human prehension is forming the basis for the unraveling of the neural circuits underlying this action.

Grasping in the Monkey

By means of single-cell recordings three specific areas involved in grasping have been uncovered in the cortex of the monkey brain: the primary motor cortex (F1), the premotor cortex (F5), and the anterior intraparietal sulcus (AIP; Figure 1(c)). In terms of neural mechanisms, performing a successful grasping action depends primarily on the integrity of the primary motor cortex (F1). Lesion of this area in monkeys produces a profound deficit in the control of individual fingers and consequently disrupts normal grasping.

Another fundamental process for a successful grasp involves a transformation of the intrinsic properties of the object, visually described, into motor actions. As for reaching, a frontoparietal neural circuit seems to be involved in visuomotor transformations for grasping. This circuit is composed of area F5 and AIP. Area F5 forms the rostral part of the monkey PMv. AIP is a small zone within the rostral part of the posterior bank of the IPS that is directly connected with area F5.

On the basis of the functional roles of neurons in areas AIP and F5, a model has been developed in which area AIP provides multiple descriptions of three-dimensional objects for the purpose of manipulation, whereas area F5 is mainly involved in selecting the most appropriate motor prototype from a motor vocabulary – for example, the type of grip that is effective in interacting with a target object. Confirmation that the AIP/F5 circuit is likely to be relevant for grasping has also been derived by reversible inactivation of each of these areas independently in the monkey. Inactivation of either AIP or F5 markedly impaired hand shaping during reaching, and the hand posture was inappropriate for the object size and shape.

Somatic receptors in muscles, joints, and skin provide information regarding the current posture of the hand and its location and orientation with respect to potential targets for grasping. To investigate the conjunction of visual and somatic processing, one study compared the timing of spike trains recorded by single-unit recording in the somatosensory cortex (SI) and the anterior intraparietal cortex of the same animals during a reach-to-grasp task. The response of cells in AIP was influenced by the shape of the target object. Neurons in SI typically responded later than did those in AIP, showing a significant increase in firing rates only after the hand touched the object, and peaking when grasping was secure. Further, SI neurons rarely differentiated the shape of the grasped object in the manner that occurred in AIP neurons.

Grasping in Humans

Neuropsychological evidence The evidence for specialized circuits for grasping in the human brain comes mainly from the neuropsychological literature. As in the monkey, lesions of the human primary motor cortex or corticospinal fibers profoundly disrupt grasping. Such lesions typically lead to grasping movements that are initially characterized by the loss of independent finger movement, although synergistic movements of all fingers (a power grip) remain intact.

In terms of the human–monkey homology, there is also some evidence that the AIP has a specific role in human grasping. In this respect it has been suggested

that the area responsible for grasping is confined to the anterior part of the human IPS, contralateral to the impaired hand (Figure 1(d)). In line with the results obtained from monkeys in which AIP was inactivated, human patients with lesions in AIP had deficits in grasping, whereas reaching remained relatively intact.

It has been found that in reaching to grasp an object, the finger grip aperture of patients with optic ataxia was abnormally large, and the usual correlation between maximum grip aperture and object size was missing. Subsequently, various patients have been described that show specific deficits in the control of grasping after damage to the SPL. Patient V.K., for example, showed an apparently normal early phase of hand opening during attempts to grasp an object, but her on-line control of grip aperture quickly degenerated, resulting in numerous secondary peaks in the grip aperture profile, rather than the single peak typical of a healthy human. Another patient, A.T., with extensive damage to the superior parietal lobe and secondary visual areas, and some damage to the IPL, showed exaggerated anticipatory opening of the fingers with poor correlation with object size, resulting in awkward grasps. However, this deficit was much less marked if neutral 'laboratory' objects, such as wooden blocks, were replaced with familiar objects, such as a lipstick. Thus, in the case of commonly used objects, cognitive cues can be used to determine the size of the object, based on prior knowledge about these objects, suggesting that the meaning attached to an object might modulate classic grasping circuits.

Evidence from neuroimaging and TMS Brain imaging experiments have investigated the existence and localization in humans of cortical circuits for grasping similar to those described in monkeys. Early attempts to use brain imaging to identify the functional anatomy underlying the generation of goal-directed arm movements during the action of reaching and grasping movements in humans were conducted with PET. When participants were asked to reach and grasp illuminated cylindrical objects or to point to the same targets with their right hand, increases in regional cerebral blood flow (compared with looking at the target) were found in many cortical and subcortical areas, including the contralateral motor cortex, premotor cortex (PMC), ventral supplementary motor area (SMA), cingulate cortex, SPL, dorsal occipital cortex, and left parietal operculum.

In another study, participants were asked to touch or grasp one of five cylinders with their right hand. Compared with touch, grasping increased activity in extensive regions of the bilateral PMC, the posterior parietal cortex (PPC), and the prefrontal cortex (PFC; Figure 1(d)). Other investigations have used 'grasping,' 'pointing,' and 'matching' conditions. In the matching condition, participants compared the shape of the presented object with that of the previous one. The comparison between grasping and pointing showed an increased regional cerebral blood flow in the anterior part of the PPC. The comparison between grasping and matching showed activity increase in the cerebellum, the left frontal cortex (FC) around the central sulcus (CS), the medial frontal cortex, and the left IPL (Figure 1(d)).

In an early PET study, participants were tested in a 'grasping' condition that was compared with two 'observation' conditions. In one observation condition, participants observed grasping movements of common objects performed by the experimenter. In the other they simply looked at the object. Grasping with the right hand significantly activated the left supramotor cortical areas, the left SPL, the cuneus bilaterally, the left putamen, and the cerebellum bilaterally.

The results from a study comparing a precision grip action toward a sweet food with the right hand, grasping with the mouth, and simply observing the sweet showed an extensive hand grasping network including the left pre- and postcentral gyri (PreCG and PostCG, respectively), along the midline in the cingulate gyrus, the precuneus, and the IPL bilaterally (Figure 1(d)). When addressing the selection and execution for particular types of grasp, it emerged that for power grips, using the whole hand, and for a precision task, using the thumb and index finger, the PreCG and the PostCG and two sites in the parietal cortex, the SPL and AIP (Figure 1(d)), were activated.

Studies conducted with fMRI provide spatial resolution superior to that achieved in PET imaging, eliminating many of the possible confounds that characterized the earlier PET studies. One fMRI study used an alternating task design, in which grasping of a rectangular object, the orientation of which could vary, was used as the activation condition and pointing toward the object was used as the baseline condition. The results showed a specific activation of the lateral bank of the AIP in grasping tasks, together with activations including the contralateral sensorimotor cortex, bilateral PMC, and the PPC. The activated part of the AIP is the same area in which lesions in humans and chemical deactivation in monkeys lead to grasping deficits (Figure 1(d)). This study was further confirmed by studies that used a region-of-interest approach and an event-related design. For example, participants were presented with a diverse and unpredictable sequence of objects (rectangular shapes of varied length and orientation) using custom equipment termed 'the grasparatus,' and had to reach

toward the long axis of the objects and grasp them using a precision grip. The results provided strong evidence that the AIP contributes to the ability to execute grasping actions toward objects.

Other studies sought to find a neural network for grasping in the human brain similar to those in area F5 of macaques. In three execution conditions, participants executed a type of grasp appropriate for the object that they viewed; imitated a pantomime action they viewed; or imitated a viewed hand grasping an object. In the baseline condition, participants executed a power grip on all trials while viewing a stationary background. One of the objects used was a large object that would normally be grasped with a power grip; the other was small and would normally be grasped by a precision grip. The areas that were activated were consistent with the monkey AIP/F5 visuomotor circuit. The results showed activation of the AIP, the inferior frontal gyrus (IFG) and the premotor cortex during grasping movements (**Figure 1(d)**).

Similarly, when comparing brain activity during a precision grip and a power grip, the activity recorded in the contralateral primary sensorimotor cortex was higher during a power grip than during a precision grip. By contrast, the activity in the ventral PMC, the rostral cingulate motor area, and at several locations in the posterior parietal cortex and the PFC was stronger during the precision grip than during the power grip (**Figure 1(d)**). The power grip was associated predominately with contralateral activity, whereas the precision-grip task involved extensive activation in both hemispheres. These findings indicate that in addition to the primary motor cortex, premotor and parietal areas are important for control of fingertip forces during precision grip. All together, imaging studies indicate that a grasping circuit similar to that of the monkey can be broadly identified in humans, but also that a much wider network of areas is engaged.

Recent work has shown that TMS has the potential to reveal important facts about the neural networks that mediate grasping. For instance, repetitive TMS stimuli applied to the left superior parietal lobe as participants reached to grasp objects that could suddenly change in size indicate that this area might be crucial for the on-line control of grasping. The future might lie in combining TMS with activation data to study functional connectivity during grasping.

Reading is clearly one of the most important human activities. Indeed, Abraham Lincoln gave a speech on inventions in which he deemed that reading was the greatest human invention in history because it made civilization and democracy possible. In addition, reading is an important venue in which to study human cognition because it is simultaneously an activity of great importance and one that can be examined in the laboratory with great precision and with minimal perturbation of the normal activity that occurs outside the psychological laboratory. The tool that allows this to happen is a machine that allows one to monitor the location of what the eyes are looking at on a moment-to-moment basis as someone reads text. Thus, although we allude to other laboratory paradigms for studying the processing of written and printed language, this article is largely limited to discussing what has been learned about reading through the study of eye movements.

First, however, we need to make clear how the eyes move as one reads. Although one has the impression that they move smoothly across the page, this is an illusion. That is, when one reads, the eyes stay relatively fixed for periods of time that are typically between approximately 200 and 300 ms and then quickly jump (in approximately 20–30 ms) to a new location. The stable periods are called fixations, and these quick, ballistic, eye movements are called saccades ('saccade' is French for 'jump'). Moreover, vision is essentially suppressed during saccades so that the only useful information is obtained during the fixations. Note that the eyes are not entirely still during fixations and the two eyes are not always pointing at exactly the same letter, but it is useful to regard both of them as fixated on a single letter during a fixation. Any corrections to what we conclude later, where we ignore these two factors, are extremely minor. As one might expect, the large majority of saccades move forward through the text, although regressions (eye movements going backward through the text) are not rare and account for approximately 10–15% of the eye movements in reading. When the reader comes to the end of a line, a large rightward, although not regressive, eye movement (called a return sweep) is made to near the beginning of the next line of text. This process is somewhat complex because the second or third word of the next line is often fixated initially (since large motor movements are often undershoots), quickly followed by leftward saccades to the first word of the next line. For this reason, the detailed studies of reading discussed in the following sections rarely involve analyses of words near the beginning and end of a line of text, and often participants read a single line of text for comprehension.

Eye movement recording has progressed to the point at which it is quite easy to record eye movements extremely accurately. The most precise eye trackers are spatially accurate so that they are no more than approximately one-half a character off and provide a millisecond-by-millisecond record in the time domain. More widely used trackers that are cheaper and easier to use are still accurate to approximately a character and are accurate in the temporal domain up to approximately 5 ms. Thus, with either type of tracker used today, one can be quite sure of what word someone is fixating and can measure the duration of a fixation with an accuracy of approximately 3–5 ms. This precision would be irrelevant, of course, if the location where the eye is pointing had little relation to the cognitive processing occurring in reading. However, the eye position is in fact quite closely linked to the underlying processes of reading.

The Perceptual Span in Reading

The most direct way in which a tight linkage between the location of an eye fixation and the underlying processing in reading has been demonstrated is through the moving window paradigm that was first used in classic experiments by McConkie and Rayner. In this paradigm, the text displayed on the video monitor depends on where the eye is looking. For example, in a one-word window condition, the word that is currently being fixated would be normal, but all the letters in the other words would be replaced by 'garbage' (e.g., random letters). However, when the eyes move and the reader fixates a new word, that word would now be normal on the next fixation and all the other words (including the previously fixated word) would have their letters replaced by random letters (Figure 1). Thus, one can think of this paradigm as one in which the reader is in a custom-tailored 'slide show,' in which he or she sees a new slide (tailored to where he or she is fixating) on each fixation. An interesting fact about this paradigm is that if the equipment is working correctly (and provided that the window is not too small), people are rarely, if ever, aware of the window; it just seems like normal reading.

The logic of the paradigm implies that if on a fixation people were encoding only the word being

```

```

Figure 1 An illustration of the moving window paradigm. The size of the window in the illustration is two words: the fixated word and the word to the right. The asterisks below the lines indicate the letter that is being fixated on a sequence of successive fixations. As indicated in the text, the size of the window can be defined in terms of either the number of letters or the number of words. In addition, the location of the window can be manipulated so that, for example, a two-word window could include the fixated word and the word to the left.

fixated, then they would read normally with a one-word window. This is not the case, however; in the one-word window condition, people tend to read approximately 200 words per minute, which is approximately 60% of the normal reading rate. However, this result does indicate that processing the word that is fixated is an important part of reading. This raises the question of how large the window has to be in order for reading to be normal. The answer from the original studies by McConkie and Rayner was that if the window extended 3 or 4 character spaces to the left of fixation to 14 or 15 character spaces to the right of fixation, reading was normal (i.e., normal comprehension and no loss in speed). Later experiments, in which the window was defined by words, indicated that in a two-word window condition (the window contained the fixated word and the word to the right) reading was approximately 90% of normal, and in a three-word window condition (the window contained the fixated word and the two words to the right) reading was normal. It thus appears that readers are spending most of their time during a fixation processing the fixated word but spending some time processing the next word and occasionally processing the one after that.

The outer limits of the window to the right are probably defined by visual acuity. That is, although one has the illusion that one can see clearly over the whole visual field, in fact, acuity is greatest in central vision (the fovea) and drops off quite quickly. However, there is no simple way to characterize the limits imposed by visual acuity, because the window is smaller if the text is quite difficult to decode (e.g., if it is very faint or in an unusual font). Moreover, it would depend on the distance of the text from the viewer and the size of the font. However, it is probably best to think of the window as being defined by the number of characters rather than in terms of a measure such as visual angle because there is probably a trade-off in acuity if the distance of the text or the size of the font changes. That is, if one makes the text larger, the letters would be easier to process (all things being equal); however, making the letters larger also forces them to be further from the fovea, and these two factors would compensate (within limits). Finally, it is interesting to note that the perceptual span for readers of languages that are more densely packed than English tends to be smaller than that for English. Thus, in the most extreme comparison, the perceptual span for Chinese readers is approximately one character to the left of fixation to two or three characters to the right.

Another fact about the perceptual span in reading is that it is asymmetric since it extends much further to the right of fixation. However, this is not a hard-wired 'biological' constraint because an experiment performed with bilingual Hebrew–English readers indicated that asymmetry of the window depended on the language being read (Hebrew is written from right to left). When these readers read Hebrew, the perceptual span was asymmetric to the left, but when they read English the span was asymmetric to the right, as with other readers of English. It is also the case that the span for beginning readers and dyslexic readers tends to be smaller than that for skilled readers. This is generally assumed to be due to the fact that beginning readers and dyslexic readers have more difficulty encoding the words in the center of vision than do more skilled readers.

Eye Fixations Reflect Ongoing Cognitive Processing

The results of the moving window experiments described previously suggest that a major part of the

agenda on a fixation is to encode the word that is fixated. A large amount of evidence supports this assertion, most notably that characteristics of the fixated word, such as its length (number of letters), frequency in the language, and predictability from the prior context in a sentence, all affect the amount of time spent on a word. Perhaps the best measure of word encoding is gaze duration, which is the sum of the duration of all fixations on a word from the first time it is fixated until it is exited. This measure, like the others discussed later, is conditional on the word being fixated on the first pass through the text (i.e., it is fixated before a word to the right of it is fixated). Other frequently used measures are first-fixation duration (the duration of the first fixation on a word), single-fixation duration (the duration of the fixation on a word conditional on the word being fixated once on the first pass), and total time (the sum of all fixation durations on a word including regressions back to the word). Another important measure is the probability of skipping a word.

As one might suspect, the properties of words indicated in prior paragraph – length, frequency, and predictability – are highly correlated. Short words tend to be frequent in the language and predictable, especially function words (articles, prepositions, conjunctions, and pronouns). However, experiments can unconfound them. For example, in an experiment examining word frequency, two words matched in length and predictability but varying in frequency are inserted into the same sentence frame. In the typical experiment, a given participant reads one of the two sentences, but the design is counterbalanced so that equal numbers of participants read each sentence. In addition, the sentences are closely matched on 'naturalness' (as judged by other participants). Moreover, even low-frequency words are selected so as to be easily within the vocabulary of all participants. The standard finding is that the average gaze durations on low-frequency words are between 30 and 50 ms longer than those on high-frequency words, with the difference depending on the difference in frequency between the two sets of words. This difference does not merely reflect some very long times on the low-frequency words. When one plots the histogram of gaze durations for the two sets, the difference is seen largely as a shift of the entire distribution. Similar but smaller effects are observed for first- and single-fixation durations on the word.

Similar findings are observed for word length and predictability (when the other factors are equated). That is, more predictable words are fixated for shorter periods of time than less predictable words, and shorter words are fixated for shorter periods of time than longer words. In addition, these variables also influence the probability of skipping a word. Shorter, more frequent, and more predictable words are skipped more often than longer words. The influence of word length on these measures may not seem very important since it makes sense that when there is a longer word to perceive, it takes more time to do so. However, this again shows that eye movements are registering moment-to-moment processing in reading. The skipping data deserve additional comment. The effect of word length on skipping may be largely due to factors other than ongoing cognitive processing. For example, it may be that the eyes may be biased to move forward a distance approximately equal to the average saccade length in reading, so a saccade that is planned to be short will tend to be longer than planned and a saccade that is planned to be long will tend to be shorter than planned. (This idea was touched on when we discussed return sweeps.) Thus, shorter words may tend to be skipped largely because of errors in motor programming rather than because of the ongoing cognitive processing. However, the same reasoning does not apply to skipping more frequent and/or predictable words. The fact that these are skipped more often indicates that the word to the right of fixation is sometimes processed and that this processing influences where the eye moves. We return to this point when we outline our model of reading.

Our discussion to this point has documented that the time to identify a word (as indexed by variables such as frequency, predictability, and length) has a strong influence on how long the word is fixated, and that these variables also influence whether a word is skipped. This suggests that word identification may be the primary engine that drives the eyes forward in reading and also may be the process that largely determines reading speed. We think that this suggestion is reasonable; however, it is an oversimplification. The next two sections discuss research that indicates that much more is going on in reading. The first discusses whether word identification can be viewed as a simple process in which the letters are encoded and readers merely 'look up' a word in a mental dictionary in a process that only involves letters and words or whether other coding is involved, such as encoding of sound or of morphemes. The second discusses the influences of 'higher level' factors such as syntactic parsing; some of these influences are surprisingly immediate.

The Processing of Words

From approximately 1970 to 1990, the literature in cognitive psychology was dominated by a view in which word encoding was a process by which printed

words made contact with an orthographic lexicon – a mental dictionary that was accessed by a particular sequence of letters. The idea was that other codes – such as the sound of the word, the meaning of the word, and the knowledge of what part of speech it is – were accessed only after this initial look-up process. Much of the work in the past 20 years, however, has indicated that the process is more complex.

First, we consider the issue of where and when phonological coding (i.e., access to the spoken form of language) occurs. It is a common belief that skilled readers go directly from print to meaning without accessing the sound of the language. However, the data indicate that this is false and that access to sound occurs quite early in the process of identifying printed words and influences the process quite strongly. In a classic experiment, participants were asked to make meaning judgments on whether a single word presented in isolation was a member of a semantic category (e.g., whether 'maple' is a tree). The participants were both slow and made large numbers of errors (>10%) in judging, for example, that 'beach' is not a tree. Indeed, other experiments demonstrated effects that were almost as large using nonword homophones (e.g., judging that 'tayble' is not furniture). If readers went directly from print to meaning, and only later encoded the sound of a word, this should not happen.

The importance of phonological coding in early stages of word recognition has also been demonstrated in silent reading of text. Many of these experiments use the boundary paradigm, which is similar to the moving window paradigm but only involves a single display change. In it, there is an invisible boundary just to the left of a target word (**Figure 2**), but before the reader crosses the boundary, there is typically a preview different from the target word. However, when the eyes cross the boundary, the preview is replaced by the target word. The sentence always makes sense with the target word and, as with the moving window experiments described previously, readers are almost always unaware of the identity of the preview and of the display change. In early experiments involving the boundary technique, it was demonstrated that if there was letter overlap between the preview and the target, gaze durations were shorter on the target word than if the preview shared no letters with the target. This indicates that some partial information from the preview is extracted that facilitates processing of the word when it is fixated. However, this could either be orthographic (letter) information or phonological information. A later experiment demonstrated that at least part of the information was phonological. It employed previews that were either homophones of the target word or control words that were matched on the number of letters they had in common with the target word (**Figure 2**). It was found that fixation times on the target word were shorter when the homophone was the preview. This indicates not only that phonological coding occurs in reading but also that it occurs early – even before a word is fixated.

```
                    |
John walked by the beech on his way to the store.
        *

                    |
John walked by the beech on his way to the store.
             *

                    |
John walked by the beach on his way to the store.
                      *
```

Figure 2 An illustration of the boundary paradigm. The vertical mark indicates the boundary (which is not visible to the participant). The display change involves only a single word location, and the only display change occurs when the boundary is first crossed. In this illustration, a homophone of the target word is the preview. Other possible previews could be 'bench,' 'broad,' 'bsfhfs,' or 'xxxxx.' In fact, fixation time on the target word is shorter when 'beech' is the preview rather than 'bench' (indicating phonological coding of the preview), but 'bench' is a better preview than any of the others, indicating orthographic coding of the preview.

A second issue in the encoding of words is whether one goes directly to a single 'lexical entry' (be it orthographic or phonological) for all words or whether the meaningful parts of complex words are part of the encoding process. For example, when one sees the word 'unlikely,' does one treat it as a unit, or do the morphemes un- (meaning not) and -likely play a role in the encoding process? One way this has been investigated is to determine whether the frequency of the component morphemes plays a role in the speed of word encoding as well as the frequency of the entire words. In the typical experiment using this paradigm, either the frequency of an individual morpheme is varied or the frequency of the whole word is varied while holding the frequency of the other constant.

The original experiments using this paradigm were done with long (>10 letters) two-component Finnish compound words (e.g., vaniljakastike = vanilla sauce), and quite large effects (>70 ms) were obtained from varying both the frequency of the components and the frequency of the entire compound word. Later experiments using this paradigm with shorter Finnish compounds, however, obtained much smaller effects of the components. Consistent with these findings, only small effects of the components have been found with five- to nine-letter English words. It thus appears that both the whole word and its morphemic components are active

in accessing a complex word, but there is a 'race' between the process that is looking up the word and the process that is constructing it from the parts, and the process that looks it up directly tends to win the race unless the word is fairly long. Similar results have been obtained with English prefixed words, where the frequency of the whole word is most important for shorter prefixed words, and the frequency of the root (e.g., 'likely' in 'unlikely') plays a major role for longer prefixed words.

Finally, it is important to note that other properties of the fixated word influence how long readers look at it. That is, to simplify our previous exposition, we have used the frequency of a word in the written language as the sole indicator of difficulty. However, this is clearly confounded with a number of important variables, such as the frequency in the spoken language and the age at which the word was acquired. Several studies have shown that the age of acquisition is an important variable and has a significant effect even when word frequency is controlled. Another important variable is whether a word has several distinct meanings (lexical ambiguity). Readers tend to look longer at balanced lexically ambiguous words (those whose meanings are approximately equal in frequency) than control words matched on length and frequency in neutral contexts. However, when the context instantiates one of the meanings, there is no difference between the ambiguous word and the control word. Conversely, readers do not look longer at biased ambiguous words (those in which one of the meanings is dominant (i.e., much more frequent)) than control words in a neutral context. Here, the reader apparently takes the dominant meaning and goes with it, but if the subsequent context instantiates the less frequent meaning there is considerable disruption. However, when the preceding context instantiates the subordinate meaning, readers look longer at the ambiguous word than at the control word. These findings clearly demonstrate that the number of meanings of a word and the nature of the context interact in influencing how long readers look at such words.

Processing of Syntax and Global Meaning

Although written text has some ambiguity at the lexical and phonological level, there are also ambiguities at the level of syntax. Thus, for example, a sentence such as, 'While Mary was mending the sock fell off her lap' is ambiguous in that 'the sock' can initially be taken as the object of 'was mending' (in this case, an incorrect parse of the sentence) or as the beginning of a new clause (in this case, a correct parse of the sentence). Numerous studies using syntactically ambiguous sentences have examined readers' parsing strategies, and the resulting eye movement data have been very informative. In these studies, readers are often led 'down the garden path' in that they expect one interpretation, but an alternative interpretation turns out to be correct. It appears that with these types of ambiguity, readers are committed to one interpretation (hence, they can easily be 'garden-pathed'), but when they encounter disambiguating information, they revise their initial parse. Having to deal with the disambiguating information typically produces either very long fixations or regressions back to where the reader would have been led astray (or both).

The global meaning of a passage can also influence eye movements. Thus, readers often need to engage in anaphoric reference (tying together an anaphor such as 'he,' 'she,' or 'they' to a prior antecedent). When there is ambiguity regarding the antecedent, fixation times increase and readers are also sometimes forced to make a regression back in the text. Likewise, clever experimental manipulations have revealed that when readers make inferences as they read, the nature of the inferences can be inferred from the pattern of eye movements.

Models of Eye Movements during Skilled Reading

As should be clear from the previous discussion, there is still much to be learned about how people go from the marks in the page to understanding a novel, an encyclopedia article, or even a relatively simple paragraph. Hence, current models of reading have a more modest goal: they are primarily interested in trying to understand how the cognitive processing of the text is related to the movement of the eyes through the text. As a result, most of the models proposed in the past 10 years have basically assumed that most of the control of eye movements is related to identifying individual words and that there is a secondary role for the higher-order processes discussed in the previous section. That is, in most models, the role for such secondary processes is largely to stop processing when difficulty is encountered (such as in the syntactic misparsing example discussed previously), and that the normal, forward, movement of the eyes is largely guided by word identification. Empirically, this assumption is reasonable given that the characteristics of individual words, such as their frequency in the language, do produce large effects on the fixation durations on those words. In addition, it seems unlikely that the eyes could move three or four times per second if the reader is waiting on each fixation to make sure that the fixated word was a good fit into the ongoing parse of the sentence and into the ongoing discourse structure.

As a result, most models have striven to explain how word identification moves the eye through the text. We concentrate on the E-Z Reader model, which we think is the simplest and illustrates most of the major points. The E-Z Reader model makes the simplest possible assumption about word identification: Words are identified serially – one word at a time. When the identification of one word is completed, covert attention shifts to the next word and processing of that word begins so that processing of most words starts before they are fixated and continues when they are fixated. However, one complication of the model is that there is a slightly different signal to make an eye movement to the next word; a slightly earlier stage of word identification is the signal to fixate the next word. The target of a fixation is the center of the next word. A major motivation for positing the two stages of word processing is that the assumption allows one to explain why some frequency effects spill over to the next word.

One can then easily predict that the frequency and predictability of a word affect the time to fixate that word if one assumes that word identification time is influenced by these variables. However, such a model would predict that all words would be fixated. The mechanism for skipping in the E-Z Reader model was influenced by experiments that indicated that saccades can be canceled and replaced by other saccades if the signal for the second saccade occurs early enough. In the model, this is captured by positing that a program for a saccade is in two stages. That is, after the signal to make a saccade enters the motor system, there is an earlier labile stage in which the program can be canceled, followed by a later nonlabile stage in which the earlier program cannot be canceled. This explains skipping in the following way: If the reader is fixating word_n and has programmed a saccade to word_{n+1} and word_{n+1} is easy to process (e.g., if it is a short function word), then completion of the first stage of processing of word_{n+1} (which produces a command to fixate word_{n+2}) may follow quickly enough after the command to fixate word_{n+1} so that the first program is canceled and the reader goes directly to word_{n+2}.

There are other aspects of the model that handle refixations on words and other phenomena, but we only have space to outline the basic idea of the E-Z Reader model. Most important, the model can not only explain the phenomena on word processing described in the previous section in the qualitative manner but also produces good quantitative fits of the data and has made several nonobvious predictions that have been confirmed. As a result, we think it is a sufficient explanation of the reading process and, if true, allows for a relatively simple interpretation of eye movement data. For example, even in this simple model, one cannot assume that the mean gaze duration time on a word is equal to the mean time to identify the word, but under the assumptions of the model, one can infer that they are closely related. However, these simple assumptions may not be correct, and other models, which can also model eye movement data fairly well, have assumed that words are processed in parallel: two to four words may all be simultaneously processed at a point in time. Some experiments have attempted to distinguish between these assumptions. None, however, have been conclusive.

Summary

Reading is a complex skill that involves coordination of the language processing system and the eye movement system. Data indicate that forward movement of the eyes through the text is largely driven by the identification of words but modulated by other processes such as sentence parsing. On some level, this appears to be amazing because fixations in reading are usually slightly less than 0.25 s, and within this time, a word has to be encoded and a signal sent out to the eye movement system to execute a saccade based on this encoding. This can be accomplished, in part, because the processing of words begins even before they are fixated. Moreover, several models of eye movements can account for many of the phenomena of eye movements in reading while making reasonable assumptions about the time to encode words and the time to execute eye movements.

Reasoning and Problem Solving: Models

A K Barbey and L W Barsalou, Emory University, Atlanta, GA, USA

Introduction

Neuroscience research has increasingly provided evidence that informs theories of reasoning. We begin by defining classic forms of reasoning; and summarizing psychological contemporary theories. We then review empirical evidence from neuroscience that bears on these theories. Finally, we summarize current challenges and identify promising areas for future research.

Definition and Types of Reasoning

Reasoning is a hallmark of human thought, supporting the process of discovery that leads from what is known or hypothesized, to what is unknown or implicit in one's thinking. Reasoning can take the form of deductive inference, whereby the evidence guarantees the truth of the conclusion. Alternatively, when reasoning depends on conditions of uncertainty, it takes the form of inductive inference, whereby the evidence provides only limited support for the truth of the conclusion. The deductive inference that a storm has emerged is supported by evidence that it is raining, whereas observing lightning clouds provides only limited support for the inductive inference that it will rain. Many forms of reasoning typically depend on conditions of uncertainty, including problem solving, causal reasoning, and analogical inference.

Problem solving refers broadly to the inferential steps that lead from a given state of affairs to a desired goal state. For example, deciding who to vote for in a presidential election, diagnosing a patient on the basis of observed symptoms, or preparing for a mountain climbing expedition all depend on problem solving. Problem solving often requires the process of planning, namely, formulating a method for attaining a desired goal state. Planning a mountain climbing expedition, for example, requires scheduling the season of the expedition by predicting the consequences of taking the trip during different seasons. This is accomplished by modeling the situation and observing the consequences of possible actions (e.g., the occurrence of snow in winter introduces new challenges).

Prediction and explanation further depend on causal reasoning (i.e., the ability to infer causal relations). For example, knowledge that cold winter weather can cause an accumulation of snow in the mountains, which in turn can cause an avalanche, supports the prediction that an avalanche is possible during winter.

Finally, new predictions and explanations can be generated by analogical reasoning, whereby relations from one domain are mapped onto another domain. For example, students can conceptualize particle motion in an atom through an analogy to the solar system.

Theoretical Perspectives on Reasoning in the Psychological Literature

The psychological literature contains various theories that address the cognitive architecture and symbolic representations that underlie reasoning. After reviewing these theories, we turn to neuroscience evidence that bears on them.

Cognitive Architecture

One major distinction can be drawn between theories that view the mind as containing specialized reasoning modules, versus theories that view the mind as containing general-purpose reasoning systems. According to the modular view, the mind consists of specialized modules that are unavailable to conscious awareness and deliberate control (cognitively impenetrable), and that are only able to process specific types of information (information encapsulation). Advocates of this view have proposed a diversity of modules that underlie reasoning, including modules for semantic inference, communicative pragmatics, social exchange, intuitive numbers, spatial relations, naive physics, and biomechanical motion. If cognitive architecture emerges from an underlying neural architecture, then strong modular views predict that the neural systems for reasoning should be relatively localized, implementing modules that are cognitively impenetrable and informationally encapsulated.

Alternatively, dual-process theorists propose that reasoning is based on two general-purpose systems: an associative system and a rule-based system. The associative system uses basic cognitive operations such as association, similarity, and memory retrieval to produce primitive judgments quickly and unconsciously. The rule-based system reflects more evolutionarily advanced mechanisms that implement reasoning procedures deliberately and consciously. For example, inductive reasoning largely depends on the retrieval and evaluation of world knowledge, whereas deductive reasoning depends on rule-based, formal procedures.

The dual-process theory further motivates the cognitive demand hypothesis: when people have little time and limited processing resources, incentives,

and/or external aids available for making a judgment, they only use the associative system when reasoning. Conversely, when people have more time and greater processing resources, incentives, and/or external aids available, they also use the rule-based system. The dual-process model predicts that reasoning recruits different neural systems, depending on cognitive demand. When tasks are easy, the associative system is sufficient for correct reasoning and primarily recruits left inferior frontal gyrus, especially Broca's area, in addition to the temporal lobes and posterior parietal association cortex. As tasks become more difficult, the rule-based system becomes required for correct reasoning and recruits the prefrontal cortex, especially the ventrolateral subregion, which has been implicated in rule maintenance.

A second theory that provides a general-purpose account of reasoning is grounded in a somewhat different pair of systems: the linguistic system and the conceptual system. According to this view, the brain's language system initially produces relatively superficial information about a reasoning problem, such as word associates, syntactic structures, etc. As linguistic forms become generated, their meanings become increasingly represented in the conceptual system. A key assumption of this approach is that superficial processing based on linguistic representations may often be sufficient for adequate reasoning performance. When it is not sufficient, conceptual representations must be generated to produce more sophisticated reasoning. Thus, consistent with the dual-process model, this view predicts that differences in the cognitive demands of a reasoning task (i.e., superficial vs. deep processing) will differentially engage neural systems.

In general, both dual coding frameworks predict that reasoning will recruit neural systems that support two forms of coding. One important set of systems underlies language processing, including the left frontotemporal language system. A second set of important systems underlies conceptual processing, mental simulation, and imagery, including bilateral sensorimotor areas.

Representation in Reasoning

A second major distinction can be drawn between theories of reasoning that are based on amodal versus modality-specific representations. According to standard theories, the modality-specific states that are active while perceiving an entity are redescribed into amodal representations that bear no correspondence to the neural systems producing them. For example, the concept 'chair' is represented by redescribing the modality-specific states that underlie the perception of a chair into amodal representations (e.g., feature lists, semantic nets), processed by classic symbolic mechanisms (e.g., predication, argument binding). Thus, amodal theories predict that conceptual processing will recruit brain regions outside sensorimotor areas that underlie language and rules, including left prefrontal and superior temporal regions implicated in formal, rule-based operations.

In contrast, embodied theories of knowledge propose that knowledge and meaning are grounded in modality-specific representations. Increasing empirical evidence from both the cognitive and the neuroscience literatures suggests that modality-specific representations underlie higher level cognition. According to this framework, concepts are represented by simulating the modality-specific states that were initially activated during perception, action, and interoception. Embodied theories propose that simulations are organized at a higher level by simulators that integrate information across a category's instances. Over time, for example, visual information about how cakes look becomes integrated in a 'cake' simulator, along with gustatory information about how cakes taste, somatosensory information about how they feel, motor programs for interacting with them, emotional responses to experiencing them, and so forth. The result is a distributed system throughout the brain's modality-specific areas that establishes conceptual content for the general category of 'cake.' Thus, embodied theories predict that conceptual processing will recruit a broadly distributed system of modality-specific brain regions.

Embodied theories further motivate the task specificity hypothesis. According to this hypothesis, the neural areas underlying a particular type of reasoning, such as deduction, may show little in common, as the specific materials and tasks vary. Because different materials and tasks produce different patterns of modality-specific activation, the same general form of reasoning does not show a single, stable pattern, and no common areas may emerge. In contrast to the 'cognitive demand hypothesis,' this view predicts that significant differences in the task and/or materials – even those that do not affect cognitive demand – are likely to dominate neural activation more than the type of reasoning performed.

Mental Models versus Mental Logic

A third major distinction can be drawn between theories of reasoning that are based on visuospatial models versus theories that are based on logical operations. Mental-model theory proposes that deductive and inductive reasoning depend on spatially organized mental models. According to this view, an argument is

evaluated by generating alternative models of its premises, where each model represents possible circumstances that render the premises true. If all the models constructed from the premises are consistent with the truth of the conclusion, then the argument is judged to be deductive or valid. If, however, only a limited number of models render the conclusion true, then the argument is judged to be inductive or probabilistic.

Given the proposed role of mental models in both deductive and inductive reasoning, this theory predicts that these forms of reasoning will recruit common neural systems. Specifically, mental-model theorists have predicted that deductive and inductive reasoning will both primarily recruit right-hemisphere regions. Furthermore, to the extent that mental models represent situations spatially, this view predicts that parietal and occipital regions implicated in visuospatial processing will be engaged.

In contrast, mental logic theory offers an account of deductive reasoning that is based on the application of formal deductive rules according to formal syntactic operations. Thus, rule theorists have predicted that reasoning is likely to recruit left prefrontal and superior temporal regions implicated in formal, rule-based operations.

Empirical Evidence on Reasoning from the Neuroscience Literature

We next present empirical evidence from neuroscience that bears on the psychological theories just reviewed. We begin with research on deductive reasoning, and also address research that compares deductive and inductive reasoning. We then review research on problem solving, causal reasoning, and analogical reasoning.

Deductive Reasoning

The brain systems that implement deductive reasoning depend on whether the reasoning problem consists of familiar versus unfamiliar semantic content. When reasoning about familiar semantic content (e.g., All dogs are pets / All poodles are dogs / Therefore, all poodles are pets), a left frontotemporal system is engaged, including left inferior frontal cortex (BA 47), left middle/superior temporal cortex (BA 21/22), and left temporal pole (BA 21/38). Previous research has implicated this system, not only in deductive reasoning, but also in memory and language tasks that employ familiar semantic content. In general, linguistic processing appears central to all these tasks.

In contrast, reasoning about unfamiliar semantic content (e.g., All P are B / All C are P / Therefore all C are B) activates a bilateral frontoparietal system, including bilateral dorsal (BA 6) and inferior (BA 44) frontal lobes, bilateral superior and inferior parietal lobes (BA 7), and bilateral occipital lobes (BA 19). This pattern of activation is also found during the processing of spatial information, and is similar to the neural activity observed while people make transitive inferences about geometrical shapes.

Thus, deductive reasoning recruits left and right prefrontal cortex asymmetrically as a function of familiarity. Across both familiar and unfamiliar deduction problems, left prefrontal cortex is generally active, suggesting that this region is necessary for deductive inference. Conversely, right prefrontal cortex is engaged only when a problem involves unfamiliar semantic content or a conclusion that conflicts with prior beliefs (e.g., No harmful substances are natural / All poisons are natural / Therefore, no poisons are harmful). Whereas language may often dominate familiar reasoning, language and spatial/visual processing may often be central for unfamiliar reasoning.

The brain systems that implement deductive reasoning also depend on whether a reasoning problem produces correct versus incorrect conclusions. Research on this issue has used inhibitory belief problems, namely, problems whereby individuals must inhibit a highly accessible belief that could interfere with correct reasoning (e.g., No addictive things are inexpensive / Some cigarettes are expensive / Therefore, some cigarettes are not addictive). Drawing a correct conclusion on these problems requires that individuals (1) detect the conflict between their prior beliefs and the logical inference, (2) inhibit the prepotent response associated with their belief bias, and (3) engage the appropriate reasoning mechanisms. In contrast, drawing an incorrect conclusion on these problems results from failing to detect the conflict between beliefs and logical inference, and/or failing to inhibit the prepotent response associated with a belief bias.

When people draw correct conclusions on inhibitory belief problems, right inferior prefrontal cortex becomes active. When they draw incorrect conclusions, ventromedial prefrontal cortex is active instead. Activation in right inferior prefrontal cortex when drawing correct conclusions appears to reflect the detection and/or resolution of the conflict between belief and logic. Conversely, activation in ventromedial prefrontal cortex when drawing incorrect conclusions appears to reflect the role of nonlogical mechanisms, perhaps associated with greater affective processing.

In summary, the neural systems that underlie deduction vary considerably, depending on task factors and

cognitive demand. Consistent with the task specificity hypothesis, the areas that support deduction vary with the familiarity of the materials, and with whether belief violations occur and are detected. Consistent with the cognitive demand hypothesis, more neural areas are recruited for difficult unfamiliar problems than for easier familiar ones. Consistent with the modularity view, left prefrontal cortex generally appears active across most deduction paradigms, suggesting that it is essential for deductive inference.

Deductive versus Inductive Reasoning

Many experiments have asked individuals to perform both deduction and induction in the same experiment, so that the neural circuits underlying these two types of reasoning could be distinguished. One neuroimaging experiment used a categorical syllogism task consisting of three conditions – deduction, induction, and baseline – to assess this issue. In the deduction condition, individuals received a valid or invalid categorical syllogism (e.g., None of the bakers play chess / Some of the chess players listen to opera / Therefore, some of the opera listeners are not bakers). The task was to indicate whether the conclusion was valid (i.e., whether the conclusion was guaranteed by the truth of the premises). In the inductive reasoning condition, individuals only received invalid categorical syllogisms (e.g., Some of the computer programmers play the piano / No one who plays the piano watches soccer matches / Therefore, some computer programmers watch soccer matches). The task was to indicate whether the conclusion was probable or improbable. The deduction and induction conditions were each compared to a baseline condition, in which a categorical syllogism with anomalous semantic content was presented (e.g., All the engineers own a computer / None of the engineers has been to school / Therefore, all the people who own computers are married). Importantly, the categorical syllogisms were fully counterbalanced across individuals so that the same materials occurred in every condition.

Deductive reasoning (deduction minus baseline) produced activation in the left dorsolateral frontal cortex (BA 6), broadly consistent with the left frontal activation observed by other researchers for familiar semantic content. When deduction was compared directly to induction, however, a different pattern emerged, namely, activation in bilateral posterior regions, with a right-hemisphere prevalence, including associative visual cortex (e.g., cuneus, precuneus, middle and superior occipital gyri), as well as right superior parietal lobe (BA 7) and thalamus. These areas have been reported for visuospatial tasks that require form discrimination and imaginative operations. These areas have also been reported for deductive reasoning tasks that employ visuospatial materials. Such activations suggest that people use visuospatial representations, such as Venn diagrams or Euler circles, to support deductive reasoning on categorical syllogisms. In addition, activation was also found in right anterior cingulate (BA 24/32), implicating attention and executive control in deductive reasoning. Inductive reasoning (induction minus deduction) revealed activation in left dorsolateral frontal (BA 8 and 10) and right insular cortices. These regions are known to be involved in probabilistic reasoning tasks that require the estimation of relative frequencies and other quantities (e.g., How fast do race horses gallop?).

A subsequent neuroimaging study extended the methods and design of the study just described to a deduction task that employed conditional statements instead of categorical syllogisms (e.g., If he is an electrician, then he spent two years in night school / He is an electrician and owns a computer / Therefore, he spent two years in high school). In contrast to the categorical syllogisms used in the previous study, visuospatial processing did not seem relevant to these conditional syllogisms. Thus, these researchers predicted that the new task and materials would not recruit brain regions that perform visuospatial processing. Consistent with this prediction, deductive reasoning (deduction minus induction) revealed a major focus of activation in right inferior frontal cortex (BA 44), in right anterior cingulate (BA 24), and in right middle temporal cortex (BA 21). These researchers concluded that this frontotemporal system constitutes a logic-specific network in the right hemisphere that is comparable to the language-specific network in the left hemisphere. Specifically, these researchers argued that this right-hemisphere system implements a calculus of mental transformations that underlie formal deduction.

In a further comparison, inductive reasoning (induction minus deduction) revealed large intense activations in the left inferior frontal (BA 47) and left insular cortices, in addition to left posterior cingulate (BA 31), parahippocampal (BA 36), left medial temporal (BA 35), and superior and medial prefrontal cortex (BA 9). These areas are broadly consistent with the left frontal (BA 8 and 10) and insular areas found in the previous study, known to be involved in the recall and evaluation of familiar world knowledge. Consistent with standard theories of inductive reasoning, the recall and evaluation of familiar world knowledge appear to play central roles during induction.

Another neuroimaging study developed a category learning task to assess the component processes of inductive reasoning. Of primary interest were the neural systems that support rule application versus

rule inference during category learning. Stimuli consisting of novel animals were presented to individuals, who were asked to judge whether all the animals in a set were from the same category. In the rule application condition, a rule was provided that specified the criteria for category membership. In the rule inference condition, individuals had to infer the rule with no instruction. Each condition was further divided into an easy and difficult condition based on the computational demands of the task. These researchers found that rule inference (rule inference minus rule application) preferentially recruited bilateral hippocampus, an area in which activation is modulated by stimulus novelty. In contrast, rule application (rule application minus rule inference) revealed activation in the presupplementary motor area (BA 8). This area is implicated in the anticipation of motor activity and likely reflects an anticipatory response to category exemplars, a response that is absent when the categorization rule is unknown.

In addition to the episodic encoding of novel stimuli, inductive reasoning requires the generation and testing of hypotheses. For example, inferring the basis for category membership requires generating and testing possible rules, such as "has spots on the abdomen" or "has only two appendages" for a category of fictional animals. To assess the neural systems that underlie hypothesis selection, these researchers evaluated the task by difficulty interaction: {hard rule induction minus hard rule application} minus {easy rule induction minus easy rule application}. This comparison assessed the effects of increased difficulty due to subtle variations in the stimulus features of animals that satisfied or violated the category membership rule. The result was an activation in right lateral orbital prefrontal cortex (BA 47 and BA 11), an area implicated in complex reasoning tasks such as analogical and metaphorical transfer. Across different types of reasoning, difficult problems often activate this area.

In summary, current findings from neuroimaging studies of deduction and induction again suggest that the neural bases of reasoning are highly sensitive to the particular tasks and materials employed. For example, deductive reasoning from conditional statements engages a right frontotemporal system, thought to support the application of formal deduction rules, whereas deductive reasoning from categorical syllogisms activates a parieto-occipital system that supports visuospatial processing. Furthermore, the latter result differs from the findings of other researchers, who have found that a left frontotemporal system supports deductive inference in a categorical syllogism task. The observed differences on the same fundamental reasoning process – deduction – probably reflect methodological differences between the tasks and materials used across studies. Furthermore, the fact that different materials are often used on deduction and induction tasks suggests that different activations for these two forms of reasoning may often be driven by differences in materials rather than by differences in reasoning.

Consistent with the task specificity hypothesis, the neural processes that underlie a given type of reasoning (e.g., deduction) may depend more on the tasks and materials used than on the type of reasoning *per se*. Although left prefrontal cortex is often active on deduction tasks (as described in the previous section), it was not active for some of the studies discussed in this section. Perhaps the one consistent finding so far is that reasoning about familiar materials tends to utilize left-hemisphere language and knowledge networks. Conversely, reasoning about less familiar problems tends to utilize bilateral systems that include right-hemisphere mechanisms. This pattern is consistent with theories that postulate two different reasoning systems, one that processes language, and one that processes spatial/visual information.

Problem Solving and Planning

Depending on whether a problem-solving task is well structured or ill structured, different brain systems are engaged. On well-structured problems, such as the Tower of Hanoi, the starting state, the goal state, and possible transformations are specified completely. For example, the starting state consists of three pegs mounted on a platform and three disks of varying sizes stacked in descending order on the first peg. The goal state is to stack the disks in descending order on the third peg. The possible transformations are restricted to moving disks such that (1) only one can be moved at a time, (2) any disk that is not removed must remain on a peg, and (3) a larger disk cannot be placed on a smaller disk. In such tasks, well-structured planning typically recruits left prefrontal cortex, including frontopolar, dorsolateral, and ventrolateral regions.

In contrast, an ill-structured planning problem is specified incompletely. In the Multiple Errands Task, for example, individuals are taken to an unfamiliar neighborhood and asked to complete errands, such as buying a loaf of bread, according to the following rules: you are to spend as little money as possible (within reason) and take as little time as possible (without rushing excessively). You are not to use anything not bought on the street (other than a watch) to assist you. You may perform task steps in any order. In such tasks, ill-structured planning typically activates right dorsolateral prefrontal cortex

(DLPFC), in contrast to the left prefrontal regions that support well-structured planning.

The neural systems underlying planning are further differentiated into subsystems for plan formation versus plan execution. One finding is that DLPFC supports sequential operations during plan formation, whereas medial ventral prefrontal cortex (MVPFC) plays a motivational role in plan execution. More specifically, DLPFC appears to support the generation of hypotheses and the construction of plan steps, whereas the MVPFC appears to support the affective processing required for plan execution (e.g., initiative and determination).

Lesion studies complement the neuroimaging studies just reviewed. One representative study evaluated problem solving in patients with frontal lobe lesions (FLLs) on the Water Jug problem. Patients had to construct unique action sequences that transferred specific quantities of water between jugs of different sizes (e.g., Jar A = 8 units of water, Jar B = 5 units of water, Jar C = 3 units of water). Specifically, individuals had to construct an action sequence that achieved a goal state given by the experimenter (e.g., Jars A and B must contain 4 units of water, and Jar C must contain 0 units). The researchers found that patients with FLLs struggled to make counterintuitive moves that were required to solve the task but that appeared to deviate from the desired goal state. Furthermore, left and bilateral FLL patients were more impaired than right FLL patients were, suggesting that poor performance in the Water Jug task was primarily linked to left DLPFC damage.

In summary, these findings demonstrate that problem solving and planning generally depend on prefrontal systems. Because DLPFC appears important for most problem-solving tasks, modular views receive support. Differences in task conditions modulate the active areas of the prefrontal cortex, however, providing support for the task specificity hypothesis. For example, well-structured versus ill-structured problems rely on left versus right prefrontal regions, respectively. This pattern is also consistent with theories that assume two different systems, such as dual-process and dual-code theories, support reasoning. Finally, distributed theories receive support, given that multiple systems typically underlie problem solving. For example, problem solving requires both planning and execution, and also both reasoning and motivation, with different neural systems supporting each component process.

Causal Reasoning

Several studies have evaluated the neural systems that support the perception of mechanical causation in the classic Michotte launching event. In a launching event, a ball travels horizontally across a computer screen and collides with a ball located in the center. The collision results in the second ball 'launching' away from the first, horizontally, across the screen, thereby eliciting the perception that the first ball caused the second to move. One study compared the neural response produced by the launching event to the response elicited by a control event in which the first ball passed below the second ball without a collision (noncausal condition). Of primary interest were the neural systems engaged when individuals judged either (1) the presence or absence of causation versus (2) the direction of the ball's motion. A reliable increase in medial frontal activation occurred for judgments of causality relative to judgments of ball movement. Moreover, this increase occurred during both the causal and noncausal conditions, suggesting that the signal increase was specifically associated with the process of making a causal judgment, not with the perception of actual causality.

Another study evaluated whether causal perception and causal inference rely on common or distinct hemispheric regions. Two callosotomy (split-brain) patients and a group of neurologically intact patients were tested. Of primary interest was neural activity in the left versus right hemispheres during (1) the perception of causal events (i.e., the Michotte launching event) and (2) causal inference tasks when the relation between a candidate cause and an observed effect had to be inferred (rather than perceived directly). Perception of causality and causal inference depended on different hemispheres of the divided brain. Whereas causal perception engaged the right hemisphere, causal inference engaged the left-hemisphere.

Another study assessed the brain systems for processing evidence that was either consistent or inconsistent with an individual's existing causal beliefs. Individuals received evidence on the effectiveness of drugs designed to relieve depressive symptoms. Two factors were manipulated: the plausibility of the theory that explained the drug's action, and the consistency between theory and data. When individuals reasoned with evidence that was consistent with existing causal beliefs, a network of brain regions widely associated with learning and memory was engaged, including the caudate and the parahippocampal gyrus. In contrast, when they reasoned with inconsistent evidence, a different pattern of activation occurred that is widely associated with error detection and conflict resolution, including the anterior cingulate cortex (BA 24/32), posterior cingulate, and precuneus (BA 7). The researchers concluded that people's beliefs and expectations act as a filter during evidence evaluation. When

evidence is consistent with existing causal beliefs, the neural systems underlying those beliefs implement causal reasoning. When evidence is inconsistent with existing beliefs, a different neural system detects this inconsistency and triggers the construction of a novel causal explanation.

The observed findings demonstrate that causal reasoning is supported by a broadly distributed neural system that is highly sensitive to the causal reasoning task (i.e., causal perception versus causal inference) and the consistency of causal evidence with existing beliefs. These findings provide support for theories of reasoning that are (1) based on distributed rather than localized representations (e.g., dual-process, dual-code, embodied theories), (2) incorporate the role of existing knowledge rather than operating on the basis of purely logical representations (e.g., dual-process, dual-code, embodied, mental-model theories), and (3) advocate the task specificity hypothesis (e.g., dual-process, dual-code, embodied theories).

Analogical Reasoning

Several studies have found that analogical reasoning engages frontopolar cortex. Furthermore, different components of analogical reasoning appear to differentially engage frontopolar versus dorsolateral prefrontal areas. Whereas dorsolateral areas are recruited for processing externally generated information (e.g., the monitoring and manipulation of presented facts), frontopolar areas are recruited additionally for the evaluation and manipulation of internally generated information.

One study assessed the neural systems that support analogical reasoning in the Raven's Progressive Matrices task. Study participants received a 3×3 matrix of figures with the bottom right figure missing, and had to infer the missing figure by selecting one of four possible alternatives. Participants received three types of problems that differed in their degree of relational complexity (0-relational, 1-relational, 2-relational). The 0-relational problems involved no relation of change and thus required no relational processing. The 1-relational problems involved one relation of change in either the horizontal or vertical dimension, and thus required relational reasoning. Finally, the 2-relational problems involved two relations of change, in both the horizontal and vertical directions, and thus required even more relational reasoning.

A region-of-interest analysis was performed to assess the role of prefrontal cortex in processing multiple relations simultaneously (i.e., relational integration). This analysis produced two main findings. First, activation occurred in frontopolar prefrontal cortex (BA 10), reflecting the internal generation of relations required to form complex analogies. Interestingly, this activation only occurred for 2-relational problems, not for 1-relational problems, suggesting that frontopolar cortex is important for processing complex relational structures. Second, activations also occurred in right DLPFC (BA 46), which reflected greater manipulation of externally presented information in more complex problems. Other studies using the Raven's Progressive Matrices task have found similar results, and have also reported bilateral posterior parietal activations (BA 7).

In another study, individuals received a source picture of colored geometric shapes, followed by a target picture of colored geometric shapes. Pictures that did not share similar geometric shapes but that did share the same system of abstract visuospatial relations were also presented. Individuals judged whether each source-target pairing was analogous (analogy condition) or identical (literal condition). Analogical reasoning (analogy minus literal) recruited the dorsomedial frontal cortex (BA 8) and left-hemisphere regions, including frontopolar (BA 10), inferior frontal (BA 44, BA 45, BA 46, and BA 47), and middle frontal (BA 6) cortices, and also inferior parietal cortex (BA 40). These findings suggest that analogical reasoning is mediated by a predominantly left-hemisphere frontoparietal system.

Another study systematically evaluated the component processes of analogical reasoning. Specifically, this study assessed the neural systems that underlie (1) the storage of abstract relations in working memory and (2) the process of integrating abstract relations to form analogies. These researchers also found that analogical reasoning activated a left frontoparietal system, with some regions of this circuit mediating working memory processes and others mediating abstract relational integration. In particular, left frontopolar regions (BA 9/10) were again central to the processing of relations that underlie analogical reasoning.

In summary, the observed findings for analogical reasoning are consistent with theories that advocate distributed rather than localized representations (e.g., dual-process, dual-code, embodied theories). As we saw, distributed frontal and posterior systems appear to play a wide variety of roles as representations are retrieved, stored, and integrated. Findings on analogical reasoning further support the cognitive demand and task specificity hypotheses (e.g., dual-process, dual-code, embodied theories). Different kinds of information recruited different prefrontal areas (e.g., external vs. internal information), and the harder the reasoning, the more areas recruited (e.g., 1-relation

vs. 2-relation problems). The general importance of frontopolar cortex for generating relations internally suggests that this area is especially important for processing complex analogies.

Summary, Conclusions, and Future Directions

The findings discussed in this article support the following conclusions about the neural bases of reasoning. First, deductive reasoning does not appear to recruit a unitary neural system but instead engages different brain regions based on the particular reasoning task and materials employed. Second, inductive inferences drawn from familiar categorical syllogisms and conditional statements engage a left-hemisphere language and knowledge network implemented in frontal and temporal regions. Third, problem solving generally recruits prefrontal regions, including bilateral DLPFC and MVPFC. Fourth, causal reasoning does not engage a single neural system but instead recruits different systems based on the causal reasoning task and the consistency of causal evidence with background beliefs. Finally, analogical inference selectively recruits frontal and parietal regions, with frontopolar cortex becoming increasingly important as task complexity increases.

The neuroscience evidence reviewed helps evaluate current psychological theories. First, reasoning typically recruits broadly distributed neural systems, providing evidence inconsistent with the relatively localized predictions of modularity theory. Possible exceptions include the importance of certain frontal regions for problem solving (left DLPFC) and analogical reasoning (frontopolar cortex). Second, the results demonstrate that reasoning does not solely recruit left-hemisphere regions for language and rule-based operations. Instead, reasoning often engages bilateral and posterior regions beyond those implicated by amodal and mental logic theories of reasoning. Third, the predominantly right-hemisphere system predicted by the mental-models theory across both deduction and induction is inconsistent with many patterns of left-hemisphere and bilateral activation observed across studies. Fourth, dual-process, dual-code, and embodied theories are generally consistent with the reviewed findings. These theories receive support because they predict the presence of (1) broadly distributed neural systems and (2) multiple reasoning systems (e.g., associative vs. rule, language vs. knowledge). These theories also receive support from the many studies that exhibit effects of task specificity and cognitive demand. As task conditions change, so do the neural systems that represent and process the relevant information.

In general, reasoning tends to recruit broadly distributed and diverse neural systems. The difficulty of establishing specific neural systems for a given type of reasoning (e.g., deduction) strikes us as one major challenge for future research. Does a particular type of reasoning consistently activate a specific neural circuit across wide variation in tasks and materials? If so, what is this circuit? Another major challenge is that the multifaceted nature of the neurobiological evidence and cognitive theories results in a many-to-many mapping: neural regions often serve multiple cognitive functions that can be mapped onto multiple cognitive theories. Sorting out the functional roles of particular brain areas and their roles in psychological theories of reasoning should be another major goal in this research area.

Many other challenges also await future research in this area. For example, do the results from the laboratory tasks reviewed here generalize to everyday reasoning tasks? Rather than occurring in a vacuum, everyday reasoning often occurs in social situations and is associated with emotional affect. What are the neural bases of reasoning under these conditions? How do social and emotional processes modulate reasoning? Future research should also address the important distinction between reasoning to a conclusion versus recognizing a conclusion. Because many real-world situations require that people generate valid conclusions (not just recognize them), future neuroscience research should assess the neural bases of this process. Future research should also continue to address the role of task difficulty in reasoning. Does task difficulty result in the recruitment of more brain regions, or are the same regions activated more intensely? Future research should also address the effect of learning on the neural systems that underlie reasoning. Do novices and experts engage similar neural systems during reasoning?

Finally, researchers should develop psychological theories that motivate fine-grained neurobiological predictions, and should design experiments that distinguish between theories, rather than simply attempting to confirm one. Although much progress has been made in framing the issues and establishing preliminary evidence, neuroscience research on reasoning is still in its infancy. We anticipate major advances in coming years.

Receptor Trafficking

R L Stornetta and J J Zhu, University of Virginia School of Medicine, Charlottesville, VA, USA

© 2009 Elsevier Ltd. All rights reserved.

Glutamate receptor trafficking plays a key role in synapse formation and elimination. Soon after the formation of presynaptic and postsynaptic contacts, *N*-methyl-D-aspartate (NMDA)-sensitive glutamate (Glu) receptors (-Rs) arrive in excitatory synapses, resulting in silent synapses. Activation of NMDA receptors then triggers synaptic delivery of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA)-sensitive Glu-Rs into these synapses, transforming the silent synapses into mature or functional synapses. Synapse elimination reverses the processes: AMPA-Rs are removed from synapses prior to removal of NMDA-Rs. Silent synapses are abundant in young animals. Their number declines with increasing age and stabilizes in the adult. Synaptogensis occurs rapidly during early postnatal development, with a much slower rate in the mature brain. Synapse elimination reduces the number of synapses, which is initially far greater than the number retained in the adult brain. The relatively stable numbers of total and mature synapses in adult animals reflect the balanced processes of synaptic delivery and removal of NMDA-Rs and AMPA-Rs.

AMPA-R Trafficking

AMPA-Rs are tetrameric proteins which are composed of GluR1, GluR2, GluR2L, GluR3, GluR4, or GluR4c – six subunits that are coded by four genes, GluR1–4. The cytoplasmic C-termini of the constituent subunits, which can be either long or short, govern the synaptic trafficking characteristics of AMPA-Rs. At least five distinct synaptic AMPA-R trafficking events exist at synapses (Figure 1). AMPA-Rs with long cytoplasmic termini (i.e., GluR1-, GluR2L-, or GluR4-containing AMPA-Rs) are driven into synapses by synaptic activity. This process mediates synaptic potentiation (e.g., long-term potentiation (LTP)). Soon after synaptic potentiation, some of the newly delivered AMPA-Rs with long cytoplasmic termini are removed from synapses in an activity-dependent manner during depotentiation. Other synaptic GluR1-, GluR2L-, or GluR4-containing AMPA-Rs are eventually exchanged with AMPA-Rs with only short cytoplasmic termini (i.e., GluR2-containing AMPA-Rs). GluR2-containing AMPA-Rs constitutively cycle between synaptic and nonsynaptic sites. Synaptic AMPA-R exchange and cycling processes require no synaptic activity. These two processes are important for maintaining synaptic strength despite continuous protein turnover. GluR2-containing AMPA-Rs can be removed from synapses during activity-induced synaptic depression (e.g., long-term depression (LTD)).

Multiple mitogen-activated protein kinase (MAPK) signaling pathways function to relay intracellular signaling that controls three activity-dependent AMPA-R trafficking events. During LTP, activation of NMDA-Rs and an influx of calcium stimulate the small GTPase Ras–extracellular signal-regulated kinase kinase (MEK)–extracellular signal-regulated kinase (ERK) and phosphoinositide 3 kinase (PI3K)–protein kinase B (PKB; also called Akt) signaling pathways, which phosphorylate AMPA-Rs with long cytoplasmic termini and drive them into synapses. During depotentiation, activation of NMDA-Rs and an influx of calcium stimulates the small GTPase Rap2–c-Jun amino-terminal kinase (JNK)–protein phosphatase 2B (PP2B) signaling pathway, which dephosphorylates AMPA-Rs with long cytoplasmic termini and triggers synaptic removal of these receptors. During LTD, activation of NMDA-Rs and an influx of calcium stimulates the small GTPase Rap1–p38 MAPK signaling pathway, which phosphorylates AMPA-Rs with only short cytoplasmic termini and leads to synaptic removal of these receptors.

Expression of AMPA-R subunits, regulated by a number of factors, such as developmental stage, brain region, and cell type, affects synaptic AMPA-R trafficking. For example, in hippocampal CA1 neurons, GluR4 is expressed only in the first postnatal week. The expression of GluR2L peaks at the end of the second postnatal week and declines by half in the adult. GluR1 expression increases with increasing age and reaches a maximal expression level after the third postnatal week. In addition, distinct patterns of synaptic activity seem to stimulate different signaling pathways and drive synaptic delivery of different AMPA-Rs. Whereas experience-independent or spontaneous synaptic activity is sufficient to drive synaptic delivery of GluR4- and GluR2L-containing AMPA-Rs, sensory experience-dependent activity and/or coactivation of other physiological factors (e.g., neuromodulators, hormones, and neurotrophic factors) is required for synaptic insertion of GluR1-containing AMPA-Rs in the intact brain. Thus, dependent on particular populations of synapses and developmental stages, transformation of silent synapses to functional synapses or synaptic delivery of AMPA-Rs requires different types of activities. Expression of other molecules, particularly those associated with the postsynaptic density (PSD), also influences synaptic AMPA-R trafficking. The synaptic functions of these proteins, including transmembrane AMPA-R regulatory proteins, PSD95,

Figure 1 Model for synaptic AMPA-R trafficking. LS, lysosome; V/ES, vesicles/endosomes.

Figure 2 Model for synaptic NMDA-R trafficking. LS, lysosome; V/ES, vesicles/endosomes.

PSD93, and SAP97, are covered in more detail elsewhere in this encyclopedia.

Another factor that influences synaptic trafficking of AMPA-Rs is the egress of AMPA-Rs from the endoplasmic reticulum (ER). The ER has a rigorous quality control process to ensure that only properly assembled AMPA-Rs exit. As is the case with AMPA-R trafficking at synapses, the cytoplasmic C-termini of AMPA-R subunits define the properties of intracellular AMPAR trafficking. AMPA-Rs with long cytoplasmic tails mature and leave the ER rapidly, but AMPA-Rs with short cytoplasmic tails are largely confined within the ER; they mature and travel out of the ER at a much slower rate. Interestingly, the ER retention of GluR2-containing AMPA-Rs is controlled by Arg607 at the Q/R editing site in the GluR2 channel pore region: in GluR1, GluR3, and GluR4, there is a glutamine (Q) at this critical pore site, whereas in GluR2 the uncharged glutamine is replaced by a charged arginine (R). Reversion to Gln (R607Q) results in relief of the ER retention and rapid release of GluR2 from the ER. Low expression in neonatal neurons, reduced ER exit, or increased demand in young and adult neurons can result in an undersized intracellular pool of GluR2 subunits, which may be responsible for physiological and pathological expression of calcium-permeable GluR2-lacking AMPA-Rs at synapses.

NMDA-R Trafficking

NMDA-Rs are tetrameric complexes consisting of two obligatory NR1 subunits and up to two of four NR2 subunits (NR2A–D). The NR2A and-2B subunits are the primary NR2 subunits and are fairly widespread, whereas the expression of NR2C and NR2D is regionally and developmentally restricted in the brain. The NR2 subunits govern synaptic trafficking properties of NMDA-Rs. Two major synaptic NMDA-R trafficking events take place at synapses (Figure 2). NR2B-containing NMDA-Rs constitutively cycle between synaptic and nonsynaptic sites, and this process requires no synaptic activity. In contrast, NR2A-containing NMDA-Rs traffic into synapses by replacing synaptic NR2B-containing NMDA-Rs, and this process requires synaptic activity. The replacement is regulated by synaptic activity and is triggered by ligand binding to NR2B-containing NMDA-Rs. NR2A- and NR2B-containing NMDA-Rs differ significantly in their biophysical properties. These properties, together with the precise subcellular localization of NMDA-Rs, may determine which downstream signaling pathways (e.g., Ras–ERK, Rap2–JNK, or Rap1–p38 MAPK) are stimulated and which synaptic AMPA-R trafficking events are initiated.

Synaptic trafficking of NMDA-R is regulated by other factors. For instance, development has a significant impact on synaptic delivery of NMDA-Rs. Synapses in neonatal neurons have primarily NR2B-containing NMDA-Rs. However, at mature synapses, NR2A-containing NMDA-Rs predominate and NR-2B-containing NMDA-Rs are mostly extrasynaptic. Unlike AMPA-Rs, the number of NMDA-Rs per synapses remains approximately constant during postnatal development. This is important for maintaining synaptic efficacy and plasticity within the homeostatic range.

The ER selectively retains unassembled NMDA-R subunits and ensures only the forward trafficking of NMDA-Rs with certain subunit combinations, which determines the available intracellular pool size of functional NMDA-Rs. A large fraction of endogenous NR1 resides in the ER, waiting to be assembled with the NR2 subunits. By regulating NR1 mRNA splicing and NR1 subunit phosphorylation, neuronal activity and intracellular signaling bidirectionally modulate

the speed of forward trafficking of NMDA-Rs from the ER to synapses. For example, low neuronal activity results in synthesis of NR1 subunits with a divaline-based ER-export motif that speeds up the exit of NMDA-Rs from the ER, whereas high activity results in synthesis of NR1 subunits without the motif that conversely slows down the assembly of NMDA-Rs and their ER egress. Moreover, protein kinases, such as protein kinase A and protein kinase C, phosphorylate NR1 subunits and facilitate the assembly of NMDA-Rs and their ER exit.

Conclusion

AMPA-R and NMDA-R trafficking, which plays a key role in controlling synapse formation and elimination and in regulating synaptic transmission and plasticity, has been the subject of an intense and diverse investigation in the past decade. A considerable amount of information is now available on membrane trafficking of AMPA-Rs and NMDA-Rs at synapses. Only a limited amount is known about AMPA-R and NMDA-R assembly, quality control, and exit from the ER. Even less is known about how AMPA-Rs and NMDA-Rs traffic toward synapses after exiting the ER. For example, given that different populations of synapses in single neurons have distinct AMPA-R and NMDA-R compositions, how AMPA-Rs and NMDA-Rs recognize different types of synapses and how synaptic activity or intracellular signaling direct different groups of AMPA-Rs and NMDA-Rs to specific synapses after departing the ER remains unclear.

Recognition Memory

C E Stern and M E Hasselmo, Boston University, Boston, MA, USA

Introduction

Recognition memory refers to the capacity to accurately identify a particular item or stimulus as having been encountered previously. For example, a witness to a crime might be asked to identify a crime suspect or a weapon using recognition memory. The ability to accurately recognize an item requires that the subject first be able to encode stimuli into memory, and subsequently be able to discriminate between new and previously viewed stimuli. In the crime example, the witness would first need to accurately encode the information at the time of the crime, and then at a later time would need to be able to accurately identify the suspect or select the suspect from a line-up of other subjects who the witness had not encountered before. In research on memory function, recognition is often tested by having subjects distinguish between previously presented stimuli and stimuli that were not previously presented (termed lures).

There is a long history of research suggesting that recognition memory is composed of multiple components. In the 1970s, Atkinson and Juola described two processes important for recognition, an initial fast familiarity process and a slower process necessary for retrieving specific detailed information. For example, if you pass someone in an airport or supermarket, you may instantly recognize that person as familiar, followed by a slower search through memory as you retrieve detailed information about who that person is, his or her name and relationship to you, and where you last met that person. In some cases this 'retrieval attempt' is successful. In other cases, you might simply recognize the person as being familiar but be unable to generate details such as the person's name or where you met him or her. In 1983, Endel Tulving proposed that recognition could be divided into 'recollection' (or 'remembering') and 'familiarity' (or 'knowing'). The recollection process is proposed to involve retrieval of the prior episodic experience of encountering the previously presented stimulus, which includes remembering contextual details associated with that event. In contrast, familiarity is proposed as a process that does not rely on any explicit remembering of the details of the spatial or temporal context of the prior event.

In addition to dissociating the processes of recollection and familiarity, memory researchers make a distinction between the processes of recognition and recall. Both recognition and recall require that stimuli be encoded, stored, and retrieved from memory. However, recall places a much greater demand on the retrieval system, whereas recognition tests can assess whether information was encoded while placing less demand on memory retrieval systems by simply requiring that the subject distinguish previously learned information from new information. One analogy is that recognition memory tests resemble 'multiple choice' exams, where the answer is present but must be identified from false 'lures,' whereas a recall test resembles a 'fill in the blank' exam, where the subject must retrieve the learned information from long-term memory in order to generate the answer. When memory declines, such as during aging and in diseases such as Alzheimer's disease, recall performance declines earlier and faster than recognition performance. A person may therefore be unable to recall someone's name, but if he or she is provided with multiple choices, he or she can recognize the correct one.

Recall can be divided into two types, free recall and cued recall. Both free recall and cued recall involves the retrieval or recall of a previously presented stimulus without the stimulus being presented during the test period. In a free recall task, stimuli are presented during the sample period, and during the test period the subject is requested to generate as many stimuli as possible. Usually answers are provided verbally. In a cued recall test, the experimenter provides a cue, such as "name the animals that were on the list," that assists the subject in recalling the stimuli. In one specific type of cued recall task, known as a paired associates test, stimulus pairs are presented during the sample period, and during the test period only a single stimulus in a pair is presented, and the subject must generate the previously paired stimulus. Free recall and cued recall can only be performed for stimuli that can be generated by the subject, and therefore usually requires the use of verbal stimuli in humans. Because recognition can be tested without requiring the subject to generate the previously presented stimulus, it proves very important in neuroscience studies of memory function in animals.

In the following sections, work on the neuroscience of recognition memory in humans and in animals is described in greater detail. First, an overview of recognition memory tests is provided, followed by sections describing lesion studies of recognition memory

in humans and animals, electrophysiological studies of recognition memory in animals, imaging studies of recognition memory in humans, and computational studies of recognition. The human and animal studies indicate an important role for medial temporal lobe structures in the encoding of stimuli for subsequent recognition.

Recognition Memory Paradigms

Recognition memory has been studied extensively in human subjects using a number of different paradigms. In one classic recognition memory task, the experimenter first presents subjects with a series of stimuli to be learned. After a variable delay period, the experimenter then presents the subject with a list of previously presented stimuli mixed with new ones (lures). The subject simply responds 'yes' or 'no' to each stimulus. This recognition paradigm is known as a simple 'yes/no recognition test.' In another common recognition test, a single stimulus or set of stimuli are presented during a sample period, followed by a delay period of different durations, after which recognition is tested by presenting both a previously viewed sample stimulus and a novel lure at the same time during the test period. The subject must generate a response indicating which stimuli (target stimuli) were previously presented and which stimuli (lures) were not previously presented. This method is known as a 'forced choice recognition memory test.' The simple 'yes/no recognition test' cannot be used effectively with patients with memory disorders, as they will often respond "no" to all stimuli. The method is not often used because of this response bias. The forced choice recognition memory test is less sensitive to response bias, and can more sensitively assess recognition memory impairments and measurements of response bias can be generated. There are a number of variations of these two basic behavioral designs that have been created and are described here.

More recent studies have elaborated on the simple 'yes' or 'no' response to more accurately characterize the two processes that combine to support recognition memory, recollection and familiarity. Both recollection and familiarity would generate a 'yes' response in a yes/no or forced choice recognition memory paradigm. By modifying the task, the experimenter can distinguish between recollective and familiarity responses. The distinction between a strong feeling of recollection and a weaker sense of familiarity are sometimes referred to as the 'remember' versus 'know' distinction. In experimental tests of these processes, a subject may be requested to identify whether they have a distinct recollection of the event of observing the stimulus ('recollection') or whether they only have a general feeling of familiarity about the stimulus ('familiarity'). They may also be asked to retrieve information about contextual information related to the stimulus. Alternatively, in another twist on the yes no recognition test, subjects may be requested to use an arbitrary scale to provide information about the strength of their memory or their level of confidence in remembering an item or event. Some behavioral and imaging studies have used a simple three-point scale, corresponding to high-confidence yes (recollection), low-confidence yes (familiarity), and new (for the lures). Others have used five or six point scales ranging from a high-confidence 'yes' (identify target) response (numerical value five or six) to a high-confidence 'no' (reject lure) response (numerical value one). Studies of behavioral confidence rankings have been used to support a two-process theory of recognition memory in work by Yonelinas. This work uses signal detection theory-based receiver operator characteristics (ROC) curves to analyze the nature of recognition memory. This work used the distribution of proportions of responses to argue that recognition memory includes a graded mechanism of familiarity recognition, and a high threshold process of recollection-based recognition. The Yonelinas model assumes that previously presented items give rise to a range of confidence ratings based on their familiarity, while new items (lures) give rise to some familiarity but not as much as the previously presented items. In contrast, when recollection is triggered for an individual item, the recollection process is assumed to provide sufficient confidence for subjects to respond with certainty in the highest 'yes' category (allowing the responses to cross a high threshold criterion). In the dual-process model, familiarity is a variable phenomenon and recollection is an all or nothing response. There have been studies that suggest distinct medial temporal lobe regions support recollection and familiarity-based recognition. However, the studies remain controversial. Some researchers support the idea that the hippocampus is required for recollection, whereas parahippocampal structures support familiarity; however other data suggest that recollection and familiarity are part of a unified single process (see Wixted, 2007), supported by the same neuroanatomical structures within the medial temporal lobe. Similar controversy surrounds efforts to make distinctions between regions supporting encoding during the sample period versus separate regions mediating recognition during the testing period.

Another common recognition memory task is known as the 'delayed match to sample task' or DMS task. The DMS task involves presentation of single sample stimuli followed by a delay period,

followed by a pair of test stimuli, where one stimulus matches the presentation stimulus and one does not match the sample stimulus. The subject must select the stimulus that matches the sample stimulus. In a variant of this task known as a delayed nonmatch to sample or DNMS task, the subject (human or animal) must select the nonmatching 'novel' stimulus. A further variation involves continuous presentation of stimuli, in which the subject must respond on the basis of whether the current stimulus matches the stimulus presented *N* trials previously (an '*N*-back' task) which can be extended to longer intertrial intervals. Since it typically uses very short delays, the *N*-back task is considered to be a working memory task.

The delayed match to sample or delayed nonmatch to sample task design have been used most extensively in studies of the neural basis of recognition memory in animals. In these paradigms, the animal encounters the sample stimulus, and after a delay period is presented with a pair of stimuli and must respond to either the match (target) or nonmatch (lure). Alternatively, the sample stimulus could be followed sequentially by single lure stimuli (during which the animal withholds its response) until the target stimulus appears and the animal must generate a response. Performance of these tasks require recognition memory, but the process of recognition could be interpreted as involving either short-term active maintenance of the stimulus (working memory) or long-term synaptic encoding of the stimulus, depending on the length of the delay.

Other paradigms used in animals include presentation of a longer list of sample stimuli, which could include a series of visual stimuli presented to monkeys, or a set of odor stimuli presented to rats. After a delay period, the animals are then tested with a forced choice design, in which the animal encounters pairs of stimuli each of which includes one sample stimulus and one lure stimulus. In rats, recognition memory is commonly tested using the nonmatch to sample paradigm, to capitalize on the natural tendency of rats to explore novel stimuli more extensively than familiar ones. The rat can be presented with a sample stimulus, and subsequently when presented with an identical sample stimulus and a novel lure, it will spend more time exploring the novel lure.

Lesion Studies of Recognition Memory

There is extensive lesion evidence supporting the idea that the medial temporal lobe structures, including the hippocampus and neighboring parahippocampal regions, are critical for encoding information into long-term memory. Research on the neuroanatomical structures critical for memory function focused in on the medial temporal lobe following the case of patient HM, first described by Scoville and Milner in 1957 and subsequently studied by Milner and Corkin. Patient HM showed a striking impairment of declarative memory encoding following bilateral removal of his medial temporal lobes in an attempt to control epileptic seizures. Initial descriptions of patient HM's impairment focused on his almost total loss of free recall and severe impairment of cued recall performance. Similarly, other hippocampal amnesics show strong impairments of free recall and cued recall. There is some sparing of recognition memory in hippocampal amnesics, and the amount of impairment appears to be associated with the magnitude of damage of parahippocampal structures including the entorhinal cortex, perirhinal cortex, and parahippocampal gyrus.

Lesion studies in humans have also addressed the question of whether the processes of recollection and familiarity are subserved by different regions within the medial temporal lobes. However, the results continue to be controversial. Researchers including Yonelinas have argued that hippocampal lesions cause a greater impairment of recollection-based recognition than familiarity-based recognition. On the other hand, studies by Manns and Squire have demonstrated impairments of both recollection and familiarity-based recognition associated with medial temporal lesions.

In animals, lesions have been demonstrated to impair recognition memory in delayed nonmatch to sample tasks. Researchers including Squire and Zola-Morgan have demonstrated that lesions of the hippocampus alone cause some impairments in recognition of stimuli after delays of 8 s to many minutes. These studies also demonstrate that lesions that include parahippocampal structures, such as the perirhinal cortex and parahippocampal gyrus, cause much stronger impairments in recognition performance in delayed nonmatch to sample tasks, supporting an important role for parahippocampal structures in recognition memory. Impairments of performance in object or odor recognition tasks have also been shown with inactivation or lesions of the perirhinal cortex in rats. Selective impairments of the encoding of stimuli for subsequent recognition have been induced with manipulations that block acetylcholine receptors or remove the cholinergic innervation of the perirhinal cortex. Recent work by Fortin and Eichenbaum has used modified variants of tasks designed for human studies of recollection and familiarity to examine these processes in rats, demonstrating that hippocampal lesions appear to selectively reduce the high threshold recollection-based recognition, in contrast to the more variable familiarity-based

recognition. However the role of the hippocampus and perirhinal cortex to recollection and familiarity remains controversial (see Wais et al., 2006).

Electrophysiological Studies of Recognition Memory

As noted above, most studies of memory function in animals use tasks that test recognition memory, since it is not feasible to have animals perform recall tasks. Thus, most studies of electrophysiological activity associated with memory function have been performed during short- or long-term recognition memory paradigms. In both monkeys and rats, unit recordings studies analyze the generation of action potentials by individual neurons during performance of such tasks. The activity associated with recognition can be evaluated by comparing the response during the test period to a previously presented target stimulus with the response to a nonpresented lure, or by comparing the response to the target stimulus with the response to the same stimulus during the sample period. A number of studies have shown increases or decreases in neural activity for a previously presented target stimulus in comparison to nonpresented lures. Studies by researchers including Malcolm Brown and Earl Miller demonstrate a significant decrease in response to a previously presented stimulus in comparison to the sample response for neurons in regions of temporal lobe including parahippocampal cortices. This effect is commonly referred to as match suppression or repetition suppression. Miller demonstrated that repetition suppression occurs even for repeated distractor stimuli presented during a delay period, whereas enhancement of the target test stimulus relative to the sample stimulus (match enhancement) only occurs for the target stimulus and not for distractor stimuli. Increased responses to matching stimuli were shown in the anterior thalamus in studies of a serial recognition task.

Across short delays, the process of recognition could be supported by active maintenance of information during the delay period. In support of active maintenance, a number of unit recording studies performed during DMS by researchers such as Niki and Fuster have demonstrated that some neurons activated by the sample stimulus will maintain their activity during the delay period until the test stimulus is presented. This delay period activity could reflect active maintenance of the stimulus for performance of the recognition task. The persistent activity could arise from intrinsic mechanisms within individual neurons, or from excitatory feedback between neurons in a population. This type of persistent spiking activity could contribute to the increase in cerebral blood flow measures seen during the delay period of DMS or two-back tasks in human subjects.

Functional Imaging of Recognition Memory

Considerable research has focused on imaging changes in blood flow and metabolism associated with performance of recognition memory tasks. Despite considerable evidence from human and animal lesion studies regarding the importance of the hippocampus and medial temporal lobes for encoding and recognition, early imaging studies using positron emission tomography (PET) primarily identified changes in activity in cortical structures outside of the medial temporal lobe, most notably within the prefrontal cortex. The tasks used in these earlier studies focused on the recognition of verbal stimuli learned prior to scanning. When the task design was altered to focus on examining functional changes during the encoding period, Stern and colleagues identified robust functional magnetic resonance imaging (fMRI) activation of the hippocampus and parahippocampal structures. As fMRI techniques developed, it became possible to focus on event-related activity during individual trials involving presentations of single stimuli. Researchers designed studies to focus on how the event-related activity during presentation of single stimuli during the encoding period would correlate with performance for those individual stimuli during a subsequent recognition memory task. These studies demonstrated a subsequent memory effect, in which increases in fMRI activity in the hippocampus and parahippocampal gyrus were noted for stimuli that were remembered, but not for stimuli that were subsequently forgotten. In addition to activity in medial temporal lobe sites, imaging studies have provided data that support the idea that encoding and subsequent recognition requires widespread activity including activity in the prefrontal cortex and parietal lobes. Research is ongoing to determine whether the prefrontal and parietal activity is related to the successful retrieval of information from memory, or due to control mechanisms driving recollection attempts.

Imaging studies have also addressed the hypothesis that recollection and familiarity are dependent on different regions within the medial temporal cortex. Based on animal studies and anatomical differences between the hippocampus and parahippocampal regions, several researchers have suggested that the hippocampus might be necessary for recollection, whereas the parahippocampal gyrus might be sufficient and necessary for supporting familiarity. Proponents of this account suggest that the parahippo campal

regions are associated with successful item recognition, whereas hippocampal activity is necessary for successful source memory, which includes information about contextual details. However, the imaging studies are inconclusive at this time, and the issue remains controversial.

The recognition of stimuli in working memory tasks has been examined using the *N*-back task and the DMS. These tasks probably require active maintenance of previous stimuli rather than modification of synapses. The *N*-back task typically causes extensive activity in prefrontal cortex and parietal cortex, which increases when the memory load is increased by increasing the value of 'N' to require matching with a stimulus presented three or four stimuli previously. When familiar stimuli are used in a delayed matching task, it does not cause significant medial temporal lobe activity, but when novel stimuli are used it causes a significant increase in medial temporal lobe activity, which is correlated with subsequent recognition memory for the stimuli. This could reflect a greater role for medial temporal lobe structures in active maintenance and encoding of novel stimuli.

Computational Modeling of Recognition Memory

The processes involved in recognition memory have been modeled on a number of different levels. Many modeling studies have focused on the mechanisms of active maintenance, in which persistent spiking activity of a population of neurons during the delay period is proposed to form the basis for retaining information about the stimulus presented during the sample stimulus. Most models of active maintenance focus on the role of excitatory recurrent connections within cortical structures such as the prefrontal cortex. These excitatory recurrent connections can cause a population activated by the sample stimulus to continue to reactivate its component neurons, causing the population to maintain activity for the full delay period, retaining the information until the test period when a comparison can be made. In contrast, other recent models of active maintenance focus on intrinsic single-cell mechanisms, in which a single neuron can maintain persistent spiking activity without requiring excitatory synaptic feedback between neurons. This mechanism would be particularly appropriate for novel stimuli for which a representation has not previously been formed.

For recognition over longer periods, it is not possible to maintain persistent spiking representing all previously viewed stimuli. In this case, some representation of stimuli based on changes in synaptic connections between neurons would be more appropriate. Computational models have demonstrated how presentation of a sample stimulus could induce Hebbian synaptic potentiation, in which synapses are strengthened dependent upon presynaptic activity coupled with postsynaptic activity. This synaptic modification results in greater activity of neurons during the test period if they were previously active during the sample period (match enhancement). Match suppression or repetition suppression can be obtained by competitive long-term depression of synapses for nonactivated neurons. Alternately, researchers have proposed that repetition suppression might arise from Hebbian long-term depression which provides a mechanism for recognition memory with higher capacity than Hebbian long-term potentiation. The above processes focus on responses to the item alone and could be seen as reflecting familiarity processes. The separate theoretical processes of recollection-versus familiarity-based recognition have been modeled as different processes in different structures. In contrast to familiarity, which could involve an increase or decrease in activity of the neurons representing the sample stimulus, recollection may involve a test item reactivating a full representation of contextual features associated with a specific episode. This recollection process could involve more complex neuroanatomical circuits required for reactivation of the temporal or spatial context of the item being recognized.

Red Nucleus

L E Miller, Northwestern University Feinberg School of Medicine, Chicago, IL, USA
A R Gibson, Barrow Neurological Institute, Phoenix, AZ, USA

Location and Subdivisions of the Red Nucleus

The red nucleus (RN) comprises a large group of cells located in the ventral medial mesencephalon. Caudally, the RN is bounded by the decussation of the superior cerebellar peduncle, and rostrally the RN reaches approximately to the level of the habenulo-interpeduncular tract (fasciculus retroflexus). The primate RN is distinguished by two characteristics: one is the presence of extremely large cells at its caudal pole, and the second is the presence of a large body of small cells rostral to the giant cells. The nucleus is thus commonly divided into a caudal magnocellular division, RNm, and a rostral parvicellular (or parvocellular) division, RNp.

The defining characteristics of the RN are inputs from the cerebellar nuclei and cerebral cortex and projection to either the contralateral spinal cord via the rubrospinal tract (RST) or ipsilateral inferior olive (IO) via the central tegmental tract. The very largest cells of RNm project to the contralateral spinal cord, and the smallest cells of RNp project to the ipsilateral IO. The projections are mutually exclusive, but both cell populations receive input from the cerebellar nuclei as well as from the cerebral cortex.

Connections of the RN do not precisely correlate with cell size. Early studies of the RN recognized that axons from many small and medium-size cells decussate and join the RST. However, since the smaller cells that decussate do not all project to the spinal cord, neither cell size nor spinal projection alone provides an adequate basis for dividing the nucleus into functional groupings.

This article uses as much of the traditional nomenclature as possible: RNp will be used to identify small cells that project to the ipsilateral IO. RNm will be used to identify large cells that project to the contralateral spinal cord (Figure 6(b)). Thus RNm and RNp do not include the small and medium-size cells that project to the contralateral brain stem and spinal cord. An additional term, parvicellular contralateral red nucleus (RNpc; Figure 6(a)), is introduced to identify this group of cells. To a first approximation, RNm comprises the most caudal portion of the nucleus, RNp comprises a rostral-medial portion of the nucleus, and RNpc comprises a rostral-lateral portion of the nucleus. An additional population of small interneurons, which are probably present throughout the RN, is not addressed by this nomenclature.

Species Variation of the Red Nucleus

The RN varies between species. Much of the variability is due to RNp, which is a distinct nucleus. The size of RNp parallels that of several other brain stem areas that are connected to the motor cortex, such as the pontine nuclei, the principal division of the IO, and the lateral cerebellum. Figure 1 illustrates parasagittal sections through the brain stem of a cat and a monkey following injections of wheat germ agglutinin–horseradish peroxidase (WGA-HRP) into motor cortex. RNp is much larger in the monkey than it is in the cat – massive terminations outline the monkey RNp. A similar expansion of terminals is apparent in the pontine nuclei. RNm, on the other hand, is roughly the same size in cat and monkey. In neither species is there a dense input from motor cortex to either RNm or RNpc.

The size of RNm varies with the size of its major input source, the interpositus nucleus (NI) of the cerebellum. NI does not share the progressive and extreme enlargement that is seen for the cerebellar dentate nucleus in monkeys, apes, and humans. In humans, RNm is greatly reduced in size, and the RST may not descend below the cervical cord. The loss of RNm in humans is mystifying since its evolution appears to be associated with the presence of limbs; snakes and fishes do not have the equivalent of an RNm. The smaller RNm in humans may simply reflect a shift in emphasis from large cells projecting to lumbar cord to smaller cells projecting to upper cervical cord and brain stem.

It is likely that RNp, RNm, and RNpc exist in all mammalian species. However, in species below primates, RNp has been confused with RNpc. In primates, there has been little effort to distinguish small cells projecting to the IO from small cells contributing to contralateral projections. RNp is greatly expanded in mammals with a large motor cortex, whereas RNm and RNpc have probably remained relatively constant across species.

The RNm

RNm is defined by the presence of very large cells (Figure 6(b)), but there is actually a gradation in cell size within RN. The gradation follows the general principle that neurons supporting long axons tend to have larger cell bodies than those supporting short

Figure 1 Comparison of monkey and cat red nucleus (RN). Parasagittal brain stem sections following injection of wheat germ agglutinin–horseradish peroxidase into primary motor cortex (area 4) in cat (a) and monkey (b). While the size of magnocellular RN (RNm) is unchanged across species, note the tremendous expansion of the olivary projecting parvicellular (or parvocellular) red nucleus (RNp) in monkey. RNp is divided at this laterality by the fascicularis retroflexus. The pontine nuclei, which relay cortical input to cerebellar cortex, are also greatly enlarged in the monkey. Darkfield polarized light illumination was used in this and following photographs. Labeled areas are light. Magnification ×4.3 (a); ×5.1 (b). CST, corticospinal tract.

Figure 2 Input–output connections of magnocellular red nucleus (RNm). Parasagittal section through the brain stem and cerebellum of a cat following wheat germ agglutinin–horseradish peroxidase injection into contralateral RNm. Anterograde labeling of fibers highlights the rubrospinal tract (RST) and terminals within the lateral reticular nucleus (LRN). Retrograde labeling of cells in the cerebellar anterior interpositus (NIA) and posterior interpositus (NIP). Magnification ×3.6. BC, brachium conjunctivam. Adapted from Robinson FR, Houk JC, and Gibson AR (1987) Limb specific connections of the cat magnocellular red nucleus. *Journal of Comparative Neurology* 257: 553–577, with permission.

axons. Therefore, the very largest RNm cells, which are located ventrally in the nucleus, project to the lumbar cord. Cells projecting to the cervical cord tend to be somewhat smaller and lie dorsally to those projecting to lumbar cord. Even smaller cells, prevalent at rostral levels of the nucleus, project to the contralateral brain stem and also contribute to spinal projections. The topography within the RN is quite sharp, and very few cells project to both lumbar and cervical levels.

RNm Anatomy

Cerebellar input to the RNm arises from the anterior NI (NIA) and medial regions of posterior NI (NIP). Figure 2 illustrates a parasagittal section through the cat brain stem after an injection of WGA-HRP into the contralateral RNm. Large numbers of retrogradely labeled cells can be seen in NIA and NIP, and anterogradely labeled fibers can be seen forming the RST. The projection from interpositus to RNm is somatotopically organized: cells that discharge during hind limb movements are located medially in NIA and NIP and terminate in ventral and lateral RNm. Cells that discharge during forelimb movements are located more laterally in NIA and NIP and terminate in dorsal and medial RNm. The most lateral cells of NIP project to the superior colliculus rather than to the RN.

Cerebral cortical input to RNm is relatively limited, arising from cells deep in layer V of posterior motor cortex (area 4), including some Betz cells. Presumably, the input from Betz cells is a collateral input from corticospinal neurons. The fine caliber of collateral projections may contribute to the relatively light labeling seen in RNm after injection of anterograde tracers in motor cortex. However, physiological studies also indicate that the input from motor cortex to RNm is relatively weak in comparison with the input from interpositus.

Other significant inputs to RNm arise from the cuneate, trigeminal, and gracile nuclei, including inputs from the spinal cord. All these inputs conform to the RNm somatotopy, and they are likely to account for sensory properties displayed by RNm neurons. Trigeminal connections are located in a dorsolateral location and

indicate that RNm probably has a smaller-celled projection to the brain stem related to jaw movements. This projection would not be identified by retrograde labeling from the spinal cord, so it is likely that the size of RNm has been somewhat underestimated.

The axons of RNm neurons decussate and travel immediately ventral to the superior cerebellar peduncle to form the RST. The RST turns ventrally at the level of the pons and travels along the ventral-lateral edge of the brain stem to join fibers in the dorsolateral funiculus of the spinal cord. Most of the spinal terminations of RNm lie in Rexed's laminae V–VII, but at C8-T1 a small patch of terminations is located laterally among motor neuronal pools of lamina IX. Lamina IX terminations have been confirmed in monkey, cat, and rat. In all species, the terminations correspond to the location of motor neuronal pools that innervate muscles that move the digits of the forelimb. Figure 3 illustrates frontal sections of the cat spinal cord at C8. Panel (a) illustrates RNm terminations, and panel (b) illustrates retrogradely labeled motor neurons after injection of a digit extensor muscle, extensor digitorum communis. Although the direct projections to spinal motor neurons are fewer than those to interneuronal projections, the importance of RNm and its cerebellar input nucleus, NIA, for the control of digit movements is further emphasized by the results of physiological experiments.

In addition to its spinal projections, RNm (together with the motor cortex) has prominent projections to ventral regions of the gracile, cuneate, and trigeminal nuclei, among cells that project to the IO. These projections may provide a substrate for modulation of olivary activity by descending motor signals. Beyond these focused projections, there are less well-defined, finer projections to large regions of brain stem reticular areas.

RNm has both direct and indirect connections back to the cerebellum. A prominent indirect feedback pathway is provided by RNm terminations in the contralateral lateral reticular nucleus (Figure 2), which supplies mossy fiber input to the cerebellar cortex, as well as to interpositus. Terminations within lateral reticular nucleus are topographic, such that RNm terminations are separate from cortical or spinal terminations. It is likely that the RNm terminations are collaterals of spinally projecting axons. Along with the cortical projections through the pontine nuclei, these projections may provide efference copy signals to the cerebellum.

Figure 3 Spinal projections of magnocellular red nucleus (RNm). Frontal sections through the cervical enlargement at spinal segment C8 of the cat. (a) Anterograde labeling of fibers demonstrates a dense plexus among interneuronal regions with a small focused termination in lateral motor neuronal pools. (b) Labeled motor neurons following horseradish peroxidase injections into a digit extensor muscle, extensor digitorum communis (EDC). The location of these motor neurons matches RNm ventral horn terminations shown in (a). Magnification ×25.

RNm Function

Chronic lesions and reversible inactivation of RNm

In cats and monkeys, permanent lesions of the RNm or rubrospinal tract cause only relatively mild deficits that are predominantly related to the animal's ability to grasp objects. Temporary inactivation of the cat RNm produces deficits in grasping. The deficit appears to be related to particular muscles rather than the grasping movement *per se*, since the cats also drag the dorsum of the paw during walking. Movement deficits are much greater and more persistent if RNm lesions are combined with lesions of the pyramids, thereby also removing the influence of the corticospinal tract. These animals lose virtually all ability to use the affected limb independently, although they are still able to maintain a reasonably normal posture and to locomote. This remaining

capability is probably due to corticobulbar projections to several other brain stem motor nuclei that project bilaterally to the spinal cord (collectively referred to as the ventromedial brain stem system). The ventromedial system is primarily concerned with control of midline and axial musculature.

Electrophysiological evidence of spinal projections from RNm Electrophysiological observations are consistent with the anatomical connections of the RNm and with the behavioral deficits resulting from lesions. In dorsolateral regions of the nucleus, cells discharge at high rates during face and mouth movements. Cells within dorsomedial regions, which project to cervical cord, discharge at high rates prior to and during movements of the contralateral forelimb. Cells in ventrolateral RNm, which projects to lumbar cord, discharge during movements of the contralateral hind limb.

As in the primary motor cortex, small movements can be evoked by stimulating within RNm, using brief trains of electrical pulses. Within the forelimb regions of RNm, this microstimulation typically causes brief twitches of the digits, generally in the extension direction, rather than flexion. These effects can be quantified by recording the electrical activity related to muscle contractions and averaging the tiny fluctuations with respect to the time of these stimulus pulses (stimulus-triggered averaging). Similarly, one can average electromyographic activity relative to individual action potentials recorded from RNm neurons (spike-triggered averaging). This approach allows one to survey the connections to the muscles made by individual neurons. Such studies have shown that RNm neurons activate groups of three to six muscles of the limb, with a strong bias toward the distal extensor musculature. An analogous region ventrolateral in the nucleus contains neurons projecting to the lumbar cord and discharging during movements of the hindlimb, especially extension movements of the toes. At the lowest currents, stimulation in hindlimb areas of RNm produces toe extension (dorsiflexion).

Many textbooks state that the RN is involved in flexion movements of the proximal limb, but this statement is based on results from stimulation in decerebrate preparations and is not consistent with results from intact animals. Neurons within RNm do influence proximal muscles, but their major emphasis is on distal limb muscles, especially extensors. It may be that the influence of RNm on proximal limb musculature primarily serves to support digit movements.

Signals recorded from RNm Averaging methods, together with anatomical tracing and lesion studies, provide a rather consistent picture of the spatial organization of RNm output. By studying the modulation of signals produced by RNm neurons during movement, one can relate the timing of these control signals to the movement. Typically, an experimental animal is trained to control the movement of a cursor on a screen by moving a manipulandum, analogous to a video game joystick. Particular movements can be required by displaying a sequence of targets on the screen and by the use of different types of manipulanda. Figure 4 shows several different devices operated by various movements of the arm and hand. Of these three devices, the throttlelike device (panel C), which requires a coordinated action of digits and wrist, is one of the most reliable means of evoking discharge from forelimb RNm neurons. The same cells show large bursts of activity as a monkey reaches toward and grasps a small piece of food, such as a raisin. However, discharge modulation shows little dependence on the direction of reach. If the monkey makes a limb movement without a grasp, such as when holding a piece of food or a device handle, there is little discharge modulation in RNm (or in interpositus, which provides RNm input). In general,

Figure 4 Movement specificity of magnocellular red nucleus (RNm). Three different devices used to elicit specific movements from monkey subjects during recording from neurons in the forelimb area of RNm. (a) Manipulandum used to restrict movements to the elbow joint. Pivot joints are indicated by +. E, extension; F, flexion. Arrows indicate directions of movements. (b) Manipulandum used to restrict to metacarpal phalangeal joints. The largest discharge typically occurred during the coordinated wrist and digit movements necessary to operate the device in (c). Adapted from Gibson AR, Houk JC, and Kohlerman NJ (1985) Magnocellular red nucleus activity during different types of limb movement in the macaque monkey. *Journal of Physiology* 358: 527–549.

Figure 5 Integrated magnocellular red nucleus (RNm) discharge matches movement. (a) Summed discharge of an RNm neuron during movements of the device in Figure 4(c). Increases in firing rate (solid vertical lines) occurred slightly more than 100 ms prior to changes in movement speed (dashed lines). (b) Mean discharge rate during these movements was well correlated with the speed of the corresponding movement. Sp. indicates spontaneous discharge rate. H56b is designation of subject. Cusum, cumulative sum of spikes. Adapted from Gibson AR, Houk JC, and Kohlerman NJ (1985) Relation between red nucleus discharge and movement parameters in trained macaque monkeys. *Journal of Physiology* 358: 551–570, figures 2 and 6.

movements requiring use of the digits, perhaps in coordination with other limb parts, are the most important factor for eliciting high discharge rates from RNm.

Discharge from RNm neurons is typically phasic: discharge onset occurs approximately 100 ms before movement onset, and discharge offset leads movement offset by a somewhat shorter latency. The lead in discharge onset and offset suggests that RNm discharge is a movement command signal, not primarily driven by movement feedback. For some cells, as in the example in Figure 5, the timing and magnitude of discharge mirror the timing and magnitude of movement with remarkable fidelity. This is reflected in the similarity between a cumulative sum of spikes (Cusum) and the position of the manipulandum. In fact, there is a highly significant linear relation between the speed of these movements and the rate of discharge, as shown in the scatter plot in panel B.

The correlation between discharge rate and movement speed has led to the proposition that the signals from RNm encode kinematic properties. However, subsequent work has also found correlations with force, the first time derivative of force, and muscle activity, particularly among distal extensors. Much of the phasic nature of the RNm signals may actually reflect the significant acceleration- and velocity-related forces that occur during limb movement rather than the speed of the movement *per se*.

The Contralaterally Projecting RNpc

At more-rostral levels of the cat RN, a dorsolateral extension of the nucleus containing cells of mixed sizes becomes prominent. The axons of some of these cells decussate and join with other RST fibers at the level of the pons. Due to the crossed descending projection to the facial nucleus and spinal cord, RNpc is more closely associated with RNm than with RNp. However, RNpc has considerably more extensive connections with other mesencephalic regions than does RNm. Although most of the anatomical data relevant to RNpc is based on cat studies, a smaller-celled rostral-dorsolateral extension of the RN has also been noted for the rat, monkey, and human.

RNpc Anatomy

RNpc of the cat receives cerebellar input from rostral dentate and a caudal lateral segment of NIA. The same region of NIA receives input from a region of the IO that contains cells responsive to cutaneous stimulation of the face. Unlike RNm, RNpc also receives a large input from other areas of the mesencephalon. The most prominent of these inputs include regions immediately rostral to the RN, such as the fields of Forel, the dorsal half of the zona incerta, and the anterior pretectal nucleus. These nuclei, in turn, receive inputs from many other areas of the brain, including the cerebellar dentate nucleus and the entopeduncular nucleus, the feline equivalent of the internal segment of the globus pallidus. Cerebral cortical inputs to RNpc have not been well investigated. For the cat, RNpc receives input from rostral regions of the suprasylvian gyrus, but the monkey dorsolateral extension of RN, which may be a component of RNpc, does not appear to receive cortical input.

Prominent brain stem terminations of RNpc include the contralateral facial and spinal trigeminal nuclei. RN cells projecting to the facial nucleus are located in the rostral-dorsal extension of the nucleus. The labeled cells in Figure 6(a) illustrate the location of RNpc cells projecting to the intermediate division of the contralateral facial nucleus. In the rat, the population of RNpc cells projecting to the facial

Figure 6 Facial nucleus projections of parvicellular contralateral red nucleus (RNpc). (a) Retrogradely labeled cells (white) in dorsolateral RNpc following injection of wheat germ agglutinin–horseradish peroxidase centered on the intermediate subnucleus of the contralateral facial nucleus (AP 5.0). This subnucleus innervates the orbicularis oculi muscle, which is important for making eyelid movements for facial expression and protection. (b) The large cells of magnocellular red nucleus (RNm; AP 4.0) have no projections to the facial nucleus. Magnification ×14. AP, anterior–posterior plane; NIII, oculomotor nerve (third nerve); OCN, oculomotor nucleus; SN, substantia nigra.

nucleus is distinct from the population of cells projecting to the spinal cord, and it is likely that this is true for other species. The strong projection of RNpc to facial motor neurons is an exception for the RN, since most terminations of RNm are on spinal interneurons rather than motor neurons.

The most rostral dorsal regions of RNpc project to the upper cervical cord. The projection is heaviest to interneuronal regions of C1 and largely disappears at levels below C4. There are no terminations within spinal motor neuronal pools. The larger cells in ventral areas of RNpc discharge during hind limb movements and probably project to lumbar levels, although their terminations have not been specifically traced. The cat RNpc also has reciprocal projections to several of the mesencephalic nuclei that provide input including zona incerta, fields of Forel, and the anterior pretectal nucleus. Many studies in species below primates have attributed these connections to RNp; however, the extent that cells projecting to the IO share these connections is not known.

RNpc Function

Only a few studies have been aimed at determining the functional characteristics of RNpc. In the monkey, cells in the rostral dorsolateral extension of the RN show relatively large increases in discharge rate during movements of the contralateral limbs or mouth. The discharge rates are somewhat lower than those seen for RNm, but the cells fire in a consistent fashion during movement, which is similar to cells in RNm.

In the cat, stimulation of fibers exiting RNpc produces poststimulus facilitation in muscles of the contralateral limb. In contrast to RNm, muscles of the proximal limb are more likely to be facilitated than are those of the distal limb. The discharges of cat RNpc cells during reaching are tightly related to movement, but the peak discharge rates are lower than those seen for RNm. Chemical inactivation or activation of the cat RNpc produces disturbances of reaching as well as digit use during a prehension task and can also produce torsion of the neck.

There is a growing body of evidence that the cerebellum is a necessary structure for motor adaptation and the formation of classically conditioned responses. As seen in Figure 6(a), RNpc has a significant projection to the intermediate division of the facial nucleus, which innervates muscles surrounding the eye that are important for protective responses. Inactivation of the RN impairs the expression of the conditioned eyeblink response, and it is likely that projections to the facial nucleus are part of the pathway carrying conditioned responses. Conditioned withdrawal responses of the limbs are eliminated by section of either the superior cerebellar peduncle or the RST. RNpc or RNm or both parts of the RN may be important for relaying learned motor activity from the cerebellum to the spinal cord.

The Ipsilaterally Projecting RNp

RNp is prominent only in primates, and this, coupled with the fact that large RN cells are reduced in

number in apes and humans, has led to the impression that RNp has subsumed function of RNm. Although the properties of RNp have not been studied extensively, it is clear that the nucleus has little commonality with RNm. The expansion of RNp is more likely to represent an expansion in its functionality rather than a trade-off with existing structures.

RNp Anatomy

In contrast to RNm, RNp receives an extensive cortical input from primary motor cortex (Figure 1(b)), as well as from other cortical areas, including the supplementary motor area, anterior cingulate cortex, parietal cortex, and, possibly, frontal eye fields. Some of the projections, such as those from supplementary motor area, are bilateral, although the ipsilateral projections are stronger. The cortical projections to RNp are somatotopic, with face being located medially, arm centrally, and leg laterally. The motor cortical projections to RNp and RNm arise from different populations of cells. The cells projecting to RNp are located dorsally in layer V and do not include Betz cells, which are deep in layer V.

Although cortical inputs to RNp have been reasonably well studied, little is known about other potential inputs. The cerebellar dentate nucleus projects to RNp, but the extent and topography of the input are not known. Essentially nothing is known about other potential brain stem inputs to RNp. The literature on RNp afferents in species below primates, typically, has not distinguished RNpc from RNp.

Efferent projections from RNp to the ipsilateral IO are well documented. The projection is largely confined to the principal nucleus of the IO, which projects to lateral cerebellar cortex and dentate. Other efferents include projections to the pontine reticular formation, but these have not been investigated in detail.

RNp Function

Cells in the monkey RNp discharge at low, irregular rates and show no obvious relation to movement. At first, this seems paradoxical, since the largest input to RNp derives from motor cortex. However, the cortical cells that project to RNp are not Betz cells and may not have movement-related discharge (even a significant percentage of corticospinal cells in motor cortex lack movement-related discharge). IO cells also fire at low irregular rates and have little relation to active movement, so many of the discharge properties of the IO may be present in its afferent sources.

One popular hypothesis about IO function is that it compares actual movement with intended movement to generate an error signal for cerebellar processing. RNp is considered a key element in providing efference copy signals to IO from the cerebellum and motor cortex. Clearly, the properties of RNm and RNpc fit this function better than do those of RNp. If error information is supplied by RNp, then the comparison is likely to be made within or prior to RNp.

Summary

Cells within RN are associated with one of two distinct neural pathways. RNp is part of a major pathway connecting cerebral cortical and dentate output to the ipsilateral principal division of the IO. RNp is well developed only in primates and has often been confused with RNpc in lower species. During movement, RNp cells discharge at low irregular rates that do not relate to movement, which is similar to their target neurons in IO. RNm and RNpc are part of a major pathway that connects cerebellar output to motor and premotor structures in the contralateral brain stem and spinal cord. The cells in these parts of the RN discharge consistently and at high rates when the corresponding parts of the contralateral body are moved. The largest cells in RNm focus on control of movements that involve the digits of the forelimb and hind limb. RNpc projects to the facial nucleus, upper cervical segments, and probably the lumbar cord. It is thought to be important for control of head and face movements, as well as movements of the proximal limbs.

Introduction

Communication happens when individuals exchange information by means of a common system of behavior, an inherently social event. Human language is a particularly remarkable example, and the quest for its evolutionary origins is a scientific problem of continued interest. One popular approach is to examine the cognitive capacities of nonhuman animals, especially those of primates, during natural acts of communication. The comparative approach is based on the premise that human language is built on a number of cognitive capacities with independent evolutionary histories, some with phylogenetic roots deep in the primate lineage.

Precisely what capacities are required for language? An article by Hockett in 1960 has been particularly influential. He identified 13 different design features that are common to all languages. Some are shared with animal communication systems; others appear to be uniquely human. The distinction between human speech and primate vocal behavior is particularly interesting since the two differ in only four design features (Table 1).

Referential Communication and Semanticity

A key property of language is that it allows speakers to use distinct utterances in order to convey information about objects and events in the outside world. This by itself is not a uniquely human trait, however. Honeybees are able to communicate about the location of distant food sources, and many animal species produce acoustically different alarm calls for different predators. For nonhuman primates, the classic example for such referential signals is the vervet monkey alarm calls. These primates produce acoustically distinct vocalizations to some of their predators, such as eagles, leopards, or pythons. When others hear a group member's alarm call to a python, they respond in ways that suggest the call is meaningful to them, for instance, by scanning the surrounding area for the snake they assume is present. Another example is the West African Diana monkeys, which produce acoustically different alarm calls to leopards and crowned eagles. These calls convey the biological class of the predator and are not simple responses to situational circumstances or perceived threat (Figure 1).

Eavesdropping is common in alarm situations, both within and across species. For example, yellow-casqued hornbills live sympatrically with Diana monkeys in the Taï Forest, Ivory Coast, and occasionally feed on the same trees. Crowned eagles threaten both species, but only leopards also attack the monkeys. Field playback experiments have shown that the hornbills not only recognize these two predators by their calls but also discriminate between the eagle and leopard alarm calls of the Diana monkeys, despite the fact that acoustic differences are very subtle (Figure 2).

Although the relation between monkey alarm calls and their meanings is arbitrary, the ontogenetic processes leading to the link are not. Infant vervet monkeys give eaglelike alarm calls to numerous flying objects, such as storks or falling leaves, and only with experience do they learn to restrict call use to the genuinely dangerous raptor species. The main alarm-call types develop fairly rigidly, as do the underlying psychological states that elicit them. Social learning subsequently leads to fine-tuning of the range of events that warrant call production, within the predetermined categories. Although widely accepted, the empirical basis for this model is not very strong, suggesting that further research could alter our understanding of how primates acquire semantic competence.

What sorts of mental processes do animals experience when responding to predator-specific alarm calls? Are these calls truly meaningful to them, in the sense that they are linked with specific mental representations, or are call production and comprehension possible without complex processing – a kind of cognitive knee-jerk reflex? These are difficult problems and some researchers thus prefer the term 'functional reference' to acknowledge that what superficially resembles human referential communication may be the product of different cognitive processes. For nonhuman primates, at least, there is relatively good evidence that individuals experience some fairly specific mental representations when hearing each other's calls.

In one study, the cognitive processes experienced by primates when listening to their own eagle or leopard alarm calls were investigated. The question was whether monkeys simply responded to the physical

Table 1 Design features in which human speech is thought to differ from primate communication

Design feature	*Human language*	*Primate communication*
Displacement	Information about past, present, and future events	Communication about present events only
Productivity	Generation of novel meanings; familiar pieces are reassembled into new utterances	No semantic creativity; closed call systems
Transmission	Socially learned and culturally transmitted	Genetically hard-wired signals
Duality of patterning	Small stock of meaningless phonemes to build meaningful morphemes	Holistic utterances, no permutations

Adapted from Hockett CF (1960) The origin of speech. *Scientific American* 203: 89–96.

features of the calls or whether they were capable of generating a mental representation of the corresponding predator (i.e., the semantic content of their calls). In the experiment, different groups of Diana monkeys were exposed to one of three different prime stimuli: the shrieks of a crowned eagle, a male's alarm calls to an eagle, or a male's alarm calls to a leopard (Figure 3). Five minutes later, the same monkey group heard a second stimulus, the shrieks of a crowned eagle. Hence, depending on the condition, the two playback stimuli did or did not correspond semantically. Results showed that eagle shrieks did not elicit new alarm calls when monkeys were previously primed with eagle shrieks or monkey eagle alarm calls, in contrast to when they were primed with monkey leopard alarm calls (Figure 3). Therefore, when responding to each other's vocalizations, nonhuman primates activate mental representations, which are responsible for subsequent behavioral patterns.

The Semiotic Triangle

In humans, the relation between speech utterances and world entities is mediated by mental concepts in the form of a semiotic triangle (Figure 4). A number of studies suggest that this model may also be useful in explaining some animal communication systems. For phylogenetic reasons, the focus is on nonhuman primates, although an increasing number of nonprimate species have demonstrated that some of the crucial cognitive capacities are not uniquely primate.

Thoughts

Accessing mental processes in animals is not a trivial task – the 'other mind' problem in philosophy. Although it is possible to systematically study an animal's behavioral responses to a stimulus, the only way to access underlying cognitive processes is by inference. A common custom is to select the most parsimonious mechanisms from a selection offered by human psychology, but this practice habitually causes discomfort and ongoing debate. Nevertheless, much empirical progress has been made in describing how animals mentally represent their worlds – that is, the kinds of conceptual structures they build and maintain to interact with their environment. It is important to know that in humans mental concepts can exist independently of language. Some mental concepts are well established in prelinguistic infants well before language is acquired. In some cases, infants have demonstrated competence in dealing with abstract mental concepts in ways that exceeded that of adults.

One important technique to study concept formation in animals is to train individuals to respond to a number of real-world exemplars, which are members of a particular category. In a subsequent testing phase, subjects are then asked to make choices in response to novel stimuli. In one pioneering study, pigeons learned to distinguish between unfamiliar photographs that did or did not contain trees, suggesting they possessed a natural concept for tree. An intriguing example is honeybees, which have been shown to form concepts of sameness and oddity. Thus, complex abstract concepts are widespread throughout the animal kingdom and are not restricted to primates or even vertebrates.

Human intelligence is thought to have evolved in the social realm, however, and research on social concepts is therefore of particular interest. One study of long-tailed macaques has become somewhat of a classic. Monkeys were trained to select photographs showing pairs of familiar group members, either mother–offspring dyads or other pairings. The study animals successfully mastered novel dyads, demonstrating that they utilized a concept analogous to the human mother–child affiliation. It has also been claimed that chimpanzees are able to match black-and-white photographs with faces of unfamiliar mothers and their sons, providing further support for mother–offspring social concepts in primates but also suggesting that phenotypical markers play a role during categorization. In another study, rhesus monkeys watched video clips showing an agonistic interaction between two unfamiliar conspecifics. Not only was it

Figure 1 Diana monkey alarm calls convey information about the biological class of the predator, not its distance or direction of attack. Nearby group members respond with the same vocal behavior to the growls of a leopard (or shrieks of a crowned eagle, respectively) regardless of whether or not the calls were broadcast at close distance or from within the canopy above or on the ground. Adapted from Zuberbühler K (2000) Referential labelling in Diana monkeys. *Animal Behaviour* 59: 917–927.

possible to train subjects to select the dominant individual in the interaction but also the subjects continued to do so when watching novel video clips – a demonstration that they possessed a social concept for dominance.

Despite these examples of primate social intelligence, there is a widespread consensus that nonhuman primates are unable to attribute mental states to one another, an activity that humans engage in from early childhood. However, empirical work has led to some

Figure 2 Responses of yellow-casqued hornbills of Tai forest to various predator-related acoustic stimuli. (a) Spectrogram of typical 'long' calls. Rate of production of this call type increased after playback of eagle calls and Diana monkey eagle alarm calls. Five individual calls are presented here. (b) Median and interquartile ranges of differences between the number of hornbill calls before and after playback of different stimulus types. Hornbills increased numbers of calls after playback of eagle shrieks significantly more than after playback of leopard growls. The same differences were found after playback of Diana monkey eagle and leopard alarm calls (Diana E and L). Adapted from Rainey HJ, Zuberbühler K, and Slater PJB (2004) Hornbills can distinguish between primate alarm calls. *Proceedings of the Royal Society of London Series B-Biological Sciences* 271: 755–759.

interesting amendments. Chimpanzees have been found to be capable of predicting the movements of more dominant competitors based on assessing the competitor's visual perspective. Related to this, when chimpanzees and other great apes interact with a human experimenter who is looking behind a barrier, they tend to position themselves such that they can see what the experimenter is looking at, suggesting that they attempt to take the experimenter's visual perspective. A number of non-ape species have shown comparable skills. When given the choice between two experimenters who were capable or incapable of seeing a food item, rhesus monkeys preferentially retrieved the food items from the visually unaware experimenter. In an experiment with ravens, the view of individuals during caching was manipulated, thereby creating competitors that were either knowledgeable or ignorant of the cache location. Results

Figure 3 Design and results of a prime probe experiment to investigate the cognitive processes underlying Diana monkey alarm-call production. Analogous results were obtained if leopard growls were used as predator stimuli. Adapted from Zuberbühler K, Cheney DL, and Seyfarth RM (1999) Conceptual semantics in a nonhuman primate. *Journal of comparative Psychology* 113: 33–42.

demonstrated that ravens adjusted their subsequent behavior depending on a competitor's knowledge – that is, whether or not it previously had witnessed the caching event. In addition, ravens can follow gaze around barriers similar to primates, further suggesting that they make judgments of the visual perspective of other individuals.

In summary, although primates and other animals are able to understand what others see or have seen in the past (i.e., that they know), there is currently no evidence that they can reflect on what they know or that they recognize and share each other's intentions, which has potentially significant consequences, particularly for cultural development.

Symbols

Vocal repertoires Primate vocal repertoires, and those of many other species, are often said to be genetically predetermined, suggesting that individuals have little control over vocal production, similar to some nonverbal utterances in humans, such as laughing or crying. Although the main thrust of this argument remains unchallenged, some empirical studies have provided a number of clarifications.

Figure 4 The semiotic triangle of referential communication.

First, several studies have shown that adult primates can change the acoustic structure of some of their calls, usually following significant social events. In Campbell's monkeys, adult females exchange contact calls as part of their daily social interactions. Each individual produces a certain number of acoustic variants, but these patterns collapse after changes in group composition. Playback of females' currently produced call variants reliably triggered vocal responses from other group members, whereas the same female's former, no longer used call variants caused long-term cessation of vocal behavior, indicating that the calls form part of a long-term social memory. Chimpanzee pant hoot vocalizations are a further example of vocal behavior that can undergo acoustic modifications depending on the social circumstances.

Second, the apparatus used by nonhuman primates for vocal production is not fundamentally different from that of humans. Sound is generated by the larynx, from which it radiates into the supralaryngeal vocal tract that acts as an acoustic filter. During speech, the shape of the vocal tract changes rapidly due to the movements of the various articulators, such as the lips, tongue, jaw, or larynx. The same basic processes have been found in Diana monkeys. Males produce alarm calls that contain formants with variable structure. Crowned eagles elicit calls with little or no formant transition, whereas leopards elicit calls with strong transitions (Figure 5). These acoustic modifications are the result of constrictions in their vocal tract formed by various articulators, similar to what takes place during speech production.

Figure 5 Vocal production mechanisms in a nonhuman primate. (a) Cross section of a Diana monkey vocal tract highlighting locations where acoustic filtering takes place due to constrictions. T, tongue; M, mandible; uL, upper lip; lL, lower lip; P, palate; Tr, Trachea. (b) Formant structure and transitions in Diana monkey eagle and leopard alarm calls. F1, first formant; F2, second formant. Adapted from Riede T, Bronson E, Hatzikirou H, and Zuberbühler K (2005) Vocal production mechanisms in a non-human primate: morphological data and a model. *Journal of Human Evolution* 48: 85–96.

Despite these similarities, there are vast differences between human and nonhuman vocal production. Humans are enormously skillful in producing rapid and precise articulatory movements, particularly with the tongue. As a result, humans are able to create a rich array of sounds, whereas sound production in nonhuman primates seems to be confined to a limited number of call types. For example, whereas modern English operates with approximately 40 different phonemes, male Diana monkeys possess only two (Figure 5). It has been suggested that this human specialization may be linked to a particular gene, *FoxP2*, since damage to this gene causes a severe speech disorder due to a lack of orofacial control. The human *FoxP2* is slightly different from those of the other nonhuman primates, suggesting that human–primate difference in orofacial control could be caused by this genetic difference.

Combinations of calls In contrast to speech, animal communication is considered to be holistic and lacking features that mark particular relationships between one call and another – Hockett's notion of duality of patterning. Although some animals combine acoustic units into patterned sequences, this behavior usually only serves to advertise identity, status, or quality, with no evidence of any sort of referential function.

A number of studies have provided empirical evidence that may require revision of current theory. At least two species of nonhuman primates have been found to combine calls into structurally more complex units, thereby modifying the semantic content of the entire utterance. An example is provided by free-ranging Campbell's monkeys. Like the Diana monkeys described previously, male Campbell's monkeys produce acoustically distinct alarm calls to leopards and eagles. However, if males witness other disturbing events that are not directly linked with these predators (e.g., a falling tree or a fleeing forest duiker), they usually produce a pair of low-sounding 'booms' before giving a series of alarm calls. Playback experiments have shown that other monkeys ignore such boom-introduced alarm calls, suggesting that the booms selectively change the meaning of subsequent alarm calls from predator-specific alarm signals to more general sign of disturbance (Figure 6).

Second, work on free-ranging putty-nosed monkeys in Nigeria has revealed similar results. In this species, the males produce two basic alarm call types, the 'hacks' and 'pyows.' These calls are not predator specific because males produce them to both eagles and leopards. Instead, callers concatenate the two calls into different sequence types, and these sequences are predator specific. In other words, putty-nosed monkeys encode predator class at the level of the call sequence and not at the level of the individual call. In addition, the males produce a peculiar pyow–hack sequence used to instigate group progression.

In summary, some primates do assemble calls into higher-order sequences and thereby generate information that is unrelated to the meaning conveyed by constituent elements. Although these combinatorial

Figure 6 Diana monkey responses to Campbell's monkey eagle or leopard alarm calls in the presence or absence of preceding boom calls. Artificially adding boom calls prior to an alarm-call sequence deletes the predator-specific meaning of these calls. The hatched bar indicates the median number of Diana monkey eagle alarms in the first minute after playback, the solid bar indicates the median number of Diana monkey leopard alarm calls. systems may lack the generative power of recursion, they provide an efficient means of increasing message repertoire without the need to invent new calls.

Referents

The final element in the semiotic triangle is the referent – that is, the kinds of entities that trigger vocal behavior in nonhuman primates. Most progress has been made in two contexts that are of particular evolutionary relevance: finding food and avoiding predators.

Food discovery Many primates vocalize when finding food. Although the underlying mental processes are not well understood, two factors appear to be particularly relevant: the social setting during call production and the food. Food-associated calls attract nearby listeners, and in some species callers exert some control over this process by adjusting call production. For example, chimpanzees are more likely to produce food-associated calls, the so-called rough grunts, if the food source is divisible and anticipated competition is likely to be low, a pattern also found in bonobos. These processes are not limited to primates. Male chickens produce specific calls upon discovering food, more likely so in the presence of a potential mate. Hens respond to the calls with anticipatory feeding movement, suggesting that the calls contain basic referential information. In ravens, there is a relation between food type encountered by the caller and call rates produced.

In chimpanzees, food quality is unrelated to call rates. In one study, calls from captive individuals were recorded in response to nine different food items, ranked by the individuals as high, medium, or low preference. There was no evidence for food labels with the low and medium preference class; acoustic differences were only significant between the three preference classes. Surprisingly, however, calls given to the high preference foods were acoustically distinct, suggesting that referential labels for food items can emerge in captive conditions. In a related study, it was investigated whether these call variants are meaningful to recipients. Rough grunts, given in response to bread and apples, were played back to recipients, and the subsequent amount of search effort underneath an apple and a bread tree was measured. Results demonstrated that the focal animal spent significantly more time and search effort underneath the correct tree (i.e., the tree corresponding to the call type played before), demonstrating that chimpanzees are able to attend to the subtle acoustic differences inherent in their food calls and that they are meaningful to them (Figure 7).

Predator detection Predator-specific alarm calls are a common feature of primate and nonprimate vocal behavior. Monkeys convey the biological category of the predator, but other information is sometimes also encoded. For example, some species, such as white-browed scrubwrens or California ground squirrels, adjust their calling behavior as a function of predator distance. Domestic chickens mainly distinguish between events on the ground or in the air, regardless of predator species. Gunnison's prairie dogs' alarm calls differ depending on the color of

Figure 7 Chimpanzee food grunts are referential signals. (a) Rough grunts given in response to two different food items – bread (top) and apples (bottom). (b) Search behavior of the focal animal in response to playbacks of apple grunts and bread grunts given by different group members. The subject devoted more search effort underneath the food tree, indicated by the food grunts played back earlier. clothes and general shape of human experimenters, and black-capped chickadees' alarm calls convey the size of potential predators with the number of D-notes in the 'chick-a-dee' alarm calls, a relevant source of information for recipients.

Similar to food calls, alarm call production in primates is under significant social control. In vervet monkeys, high-ranking individuals alarm-called at higher rates than low-ranking ones. The presence of offspring also increased alarm call rates in females, whereas males called at higher rates when with an adult female than when with other adult males. Primates may even keep track of the alarm-calling behavior of other group members. A field study reported that male Thomas langur responded with alarm calls to a model tiger and continued to do so until every member in their group had give at least one alarm call, suggesting that males keep track of which group members have and have not yet called.

Social events Primates routinely use vocalizations during social interactions, and in some cases the acoustic structure of calls varies with the social situation. The social calls of baboons have been studied in depth. During social interactions, subordinate animals tend to produce fear barks to approaching dominant group members, whereas dominants give grunts to signal their willingness to interact peacefully. These types of call exchanges have been used to experimentally mimic different types of social interactions to nearby listeners. In one experiment, individuals not only recognized the rank orders of the different group members but also recognized to which matrilineal kin group the individuals belonged.

Similarly, chimpanzees often scream when participating in agonistic interactions. In one study at Budongo Forest, Uganda, the vocal behavior of a large number of different individuals was recorded during agonistic interactions, such that each individual contributed the same number of calls both as a victim and as an aggressor. Results showed that the screams given in the two roles differed in a number of subtle acoustic features, providing reliable cues of the identity of the individuals involved and their social role. The degree to which listeners take advantage of this rich set of acoustic information needs to be explored.

Conclusion

The long-standing notion that the meaning of an utterance is nothing more than its use also has some relevance in animal communication. Nonhuman primates heavily rely on vocal communication, particularly those species whose primary habitat is the forest, where visual contact is limited and unreliable. Primates actively attend to each other's calls, and they are able to extract multifaced levels of information from individual calls and the way in which calls are arranged into different sequences. There is also evidence that primates understand something about the causal structure of the events that were responsible for the production of the various vocal signals produced by conspecifics and other animals. At the same time, primates have only limited control over their articulators and the vocal signals they can produce, but many of the fundamental principles of speech production are already well established.

A neglected area of research relates to the problem of how much primates take their audience into account and whether callers intentionally inform each other about events they have just witnessed rather than responding to the events directly. Anecdotal observations with chimpanzees suggest that individuals utilize vocalizations to affect the behavior of particular group members, although there is no clear evidence that this is for the sake of sharing information only. Chimpanzees are able to make judgments about other's intentions, even without being specifically trained to do so. For example, individuals behave differently depending on whether a human experimenter is unwilling or unable to give them food. Similarly, free-ranging baboons recognize when a call is directed at themselves rather than at other individuals. After hearing a threat grunt of a more dominant female, subjects moved away more quickly after having received aggression than grooming from that female, suggesting that baboons make inferences about the target of the caller's attention – a first crucial step toward the recognition of other individuals' intentions and motives.

One central Hockettian claim that has received comparably little attention throughout the years is that animal communication is thought to take place in the here and now only (Table 1). This point is interesting because the past is clearly an important psychological variable for many animal species. For example, there is evidence that scrub jays are able to recall particular food caching events in the past, including where and when they have occurred. Free-ranging gray-cheeked mangabeys of Kibale Forest, Uganda, can take the weather condition over the previous few days into account when searching for figs. The monkeys were more likely to revisit fig trees following several days of warm and sunny weather compared to after cooler, cloudier periods, presumably because they knew that temperature and solar radiation affect the ripening rate of figs. Given that animals are able to process information about past events, particularly in the context of foraging,

why is there no evidence that they also communicate about them? Perhaps there are deep reasons for this; perhaps future empirical work will reveal unexpected communication capacities.

Human language is a culturally transmitted behavior. It is maintained by children who try to understand and mimic utterances produced by relevant social figures, a process that starts very early in life. A number of studies have shown that nonhuman animals, including dogs, birds, and apes, can be brought to understand spoken language to some degree. Social processes, particularly the ability to share attention and intention, appear to play a crucial role in language acquisition in humans, an ability that emerges early on during human ontogeny. The degree to which joint attention and joint intention and related social processes play a role in the acquisition of meaning in animal communication is not well understood. The current state of the art is that even human enculturated apes show a total lack of attempts to share attention with others. This peculiar lack of social intelligence is widely regarded as the main reason why humans' common system of behavior to exchange information, spoken language, is so much more complex and powerful than those of any animal species. As usual, however, future work may tell a different story.

Reflex Circuits

T R Nichols, Emory University, Atlanta, GA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The reflex has long been a central concept in physiology and psychology. During the late nineteenth and early twentieth centuries, the reflex was considered a unit of function and was used as the basis for the experimental investigation of the central nervous system. However, as recognized by Sir Charles Sherrington, the simple reflex arc is an abstract concept since the associated pathways are embedded in a larger system of neural circuits. Sherrington recognized that reflexes vary in complexity and that coordination results in part from a compounding of reflexes that may work together or in opposition. The philosopher John Dewey criticized the concept of the reflex arc in psychology for similar and for several additional reasons. A simple stimulus and resulting response may be a convenient experimental or clinical tool but does not capture the closed-loop nature of most sensorimotor processes, nor does this notion recognize that most reactions occur as components of ongoing behaviors. The term 'reflex arc' implies a stimulus and response but makes no provision in itself for communication from response back to stimulus. An exemplary notion in the motor control literature is that of clasp knife inhibition. This response is a useful clinical sign, but the functional interpretation common in textbooks that this response normally serves a protective function in the musculoskeletal system was taken out of the context of normal function. The implicated group III and group IV receptors in fact do not require excessive forces for stimulation, and the profound inhibition observed under pathological circumstances has not been observed in the normal state. How the associated spinal pathways operate in the normal animal in a way that is consistent with stability remains unknown.

The above issues have been extended in contemporary work on spinal circuits in several ways. First, it is generally recognized that reflex circuits are organized hierarchically. Sensory feedback may influence motor neuronal output directly, in a distributed fashion to motor neurons controlling other muscles directly or through interneuronal circuits, or through pattern-generating networks. Second, sensory feedback represents a number of different variables, and the composition of a set of such signals is dependent on behavioral or mechanical context. Third, reflex pathways are embedded in closed-loop neuromechanical circuits. For example, while signals representing muscular length are processed and distributed by circuits in the spinal cord, muscular force is transformed mechanically by the architecture and dynamic properties of the musculoskeletal system into changes in length. These biomechanical transformations are essential components of the control system. Rather than merely providing different responses to different stimuli, this control system endows the motor actuator with appropriate mechanical properties and promotes coordination and stability among the segments of the body. Each of these points will be considered in turn.

The Hierarchical Organization of Spinal Circuits

The Regulator

An important structural basis for the integration of reflex circuits in the spinal cord is the hierarchical design of the associated pathways. At the most elemental level is the monosynaptic reflex that arises from muscle spindle receptors, excites motor neurons through a single synaptic connection, and generally results in force production and then changes in lengths of muscle units, completing a loop back to the muscle spindle. Although this pathway is usually viewed as a private pathway, and is therefore modular in structure, the pathway arising from force receptors is far from private, as will be argued in the next section. The feedback from muscle spindles and other receptors is also distributed to other muscles through interneuronal networks. The muscle targets may cross the same or different joints in the limb or may be located in other parts of the musculoskeletal system. At this hierarchical level (the regulator, Figure 1), monosynaptic and polysynaptic pathways form distributed networks in the spinal cord.

Pattern Generating Networks

It has been established that the spinal cord contains pattern-generating networks that are capable of rhythmic activity in the absence of sensory feedback. Additional evidence suggests that the motor commands are organized in the form of synergies of muscles or motor units. It has been established that sensory feedback from muscles and skin impinges on these central pattern generators and is capable of modulating the magnitude of the output signals or resetting the rhythmic activity. On the basis of more-recent evidence, it has

Figure 1 The organization of circuits of the spinal cord is hierarchical. The musculoskeletal actuator consists of the musculoskeletal system. This actuator has intrinsic properties that provide an initial mechanical response to perturbations. Feedback from a variety of receptors reaches the spinal cord and influences a variety of spinal pathways. The pattern generator sets the timing of muscular activity during locomotion. The selector determines which groups of muscles or motor units are active during a given task. The regulator is a network of pathways that receives sensory feedback. This module regulates the stiffness of the limb and promotes interjoint coordination. It is capable of mediating basic postural responses in conjunction with sensory feedback from other limbs. Central commands or signals for modulation from the brain stem or other areas in the spinal cord affect these hierarchical stages.

been suggested that the pattern generators are composed of two levels of processing. The first generates the appropriate timing signals, and the second selects the appropriate synergies on the basis of the behavioral context. For example, in walking on ramped surfaces, different patterns of muscular activity are required to achieve the appropriate balance of forces. Feedback that reflects the orientation of the animal with respect to gravity may influence the selection level appropriately. Other networks mediate responses to postural disturbances, although it is not clear whether these networks are located in the spinal cord, brain stem, or both. These networks are driven by feedback from skin and muscles, and the outputs appear to be organized into synergies as well. These hierarchical levels are shown schematically in Figure 1. Sensory feedback is essential to the operation of each of these levels.

Sensory Feedback Is Multivariable and Context-Dependent

Reflexes are usually defined in an experimental context. One or more channels of sensory information can be stimulated either electrically or mechanically. The response will result from the actions of one or more reflex pathways associated with any of the above hierarchical levels. The reflex thus defined might or might not be composed of a natural combination of individual pathways in view of the artificial or isolated nature of the stimulus. During natural movements, sensory pathways will be recruited or modulated up or down in a variety of combinations and engage different combinations of the hierarchically arranged pathways. Resulting alterations in motor neuron firing will bring about mechanical changes in the musculoskeletal system, closing the loop back to the sensory receptors. The sensory pathways can be modulated through neuronal mechanisms in the spinal cord. They can also be modulated by virtue of the influence of mechanical context on sensory transduction.

Golgi Tendon Organs

The fundamental mechanical variables, length and force, are sensed by muscle spindle receptors and Golgi tendon organs, respectively. Golgi tendon organs are particularly sensitive to active contractile forces and provide interneurons in the spinal cord with a measure of total muscular force although the feedback may fade as a result of presynaptic inhibition in the spinal cord. Increased force can occur during active shortening when muscles contract concentrically, during active lengthening due to intrinsic mechanical properties of contracting motor units, or during active lengthening when the stretch reflex recruits additional motor units. There is electrophysiological evidence of oligosynaptic inhibition of parent motor neurons from tendon organs, but this connection is rather weak and has not been observed in muscle stretch. Pathways arising from these receptors can, however, excite motor neurons of the parent muscle during locomotion but generally inhibit motor neurons of muscles spanning joints or axes of rotation different from the parent muscle's over a variety of behavioral conditions.

Muscle Spindle Receptors

Muscle spindle receptors respond in a nonlinear fashion to changes in the lengths of muscle fibers in large part because of the mechanical properties of the contractile intrafusal muscle fibers. There are two types of these receptors, primaries and secondaries. The nonlinear properties and dynamic responsiveness are similar in the two types but are more extreme in the

primary receptors. A functional consequence of these nonlinear properties is that the response properties of the receptors depend on mechanical context, as illustrated by the following examples. First, muscle spindles increase firing to stretch more than they decrease firing to release and so are more sensitive during eccentric than concentric contractions. Second, these receptors have a decreasing sensitivity to velocity as velocity increases. Third, muscle spindle receptors appear to be more sensitive to length change during quiet standing than ongoing locomotion. Responses to increases in muscle length occurring after a period of isometric loading are characterized by an initial burst and a large dynamic response. Responses to increases in length occurring during ongoing movements are characterized by a smaller dynamic response, lack of an initial burst, and overall more linear behavior. The nonlinear properties described above may be more important during transitions between quiet standing and movement or during changes in movement direction.

Modulation of discharge characteristics of muscle spindle receptors also occurs through neural inputs by virtue of the gamma motor innervation of intrafusal fibers. Some gamma motor neurons apparently fire according to a template of the expected movement, while others bias the firing of the spindle receptors. A third type can modulate the sensitivity of the spindle receptors during certain phases of movement or perhaps in the process of learning a novel task.

Since muscle spindles signal changes in length of muscle fibers, increases in muscular length that can occur during some active contractions can occur mostly in the tendon, resulting in little change in firing rate of the spindle receptors. This situation can occur during walking down a ramp, a task that features eccentric muscular contractions. Under these conditions, force feedback from Golgi tendon organs would predominate, illustrating the importance of context in the composition of sensory feedback.

Primary receptors of muscle spindles project back to the parent muscle, to other levels in the hierarchy of spinal circuits, and also to the cells of origin of projection pathways to the cerebellum, cortex, and other supraspinal structures. Although individual muscle spindles code the length changes of parent muscle units, the projection cells of the spinocerebellar tract to which they project code more global variables related to limb length and orientation, indicating that considerable synthesis of proprioceptive information occurs at the level of the spinal cord. This information could be used for the local regulation of balance and stability. Muscle spindles in muscles of the neck also have specialized projections to regulate muscular tone and influence the selection modules. These pathways interact with feedback from the vestibular apparatus to regulate patterns of muscular activity during locomotion on irregular and sloped surfaces.

Secondary spindle receptors project to interneurons in the spinal cord. Pathways arising from secondaries are more divergent in the spinal cord than are pathways from the primaries but include excitatory actions on motor neurons of the parent muscle. The projection interneurons fire rhythmically during locomotion. These interneurons also receive inputs from the vestibulospinal and reticulospinal tracts, indicating a potential role in postural regulation. Muscles also contain many other varieties of receptors, such as those associated with lightly myelinated or unmyelinated sensory nerve fibers. These group III and group IV receptors code mechanical signals as well as pain and metabolic feedback. Pathways from these receptors are less well understood than those from muscle spindles and tendon organs, but evidence exists that feedback from these receptors does impinge on spinal circuits and can influence motor unit firing.

Cutaneous Receptors

The other major sources of feedback for the reflex circuits associated with skeletal muscles are the skin and connective tissue elements associated with joints. Feedback from the skin is mediated through interneuronal circuits to influence muscular activity through the hierarchical levels described above. These pathways may exhibit local sign, in which muscular responses tend to diminish the effects of a noxious stimulus on the same patch of skin. For example, when the receptive field of the feline caudal cutaneous sural nerve (lateral side of ankle) is stimulated, muscles are activated which plantarflex and abduct the ankle. These actions tend to remove the limb from the stimulus. Cutaneous pathways also have more global actions on the animal, including flexion–withdrawal responses and adjustments in muscular tone of the four limbs. It has been speculated that cutaneous information from the paws in cats may provide directional information to the circuits generating responses to postural perturbations. The functions of feedback from receptors in joints and connective tissue elements such as the anterior cruciate ligament are not well understood, but the associated pathways do excite or inhibit gamma motor neurons and therefore influence proprioceptive feedback from muscle spindle receptors.

Autonomic Reflex Circuits

The spinal cord also contains reflex circuits arising from receptors located in the bladder, bowel, and sexual organs. Pathways from stretch receptors in

the bladder wall project to micturition control centers in the brain stem. Spinal mechanisms promote storage of urine (contraction of sphincter and relaxation of the detrusor muscle) through sympathetic and somatic pathways, while brain stem mechanisms that inhibit sympathetic output and enhance parasympathetic output are required for reflex emptying of the bladder.

Reflexes Are Embedded in Neuromechanical Circuits

Mechanical Component

The mechanical state of the musculoskeletal system will determine the constellation of sensory feedback that arrives in the spinal cord. The musculoskeletal system consists of linked segments that are spanned by muscles and connective tissue elements. Some muscles span a single joint while others span more than one joint. Many joints rotate about more than one axis, and some muscles contribute to more than one axis of rotation. Muscular contractions cause mechanical changes in the musculoskeletal system by exerting forces that are transformed into torques about the spanned joints. These forces are also communicated by way of physical forces to other joints and axes of rotation and to other limbs and body segments. These physical forces consist of inertial coupling and the viscoelastic properties of connective tissue and muscle. Muscles exert forces through tendons of insertion and also through fascia that provides mechanical coupling across several joints. The distribution and extent of these mechanical effects depend on the architecture of the musculoskeletal system as well as the intensive and extensive properties of the tissues involved. These properties are in turn influenced by the configuration of the skeleton and the distribution of muscular activity. According to this mechanical description, the musculoskeletal system can be seen as a circuit based on the variables length and force. This circuit determines how mechanical variables are transformed into the neural representations in the spinal cord.

Mechanical perturbations applied to the body are resisted by mechanisms that are intrinsic to the musculoskeletal system in addition to reflex mechanisms. The intrinsic responses arise from the viscoelastic properties of muscles and connective tissue elements, as well as inertial properties of the system. These intrinsic properties provide a fundamental basis for stability and coordination on which the actions of reflex circuits are superimposed. These intrinsic properties provide reactions to mechanical disturbances that are not subject to the time delays of neural pathways.

Neuromechanical circuits are organized in a distributed fashion rather than a modular plan by virtue of the structure of both neuronal and musculoskeletal components, as illustrated by the schema shown in Figure 2. The stretch reflex is often depicted as a single loop in which muscular force is transformed into length changes through the load supported by the muscle. As stated above, however, muscular action results in mechanical changes throughout the musculoskeletal system by way of mechanical coupling. For example, forces exerted by biarticular muscles will exert torques about both spanned joints and cause length changes in a number of different muscles. The load that transforms muscular force into length changes is actually an extensive, distributed system. The length changes occurring in the muscle are due to mechanical interactions throughout the musculoskeletal system and not

Figure 2 The interface between the musculoskeletal actuator and regulator consists of muscle units and sensory receptors. Excitation–contraction mechanisms of the muscle unit (M) convert neural information from spinal motor neurons (U) into mechanical signals, and receptors do the reverse. Muscle spindle receptors (S) are influenced by length changes (*l*) resulting from dynamics of the musculoskeletal system. Muscle spindles project to the regulator by way of monosynaptic and polysynaptic connections to motor neurons. Muscle length also provides direct mechanical feedback to the muscle unit (*m*). Golgi tendon organs (T) respond primarily to active contractile forces (*f*) in the muscle that contains them. These receptors project to interneurons in the spinal regulator. During locomotion, excitatory projections to the parent motor nucleus are opened. Under a wide variety of conditions, tendon organs project to muscles that exert torques about other joints or axes of rotation than the parent muscle by inhibitory connections.

merely the forces exerted by the muscle. Although the feedback from the spindle receptor may exert major effects on the motor neurons of the parent muscle, the signals encoded by the spindle receptors in the muscle are not private to the muscle. Furthermore, the preferential sensitivity of muscle spindle receptors for active lengthening indicates that they respond more vigorously to external perturbations or stretches due to contractions of other muscles than the shortening contractions of the parent muscle.

Neural Component

At the level of the spinal cord, the feedback from muscle receptors is distributed not only to the parent muscle but to others as well. In the cat, muscle spindle receptors project mainly to the parent muscle, but muscle spindles from the vastus intermedius muscle project monosynaptically to the soleus muscle as well. Therefore, knee communicates to ankle not only mechanically through biarticular muscles but also through the neuronal pathways of length feedback. On the output side, activity in one motor nucleus communicates with other motor nuclei through the distribution of Renshaw inhibition. Renshaw cells are excited by recurrent collaterals of motor axons and project back not only to the parent motor neurons but to other motor neurons as well. Signals from muscle spindle receptors also impinge on the selection and oscillator components of the spinal networks and therefore are distributed widely through the musculoskeletal system. At all hierarchical levels, reflex circuits become distributed by virtue of both mechanical and neural components.

Muscle spindle receptors are stimulated by length changes brought about by musculoskeletal dynamics, and their responses are not simply related to the contractile output of the muscles containing them. In contrast, the firing rates of Golgi tendon organs follow the active contractile forces exerted by the parent muscle, whether in active lengthening or shortening. As noted above, feedback from Golgi tendon organs is distributed widely to motor neuron pools in the limb and presumably the trunk. The cross-joint inhibitory actions constitute neural linkages that parallel the direct mechanical linkages of multiarticular muscles. Force feedback is itself force-dependent, so that the extent of neural coupling across joints and axes of rotation increases at higher forces, reducing the degrees of freedom of the corresponding musculoskeletal elements.

The myotatic unit can be used to illustrate how elements in the musculoskeletal and nervous systems combine to form a neuromechanical circuit. Although the myotatic unit is not a universal building block of musculoskeletal control, it can be excerpted experimentally in the distal limb musculature. The neuronal component consists of excitatory feedback from muscle spindle receptors to the parent motor neurons (the stretch reflex) and inhibitory feedback to antagonists. The mechanical component consists of the reciprocal mechanical linkage of the two muscles. An external perturbation that causes movement of the joint so as to stretch the antagonist muscle is immediately met by the intrinsic resistance of both muscles. The agonist resists by increasing its force, and the antagonist resists by decreasing its force. The further excitation of the agonist muscle through the stretch reflex and inhibition of the antagonist muscle adds to the resistance of this neuromechanical apparatus to the perturbation.

Modularity

Two ideas proposed recently concern ways in which neuromechanical circuits might be modular. The first is the concept of motor primitives. According to this hypothesis, the sensorimotor apparatus in the spinal cord is subdivided into a small number of modules. Each module consists of a subset of interneuronal pathways, sensory feedback, and musculoskeletal elements. Movements are made by selection of different combinations of these modules. The modules can be recruited by centrally derived commands or by sensory feedback. In the scratch reflex, appropriate modules would be selected to achieve the local sign of this triggered behavior. The second hypothesis is that the motor apparatus consists of synergies of muscles or motor units that are brought into activity in groups. These synergies are presumably specified by the selection module as a result of either feedback or central commands. These synergies are flexible in that a given motor unit or muscle can be a member of more than one synergy. Activation of a synergy would lead to the recruitment of a particular population of Golgi tendon organs. The mechanisms by which modularity can be achieved anatomically or physiologically are unknown.

Sensory Feedback Regulates the Mechanical Properties of the Musculoskeletal System and Promotes Coordination and Stability

Sensory feedback links the mechanical and neuronal components of the circuit and, in parallel with the intrinsic mechanical properties of the musculoskeletal system, determines the mechanical properties of the complete system. As described in the section titled 'Neural component,' length feedback is organized quite differently from force feedback. Mechanical changes in the musculoskeletal system evoke a constellation of signals from muscle spindles that depend

on the length changes of the muscles. The feedback would be particularly strong in muscles undergoing active lengthening as a result of the perturbation or commanded muscular contractions. Due to the matching of intrafusal and extrafusal mechanics, the monosynaptic autogenic connections will compensate for certain muscle nonlinearities by recruiting new motor units. This integration of intrinsic and reflexive mechanisms and additional contributions of reciprocal inhibition will set the springlike mechnical characteristics of the joint. In this case, the springlike characteristics differ from those of an ideal spring in that stiffness increases with force and length. This dependence of stiffness on force has an important function in mediating the dependence of joint stiffness on the level of cocontraction, according to the lambda model of the equilibrium point hypothesis. Mechanical coupling between adjacent joints would be promoted by the stiffness of reflexive biarticular muscles.

By virtue of more divergent projections in the spinal cord, inhibitory force signals from Golgi tendon organs would interact with length signals and intrinsic properties in two ways. First, the balance of force and length feedback would determine the stiffness of the limb measured at the endpoint, as originally suggested by James Houk for single muscles. Second, force feedback would promote interjoint coordination and stability by providing neural coupling across joints and axes of rotation. Should forces in the limb increase, the gain of force feedback and therefore coupling would increase as well. Given the redundancies inherent in multisegmented limbs, these sensory pathways would promote stability across the joints of the limb in parallel with the mechanical coupling provided by multiarticular muscles.

During locomotion, a pathway of excitatory force feedback is opened. This positive force feedback appears to be primarily autogenic and has the effect of increasing stiffness and force in the muscles of propulsion. This excitatory autogenic feedback is particularly strong in the medial gastrocnemius muscle of the cat, a muscle that contributes in important ways to propulsion during walking up sloped surfaces. Positive force feedback is important in maintaining force during active lengthening in this muscle when much of the stretch is absorbed in the tendon. Under these conditions, muscle spindle receptors would provide modest feedback because the muscle fibers would be nearly isometrically loaded.

This regulatory network would be capable of mediating basic postural responses in the whole limb. Muscles would be activated according to pulling directions by pathways arising from muscle spindle receptors. Communication through propriospinal pathways and the local selector could provide the appropriate integration of responses of the supporting limbs. More complex postural responses and integration with vestibulospinal and proprioceptive feedback from the neck would involve participation of brain stem areas as well.

Reflex Circuits Are Subject to Peripheral and Central Modulation

Neuromechanical circuits are subject to both short- and long-term modulation. Short-term effects allow adaptation to changing behavioral and environmental contexts, and long-term changes occur with growth, learning, and disease. Short-term modulation has been observed in both neural and mechanical components of the motor apparatus. The dependence of the responses of muscle spindle receptors on movement history is matched to the dependence of the mechanical properties of muscle on movement history to preserve springlike behavior. Mechanical responses of muscle to increases in length are mediated largely by length feedback under quasi-static conditions. During ongoing movements, the responses include a larger contribution from intrinsic mechanics. This feature contributes to stability of the motor system. A mechanical perturbation is initially resisted by the elastic properties provided by reflex recruitment. Any ensuing oscillations are effectively damped out by the predominance of viscous intrinsic properties of muscle. This automatic change in gain is mediated by the interaction of neural and mechanical components. A second example of modulation that results from the nonlinear properties of the muscle spindle concerns the termination of a voluntary movement. Since the velocity dependence of muscle spindle receptors contributes to damping, damping is greater toward the termination of movement as the limb slows during its approach to its target position. The increased damping as well as the attraction of the final equilibrium point helps maintain the limb on target.

In the central nervous system, mechanisms for modulation are manifold. For example, the sensitivity of muscle spindle receptors can be modulated by gamma motor neuronal activity, while modulation of force feedback from Golgi tendon organs occurs centrally in interneuronal pathways. Presynaptic inhibition of sensory afferents can also regulate the gain of incoming feedback. The gain of primary spindle receptors is apparently reduced at the stance to swing transition of the step cycle to allow rapid clearance of any obstacles by the foot. Automatic postural responses can be downregulated within a few trials if inappropriate

for stability, perhaps mediated by presynaptic inhibition. Descending pathways from the brain stem can also promote bistable firing of motor neurons through serotonergic receptors. Bistable firing may help maintain upright posture for extended periods. Finally, modifications of motor behavior evoked by stimulation of the dorsum of the foot in walking cats are altered in a phase-dependent manner. During the swing phase, stimulation results in withdrawal of the foot and ankle extension to clear an obstacle. During the stance phase, the same stimulus can increase extension or increase flexion during the subsequent swing phase. Long-term changes in neuromechanical circuits also occur. For example, the gain of the stretch reflex can increase or decrease over a period of days or weeks by appropriate operant conditioning. The cellular mechanisms of these changes are complex but appear to involve both intrinsic properties of motor neurons and changes in synaptic strength.

Osmosis, Osmotic Pressure, and Steady-State Cell Volume Homeostasis

Animal cells are surrounded by semipermeable plasma membranes. Water moves across this membrane freely, whereas the majority of solutes require special transport systems to cross the membrane barrier. Any change in the concentration of solutes on one side of the membrane causes water movement along the new concentration gradient by a process termed osmosis. Such water movement can be prevented by applying to the membrane a hydrostatic force, called osmotic pressure, which may be calculated using the van't Hoff equation:

$$\pi = RT\Delta C$$

where π is the osmotic pressure, R is the gas constant, T is the absolute temperature, and ΔC is the difference in solute concentrations across the semipermeable membrane.

Since animal cells do not possess a rigid cell wall, their membranes cannot maintain osmotic gradients, and therefore any accumulation or loss of solutes is immediately followed by water flow so that the osmotic gradient dissipates. Since animal cells contain the large proportion of impermeant macromolecules such as proteins, which are predominantly anionic, that would lead to an unstable situation in which the cell would inexorably swell until the impermeant macromolecules were infinitely diluted so that the cell no longer effectively contained them. Long before this, of course, the cell would no longer be able to function as a cell. This process of cell swelling due to the presence of impermeable macromolecules in the cytoplasm is termed Donnan swelling after the Harvard physiologist who first recognized its importance.

To maintain their volume and viability, animal cells evolved a system that neutralizes their tendency to swell. The first part of this process is the accumulation of K^+ inside the cell. This is achieved by the ubiquitous Na^+, K^+ pump, which directly uses ATP to achieve a high $[K^+]$ in cells ~130 mM and a low $[Na^+]$ in cells 10–20 mM. For a membrane containing many more K^+ than Na^+ channels, the membrane potential is almost entirely a K^+ diffusion potential of ~ -90 mV with the normal low extracellular K^+ of 3 or 4 mM. If the only transport route for Cl^- is channels, intracellular chloride will be driven out of the cell by the internal negative charge and will be ~4 mM, as given by the Nernst potential with $[Cl^-]$ outside being ~130 mM plus a high $[Na^+]_o$ of an equivalent concentration. The low intracellular $[Cl^-]$ compensates for the presence of organic anions in the cytoplasm for electrical neutrality. With a low density or activity of Na^+ channels making Na^+ permeability much less than that of K^+, the whole system is in a steady state, called the Gibbs–Donnan equilibrium, which can be maintained with a minimum expenditure of energy.

Water Movement across Plasma Membranes

The processes of ion transport and osmotic regulation require that the cell membranes are freely permeable to water relative to the fastest ion movements so that the movement of water does not become rate limiting. Despite the basic characteristics of cell membranes being those of a lipid bilayer or, more strictly, a phospholipid bilayer, they are quite permeant to water. The upper limit of the permeability coefficient (P_f) for water of phospholipid bilayers is 5×10^{-3} cm s^{-1}, 10^8 higher than for Cl^- and approximately 10^{10} higher than that for K^+ or Na^+.

Nonetheless, a special class of membrane proteins accelerating water movement has been identified in many cell membranes. These proteins are termed aquaporins and are known to consist of at least 11 different members termed AQP0–10. AQP1, – 4, and – 9 are present in the brain, with AQP4 and – 9 specifically found in astrocytes and AQP1 present in the epithelial cells of the choroid plexi.

For cultured astrocytes, genetic deletion of AQP4 reduced P_f from 0.05 to 0.007 cm s^{-1} for cells prepared from wild-type and AQP4$^{-/-}$ mice, respectively. The latter value is very similar to the P_f for lipid bilayers. AQPs may be needed for water transport to keep pace with the transport of ions, which is very rapid through the various channels and transporters. Alternatively or in addition, some biological membranes can be relatively water impermeable, and the water permeability can then be regulated by AQPs. This is important in water-controlling organs such as the kidney. However, the relative significance of aquaporins in the brain is presently less understood.

Physiological and Pathological Perturbations of Cell Volume

A large variety of physiological reactions and pathological states can disrupt the Gibbs–Donnan

equilibrium and cause changes in cell volume. Changes in extracellular osmolarity represent the simplest reason for alterations in cell volume. However, in mammals only blood cells passing through kidney capillaries and a few types of epithelial cells are exposed to substantial osmotic gradients. Osmolarity of the extracellular environment throughout the body is tightly regulated, except under certain pathological conditions. For example, hyponatremia – a decrease in plasma sodium concentration – is typically caused by hormonal disorders leading to alterations in kidney function. Causes of hyponatremia include overproduction of antidiuretic hormone (ADH), glucocorticoid deficiency, and renal failure. Conversely, acute dehydration, osmotic diuresis, and decreased ADH production may initiate hypernatremia – an increase in plasma sodium concentration.

A far more common reason for cell volume alterations is changes in intracellular osmolarity. Net Na^+ uptake during activation of neuronal ionotropic excitatory amino acid receptors, such as AMPA receptors, can cause neuronal volume increase. Na^+-dependent uptake of glutamate and other neurotransmitters has been linked to cell swelling seen mainly in astrocytes. Sustained neuronal activity or pathological neuronal depolarization leads to a buildup of extracellular K^+ levels, which promote slow cell swelling because of the plasma membrane depolarization followed by $(K^+ + Cl^-)$ influx according to the new Gibbs–Donnan equilibrium. *In situ*, this latter type of swelling is also predominantly found in astrocytes.

Inhibition of energy metabolism, as seen in a number of neuropathologies, generally causes cell swelling resulting from a loss of Na^+, K^+-ATPase function, dissipation of K^+ gradient, and membrane depolarization with concomitant accumulation of Na^+ and Cl^- and cell swelling.

An opposite process of solute efflux and cell shrinkage may result from the stimulation of K^+ channels and/or Cl^- channels. Such shrinkage is thought to occur at the initial stages of apoptosis in both neuronal and nonneuronal cells.

Methods of Cell Volume Measurements

A number of methods allow for monitoring cell volume changes in different experimental systems, ranging from suspensions of roughly spherical cells to cells in the intact tissue. There is essentially an increase in complexity and decrease in precision as one advances from the dispersed cell suspensions through substrate attached cell cultures to different cells mixed in a single tissue. We cannot describe these methods in detail but will restrict our discussion to briefly mentioning the main ones.

The isotope-based methods, such as the formerly extensively used ^3H 3-*O*-methyl glucose (3-O-MG) measurements, calculate intracellular water space occupied by the isotope-labeled compound. The volume of distribution of 3-O-MG can be calculated but only based on the assumption that the concentrations of 3-O-MG are the same inside and outside the cell. In a glucose-containing medium, the 3-O-MG will trace the glucose concentrations and it requires that the transporter is of the equilibratory type and there is no concentration gradient.

Spectroscopic methods can provide a dynamic readout of the time course of swelling. These methods use changes in the concentration and therefore the signal of a fluorescence compound that remains in the cells and does not leak out with the volume changes. However, the measuring device, a fluorescence microscope, will have to record from a partial, constant volume of the cell so that the dilution of the compound is registered. The measurement is more reliable if a confocal microscope is used, in which a fixed volume can be measured in the horizontal focal plane. With rapid sampling of the cells from top to bottom and the appropriate software, entire cells can be reconstructed and there is the possibility of measuring total cell volume.

Measuring the volume of total tissue is straightforward; it is done by measuring its wet weight and referencing this to the weight after the sample has been thoroughly dried. This method has been used since early studies on tissue volume and water and ion content in animal tissues.

More dynamic but indirect methods for measuring the time course of cell volume changes involve measuring the extracellular impedance electrically using electrodes, as pioneered by van Harreveld. Since cells do not conduct current compared to the extracellular space (ECS), this can be applied to tissue slices or the intact organ *in vivo*. The volume (V) of the brain is constant:

$$V_{\text{blood}} + V_{\text{ESC+CSF}} + V_{\text{brain intracell}} = \text{constant}$$

where CSF is cerebrospinal fluid.

Using alternating current to avoid polarization effects and neuronal excitation, and Maxwell's equations, one can measure extracellular space and dynamic changes in cell volume based on the fact that membrane-delimited cells are nonconductors of current compared to the ESC.

Another method for measuring dynamic changes in the ECS has been pioneered by Nicholson and colleagues. Ion-specific electrodes are used to measure the changes in activities of a membrane-impermanent species which is restricted to the ECS. Thus, as cells swell, the species' electrochemical activity will increase, and it will decrease when cells shrink.

The light scattering method, in which cells swell when there is a decrease in light scattering, can be used for cell suspensions or tissue slices. This is also referred to as a change in the intrinsic optical signal or IOS.

A newer, noninvasive method to measure cell volume changes *in vivo*, which is widely used clinically, is the diffusion-weighted spin echo sequence with magnetic resonance imaging. This method allows one to calculate the apparent diffusion coefficient of water (ADC). A decline in this parameter means the bulk diffusion of water is more hindered. This has been interpreted in brain tissue as principally due to the movement of water from the extracellular space to intracellular space due to cell swelling. In animal models of stroke and epilepsy, the decrease in ADC correlated with increased swelling of astrocytes measured by electron microscopy.

Electron microscopy, after rapid perfusion fixation to avoid postmortem fixation artifacts, is in fact the only truly reliable method for studying the swelling of specific cells *in situ*. However, generally the cross-sectional areas of the cells in the thin sections are measured. It is time consuming, especially if three-dimensional reconstructions are attempted, and it is nondynamic.

Ionic Mechanisms Responsible for Regulatory Volume Decrease in Swollen Cells

In response to swelling, the overwhelming majority of animal cells, including neural cells, activate K^+ and Cl^- efflux through independent K^+ and anion channels. These channels are functionally coupled via the plasma membrane potential. Efflux of K^+ immediately leads to membrane hyperpolarization, increasing the driving force for Cl^- efflux. Since intracellular Cl^- concentration is typically low, Cl^- efflux is supplemented by the release of bicarbonate ions and small organic anions through the same low-selectivity anion channels.

Among the potassium channels known to be activated or modulated by cell swelling are Kv1.3, Kv1.5, mini-K, and TASK-2 (KCNK5). Although these channels are expressed in the central nervous system (CNS), their relative contribution to volume regulation in neuronal and glial cells is not known. Maxi-K channels, which are opened in response to cell swelling in many types of epithelial cells, are activated indirectly via increases in intracellular $[Ca^{2+}]$.

The molecular nature of the volume-regulated Cl^-/anion channels (VRACs), which are ubiquitous in invertebrate and vertebrate cells, is unclear. Several previously suggested candidates for the role of VRAC, including pICln, CFTR, ClC-2, phospholemman, and porin-like voltage-dependent anion channels, have been ruled out. These channels either show different biophysical properties compared to the endogenous VRAC or their respective gene knockouts do not affect endogenous VRAC currents in swollen cells. The ClC-3 gene product is still discussed as a VRAC candidate; however, ClC-3 gene knockouts did not affect the VRAC current and therefore have placed this concept in doubt.

The electroneutral K^+, Cl^- cotransporter is an alternative, nonchannel system which contributes to regulatory volume decrease (RVD) in red blood cells and some types of epithelial cells which have a relatively high intracellular Cl^- content. To date, four members of this family, KCC-1 through -4, have been cloned. Although KCC-1 is most common, KCC-2 is highly expressed in the brain, where it plays a major role in the regulation of intracellular $[Cl^-]$ in neuronal cells. The relative contribution of KCC transporters to cell volume regulation in neural cells is not known.

Ionic Mechanisms Responsible for Regulatory Volume Increase in Shrunken Cells

In the majority of cell types, regulatory volume increase (RVI) is mediated by the electroneutral Na^+, K^+, $2Cl^-$ cotransporter and/or Na^+/H^+ exchanger. The NKCC1 isoform of the Na^+, K^+, $2Cl^-$ cotransporter is ubiquitously expressed. This transporter is activated by cell shrinkage, and it contributes to compensatory accumulation of Na^+, K^+, and Cl^- and subsequent cell volume recovery. In some cell types, however, hyperosmotic activation of NKCC1 is not accompanied by RVI because of the absence of an inwardly directed net gradient of Na^+, K^+, and Cl^-. Activation of the Na^+, K^+, $2Cl^-$ cotransporter by isoosmotic cell shrinkage (e.g., due to a metabolic decrease of osmolytes in the cytoplasm) typically leads to effective RVI due to the preserved inwardly directed electrochemical gradient for the transported ions.

Volume-dependent activation of the Na^+/H^+ exchanger mediates accumulation of osmotically active Na^+ in exchange for osmotically inactive H^+ (because the latter does not exist in a free form but as a hydroxonium ion). Cytoplasmic acidification then stimulates the Cl^-/HCO_3^- exchanger, which is itself insensitive to cell volume changes. As a consequence of the cooperative work of these two transporters, cells accumulate Na^+ and Cl^- and extrude H^+ and HCO_3^-. Bicarbonate is converted to CO_2 and diffuses back to the cell, replenishing pools of H^+ and HCO_3^-. Six mammalian isoforms of the Na^+/H^+ exchanger (NHE-1 through -6) have been cloned. NHE-1 is highly and ubiquitously expressed in all tissues including the

CNS, where it contributes to cell volume regulation and cytosolic pH maintenance. Other isoforms are differentially distributed among various cell types. Interestingly, in striking contrast to all other Na^+/H^+ exchangers, the epithelial exchanger NHE-3 is inhibited by cell shrinkage.

Gene Transcription Changes in Response to Cell Volume Alterations

RVD and RVI reactions serve as emergency responses protecting cells against acute changes in volume. However, these regulatory processes cause severe disturbances in cellular ion composition, which need to be compensated for in order to return cells to their normal functioning capacities. This is typically achieved through long-term adjustments in intracellular levels of organic osmolytes resulting from the upregulation or downregulation of genes involved in osmolyte synthesis and/or osmolyte uptake. Key organic osmolytes involved in chronic adaptation to osmotic stress include *myo*-inositol, sorbitol, betaine, glycerophosphorylcholine, and taurine.

The osmotic regulation of gene expression in shrunken cells is a complex multistage process. It is initiated by volume-dependent activation of stress-related protein kinases of the mitogen-activated protein kinase (MAPK) family, which in turn triggers the expression of immediate response genes (c-*fos*, c-*jun*, CREB, Egr-1 in epithelial cells, and others). This is followed by changes in the expression of osmolyte transporters and the enzymes involved in osmolyte biosynthesis, which typically peak between 6 and 24 h after the onset of hyperosmolarity.

Osmolyte transporters upregulated by hypertonicity include the Na/*myo*-inositol transporter (SMIT), Na/Cl/betaine transporter (BGT-1), and taurine transporter. An increase in osmolyte biosynthesis is mediated by the upregulation of aldose reductase (converts glucose to impermeable osmolyte sorbitol), choline dehydrogenase (contributes to betaine production), and cysteine deoxygenase (one of the enzymes of taurine biosynthesis). Conversely, chronic hypoosmolarity downregulates expression of organic osmolyte transporters and enzymes involved in osmolyte biosynthesis, causing a long-lasting decrease in total cytoplasmic osmolyte content.

Volume-dependent regulation of gene expression has been studied in detail in renal tissue, but it also occurs in the brain.

The Cell Volume Sensor

Despite our advanced knowledge on volume-dependent ion transporters involved in RVD and RVI, the central question remains unresolved: how do cells sense changes in their volume? To explain the phenomenon of cell volume autoregulation, the concept of a volume sensor has been introduced. The volume sensor is a hypothetical molecule or intracellular structure which undergoes conformational transitions in swollen or shrunken cells. Such structural transition in volume sensor turns on signaling cascades coupled to the activation of ion transporters mediating RVD and RVI.

Cells adapted over a long time to hyperosmotic or hypoosmotic media return to their initial 'set point' volume and continue to respond to acute changes in osmolarity and cell volume. Therefore, cells seem to sense a signal or signals triggered by changes in cell volume rather than changes in cytoplasmic osmolarity.

The most commonly discussed candidates for the role of volume sensor/volume-sensing processes are mechanosensitive ion channels, the cortical cytoskeleton, and changes in intracellular concentration of ions (ionic strength) or macromolecules ('macromolecular crowding').

Mechanosensitive nonselective cation channels are directly activated in response to membrane stretching or compression and allow for membrane depolarization and Ca^{2+} influx. Elevation in intracellular $[Ca^{2+}]$ may then serve as a secondary volume signal in some but not all cell types. Two of the mammalian mechano-/volume-sensitive cation channels, swelling-activated TRPV4 (OTRPC4, VR-OAC, TRP-12) and shrinkage-activated splice variant of TRPV1, have been cloned. However, since mechanosensitive cation channels are not ubiquitously expressed, it seems unlikely that they play a universal role of cell volume regulation.

The cortical cytoskeleton supports the plasma membrane and protein compartmentalization within the plasma membrane. It is composed of spectrin heterodimers, actin bundles, and proteins involved in spectrin–actin interactions, and this network is anchored to integral proteins and acid phospholipids. Any changes in cell shape or volume are associated with reorganization of cortical cytoskeleton and trigger extensive changes in signaling molecules associated with this structure. In rat erythrocytes, disruption of the spectrin network completely abolishes volume-dependent regulation of the Na^+, K^+, Cl^-, and K^+, Cl^- cotransporters. In neural cells, various agents, which depolymerize actin filaments, modulate but do not abolish cell volume regulation. Thus, there is inconclusive evidence for the contribution of cortical cytoskeleton in cell volume regulation in neural cells.

Changes in the total activity of electrolytes (intracellular ionic strength) have also been proposed to play a key role in volume signal transduction. Several studies have demonstrated that a decrease in

cytoplasmic ionic strength serves as a signal for the indirect (via intracellular signaling) activation or modulation of volume-sensitive anion channels. In a mathematical model developed by Voets and collaborators, changes in ionic strength rather than cell volume accurately predict the time course of anion channel activation.

Variations in cell volume directly affect the concentrations of all cellular components. The total concentration of macromolecules in the cytoplasm is so high that it behaves as a nonideal solution that limits the diffusion of small and especially large molecules. The resulting nonideal interaction of macromolecules, known as macromolecular crowding, appears to crucially influence the activity of many enzymes. For example, high concentrations of macromolecules decrease the activity of lactate dehydrogenase and hyaluronate lyase but potently stimulate DNA polymerase I and DNA ligase. Thus, changes in macromolecular crowding may principally serve as a primary volume signal and activate intracellular signaling proteins. This hypothesis is supported by strong experimental evidence in erythrocytes, in which manipulating the concentration of cytoplasmic proteins and/or inert macromolecules altered the volume sensitivity of the K^+, Cl^- cotransporter and Na^+/H^+ exchanger. However, the role of macromolecular crowding in nonerythroid cells remains untested.

Mechanisms of Volume Signal Transduction

Although the precise nature of the volume sensor in unknown, it is well established that cell volume alterations activate a variety of intracellular signaling cascades. Extensive experimental evidence suggests that some of these cascades contribute to volume signal transduction, whereas activation of others seem to be epiphenomena resulting from cross-talk between intracellular signaling systems. Chemical transduction of the cell volume signal appears to be cell-type specific and varies depending on the type of volume-activated transporters.

In most animal cells studied, cell swelling leads to elevations in intracellular Ca^{2+} concentrations due to activation of membrane permeability pathways and/or release of Ca^{2+} from intracellular stores. Cell shrinkage is generally not associated with changes in intracellular Ca^{2+} concentrations. The omission of extracellular Ca^{2+} or buffering of intracellular Ca^{2+} with membrane-permeable Ca^{2+} chelators inhibit RVD in some but not all cell types. A detailed literature review by Pasantes-Morales and Morales-Mulia suggests that the high Ca^{2+} sensitivity of RVD is observed predominantly in epithelial cells and is mediated by Ca^{2+}-sensitive maxi-K^+ channels. In other cells, including neural cells, an increase in Ca^{2+} is not obligatory for swelling-induced activation of ion transporters.

In addition to intracellular Ca^{2+}, cell swelling may activate ion transport pathways via receptor and nonreceptor tyrosine kinases. Genetic deletion of the $p56^{LCK}$ kinase (a member of the *src* family of nonreceptor tyrosine kinases) blocks both anion channel activation and cell volume regulation in Jurkat cells. When injected, $p56^{LCK}$ stimulates anion channels in nonswollen cells. Broad-spectrum tyrosine kinase inhibitors and inhibitors of the MAPK cascade block activation of volume-dependent K^+ and anion channels in many cell types. In glial cells, tyrosine phosphorylation is thought to modulate volume sensitivity of ion channels rather than serve as a primary transducer of the volume signal.

Several other serine/threonine protein kinases and kinases of mixed specificity have also been implicated in cell volume transduction in a cell-type-specific manner. Kinases involved in volume regulation in swollen cells include protein kinase C (PKC), myosin light-chain kinase (MLCK), phosphatidylinositol 3-kinase (PI-3K), focal adhesion kinase $p125^{FAK}$, and a variety of kinases belonging to the cascade of MAPK, such as Jun-NH_2-terminal kinase (JNK), p38 PK, and extracellular signal-regulated kinases (ERK-1 and ERK-2).

Cell shrinkage-related signaling may involve Ca^{2+}/calmodulin-dependent kinase II (Ca/CM-PK); PKC; MLCK; tyrosine kinases Pyk2, Fgr, Syk, and Hck; and a number of the MAPK cascade members, including MKK4, MEK, JNK, p38 MAPK, ERK-1, ERK-2, and SAPK. Some of these protein kinases regulate the activity of ion transporters, whereas others likely contribute to shrinkage-induced regulation of gene expression.

Physiological and Pathological Significance of Cell Volume Regulation in the CNS

Under physiological conditions, swelling of cells is not observable in the CNS. However, in the empirical sciences, the absence of evidence is not evidence of absence because further work with different approaches or more sensitive measurements may reveal what had hitherto not been seen. It is clear that detection of small swelling of cells in brain tissue is technically very difficult. In addition, small changes in cell volume may be amplified by certain signaling events. Thus, ATP can markedly augment the release of amino acids from nonswollen or moderately swollen cultured astrocytes via a transport route that is robustly activated by much larger swelling under pathological conditions.

Figure 1 (a) Electron micrograph of a sham cat sensorimotor cortex. (b) Electron micrograph from the same region 20 min after an acceleration deceleration injury. Note the marked perivascular and neuropilar astrocytic swelling labeled A in figure. (c) A mechanism of swelling by Donnan forces due to raised $[K^+]_o$. This needs an open chloride channel, and it is proposed that the anion channel blockers indicated can block astrocytic swelling by blocking this channel. The swelling then opens volume-regulated anion channels (VRAC), which are permeable to excitatory amino acids (EAAs) and these are blocked by some of the anion channel blockers, as shown. L644,711, R(+) [(5,6 dichloro 9a-propyl 2,3,9,9a-tetrahydro 3-oxo-1*H* fluoren-7-yl)oxy] acetic acid; DCPIB, 4-[(2-butyl-6,7-dichloro-2-cyclopentyl-2,3-dihydro-1-oxo-1*H*-inden-5-yl)oxy] butanoic acid; SITS, 4-acetamido-4′-isothiocyanostilbene-2,2′-disulfonic acid; NPPB, 5-nitro-2-(3-phenylpropylpropylamino) benzoate; DIDS, 4,4′-diisothiocyanostilbene-2,2′-disulfonic acid.

Hussy and colleagues have shown that small changes in osmolarity can release taurine from specialized astroglial cells to regulate vasopressin release from neurons in the rat supraoptic nucleus by activating their glycine receptors.

Marked astrocytic swelling is seen in a number of pathological states, such as stroke, traumatic CNS injury, hepatic encephalopathy, and seizures. Such swelling, termed cellular edema, needs to be distinguished from total brain swelling, which primarily involves ECS swelling. However, both tissue swelling and cell swelling likely coexist and lead to life-threatening effects of raised intracranial pressure and shifts of brain tissue. Figure 1 shows the marked perivascular and neuropilar astrocytic swelling seen 20 min after experimental closed-head injury. Shown below the micrographs is one mechanism of swelling due to the documented rise of K^+ in the ECS which, with the opening of Cl^- channels, can lead to a Donnan-type swelling. Such marked swelling leads to activation of VRACs, which are permeable to excitatory amino acids, aspartate and glutamate. Thus, part of the excess glutamate and aspartate release in brain trauma and stroke, and generally accepted to be the initiating event for further damage, can come from swollen astrocytes. Also shown in Figure 1 are various compounds that can inhibit astrocytic swelling if given early enough and block volume-regulated anion channels. Some of these compounds (L644, 711 and tamoxifen) have been shown to be markedly effective in preventing death, disability, or brain infarct volume in animal models of ischemia and traumatic brain injury.

Reinforcement Models

The reinforcement learning algorithms proposed and developed by Andy Barto and Rich Sutton in the early 1980s have provided some of the most influential computational theories in neuroscience. The original theories were developed for explaining adaptive animal behaviors, but during the following decade they had a larger impact in the machine learning, computer science, and robotics communities than within the biological disciplines. In the mid-1990s, Wolfram Schultz produced epoch-making neurophysiological data on dopamine neuron activities, which led several theorists to propose computational learning models of basal ganglia and dopamine neurons based on reinforcement learning algorithms. This interaction between experiments and theories generated a steady and influential research trend, which has encompassed many previous and ongoing studies. Here, the temporal difference error plays the most important role in both experimental and theoretical studies of reinforcement learning. In brief, it is computed as the difference among the following three terms: the reward obtained at the current timing, the discounted expectation of the cumulative reward at the neighboring future timing, and the subtracted expectation of the cumulative reward at the current timing. In a class of reinforcement learning algorithms collectively called 'temporal difference learning,' the temporal difference (TD) error plays a central role in guiding acquisition of the predicted reward and behaviors. In the context of classical conditioning, the TD error is predicted to be positive at the time of the primary reward in early learning trials, but as learning progresses it is predicted to move at the time of a cue that indicates a future reward. If the expected reward from the cue is omitted, the TD error becomes negative at the time of the expected but nondelivered reward. Schultz and others confirmed all these predictions in studies of dopamine neuron activities. Because dopamine neurons innervate not only the basal ganglia but also a wide area of the cerebral cortex, learning in both regions might be able to be understood by reinforcement learning algorithms. Many experimental results supporting this hypothesis have been obtained from different levels (cell, circuit, brain, and behavior) utilizing different techniques (slice experiment, extracellular unit recording in behaving animals, lesion, and human imaging). It seems quite safe to state that at least some aspects of learning that are dependent on reward and penalty can be understood within the framework of reinforcement learning theory.

However, at least three difficult issues remain unresolved and should be studied from both theoretical and experimental standpoints. First, the plain reinforcement learning algorithm is too slow for practical problems to be considered as a realistic model of brain learning, which is not extremely slow. Second, although it is highly probable that dopamine neurons encode the TD error, the neural circuits and neural mechanisms needed to compute the TD error are still unknown. Third, although some functional aspects of the neural circuits consisting of dopamine neurons and the striatum of the basal ganglia might be understood by plain reinforcement learning algorithms, behavioral learning, which is dependent on global brain networks involving the cerebral cortex, cerebellum, basal ganglia, and midbrain, seems to necessitate much more complicated algorithms. This article discusses theoretical explorations for more efficient reinforcement learning algorithms and related experimental studies to resolve these difficulties.

Slow Learning of Plain Reinforcement Learning

The plain and basic reinforcement learning algorithm is attractive because it can learn new behaviors from only reward and penalty information without using explicit and quantitative models of controlled objects or environments. The trade-off is that the learning is extremely slow for any practical problem. Plain reinforcement learning algorithms can work reasonably well in a toy problem such as a discrete maze or in a game such as backgammon; however, even in such problems, tens of thousands of learning trials are often required, and millions of learning trials are not rare. Moreover, these algorithms fail badly for real-world problems such as those encountered in robotics, with continuous time and continuous state space. Performing even hundreds of learning trials is prohibitive for animal or robot learning. The slowness of the plain and basic reinforcement learning algorithm can be explained by either a spatial reason or a temporal reason. First, up-to-date humanoid robots often possess 50 degrees of freedom. Even if each degree of freedom is partitioned very roughly into five intervals, the total number of discrete regions necessary to cover the entire state space is $5^{(50\times 2)} = 5^{100} \approx 10^{70}$, which is astronomical since each degree of freedom necessitates position and velocity representations. Optimal (or suboptimal) solutions to the reinforcement learning problem are paths connecting some of these discrete regions;

these should be found by trial and error. Even if each region was examined with sub-millisecond duration, the solution would not be found within the life of the universe because of the enormous number of discrete regions. Human bodies possess at least 1000 degrees of freedom because the number of small muscles around the spine, important for posture control, is enormous. In the brain, neurons with population coding and overlapping tuning curves should replace the previously mentioned discrete partition of the state space, and 1000 degrees of freedom needs to be handled. Thus, a simple reinforcement learning algorithm cannot be expected to perform any faster than an artificial humanoid robot. Second, in most real-life examples of reinforcement learning, a reward is given to an animal only at the end of a long behavioral sequence. For example, meats can be eaten only at the end of a hunting tour lasting a few days, rice can be harvested only several months after seeds are sown, and entrance to university can be attained only after several years of hard study. The reward obtained at the terminal state of a sequence of behavioral decisions should be backtracked and temporal credit assignment to each decision should be computed. Some slow synaptic plasticity processes should propagate the representation of reward prediction at one time step to its preceding representations. Fully propagating the reward prediction from the terminal state to the initial state usually requires a very long time.

The three difficulties associated with plain reinforcement learning – slowness, computation mechanism for TD error, and incompatibility with brain structure – all necessitate specific structures, frameworks, and neural mechanisms in the brain for efficient learning algorithms, if the brain still adopts the essence of plain reinforcement learning algorithms. In computational and engineering studies aimed at finding efficient reinforcement learning algorithms, the following factors, at least, have been proposed and examined as accelerating mechanisms: hierarchy, modularity, blending with supervised learning, internal models, imitation learning, and preconditioning of search space. The first three factors are reviewed with several new models to resolve the difficulties.

Hierarchy and Modularity

If the number of regions to be explored for finding optimal solutions is astronomical, then solutions cannot be found within a reasonable amount of time, as stated previously. One possible solution to resolve this difficulty is to introduce a hierarchy in reinforcement learning algorithms. Consider a simple two-level hierarchy. In the upper hierarchy, the state space for the problem is very coarsely represented by a reasonable number of discrete regions, cells, or neurons. Because the number is not astronomically large, an optimal solution can be found in a reasonable amount of time at the upper hierarchy, but the representation of the solution is very approximate due to the coarse representation. In the lower hierarchy, the state space is finely represented by an enormous number of discrete regions, cells, or neurons. The approximate solution obtained at the upper level can constrain the possible range of the space in which the optimal solution at the fine level is explored. Thus, the reinforcement learning problem could be solved within a reasonable amount of time and with the required accuracy. The large-scale versus small-scale contrast between the higher and lower hierarchies applies not only to spatial representation but also to temporal representation. Multiple levels of hierarchy can also be introduced. However, the following theoretical issues arise from the introduction of a hierarchy. First, how to introduce coarse representations in the upper hierarchies is not at all trivial, especially if this process should be executed automatically. Second, some consistency should be maintained between different levels of the hierarchy regarding the state space representation, the trajectories and optimal solutions, the reward prediction, the reward prediction error, and the reward. These theoretical issues were studied in several proposals of hierarchical reinforcement learning algorithms (Composite Q, Feudal Q, HQ-learning, HAM, and Option). In most of these proposals, the researchers needed to specify coarse representations of the state space in the upper hierarchy. In some of them, reinforcement learning does not take place in either the upper or the lower hierarchy; that is, behaviors (policy) and reward expectation (value function) need to be prespecified by researchers. In many of the proposals, even local optimality of the obtained solutions is not theoretically guaranteed due to the lack of consistency between higher and lower hierarchies. Because of these limitations, most of the examples examined in previous proposals were discrete time and discrete space problems, such as navigation in a two-dimensional maze. The shortcomings of previous hierarchical reinforcement learning algorithms were quite serious obstacles to viewing the algorithms as possible computational theories of brain learning. In particular, the fact that researchers need to specify coarse representations in the upper hierarchy, or need to predetermine motor primitives or subgoals in the lower hierarchy, is nearly equivalent to assuming the existence of a homunculus or that those factors are all predetermined genetically, both of which are unacceptable from the viewpoint of neuroscience. One of the very rare exceptions among the continuous time and continuous state space examples was a hierarchical

reinforcement learning algorithm for standing up by a real multijoint robot.

One of the strategies common to the military, politics, and engineering is to deal with complicated and large-scale problems in a 'divide and conquer' manner. That is, to solve a difficult large-scale problem, it is first partitioned into several smaller and more tractable subproblems. Then, a responsible expert deals with each subproblem to obtain a partial solution. Finally, the obtained partial solutions are combined and a global solution to the original problem is obtained. For example, if a given problem is to move from a southern area of Kyoto prefecture in Japan to an Italian village in Sicily, taking an airport limousine to Kansai International airport is a subproblem and should be much more easily solved than the original problem. This modular approach is another promising strategy that has been explored in the context of reinforcement learning. Actually, most hierarchical reinforcement learning methods either explicitly or implicitly adopt the 'modular' approach. However, not all modular approaches are hierarchical. The most critical and difficult issue in modular reinforcement learning is how to divide or modularize the original problem into subproblems. Again, it is unsatisfactory from the viewpoint of neuroscience if researchers deal with this manually. Another difficult and important theoretical issue is to guarantee the global optimality of the entire problem since each expert deals mainly with a single subproblem and is essentially narrow-scoped. Several theoretical studies have addressed this global optimality issue.

Dividing the original problem based on space or time seems to be the most natural and efficient method for a modular approach. In a discrete state and discrete time example, such as a maze, this approach is frequently used because the division point is often very obvious, such as doors segregating different rooms and/or corridors, and the time division could follow the space division. However, note that the division of even discrete examples is still executed by researchers. Continuous state and continuous time examples, with which brains must deal, are much more complicated to modularize. In the continuous case, there is no apparent division point in either space or time. Furthermore, for neurons in the brain, which are involved in reinforcement learning of some problem, the coordinate system appropriate for the problem and its subdivisions is not explicitly provided. Each neuron receives sensory, motor, and reward information related to the problem, but there is no global picture of the whole problem and the coordinate system available to each neuron. Even in this difficult situation, modularity should spontaneously emerge via self-organization within neural networks.

One promising approach for self-organization of modularity is a modular selection and identification control (MOSAIC) model. MOSAIC was originally proposed for supervised learning in sensorimotor integration. Doya and colleagues extended MOSAIC to reinforcement learning, and further developments have been made. In the most advanced form of reinforcement MOSAIC, three different sets of expert networks self-organize through reinforcement learning (**Figure 1**). One set of experts includes predictors of state transitions. These can formally be called internal forward models. An internal forward model receives the current state and the current motor command and predicts the next time step state. In interpretations of neuroscience, forward models receive sensory feedback and an efference copy of motor commands and then predict the sensory feedback from the next time step. In MOSAIC, many forward models compete and cooperate to predict the state change based on the goodness of prediction of each forward model. That is, many forward models are different from each other; thus, they make different predictions despite receiving identical sensory feedback and motor command. Their predictions are compared with the actual sensory feedback at the next time point, and a responsibility signal for each forward model is computed. The responsibility signal for a forward model is larger when its prediction is better. The entire prediction by MOSAIC is the linear weighted sum of predictions made by its forward models, which are weighted by their responsibility signals. Two other sets of experts are for approximators of actual rewards and reinforcement learning controllers. The responsibility signals and linear weighted summation are computed similarly for these two sets of experts; however, the prediction error for the approximators of rewards involves errors in reward approximation, whereas that for the controllers involves reward prediction errors such as the TD error. The responsibility signal also gates the learning of forward models, reward approximators, and controllers by regulating learning rate by its amplitude. That is, if the responsibility signal of one expert is large, then the expert learns more. On the other hand, if its responsibility signal is small and close to zero, the expert learns little. Within this framework, three sets of experts self-organize while guided by three different kinds of error signal: prediction error in dynamics, approximation error in rewards, and reward prediction error. Consequently, modularity self-emerges without ad hoc manual tuning by researchers.

If the original reinforcement learning problem is rather simple, with a simple linear dynamics and a simple reward function shape, then MOSAIC will utilize only one forward model and only one reward

Figure 1 Overall organization of the combinatorial module-based reinforcement learning (CMRL) architecture. The architecture consists of forward modules (top left), reward modules (bottom left), and reinforcement learning (RL) controllers (right). The forward modules receive the state and action, and they segregate the environmental dynamics into several subdynamics based on the prediction error of the dynamics. Each reward module represents the local reward function, conditioned on the state variable (position and velocity) and the error of approximated reward. Then, an RL controller approximates the local value function for each configuration of a forward module and a reward module and outputs the local action. Finally, the local actions are weighted based on the squared TD errors of each RL controller. In real-world control problems, reinforcement learning has to handle nonstationary environments, in which both the dynamics of control and how the consequence of the control is rewarded change over time. One of promising strategies to deal with nonstationary environments is to decompose a complex task into several subtasks and adapt multiple RL modules for each of these subtasks. A basic assumption of this modular architecture is that the environment can be approximated as stationary within a single subtask. Previous studies of modular architecture for control attempted to separate a complex task based on the prediction error of the environmental dynamics and reported fairly good results for nonstationary dynamics. However, none of these studies addressed the dual nonstationary problem consisting of the dynamics and reward. To make RL applicable to such situations, the CMRL decomposes a complex task based on both the prediction error of the environmental dynamics and the approximation error of the reward function. First, the forward module (f_i) predicts the environmental dynamics ($\dot{x}$) from the current state and action (x, u). Second, the reward module (r_j) represents the local reward function conditioned on the state. The RL module, receiving outputs from forward and reward modules, approximates local value functions (V_k) and outputs the local greedy action (u_k). Finally, the CMRL selects actions by the sum of these local actions weighted by the responsibility signal of each RL module ($\lambda^c{}_k$), a posterior probability obtained from the squared TD errors ($\delta^2{}_k$) of each RL module (likelihood) and the usage history of component forward and reward modules (priors). These priors can be recomputed as the responsibility signals of forward and reward modules ($\lambda^f{}_i$ and $\lambda^r{}_j$) by applying Bayes rules to the prediction error of the environmental dynamics and reward approximation error, respectively. The CMRL can successfully cope with nonstationary problems such as the swinging of a pendulum, in multiple dynamics and reward conditions, and the bipedal locomotion of robots.

approximator. Accordingly, only one controller suffices to compute the necessary control commands. By contrast, if the dynamics of the original problem are highly nonlinear and consist of several qualitatively different dynamics, a set of forward models is recruited to approximate different segments of the original dynamics. If the dynamics are different, the necessary controllers are also different, even for the same reward function. Thus, a set of reinforcement learning controllers is recruited with corresponding forward models. In this nonlinear case, modular architecture dealing with nonlinear dynamics self-organizes. If the objective of the entire task changes from time to time, such as earning money and then spending it on a fan, then different reward approximators are recruited for different times, and different controllers are also needed. In this nonstationary case, modular architecture dealing with different task goals self-organizes. Thus, if the original problem contains nonlinearity and/or nonstationarity, MOSAIC automatically recruits its modular architecture to cope with the situation and self-organizes a set of controllers. A reinforcement MOSAIC model has also been extended to a hierarchical model.

Hierarchy and modularity are generally conceived as a common design principle for many different areas of the brain, based on an enormous number of previous anatomical and neurophysiological studies,

but direct support of their significance in the context of reinforcement learning mainly comes from neuroimaging studies on humans. For example, Haruno and colleagues found that the activities of many brain areas, such as the prefrontal cortex, orbitofrontal cortex, premotor cortex, supplementary motor area, cerebellum, and basal ganglia, are correlated with important variables in reinforcement learning, such as accumulated reward, learned behavior, short-term reward, and behavioral learning, even in a very simple Markov decision process with monetary reward. Furthermore, whereas the putamen is correlated with the reward prediction by action representation, which is consistent with a monkey study by Samejima and colleagues, the caudate is more correlated with the reward prediction error. Tanaka and colleagues found topographic representations of reward prediction in the medial prefrontal cortex and the insular cortex, and they found topographic representations of reward prediction error in the basal ganglia, with different values of discount factor, which is a very important parameter balancing future and immediate rewards in reinforcement learning algorithms.

How Can TD Error be Computed?

TD error plays the most critical role in solving the temporal credit assignment problem in reinforcement learning theory. Thus, Houk et al. proposed an explicit neural circuit model for computing the TD error, as shown in Figure 2(b), when they first proposed the reinforcement learning model of the basal ganglia and dopamine neurons shown in Figure 2(a). Doya then proposed the modified model shown in Figure 2(c). In both models, the primary reward information, $r(t)$, is assumed to be carried to the substantia nigra compacta (SNc) dopamine neurons by direct excitatory inputs. By contrast, the reward expectation of the next time step, $V(t+1)$, minus the reward expectation at the current time step, $-V(t)$, is assumed to be computed within the basal ganglia network utilizing double-inhibitory and inhibitory connections, respectively, from the common source of the value function $V(t)$ representation in the striatum. These models are attractive from a theoretical standpoint because the same value function $V(t)$ is the common source for positive and negative terms in the TD error, thus satisfying the most basic assumption of reinforcement learning algorithms: consistency of Bellman equation is the source of the error signal that drives learning. Moreover, these models utilize the known neural network within the basal ganglia. However, no direct physiological evidence has been obtained to support these models. Furthermore, double inhibition may not be able to explain the burst firing of dopamine neurons in response to a cue signal predicting a future reward, as in Schultz's experiment, due to the membrane properties of dopamine neurons.

Previous anatomical studies have shown that major excitatory synaptic inputs to SNc originate from the pedunculopontine tegmental nucleus (PPN), as shown in Figure 3(a). Neurophysiological studies by Kobayashi and colleagues further suggest that excitatory inputs from the PPN to the SNc might play the most central role in computing TD error. In their experiments, monkeys performed saccade tasks with variable reward amounts, which were indicated by the shape of a fixation spot. Two populations of neurons whose firing rates varied with reward amount were observed. One population of neurons seemed to encode the primary or current reward $r(t)$, whereas the other population of neurons started to fire upon the presentation of the fixation spot and maintained their firing until the end of saccade or the delivery of the primary reward, even after the fixation spot was extinguished. In addition, the firing rates predicted the amount of the future reward, thus seeming to encode the predicted reward or the value function $V(t)$. These remarkable findings directly suggest two possible neural mechanisms for computing the TD error, as shown in Figures 3(b) and 3(c). In Figure 3(b), some intranuclear circuits within the PPN or SNc, or some membrane properties of dopamine neurons in SNc, execute either temporal difference or temporal differentiation (in the case of Doya's continuous time reinforcement learning) as shown by the box in Figure 3(b). In this case, the PPN provides all of the components necessary for computing the TD error. By contrast, the model shown in Figure 3(c) predicts that the primary reward information $r(t)$ and the expected reward at the next time step $V(t+1)$ are carried by excitatory inputs from the PPN to the SNc, whereas the inhibitory input from the striatum conveys the subtracted and predicted reward information at the current time-$V(t)$. The model shown in Figure 3(c) seems more plausible because (1) no cellular or circuit mechanisms for temporal difference or differentiation are known that involve the PPN or SNc and (2) the inhibitory inputs from the striatum to the SNc are well established and it would be quite odd if they did not contribute to computing the TD error.

Heterarchical Reinforcement Learning Model

The fact that $V(t)$ and $V(t+1)$ arise from different sources (Str and PPN) in the model of Figure 3(c) casts doubt on its fidelity to reinforcement learning theory: consistency of the Bellman equation. By contrast, in the models shown in Figures 2(b), 2(c), and 3(b),

Figure 2 (a) Reinforcement learning model of the basal ganglia The modular organization of the basal ganglia, including both striosomal and matrix modules, is shown. (b, c) Houk versus Doya models of TD error computations. Possible mechanisms for TD computation of the value function represented in the basal ganglia are shown. Open circles ○ represent excitatory connections, whereas black dots • represent inhibitory connections. The large red circle represents the source of possible time delay. SNr, substantia nigra pars reticulata; GPi and GPe, internal and external segments of the globus pallidus, respectively; VP, ventral pallidum. (a) From Houk JC, Adams JL, and Barto AG (1995) A model of how the basal ganglia generates and uses neural signals that predict reinforcement. In: Houk JC, Davis JL, and Beiser DG (eds.) *Models of Information Processing in the Basal Ganglia*, pp. 249–270. Cambridge, MA: MIT Press.

the TD error is computed from the same source of the value function; thus, they conform to the most basic principle of temporal difference learning. However, deviation from this principle may lend efficiency and power to the model in Figure 3(c). If subtraction can be computed in the SNc between PPN and striatal inputs, we can introduce a supervised learning aspect into reinforcement learning. That is, the learner $V(t)$ tries to approximate the teaching signal $r(t) + V(t+1)$ and the error signal is conveyed by dopamine neurons. Indeed, many robotics applications of reinforcement learning algorithms have been forced to incorporate

Figure 3 (a) Connections of the pedunculopontine tegmental nucleus (PPN) with the basal ganglia and cortex. (i) The PPN sends projections to the thalamic cells that project to the striatum; (ii) there are reciprocal connections between the PPN and the basal ganglia output nuclei (substantia nigra pars reticulata (SNr) and internal segment of the globus pallidus (GPi)), with the latter nuclei providing a dense inhibitory projection to the PPN; (iii) a substantial projection from the PPN innervates dopaminergic neurons of the substantia nigra pars compacta (SNc), which in turn modulate striatonigral and striatopallidal pathways; and (iv) a reciprocal, putative excitatory loop is formed between the PPN and the subthalamic nucleus neuron (ST). These complex interconnections imply that the PPN has a profound and widespread influence on basal ganglia activity and, similarly, that the basal ganglia are in a position to modulate PPN activity at many different levels. (b, c) Two possible neural circuit models for computing the TD error with an emphasis on excitatory inputs from the PPN to the SNc. Str, striatum. aspects of supervised learning to attain allowable learning time. The model shown in Figure 3(c) might represent a bridge between neuroscience and these efforts in robotics; furthermore, this model led to the proposal of the 'heterarchical' reinforcement learning model shown in Figure 4. In this figure, there exist two independent closed loops: the prefrontal cortex–caudate–ventral tegmental area–PPN cognitive loop

Figure 4 A basic heterarchical reinforcement learning model consisting of caudate–prefrontal and motor–putamen loops, the ventral tegmental area (VTA), the substantia nigra pars compacta (SNc), and the pedunculopontine tegmental nucleus (PPN). Open and solid circles show excitatory (disinhibitory) and inhibitory projections, respectively. V_C, a coarse value function in the caudate nucleus; V_P, a fine value function in the putamen; r, a reward; γ, a discount factor for future rewards; ε, a time-varying weighting factor between V_C and V_P.

and the motor cortex–putamen–SNc–PPN sensorimotor loop. If these two closed loops are entirely independent, then they can provide neural mechanisms for computing the TD error in a strictly reinforcement learning manner. However, the heterarchical structure shown in Figure 4 allows the cognitive loop value function to spread to the sensorimotor loop via neural connections from the caudate to the ventrolateral part of SNc, as well as through connections from the prefrontal cortex to the part of PPN innervating the ventrolateral part of SNc. This heterarchical model captures some aspects of the hierarchical reinforcement learning models introduced previously, but it does not have a strict hierarchy; thus, the name heterarchy was adopted. Representations of the state and actions in the cognitive loop are much coarser than those in the sensorimotor loop, so reinforcement learning progresses much faster in the cognitive loop than in the sensorimotor loop, just as with the higher and lower levels of hierarchical reinforcement learning algorithms. Then, the value function $V_C(t+1)$, which was learned earlier within the cognitive loop, plays the role of a teaching signal for the sensorimotor loop. That is, the sensorimotor (putamen) loop value function $V_P(t)$ is trained to approximate $V_C(t+1)$ during the early stages of learning. However, a much more fine-grained value function will be ultimately learned using the proper reinforcement learning implemented by the sensorimotor loop. Thus, fast but accurate learning is expected in the heterarchical reinforcement learning model, and no distinct boundaries should be manually set by researchers or homunculus. For simplicity, we explained the model using only two distinct closed loops, but a full model is rather continuous and realistic. This model was motivated by the neurophysiological studies of Kobayashi and colleagues and also by the anatomical studies of Haber on the spiral connections of corticostriatal and striatonigral loops. Kobayashi and colleagues characterized PPN neural firings as encoding intrinsic motivation or internal rewards. Because the PPN also receives inputs from brain stem nuclei, some portion of the future expected reward $V(t+1)$ could be represented based on quite coarse and endogenous factors, almost excluding sensorimotor or cognitive inputs. The coarse $V(t+1)$ could still be very helpful for developing more fine-tuned value functions based on sensorimotor and cognitive inputs, in a way similar to the technique known

as value function shaping in computational studies, and it could be a clue to understand the computational advantages of intrinsic motivation.

Wavelength and Color

Intuition tells us that color is a property of objects in the physical world, but in fact, color exists only in our internal, perceptual worlds. The physical world contains lights, which are composed of many wavelengths, and it contains surfaces, which reflect and absorb these lights to varying degrees. The wavelength composition, or spectrum, of light entering our eyes thus contains information about light sources and surface reflectances, and our visual systems analyze this information so that we can interact productively with our environment. Color is the quality of visual perception associated with this analysis.

The spectrum of a light is closely related to its color. A bright light with a flat spectrum looks white and the absence of light looks black. Colored lights have nonflat spectra: Long-wavelength lights tend to look reddish and short-wavelength lights tend to look bluish (Figure 1).

If we take a light with a fixed spectrum and double its intensity (doubling the photon flux at every wavelength) it looks brighter, but its color changes little, if at all. In this case, we say that we have doubled the luminance of the light but kept its chromaticity constant. Changing chromaticity without changing luminance is a more complex operation because luminance depends on both the spectrum of the light and the spectral sensitivity of the human visual system. By convention, two lights have the same luminance if they appear equally bright to the average human observer when they are shown in rapid alternation.

It is tempting to ignore luminance when considering the neural basis of color vision. This would be a mistake because the processing of luminance and chromaticity are tightly linked in the early visual system, as evidenced by the first stage of visual processing, the photoreceptors.

Cone Photoreceptors

In daylight, vision begins with the absorption of photons by three classes of cone photoreceptor at the back of the retina. This section describes how light is encoded by the cones and how cone signals are combined into the channels that provide the basis of color vision.

Light Coding in Cone Photoreceptors

The probability that a photoreceptor of a given class absorbs a photon depends on the wavelength of the photon. The three classes of cone photoreceptor are named after the wavelengths to which they are maximally sensitive: Long-wavelength cones, or L-cones, are maximally sensitive to long-wavelength photons (560 nm); M-cones are maximally sensitive to medium-wavelength photons (530 nm); and S-cones are maximally sensitive to short-wavelength photons (420 nm) (Figure 2).

There exists an infinite array of physically different lights that stimulate the cones identically. Pairs of such lights are called metamers and are visually indistinguishable. Metamers are the foundation of many common visual displays. For example, the lights generated by a color television have spectra that differ profoundly from those in the natural world, but because television-produced and natural lights can affect the cones in the same way, they give rise to indistinguishable color percepts. Lights that look reddish tend to excite L-cones well, and lights that look blueish tend to excite S-cones well. It is thus tempting to think of each cone class as leading directly to a corresponding color percept (e.g., L-cone excitation = red). It is easy to see that this is incorrect. A flat spectrum light, which looks white, excites L-cones moderately well. Doubling the intensity of this light doubles the excitation of the L-cones, and yet the light continues to appear white, not reddish. Our perception of redness is thus not strictly a function of L-cone excitation alone.

To a first approximation, changing the intensity of a light affects all three cone classes identically; increasing light intensity increases the number of photons caught by each cone. Changes in light intensity thus preserve the relative levels of excitation across cone classes and, as mentioned previously, the color of the light. These observations suggest that color perception depends on a comparison of excitation across the cone classes.

Cone Opponency: Theory

Comparing excitation across cone classes makes good sense from a computational perspective. L- and M-cones have broad and overlapping spectral sensitivities, so most lights excite them to similar degrees. The visual system emphasizes the small differences that exist between the L- and M-cone signals, however, by subtracting them. This subtraction facilitates

Figure 1 Spectra of a bright red sunset, a dim red sunset, a blue sky, and a light with equal energy at all wavelengths (equal energy white). Figure 2 Spectral absorption functions of the three cone photoreceptors.

the discrimination of very small differences in wavelength around ~550 nm, where the L- and M-cone absorption spectra overlap.

Cone difference signals carry important information about the world around us. For example, the nutritional value of a leaf is better indicated by the difference in L- and M-cone signals than by either one alone (this fact has been suggested as a significant pressure in the evolution of opponency between L- and M-cone signals in Old World primates). This signal, however, is quite small with respect to the absolute levels of L- and M-cone excitation, which depend on ancillary factors such as whether the leaf is in direct sunlight or shadow. The differential signal is immune to the absolute levels of cone excitation and is therefore useful for finding nutritious leaves irrespective of the illumination.

Cone Opponency: Implementation

The biological substrate for the comparison of cone signals is a group of cone-opponent retinal neurons, which are excited by some cones and inhibited by others. Midget bipolar cells receive antagonistic input from L- and M-cones so their output reflects the difference between L- and M-cone excitation. Small bistratified ganglion cells are excited by S-cones and inhibited by a combination of L- and M-cones.

Cone-opponent signals in the retina are transmitted along the optic nerve to the lateral geniculate nucleus of the thalamus (LGN), where they are preserved faithfully. Neurons in the LGN are arranged in layers, each of which receives input from a different population of retinal ganglion cells. In an individual layer, neuronal cell bodies have a characteristic size after which they are named. Parvocellular neurons ('parvo' meaning 'small') receive input from the midget pathway and are thus described as having 'L versus M' or 'L – M' tuning. At least some koniocellular neurons ('konio' meaning 'dustlike') receive input from small bistratified ganglion cells and are thus described as having 'S – (L + M)' tuning. A third population of cells, the magnocellular neurons ('magno' meaning 'large'), is not cone opponent. These cells are excited by both L- and M-cones and are thus described as having 'L + M' tuning.

Magnocellular neurons have been proposed to be responsible for our sensation of luminance, and parvocellular and koniocellular neurons have been proposed to be responsible for our sensation of chromaticity. This model is supported by three observations. First, magnocellular neurons respond more vigorously to changes in luminance than do either parvocellular or koniocellular neurons. Second,

luminance flicker can be detected at much higher frequencies than chromatic flicker, and magnocellular neurons are particularly sensitive to high-frequency flicker. Third, at least two cone-opponent channels are required to account for human color perception, and neurons with L − M and S − (L + M) tuning are attractive candidates for these channels.

The truth appears to be more complex, however. Neurons in all three categories respond to changes in chromaticity as well as to changes in luminance, albeit to different degrees. Furthermore, the spatial resolution of these cell types conflicts with predictions from human psychophysics. Human observers can easily see fine spatial patterns defined by luminance modulations but have difficulty seeing similarly fine chromatically defined spatial patterns. One might thus expect that neurons with L + M tuning would have small receptive fields, implying high spatial resolution, and neurons with L − M tuning would have large receptive fields, implying low spatial resolution. The truth is exactly the opposite: Magnocellular (L + M) neurons have larger receptive fields than parvocellular (L − M) neurons.

This apparent paradox is elegantly resolved by the receptive field organization of a subclass of parvocellular neuron. Parvocellular type I neurons are excited by one cone class in the receptive field center and suppressed by another cone class in the receptive field surround. Type II neurons, in contrast, are excited by one cone class and suppressed by another cone class throughout the receptive field. A type I neuron with an L-cone-dominated excitatory center and an M-cone-dominated inhibitory surround responds well to a change in light that increases L-cone excitation and decreases M-cone excitation, and this is true throughout the receptive field. The same neuron, however, responds differently to lights that modulate L- and M-cone excitations together. Such a light drives the cell poorly if it covers the entire receptive field because center and surround contributions cancel, but a small L + M spot restricted to the center drives the cell quite well. Type I neurons thus carry information about chromaticity at coarse spatial scales and luminance at fine spatial scales, illustrating again the close relationship between luminance and chromatic processing in the early visual system (Figure 3).

Figure 3 Schematic receptive field structure of a type I parvocellular LGN neuron (top). L − M modulations excite the cell throughout the receptive field (middle), whereas L + M modulations are excitatory in the center and suppressive in the surround (bottom). A relatively small M-component to the receptive field center has been omitted from the figure for clarity.

Cone Opponency: Relationship to Opponent Colors

Although wavelength is naturally represented on a line, our perception of hue wraps around on itself, creating the familiar color circle. Red and green appear at opposite sides of the color circle because they are mutually exclusive hues: A single light never appears at once reddish and greenish. The same can be said of blue and yellow. On the other hand, bluish-reds (purple), yellowish-reds (orange), bluish-greens (turquoise), and yellowish-greens (lime) are easily seen.

In 1878, the German physiologist Ewald Hering hypothesized that the perception of any color derives from a combination of four elemental sensations: red, green, blue, and yellow. According to Hering's model, these sensations are the result of two independent physiological processes: a red–green process and a blue–yellow process. The red–green process cannot be in the red and green states simultaneously, and the blue–yellow process cannot be in the blue and yellow states simultaneously, which accounts for the mutual exclusivity of opposite hues. Hering's idea, that color vision is founded on four primary sensations, was thought originally to be incompatible with the view championed by Hermann von Helmholtz

and Thomas Young that color vision was based on three sensors in the eye. Today, the ideas can be reconciled: The three sensors of Helmholtz and Young correspond to the cones, and the two opponent processes of Hering correspond (roughly) to the cone-opponent neurons in the retina and LGN.

Cone-opponent neurons in the LGN behave similarly to the opponent process channels predicted by Hering. L- and M-cone signals cannot be dominant simultaneously in $L-M$ neurons just as the red–green process cannot be in the red and green states simultaneously. Likewise, S- and $(L+M)$ cone signals cannot be dominant simultaneously in $S-(L+M)$ neurons just as the blue–yellow process cannot be in the blue and yellow states simultaneously. Because of these relationships, $L-M$ neurons are sometimes referred to as 'red–green cells' and $S-(L+M)$ neurons are sometimes referred to as 'blue-yellow cells.' It is important to note, however, that LGN neurons differ in important ways from the processes predicted by Hering. LGN cells are not tuned to the unique hues, which are the particular shades of red, green, blue, and yellow that human observers agree are pure and uncontaminated by other hues. Thus, a change in the blueness of a light affects activity in both the $S-(L+M)$ and $L-M$ pathways. Together, these observations suggest that cone opponency at the level of the retina and LGN is important for the mutual exclusivity of complementary hues, but additional processing of color signals in the cortex may also play an important role.

Color Processing in the Cortex

Color processing in the cerebral cortex is an active area of research. This section describes some of the better understood aspects of cortical color processing.

Signal Mixing in V1

The three major cell types in the LGN project to distinct layers of the primary visual cortex (area V1, which is also called striate cortex). Magnocellular neurons project primarily to layer 4Cα, parvocellular neurons project primarily to layer 4Cβ, and koniocellular neurons project primarily to layers 2/3. Lower layer 3 receives information about increases in S-cone excitation, and upper layer 4A receives information about decreases in S-cone excitation. Whether these signals have a koniocellular or parvocellular origin is unclear.

The segregation of LGN inputs to V1 is not maintained long because intracortical connections within V1 mix signals across pathways. The nature of this mixing is beyond the scope of this article, but it is worth noting that some of the underlying intracortical circuitry is highly stereotyped and some of this signal mixing is likely important for color vision.

In principle, the mixing of LGN signals in V1 could account for the differences between the color tuning of LGN cells and perceptually opponent unique hues. For example, by mixing $L-M$ and $S-(L+M)$ signals in the appropriate proportions, the brain could create discrete classes of V1 neurons whose activity mimics the human perception of redness, greenness, blueness, and yellowness. Again, however, the truth appears to be more complicated: The distribution of preferred colors in V1 appears to be more or less random, implying indiscriminate mixing of LGN signals.

The apparent randomness of preferred colors in V1 may be a manifestation of the complexity of processing that occurs here. Neurophysiologists make simplifying assumptions about the computations that neurons perform because the full range of possibilities cannot be tested during an experiment of realistic duration. One common assumption is that V1 neurons add and subtract LGN inputs but do not perform more complex operations. LGN neurons, in turn, can be modeled as adding and subtracting cone signals, so this assumption is formally equivalent to asserting that V1 neurons add and subtract cone signals. In this case, the color tuning of a V1 neuron can be described by a set of weights with which it combines cone signals. Cone weights estimated from the activity of V1 neurons are nearly random, consistent with actual random color tuning or, alternatively, with complex, orderly color tuning that is not yet understood.

Color Processing in V1

Several important specializations for color processing have been discovered in V1. First, V1 is the earliest stage of the primate visual system to contain cells that are excited by some wavelengths and inhibited by others in the center of their receptive fields and have the reverse spectral sensitivity in the surround. These cells are called double opponent because they exhibit both wavelength and spatial opponency. The receptive fields of some double-opponent cells are nearly circularly symmetric, rendering them sensitive to spatial color contrast irrespective of orientation. Other double-opponent cells have receptive fields with elongated, side-by-side subunits, rendering them sensitive to edges of a particular orientation and chromaticity. Many double-opponent cells respond to both color and luminance modulations, again illustrating the close relationship between color and luminance processing in the early visual system (Figure 4).

A second specialization for color processing in V1 derives from the location of the cone-opponent neurons. Layers 2/3 of V1 contain small, regularly spaced

Figure 4 Schematic receptive field structure of double-opponent cells.

regions that stain darkly for the enzyme cytochrome oxidase (these regions are called cytochrome oxidase blobs). Many neurons in the blobs are cone opponent and many receive a strong koniocellular input. Koniocellular input is consistent with a role in color processing because S-cone signals, at least some of which are carried by the koniocellular pathway, play a greater role in chromatic vision than they do in luminance vision. Many neurons in the blobs project to a subcompartment of area V2, which is the next stage of cortical visual processing.

Color Processing in V2

Area V2 can be divided into three subcompartments, which are named the thick, thin, and pale stripes after their appearance when stained for cytochrome oxidase. Neurons in the thin stripes receive input preferentially from V1 neurons in the cytochrome oxidase blobs, suggestive of a role in color vision.

Our understanding of color processing in V2 is less developed than our understanding of color processing in V1. Nevertheless, a comparison between these areas reveals two interesting distinctions. First, color processing in V2 is even less linear than in V1; many V2 neurons respond to an extremely narrow range of colors that is inconsistent with a weighted sum of cone signals. Second, strongly color-responsive V2 neurons are spatially arranged according to their color tuning. For example, V2 neurons that are excited by purple are physically close to those that are excited by blue and others that are excited by red. This physical arrangement of neurons thus reflects our perception of hue similarity.

Color Processing in V4

Neurons in the thin stripes of V2 project to area V4, which was once considered a color center in the monkey brain. Early studies reported an unusually high proportion of color-tuned neurons in V4, but recent studies have reported unexceptional proportions. Lesions of V4 impair a variety of visual functions including, but not restricted to, color perception. V4 is thus unlikely to be specialized for color processing exclusively. On the other hand, some V4 neurons compensate for the spectrum of illumination in a manner similar to human color perception (human observers compensate effortlessly for surprisingly large changes in illumination, as described later). V4 is unlikely to be single-handedly responsible for this important feature of color perception but may contribute to it.

Color Constancy

Two factors largely determine the cone excitations produced by illuminated objects. Consider an apple; the first factor is the reflectance of the skin of the apple. Red Delicious and Granny Smith apples reflect different wavelengths of light with different efficiencies. Red Delicious apples reflect long-wavelength light better than do Granny Smith apples, making Red Delicious apples appear red and Granny Smith apples appear green under normal illumination.

The second factor affecting cone excitation is the spectrum of the illumination. Incandescent bulbs produce more long-wavelength light than do fluorescent bulbs. Thus, apples of both varieties reflect more long-wavelength light when lit by an incandescent bulb than when lit by a fluorescent bulb. Nevertheless, Red Delicious apples continue to look red and Granny Smith apples continue to look green under either illuminant. This consistency of color perception, which is called color constancy, implies a mechanism in the visual system that discounts the spectrum of the illumination.

Color constancy is likely a consequence of several physiological processes. Cone responses adapt over time, and this adaptation can partially account for color constancy. Some V1 neurons have been shown to exhibit a degree of color constancy which may be a consequence of double-opponent receptive field organization. Cognitive factors, such as an observer's knowledge of the physical layout of a visual scene, also play a role in color constancy. Elucidating the neural mechanisms underlying color constancy remains an important goal.

Color Processing in MT

The middle temporal area (area MT) of primate cerebral cortex is specialized for the analysis of visual motion. Neurons in this area respond well to moving luminance patterns but poorly to moving patterns defined solely by chromatic contrast. Perhaps as a consequence of this fact, moving luminance patterns are more easily seen than moving chromatic patterns.

The chromatic sensitivity of MT neurons may derive from at least three sources. First, a heterogeneous population of magnocellular neurons provides the dominant input to MT. On average, magnocellular neurons integrate L- and M-cone signals with roughly equal weight, but individual magnocellular neurons weight L- and M-cone inputs unequally. As a result, stimuli that modulate L- and M-cones with equal strength and opposite sign minimize the magnocellular population response while still driving some individual magnocellular neurons reasonably well. Second, many individual magnocellular neurons respond well to chromatic edges without regard to the colors on either side of the edge. The signals transmitted by these neurons are thus sufficient to mediate the computation of motion direction of a chromatic edge, but they are not sufficient to identify the colors on either side of the edge. Third, MT neurons receive modest inputs from koniocellular and parvocellular pathways which may provide overtly cone-opponent signals.

Color signals in different parts of the brain are probably used to perform different tasks. Color signals in MT are likely used to determine the locations of object boundaries for the analysis of visual motion but are unlikely to be important for the identification of surface properties. This task is likely performed by neurons in the ventral temporal lobe.

Color Processing beyond V4/MT

Human patients with damage to a small region of the ventral temporal lobe suffer from a disorder called acquired cerebral achromatopsia. These patients report that the colors they see in their day-to-day lives are washed out. In the laboratory, they perform poorly on tasks that require color naming or arranging stimuli according to their colors.

The part of the brain damaged in acquired cerebral achromatopsia was originally thought to be the human homolog of monkey area V4 but is now believed to be several centimeters more anterior. Currently called VO or V8, this area is strongly modulated by colored stimuli in functional imaging experiments, further suggesting its participation in color vision.

Determining whether a VO (V8) homologue exists in the monkey brain is an important direction for future research. Anatomical considerations suggest that such an area may exist in the inferior temporal cortex. Some neurons in this part of the brain respond to single hues. Others respond to multiple perceptually dissimilar hues. Some respond to highly saturated colored stimuli – in some cases irrespective of hue. Lesions of this area create a syndrome in monkeys that is similar to cerebral achromatopsia in humans. The weight of the current evidence thus suggests that a cortical area in monkeys and humans anterior to V4 is specialized for the analysis of color, but we do not yet know what processing occurs here, how this processing is implemented, and what functions it serves.

Conclusion

Color processing in the early visual system has been reasonably well described, but many fundamental questions remain: How are LGN signals combined in the cortex and what are the functional consequences of these combinations? How is color constancy achieved? What is the physiological basis for the unique hues?

The difficulty in understanding how the brain processes color information arises in part from the fact that color and other aspects of visual processing are closely related. As discussed in this article, the processing of chromaticity and luminance is tightly linked in the early visual system. Modulations of chromaticity and luminance often derive from different physical sources, and they give rise to different perceptual experiences. Nevertheless, both types of information are processed by the same neural hardware in the early visual system, and fixing one while varying the other in an experiment can lead to a confusing pattern of results.

Other examples abound. Psychophysical studies in humans have shown that the spatial, temporal, and chromatic context of a light can have dramatic effects on its color. This complicates the study of color processing: The spatial and temporal properties of the stimuli used in neurophysiological experiments, which are usually treated as nuisance parameters and fixed arbitrarily, affect color tuning measurements. This complication has a silver lining, however, because the relationships among visual attributes may provide valuable leverage into the problem. For example, the neural signals that underlie color perception should vary with the spatial and temporal properties of a stimulus in the same way that color perception does. Exploiting these relationships may help reveal how electrical signals in the brain give rise to color perception.

Representation of Movement

N S C Price and R T Born, Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Motion sensitivity is a fundamental aspect of vision for most animals. While the most obvious use for representing motion is to determine if an object is moving, analysis of motion serves a number of other roles. Assessing movements in the environment is critical to track, avoid, or intercept objects that may be food, friends, or foes. Motion analysis can be used for trajectory prediction, including determining if a moving object can be intercepted and the time to contact with the object. It also enables the resolution of ambiguities in two-dimensional relationships between objects. For example, depth information can be recovered through motion parallax, while motion segmentation can be used for camouflage breaking as occurs when a hidden animal only becomes distinct from its surroundings when it moves.

Motion can also be self-generated by eye, head, or body movements. Analyzing self-motion helps calibrate proprioception and locomotion and can be used to stabilize the retinal image to prevent motion-induced blur. The significance of analyzing motion is highlighted by the large proportion of motion-sensitive neurons in all animals that have been studied to date and the finding that while many of these species are insensitive to other visual modalities, such as disparity or color, no species lack motion sensitivity.

The focus here is on the neural representation of visual motion in primates, drawing briefly on results from models and psychophysics. The assessment addresses how the representation of movement changes along a hierarchy of brain regions that all contain motion-sensitive neurons and how this neural encoding ultimately affects perception and behavior.

Fundamentals of Motion Detection

In order to detect motion in a given direction a scene must be sampled at a minimum of two points in space at two different times. For example, the motion sensor in Figure 1(a) is sensitive to motion to the right if the time taken to traverse the distance Δd between the two input channels matches the temporal delay Δt. In addition, there must be a nonlinear interaction between the inputs from the two channels to ensure that the time-averaged output of the detector is direction selective. Early studies of the retina suggested that inhibition of responses to motion in the opposite direction to the preferred (the 'antipreferred,' or null, direction) is critical for generating physiological direction selectivity. This inhibition could either act linearly as subtraction or, more likely, nonlinearly as a shunting inhibition to suppress responses to motion in the antipreferred direction.

An early model incorporating the three basic requirements was Reichardt's cross-correlator, which was inspired by studies of the optomotor response of beetles (Figure 1(b)). The Reichardt detector is best stimulated by spatial wavelengths four times the separation of the input channels, since this leads to a 90° phase difference between the intensity variations at the two inputs (spatial quadrature). Further, for wavelengths less than twice the input channel separation the detector can suffer from spatial aliasing, as predicted by Shannon's sampling theorem. An important variant, the spatiotemporal energy model, incorporates simple linear spatial and temporal prefilters that reduce aliasing and help constrain the range of stimuli to which the detector responds (Figure 1(c)). This model highlights the idea that motion-sensitive neurons are filters tuned along a set of stimulus dimensions such as spatial and temporal frequency, rather than simply feature detectors, as suggested by the model in Figure 1(a).

With only two input channels, it is obvious that an 'apparent motion' stimulus, in which the stimulus appears at one location, and then the next, without physically moving between the two locations, could stimulate the detectors described in the preceding paragraphs as effectively as true, continuous motion. Similarly, motion sensors like the Reichardt detector can also falsely detect motion in random luminance flicker. These observations raise the obvious problem of determining whether the two input channels have been sequentially activated by one moving object or by two different objects – the so-called correspondence problem. A special form of this problem exists even for single objects that contain extended contours – as is the rule in natural scenes – due to the limited size of the sampling regions. The true direction of a moving edge viewed through a circular aperture cannot be resolved, a dilemma known as the 'aperture problem.' For example, in Figure 2(a), the edge could be moving slowly to the right, or more rapidly along a diagonal up and right, or down and right. Related to this is the issue of determining whether two adjacent local motion cues belong to one or two objects (Figure 2(b)). This problem is resolved if the vertex of an object is visible through an aperture, since it provides an unambiguous two-dimensional (2D) motion

Figure 1 Models of motion detection. (a) An elementary motion detector that prefers motion to the right incorporates spatial separation of input channels (Δx), a temporal delay (Δt) in the left channel, and a nonlinear interaction between the input channels (in this case, multiplication, '×'). (b) In the Reichardt cross-correlator, the outputs of two elementary motion detectors preferring motion in opposite directions are subtracted. (c) The spatiotemporal energy model calculates motion energy by combining the squared outputs of two oriented space and time (X, T) filters that are in quadrature. The slant in the contour plots of the space–time filters indicates that they prefer motion to the right.

Figure 2 The aperture problem and motion segregation and integration. Each row shows the view through one or two apertures at two points in time and on the right, the possible object motions that could account for these views. (a) The direction and speed of a single moving edge are ambiguous, thus creating the aperture problem. (b) The motion of two edges viewed through two apertures can be segregated, meaning that they are treated as independent objects with ambiguous direction and speed, or integrated, resulting in an unambiguous percept. (c) An object vertex provides two-dimensional information and thus an unambiguous percept of speed and direction.

cue (Figure 2(c)). Thus segmentation (determining which local motion cues belong together and which do not) and integration (combining the cues that do belong together) are important, interdependent processes for determining what global movements are actually happening in the environment.

One reason for pooling the responses of local motion detectors is to create robust responses in the face of low signal-to-noise ratios. In this context, noise could arise from local motion detectors signaling directions contrary to the true global motion direction due to flicker or spatial aliasing. Alternatively, the strength or certainty of a motion signal may be weak because of low luminances or contrasts. Two primary methods exist for decreasing noise sensitivity: first, signals from many detectors can be averaged over a large spatial region or over an extended period of time; second, a detector can incorporate motion opponency, whereby preferred and antipreferred direction motions respectively excite and suppress the detector's response. Motion opponency is explicit in the Reichardt detector (Figure 2(c)) and serves to reduce the response to stationary flicker or simultaneous motion in the preferred and antipreferred directions.

Introducing noise to stimuli has been a powerful method for probing the neural basis of motion perception. Changing stimulus strength, or dot coherence (the proportion of dots that move in a single direction versus those that move in random directions), affects both the perception and neural response to motion. Thus variable coherence dot stimuli have allowed investigators to measure the relationship between a neuron's activity and the perception of motion. The results of such studies have provided the most compelling links between neural activity and perceptual decisions to date.

Psychophysics

A student of physics can explain that motion is represented by a velocity vector, consisting of a speed and a direction. Since speed represents the change in position over time, it is conceivable that the visual system is not explicitly sensitive to motion, *per se*, but generates motion sensitivity by judging changes in position over time. However, there is ample evidence demonstrating that position and motion are independently represented. The most compelling demonstration of this independence is the motion aftereffect (MAE; also known as the 'waterfall illusion'): after observing a moving pattern, a stationary pattern appears to move in the opposite direction. This produces a strong sense of motion without the perception that the pattern changes position over time. Akinetopsia (visual motion blindness) also demonstrates the segregation of motion and position processing. In this condition, which can be caused by damage to the parieto-occipital cortex, moving objects do not appear to move smoothly and continuously but rather suddenly jump to a new location. Further, the condition is only associated with deficits in motion processing, without changes in acuity or localization abilities.

A number of fundamental psychophysical observations are critical for understanding the physiological work that will be described in subsequent sections. First, humans and primates are exquisitely sensitive at distinguishing the direction and, to a somewhat lesser degree, the speed of spatially or temporally adjacent motion stimuli. Intriguingly, the perceived speed of an object is dependent on many factors, including the contrast, size, and spatial frequency content of the stimulus, but also on how long the object has been viewed. The influence of viewing duration is also highlighted by the MAE, in which the percept of a stimulus depends on what had been viewed previously.

Psychophysical studies have shown that we can be 'fooled' by apparent motion. Thus a succession of short displacements is perceived as smooth motion, provided these displacements are less than 15–20 arc min. Watching television provides a clear demonstration of this: while objects appear to move smoothly across the screen, they are constrained spatially and temporally by the screen's pixels and refresh rate. In addition to short-range apparent motion, 'phi,' or long-range apparent motion, has been described, in which two flashes of light separated by much more than 20 arc min are interpreted as a single moving flash provided they have a suitable temporal separation. In addition, the long-range process can be distinguished from the short-range process by its sensitivity to shape and color, its failure to reverse directions for inverting contrast sequences (reverse phi), and its ability to integrate sequences across the two eyes (interocular transfer). These differences indicate the existence of multiple mechanisms in the visual system for detecting and analyzing motion.

The role of vision in guiding locomotion is evident from vection – the visually induced illusion of self-motion. This may be experienced when looking through the window of a stationary vehicle at another nearby stationary vehicle. If the other vehicle moves forward, one can experience a vivid sensation of moving backward. This arises because motion of the entire visual scene is generally attributable to eye, head, or body movements and is typically interpreted as such. This suggests that there are specialized mechanisms for detecting and interpreting optic flow fields characteristic of those generated during self-motion. These same mechanisms are also important for controlling

eye movements that serve to keep the image stable on the retina during self-motion. In the absence of such mechanisms, image quality would be severely degraded due to motion blur.

Anatomy

The basic anatomical organization of the visual system has been described as a processing hierarchy with extensive feed-forward and feedback connections between discrete areas (Figure 3). Motion processing is strongly associated with the dorsal stream, and is relatively segregated from the ventral form pathway as early as the retina and lateral geniculate nucleus (LGN). In primates, motion information is primarily carried by the so-called magnocellular stream, beginning with parasol retinal ganglion cells in the retina, which project to the more ventral, magnocellular layers of the LGN and subsequently to layers 4Cα and 6 of primary visual cortex (V1 but also known as 'striate cortex' or area 17). Subsequently, information reaches the middle temporal area (MT) predominantly through direct projections from layers 4B and 6 in V1, but also via indirect inputs from the thick stripes of V2 as well as V3. MT can be considered a motion-processing gateway in the cortex: it is the earliest of the visual areas in the hierarchy to contain predominantly motion-sensitive neurons, and the majority of these neurons are highly direction selective.

Figure 3 Major motion processing structures along the dorsal stream. Retinal information comprising konicellular (K), magnocellular (M), and parvocellular (P) processing channels originates in subsets of retinal ganglion cells and is passed to the superior colliculus and lateral geniculate nucleus. The primary stream for motion information is via the M cells in the retina and lateral geniculate nucleus through V1, then directly to the middle temporal area (MT). An indirect cortical stream also exists via V2, and much weaker inputs to MT exist via the superior colliculus and inferior pulvinar and directly from the K cells in the lateral geniculate nucleus. Information is also shared between MT and V4, and also reaches higher-order areas such as the frontal eye field (FEF), middle superior temporal area (MST), and lateral intraparietal area (LIP).

MT passes information to a number of additional cortical areas, including the dorsal and lateral compartments of the middle superior temporal area (MST), where neurons are sensitive to wide-field optic flow generated by body movements (MSTd) and pursuit eye movements (MSTl). Both MT and MST project to a range of higher-order cortical areas such as area 7a, the lateral intraparietal area (LIP), and frontal eye fields (FEFs) to guide decision making and eye movements; and to subcortical structures such as the accessory optic system, pontine nuclei, superior colliculus, and pulvinar to guide eye movements such as pursuit and optokinetic nystagmus. Although all the cortical and subcortical regions are highly interconnected, we will focus mainly on the properties of neurons in the feed-forward cortical hierarchy of the early dorsal stream, from the retina to MST. This provides a useful method for describing how the representation of movement changes from the retinal input channels sampling the visual world to neural codes more closely associated with perception.

Direction Selectivity

As early as the retina, neurons are found that prefer motion in one direction over another. Retinas in the turtle and rabbit have been studied more extensively than have those of other species, with up to one-third of all retinal ganglion cells (RGCs) in the turtle estimated to be direction selective, with similar proportions of directionally biased amacrine and bipolar cells. However, despite their presence in most vertebrate species, the role and prevalence of direction-tuned retinal cells in the primate are not clear, probably because of the large expansion of the midget (parvocellular) system in primates compared to other species. Furthermore, it appears that virtually all direction-selective RGCs in the primate retina project to brain stem structures, such as the nuclei of the accessory optic system, where they are involved in reflexes for gaze stabilization.

Both the proportion of direction-tuned neurons and the strength of their direction tuning (how much they prefer motion in the preferred direction over other directions) increase in areas along the dorsal stream. The direction selectivity underlying primate motion perception first arises in V1, where 20–30% of all cells are directionally biased. These cells are mainly confined to output layers 4B and 6, tend to respond to a narrow range of orientations, and have high contrast sensitivity and relatively small receptive fields. In V2, only ~15% of neurons are highly direction selective; however, such cells are prominent in layers 3B and 4 of the thick stripes, which receive significant projections from layer 4B in V1 and which subsequently project to MT.

In area MT, nearly all neurons are highly selective for the direction of motion. In addition, many neurons also show inhibition by motion in the null direction, a property which may give rise to the MAE. Another important feature of MT is that direction-selective neurons are organized into a map, with neurons that are tuned to the same direction of motion grouped together in columns, and adjacent columns representing different directions of motion. At subsequent processing stages, such as MST, essentially all cells are motion sensitive, but many prefer more complex types of motion rather than simple translation. In MSTd, approximately half of the cells are sensitive to translation, but many are sensitive to rotation in the fronto-parallel plane, rotation in depth, or expansion or contraction. These optic flow patterns are consistent with those produced by locomotion and, indeed, many MSTd neurons receive extraretinal inputs associated with locomotion. In contrast, neurons in MSTl are sensitive to motion produced by objects moving against a background. This requires a center-surround receptive field organization (see the section titled, 'Spatial aspects of receptive fields').

Temporal Frequency and Speed Tuning

Early quantitative studies of the visual system treated neurons as filters tuned along multiple stimulus dimensions, such as direction or speed. The full spatiotemporal frequency tuning of neurons can be tested using sine wave grating stimuli with a range of spatial frequencies (SFs) and moved with a range of temporal frequencies (TFs). Grating speed is then given by $v = \mathrm{TF/SF}$. A spatiotemporal frequency (STF) tuning plot can be generated from the responses to individual gratings (Figure 4). Simple cells in V1 are predominantly temporal frequency tuned, meaning that contours in their STF plots are oriented such that the TF giving the largest response is constant regardless of the grating's spatial frequency

Figure 4 Spatiotemporal frequency (STF) tuning. STF plots are generated by plotting a neuron's mean spiking rate in response to moving gratings with a range of spatial and temporal frequencies. Temporal frequency (TF) tuning (a) implies that contours in the STF align along a single TF, regardless of the grating spatial frequency (SF). Speed tuning (c) implies that the STF contours align with an iso-speed line, such that the ratio of preferred TF to preferred SF is a constant. (b) STF plots can also show oriented STF contours that are indicative of neither TF nor speed tuning.

(Figure 4(a)). While one-fourth of V1 complex cells and MT cells also show temporal frequency tuning, a similar proportion show form-invariant speed tuning, meaning that contours in their STF plots are oriented along an iso-speed line (Figure 4(c)). The remaining half of V1 complex and MT cells show oriented STF plots that are not aligned with a constant TF or constant speed (Figure 4(b)). The major difference between complex cells and MT neurons is that MT neurons show nonlinear interactions when tested with stimuli containing multiple spatial frequencies. Thus speed-tuning bandwidths calculated using textured stimuli are smaller for MT neurons than for V1 complex cells, and these bandwidths are narrower than would be predicted based on linear predictions from the responses to single spatial frequencies.

Temporal frequency tuning and speed tuning confer different advantages. TF tuning allows a detector to reliably judge the motion of a given object, regardless of the viewing distance. Speed tuning allows a

detector to reliably judge the motion of an object, regardless of its form. Perceptually, speed judgments are strongly dependent on the nature of the stimulus, with stimuli having low SF perceived as moving faster than those with high SF. This effect is consistent with the observation of neurons with slanted STF plots that do not show true speed tuning.

Spatial Aspects of Receptive Fields

A neuron's motion sensitivity is dependent on the spatial structure of its receptive field – its size, shape, and subdomains. In V1, V2, and MT, receptive fields have a bias toward the central 5° of the visual field and tile the entire contralateral hemisphere; however, they do not extend more than 10–15° ipsilateral of the vertical meridian. In V1, foveal receptive field sizes are extremely small (<1° diameter) but increase with eccentricity. At a given eccentricity, receptive fields are approximately two to four times larger in V2 than in V1, and larger still in MT. This changes in MST, where the tiling of receptive fields (RFs) extends 20–40° into the ipsilateral field, and foveal RFs are 10–15° in diameter. Further, the relationship between eccentricity and RF size is much weaker in MST than in V1–MT.

Receptive field size limits the separation of a motion detector's inputs, thus affecting the neuron's spatial frequency tuning bandwidth and the maximum resolvable step size that can be detected as motion. However, this maximum step size does not systematically change along the cortical hierarchy. Thus, despite MT receptive fields being ~10 times larger than those in V1 at a given eccentricity, neurons in the two areas are sensitive to a similar range of step sizes, and these step sizes match those that have been determined psychophysically. This suggests that MT does not calculate direction selectivity *de novo*, but elaborates on the motion analysis performed by output neurons from V1. Perceptually, long-range apparent motion can be perceived for displacements larger than those that stimulate V1 and MT neurons. Although not explored physiologically, this may be achieved through the attentive tracking of stimulus features that change position over time. However, the perception of long-range apparent motion suggests that motion processing may occur independently of V1 and MT at higher cortical levels than those studied so far.

From the level of the retina to MST, neurons display 'extraclassical' receptive fields or modulatory surrounds. For example, MT neurons respond well to motion in their preferred direction presented only in a small region at the center of their receptive fields. If the stimulus is enlarged to cover a suppressive surround, the neuron ceases to respond to the motion. This type of center-surround opponency for motion is likely to contribute to the extraction of local motion contrast that is created when objects move against a textured background or during pursuit eye movements, which produce a stationary object on the fovea surrounded by background motion in the direction opposite the eye movement. Center-surround receptive fields can also help assign border ownership and may contribute to motion segmentation, by determining if local motion cues belong to the same or different objects.

The opposite problem, motion integration, requires combining multiple local motion signals to determine the true direction of a larger object. The aperture problem described previously (see the section titled 'Psychophysics') provides a good demonstration of this: only by assuming that two different local motions belong to the same object can the information be combined to decode the correct direction of the object (**Figure 2(b)**). It is currently unclear by what mechanisms the visual system solves this problem. Some models propose that the visual system first extracts only the local one-dimensional (1D) motion perpendicular to the orientation of moving edges. Subsequently, this local motion information is nonlinearly combined using an 'intersection of constraints' calculation. Indeed, there is psychophysical and physiological evidence for the existence of orientation-selective filtering at early stages of motion processing followed by pattern-sensitive neurons in MT that can signal motion directions that are not orthogonal to an object's orientation. Many of these results have come from studies employing plaid stimuli, which contain two overlapping gratings with different orientations. Under some circumstances, the stimulus appears to move coherently, so that the perceived direction of motion is not orthogonal to the orientation information present in the pattern.

However, recent studies have also suggested that an alternative strategy may be employed, in which intrinsically 2D visual features, such as line endings or vertices, are first identified through nonlinearities, such as end-stopping, as found in some V1 cells. Motion information about these features is then selectively combined to calculate object motion. It is quite likely that multiple strategies are available to the visual system, with different ones predominating depending on viewing conditions. This is consistent with the concept of the visual system as a 'bag of tricks,' in which multiple mechanisms have evolved to take advantage of different environmental cues.

In MT and MST, spatial subdomains or asymmetries are evident in receptive fields, possibly as a result of combining inputs from spatially separated

V1 neurons with different preferred speeds, directions, or disparities. In addition to the preference of MST neurons for complex motion such as rotation and expansion, asymmetries within MT receptive fields appear to create neurons tuned for spatial gradients in speed or disparity. Such receptive field substructure may contribute to the perception of 3D surfaces or motion in depth.

Temporal Aspects of Motion Processing

When presented with an unchanging motion stimulus, the responses of most neurons change over time. The most commonly described changes are attributable to neural adaptation, in which the neuron's firing rate declines approximately exponentially over time. Adaptation was originally attributed to a kind of 'neural fatigue,' such as might be produced by depletion of neurotransmitter, but this cannot be the sole mechanism since adaptation is observed even when stimuli are presented briefly or when they do not elicit large responses. Further, adaptation rates and levels are highly stimulus dependent, being influenced by contrast, spatial frequency, temporal frequency, speed, and direction. Interestingly, adaptation does not simply change the amplitude of a neuron's response to a specific stimulus, but it can temporarily change a neuron's tuning. For example, after prolonged exposure to a grating, the tuning curves of V1 neurons shift away from the adapting grating's TF, SF, and direction. Conversely, attractive shifts have been observed in MT neurons, in which the preferred direction of many neurons shifts toward the direction of the adapting motion.

Neural adaptation is a very general mechanism present in multiple levels of the visual system as well as in other sensory systems. For example, photoreceptors are faced with light intensity variations spanning over 10 orders of magnitude, but the information that a neuron employing a rate code can transmit is limited by its maximum spiking rate. By adapting to the mean luminance in a scene, photoreceptors can increase the range of stimuli to which they can respond and also signal only changes in light intensity, which are of greater behavioral relevance than is the absolute light intensity (Figure 5). Similarly, a motion-sensitive neuron can adapt to the mean speed of a stimulus, reducing redundancy in the information encoded by its spikes. Perceptually, this dynamic range optimization is evident in studies of speed perception. During prolonged viewing of motion, the perceived speed of the stimulus declines approximately exponentially with viewing duration. This is accompanied by an enhanced ability to detect changes in speed, indicative of the functional role of adaptation in increasing motion sensitivity. An interesting by-product of adaptation, in combination with the directional opponency described above, is that prolonged viewing of a constant direction of motion can produce illusory motion of stationary patterns, as in the MAE.

Figure 5 The functional role of adaptation. The sigmoid curves represent the normalized stimulus–response relationship for a hypothetical neuron. In a given adaptation state (e.g., with mean stimulus intensity μ_1) the neuron's spiking rate cannot cover the full range of stimulus intensities. If the mean stimulus intensity shifts to μ_2, then the neuron dynamically shifts its tuning curve so that it can better represent changes in stimulus parameters.

Changes over time in neural responses to a constant stimulus can also reflect ongoing processing rather than adaptation. A striking example of this is that over ~60 ms, the responses of MT neurons change from reflecting the component of motion perpendicular to the orientation of a moving line segment to reflecting its true direction of motion. Similarly, when presented with plaid stimuli, consisting of two superimposed gratings, the responses of pattern motion-sensitive neurons evolve from initially being component motion sensitive. This demonstrates the dynamic coding of visual stimuli and provides further evidence that motion information may be processed collaboratively between a range of visual areas.

Higher-Order Aspects of Motion Representation

In addition to the more basic neural representation of movement that encodes the direction, speed, and location of motion within a scene, the visual system performs an array of higher-order motion computations. Areas along the dorsal stream progressively incorporate a greater proportion of extraretinal information into their coding of the retinal signal. This takes two main forms: copies of motor commands and attentional signals. So-called efference copy of eye movements and body movements can be used to help distinguish self-motion from object motion, and it can also be used to prepare the visual system for sudden changes in the visual inputs, such as those accompanying saccades. In such situations the motor

signal may allow neurons to transiently shift their spatial receptive fields or to suppress processing of the rapid self-generated motion. Attentional modulation of neural signals typically results in increased responsiveness to stimuli in the in the region of visual space to which attention is directed, or to distant objects that share features of the attended object, such as its direction of motion. Attention can also change receptive field shapes and response timings. While the precise mechanisms underlying these phenomena are unclear, many of the effects can be attributed to simple changes in response gain. Since areas further along the dorsal stream have larger receptive fields, the effect of attention acting in lower cortical areas could be to provide the higher-order areas with a representation of the visual world that is relatively dominated by the attended stimuli.

Another higher order aspect of motion representation is the integration of information between the form and motion pathways. The three-dimensional structure of objects can be extracted from motion and parallax cues generated by either object motion or movements of the observer. For example, during locomotion, objects at different distances generate distinct patterns of optic flow, leading to discontinuities in the local motion field. This allows the visual system to segment local motion vectors at the discontinuity and integrate local motion vectors on either side of the discontinuity. The perception of biological motion, in which observers recognize a moving animal or human form using only sparse information about the positions of the joints over time, may represent the highest form of the integration of local motion cues. However, it is also possible that moving animal forms are recognized predominantly from multiple template-matching operations of the static form across time, and that motion *per se*, as discussed previously (see the section titled 'Psychophysics'), is irrelevant.

Conclusion

Over four decades of physiological investigation of motion processing and over a century of quantitative psychophysical studies have given us great insight into the representation of motion at the single-neuron level and at the perceptual level. However, it is still not clear how the responses of a population of neurons are combined to generate perception, or which brain areas are associated with the perception of specific stimuli. The most basic link between a brain region and perception is that the activity in the area is correlated with the strength of the percept. In addition, microstimulation studies and lesion studies help link anatomical regions with behavior and perception. A wealth of studies has led to the strong association of MT with the perception of stimulus speed, direction, and depth, and the association of area MST with heading detection and object tracking. However, it is still not clear which neurons in these areas contribute to perception, how different neurons may be recruited for different tasks, and how their responses are combined. Determining how motion is represented at the population level for guiding perception and behavior remains one of the great technical and analytical challenges for future studies of vision.

Representation of Reward

B J Richmond, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Definition of Reward

Rewards are those conditions, events, or objects that cause approach behavior, or elicit feelings of pleasure, such as might happen with the accumulation of art or wealth. The value of the reward governs the intensity of the reaction, and, conversely, in experiments or observations the reward value is inferred from the intensity of the reaction. This latter inference is generally correct, but there are examples wherein the logic of arguments based on this inference breaks down, thus experimentalists and theoreticians studying reward-elicited effects must be alert to possible difficulties in modeling reward/response behavior.

Behavior and Behavioral Modeling

There are two classes of paradigms used to study the effects of reward. The first is classical conditioning. In classical conditioning a stimulus – say, a picture of Abraham Lincoln – is paired with an outcome occurring after a fixed interval, here a reward. After a few exposures to Abraham Lincoln's picture, responses that might have previously occurred just when the reward was delivered, such as licking, increased heart rate, or salivation, will begin to occur when the picture first appears. Thus, Lincoln's picture has become a conditioned stimulus (CS), predicting the later appearance of the unconditioned stimulus (US), which is the reward itself. This is a strong effect, so classical conditioning procedures provide a powerful means to study how learning takes place under the influence of rewards without any action on the part of the individual. All reward-related learning is probably driven, at least to some degree, through the mechanisms underlying classical conditioning.

The second class of behavior is instrumental; in this case the individual must perform an action to receive a reward. Rewards increase the likelihood of the activity that leads to the reward. Punishments, in contrast, lead to avoidance. These are the appetitive and aversive aspects of responses. Actions (except for simple reflexes) are generally driven by the desire to obtain a reward, and/or the effort to avoid punishment. Instrumental procedures require the animal in a laboratory study to interact with the environment – that is, it must do something such as press a lever, or must peck (pigeons), to obtain the reward or avoid punishment. In experiments with simple instrumental procedures such as lever pressing or pecking, the rate of responding is taken as a measure of the value of the action (the reward). If more presses or pecks are required, the time to begin pressing or pecking is related to the number of presses or pecks required to obtain the reward.

The degree of motivation used to obtain a reward depends on the value of the reward to the individual. The intrinsic value of any individual reward is a matter of biological need and individual preference. Thus, when the effects of different rewards are being compared, the individual reward preference must be assessed. Experimentally, relative reward values are frequently assessed using choice behavior – that is, experiments in which individuals choose between alternative actions, each of which gives rise to a different reward. The action chosen most often is taken to indicate the preferred reward. Through this procedure rewards can be ranked on a relative scale for the individual under study, thereby providing relative values of different rewards, different amounts of the same reward, or conditions that modify reward value.

The value of a reward can be modified by a number of factors. In general, larger amounts of reward are more valuable than smaller amounts. Rewards that are more distant in time are less valuable, and there are good descriptions of how rewards are discounted by delay to delivery (see later). Rewards can also be devalued by satiation for the particular reward. The first piece of chocolate is most appealing, and, for most people, the chocolate becomes less appealing as the succeeding pieces are eaten. Rewards that are more difficult to obtain are also devalued.

Through behavioral and theoretical analyses the concept of value has been generalized to cover the values of states that in themselves do not yield reward. These states are important to consider because so much of behavior depends on succeeding in intermediate conditions that do not inherently yield rewards. The values of these states are assessed on the same scale as for rewards, and, hence, the term 'value' does not apply only to the reward. Reward values are part of a more general concept of a value leading to action system.

Rewards are devalued or discounted by time: the value of a reward is decreased as the time to its delivery increases. This can be seen in both classical conditioning (Pavlovian) procedures and in instrumental tasks. Classical conditioning occurs when a stimulus is paired with an outcome, a reward, or punishment. The animals show an autonomic or involuntary response, such as change in heart rate or blood pressure, or change in

pupil diameter. Frequently licking is monitored as a sign of classical conditioning.

In choice experiments, individuals are offered a choice between a smaller immediately available reward and a larger, delayed reward. Experiments such as these were analyzed brilliantly by Herrnstein, who developed the 'matching law,' which says that when there is a choice, the proportion of choices will match the accumulated rewards or reinforcements in the two conditions – that is, $p_1/(p_1+p_2)=r_1/(r_1+r_2)$. This says that the probability, p, of a choice is equal to the probability with which the choice is reinforced, r. This has been shown to be generally true, but, with the increased interest in reward behavior in neuroscience and economics, the details of this relation are being examined closely.

Choice experiments have been generalized to find the relative values of the reward contingencies. In one particularly dramatic demonstration of the matching law, Oxford students stood at opposite sides of the Oxford arboretum pond, throwing bread into the two sides at different rates. The ducks in the pond distributed themselves in proportion to the amount of bread available at the two sites. Thus, not only are the ducks sensitive to the availability of reward, but the relation that could in principle be seen by testing one duck with reward probability can be seen immediately by observing a large population. The results of this experiment are interpreted in a game theoretic context. Game theory provides the mathematical framework for analyzing choices in competing situations. This particular example shows that efficacy of the so-called Nash equilibrium, the point at which competing options reach an optimal balance, so that the global gains and losses are maximized. It is consideration of these types of observations that is bringing economists, experimental psychologists, and neuroscientists together in the burgeoning study of what is being called neuroeconomics.

It should be possible to measure the equivalence between an immediate reward and a delayed, larger reward. In a large number of experiments, it has been shown that temporal discounting is well described by $V=R/(1+kD)$, where V is the state value, R is the reward (usually its size), D is the delay, and k is a constant that controls the rate of discounting with respect to time. This relation, with V directly related to the reward, and inversely related to a function of the delay, is both intuitive and amazingly accurate.

A major issue regarding reward value, or action-state values, is how the values of different states are learned and computed. In the 1970s Rescorla and Wagner, in working on this problem, developed a theoretical construct to describe how reward, and more generally state values, might be learned. A somewhat more sophisticated version of this model appeared in the work of Sutton and Barto, who were trying to solve a problem in machine learning. They wanted to find a general theoretical algorithm that would define a machine trying to learn a task from successes and failures. The general idea was to define a reward (i.e., success), and when the machine did something that provided some reward, that state would be reinforced. What they did was to optimize the total reward over time. The model, the temporal difference algorithm, is elegantly simple, and works well in machine learning. The value V at time t is described by $\delta(t)=r+\gamma V(t)-V(t-1)$, where r is the reward and γ is a discount factor. The change in value is $\Delta V(t)=\alpha\ \delta(t)$. This model also describes temporal discounting of rewards, as mentioned earlier, but it would have the reward discounted according to $1/e^{-kD}$. This exponential form has some theoretical advantages in that this form behaves better mathematically in the limit of infinite reward discounting. However, the hyperbolic form just described fits most behavioral data better. This difference, while important for theoretical modeling, is not critical here. The temporal difference model learns the values of states and simultaneously adjusts them to encourage behavior to change so as to maximize the average reward over time.

As animals and people repeatedly receive a particular reward, the value of the reward becomes less – that is, the reward is devalued. In monkey experiments, for example, this can be assessed in two steps. First, the monkey is offered choices between variously flavored food pellets. The outcome of this procedure is a ranking from most to least preferred flavor. Then, at some time, say 30 min, before some sessions, the monkey is fed a number of pellets of a usually preferred reward (perhaps as many as it will take). The monkey then can be tested either with foods directly, or it can be tasked to associate a stimulus with each of the two rewards. In this latter case, normal monkeys will select objects associated with the more preferred stimulus if there had been no devaluation procedure, or with the lower ranking stimulus if the reward had been sufficiently devalued. In another step, the experimenter can present different stimuli which, when touched or displaced, provide the monkey with a food pellet. This procedure allows the experimenter to assess whether the animal adjusts the choice of the associated stimulus under the influence of the devaluation. In other words, was the value of the stimulus or its associated action influenced by the devaluation procedure?

The value of reward is modified by the context in which it is presented. Kahnemann and Tversky showed that framing has a profound influence on

the choices that humans make. This work, which is about how reward values are modified, led to a Nobel Prize in economics. Two principles have been central to defining so-called rational behavior. The first is that reward values are transitive: if the value of A is greater than B, and B is greater than C, A should be greater than C. The other is equivalence: two conditions or states that have equivalent (not necessarily identical) outcomes should have equal value. However, Kahnemann and Tversky showed that humans, rather than showing rational behavior, are greatly influenced by the manner in which a choice is presented or framed. They showed that humans will consider two circumstances that have identical objective values as having different reward values. In one of their examples, they found that ticket-holders en route to the theater, but who lost their $10 theater ticket on the way, were less likely to buy a (replacement) ticket than were ticketless theatergoers who lost $10 in cash while en route to the theater to buy a ticket for the first time. Both conditions result in a $10 loss, but a majority of individuals will not replace the lost ticket, whereas a majority will still buy a $10 ticket after having lost $10 cash. It appears that the $10 left in the pocket has different values after the different types of loss, even though the actual values are identical.

In addition, Kahnemann and Tversky showed that by framing a problem in which the reward is stochastic in different ways again influences the choices that are made. This work has provoked a lot of study of risk aversion, and its distribution in the population. It is now clear that there is a wide spectrum of risk taking, with some individuals trying to avoid risk in almost every way, many who will take some risk, and a few for whom risk seems to have a rewarding effect. This latter group probably includes pathological gamblers and those who seem to be rewarded by engaging in activities with large physical risk.

Brain Mechanisms for Reward Evaluation

Over the past 50 years quite a bit has been learned about which brain mechanisms play a role in reward evaluation. As yet, however, there is no good overall model for how reward evaluation is carried out in the brain. The discovery that rats with electrodes placed in the hypothalamus would press a lever seemingly forever, to deliver electrical stimulation, gave great impetus to studies of the circuitry and mechanisms underlying reward-seeking behavior.

Brain regions that are involved in assessing and acting on rewards include the limbic system, the frontal and posterior parietal cortices, the medial temporal cortex, the cingulate cortex, the anterior insula, and the basal ganglia, especially many parts of the striatum. Behavioral evidence comes from observing animals with selective inactivations through ablation or other means, and humans with damage from disease or injury. Recently, functional imaging in human subjects has been making large contributions by identifying brain regions that show changes in blood flow (activations) during reward-related conditions. Finally, electrical neuronal recordings reveal signals carried by single neurons or populations related to reward evaluation.

The transmitter dopamine plays a central role in current thinking about reward, and by extension, all of those brain areas that receive dopaminergic input are under consideration. At this point, it is widely agreed that dopamine and dopamine neurons play some important role in reward learning and, for this discussion, reward value. However, it is obvious from all of the motor symptoms of Parkinson's disease, a human condition in which the dopamine neurons inexplicably die over a number of years, that dopamine must play roles in the brain other than just coding for some aspect of reward. Nonetheless, the evidence that dopamine plays an important role in reward-related behavior is compelling. Thus, the basal ganglia, which are extremely rich in dopamine, and other areas, such as the frontal cortex, amygdala, the medial part of the temporal lobe, and the posterior parietal cortex, have all been implicated in reward-seeking behavior. In the primate, where dopamine is found in at some level throughout virtually all of the cortex, including primary sensory areas, it might even turn out that reward-related learning occurs, to some degree, just about everywhere.

Dopamine neurons are located in the high midbrain in the substantia nigra pars compacta, and in the ventral tegmental area. These neurons have a slow, regularly irregular pattern of firing, and they emit a couple of extra spikes in rapid succession when a surprising event occurs, when a reward occurs, or when a stimulus predicting a reward a short time later occurs. When the effects of dopamine are decreased by depletion or receptor blockade, the ability to associate reward with predictive stimuli is impaired, showing that dopamine plays a critical role in this type of associative learning. Thus, it appears that dopamine is critical for learning the values of the associations or the states that they signify.

A strong current hypothesis about dopamine neurons is that they might carry a signal related to reward prediction error – that is, a signal related to the difference between what reward is expected and what is actually delivered, or not. This hypothesis grew from the observation that when a stimulus is paired with a reward occurring a few seconds later in a

classical conditioning experiment, the response of the dopamine neurons, which had been locked to the reward, 'moves' to the time when the stimulus-predicting reward occurs. This reward-prediction error hypothesis is very intriguing, for if it were correct, it would suggest that the brain is computing an explicit signal, like the temporal difference signal used in the actor–critic temporal difference model of Sutton and Barto. The work and debate about the exact nature of the signal carried by dopamine neurons continues, but the debate about the hypothesis has been leading to exciting research at many levels of biophysics, single-neuron recording, and human imaging.

Most of the brain regions that play important roles in reward, in addition to their complex interconnections, are generally ones that are rich in dopamine fibers and receptors. These areas have dense interconnections that certainly are important for the signal processing underlying reward evaluation. However, the roles of the connections are poorly understood. For ease, rather than trying to elucidate all of the possible interactions, the discussion here now focuses on a partial list of important findings, relying on the presence of dopamine mechanisms as a common feature.

The basal ganglia, especially the striatum, have a large role in reward-related behavior. It has been proposed that the striatum implements something akin to the actor–critic components of the temporal difference model. From lesion data on learning of reward values, a case can be made that the ventral striatum acts like a critic, evaluating whether a response leads to the predicted outcome, and the dorsal striatum acts like an actor, guiding the actions. Whether or not this model is exactly correct, it offers a clear interpretation for several ablation experiments and provides an important framework for further experiments.

Several lines of evidence suggest that orbitofrontal cortex is critical for evaluating reward values. Experimental ablations of orbitofrontal cortex impair judgment of reward value and reward contingency. Ablations of the amygdala also damage the judgment of reward value, but not of reward contingency; that is, ablations of both orbitofrontal cortex in monkeys reduces or eliminates reward devaluation, but object reversal learning is only damaged after orbitofrontal lesions. Single neurons in orbitofrontal cortex seem to encode information about reward desirability or value. Human imaging shows activations or orbitofrontal cortex when the individuals are engaged tasks requiring planning and judging the value of a stimulus or situation as it pertains to the value of actions or rewards related to outcome. Thus, orbitofrontal cortex seems to be critical for the computation or representation of actual current value.

The lateral prefrontal cortex has dopamine receptors throughout it. Lesions of this tissue interfere with learning or changing choices in response to new rules. Physiological studies including single-neuron recording and imaging show activations related to upcoming choice of action, so rather than computing value or reward, this tissue appears to be critical for using the value to guide an upcoming action.

The anterior cingulate cortex is activated in humans when they are engaged in risk-taking tasks, and in tasks when they must monitor their own activity, especially the successes and the errors, as a means of improving performance. Behavioral experiments suggest that the cingulate is important for evaluating the trade-off between an immediate reward and a delayed, but bigger, reward. Normal rats might be willing to climb a big barrier to get a large reward even though a smaller reward is available by surmounting a smaller barrier; after cingulate ablation the rats choose the less demanding route for the smaller reward. In single-neuron recordings in monkeys, the neurons in the anterior cingulate cortex are sensitive to reward contingency and the neurons in the posterior cingulate are sensitive to different reward sizes and respond during the preparation to switch motor activity so as to increase reward, a function that seems once again similar to the long-time goals that form the base of the theoretical treatments of reward (e.g., the temporal difference models).

Recent work has shown activation of the insula and ventral striatum during some risk-taking tasks. From earlier work in animals, the insula has been related to gustatory and/or taste activation. The posterior part is more connected with cortical motor areas. The insula seems well positioned to play a role in reward evaluation, especially with regard to actual reward delivery.

Conclusions

Motivated behavior arises through expectation of reward or avoidance of punishment. Many factors contribute to the computation of the current value of a particular state. These include whether a reward will be delivered, how soon and how desirable a reward that might be delivered will be, and how aversive the effort to gain the reward is likely to be. Over the past 30 years some theoretical constructs have been developed that provide structures for organizing and evaluating results from behavioral, pharmacological, and physiological experiments. There seem to be connections between these biological experiments and the factors that these theories demonstrate are needed to influence motivation. The next few

years will provide the data to refine the theories and help choose among them.

Introduction

An essential regulatory function of the nervous system is to maintain homeostasis of respiratory gases. The neural system regulating breathing must coordinate rhythmic contractions of the respiratory muscles to generate appropriate lung ventilation for oxygen and carbon dioxide exchange. Nonhomeostatic functions of the respiratory system must also be served, including speech, sniffing, behavioral displays, and airway defense. This system is functional at birth and adapts continuously throughout life, maintaining homeostasis despite changing environmental conditions, activity levels, and physical properties of the lung/chest wall system during development, exercise, pregnancy, aging, and disease. In this article, we provide a brief introduction to features of the respiratory control system that enable its regulatory functions, followed by more extensive discussion of chemoreceptors, respiratory plasticity, ventilatory control disorders that challenge homeostasis, and integrated ventilatory responses to physiological stimuli.

Fundamental Elements of Ventilatory Control

Breathing Is Automatic and Not Autonomic

The control of breathing is an automatic process that works without conscious intervention when asleep, anesthetized, or awake and not specifically thinking about breathing. Conscious factors can override or modify automatic functions of the respiratory control system for a limited period. For example, an individual can voluntarily speak, smell, hyperventilate, or hold their breath. However, automatic functions ultimately mandate a return to normal breathing. Because the control of breathing is largely automatic and the regulation of breathing is intimately associated with autonomic functions, the respiratory control system is often confused as part of the autonomic nervous system. However, ventilatory control is in many respects more similar to systems controlling somatic motor functions, such as walking.

Ventilatory Control Processes

Figure 1 is a schematic of neural processes involved in the control of breathing. Breathing rhythm begins in the medulla. Supramedullary brain structures, including the pons, cerebellum, and forebrain, modulate breathing, but breathing continues without them. The ventral respiratory column (VRC) is a long, bilateral column of respiratory-related neurons in the ventrolateral medulla; the VRC contains functionally distinct neuron populations that are active during different phases of the respiratory cycle. Recent hypotheses suggest that two neuron clusters of the VRC underlying respiratory rhythm generation – the pre-Bötzinger complex (preBötC) and the retrotrapezoid nucleus/parafacial respiratory group (RTN/pFRG) – represent interactive (functionally coupled) respiratory rhythm generators that collectively establish breathing rhythm.

VRC neurons also craft the spatiotemporal details of a breath, a process known as respiratory pattern formation. VRC inspiratory and expiratory premotoneurons integrate a variety of CNS inputs, and differentially distribute respiratory synaptic drive to inspiratory and expiratory motoneurons innervating respiratory muscles of the thorax, abdomen, and upper airway. Phrenic motoneurons in the cervical spinal cord innervate the diaphragm and drive inspiration. During quiet breathing, the diaphragm actively contracts during inspiration and relaxes during expiration, which is passive in most mammals. During elevated respiratory drive or lung disease, accessory inspiratory muscles (e.g., external intercostals) and expiratory muscles (e.g., internal intercostals, abdominal muscles) contribute more to ventilation. Brain stem motoneurons innervating the upper airway muscles (e.g., hypoglossal) preserve airway patency during breathing. During each inspiratory effort, synaptic inputs activate hypoglossal motoneurons, flattening and stiffening the tongue to prevent collapse into the airway. Respiratory motoneurons integrate multiple synaptic inputs and exhibit neuroplasticity (see later), thereby contributing to respiratory pattern formation.

Rhythm generation and pattern formation are modified by feedback, feed-forward, and adaptive control mechanisms that confer flexibility and plasticity to this critical regulatory system. Sensory receptors provide feedback concerning chemical (O_2 and CO_2) or mechanical conditions (e.g., lung inflation) and initiate reflexes to regulate these variables within reasonable limits. More rapid responses are possible via feed-forward regulation. Longer lasting or repeated disturbances require long-lasting adaptations, or plasticity. Modulatory neurons modify the intrinsic respiratory

Figure 1 Schematic representation of neural processes fundamental to the control of breathing. Respiratory rhythm generation establishes the timing of a breath (i.e., breathing frequency) and originates in specialized neurons of the medullary ventral respiratory column, including the pre-Bötzinger complex and the retrotrapezoid nucleus/parafacial respiratory group. Respiratory pattern formation establishes the detailed spatiotemporal outflow of respiratory motoneuron pools that innervate different respiratory muscles. Neurons participating in pattern formation are diffuse and arise from rhythm-generating neurons, inspiratory and expiratory premotoneurons in the ventral respiratory column, and respiratory motoneurons of the brain stem and spinal cord. The intrinsic respiratory rhythm and burst pattern are modified extensively by sensory inputs (i.e., chemoreceptors and mechanoreceptors) and modulatory inputs, such as monoaminergic or peptidergic inputs from multiple sources. Other modulatory inputs arise from cortical processes, and cardiovascular and pain networks. The respiratory control system exhibits the capacity for plasticity. Plasticity can occur at multiple neuroanatomical sites in this system. To date, plasticity has been studied most extensively in chemoreceptors and in respiratory motoneurons. The motor output is distributed to respiratory pump muscles of the thorax and abdomen as well as the upper airway muscles that regulate airway resistance and stability.

rhythm and pattern. For example, brain stem serotonergic and noradrenergic neurons have been implicated in central chemoreception and/or the initiation and orchestration of respiratory plasticity. Modulation and plasticity can occur at multiple points in the respiratory control system, including sensory receptors, feed-forward neural pathways, VRC neurons, and respiratory motoneurons.

Chemoreceptors and Chemoreflexes

Two essential goals of the respiratory system are to obtain adequate O_2 into the body for aerobic metabolism, and to eliminate the resultant CO_2. As CO_2 is a major determinant of blood and tissue pH, it is tightly regulated to maintain short-term acid/base homeostasis (the kidneys contribute to longer term pH homeostasis). Arterial CO_2 is the primary regulated variable in ventilatory control under normal conditions. For example, when arterial CO_2 pressure (normally ~40 mmHg) is elevated by only 1 to 3 mmHg, ventilation doubles. In contrast, arterial O_2 pressure (normally ~100 mmHg) changes up to 20 mmHg are virtually ignored by the system. Oxygen-sensitive chemoreceptors stimulate breathing acutely only when O_2 partial pressure falls by 30 mmHg or more. However, over longer periods (hours or days), O_2 is more effective at triggering respiratory plasticity (see later).

Sources of Chemoreceptor Feedback

Chemoreceptors provide sensory feedback concerning CO_2 or O_2 changes and initiate chemoreflexes, adjusting breathing to minimize deviations in blood gas levels via negative feedback. In mammals, O_2-sensitive chemoreceptors are found in the peripheral nervous system, whereas CO_2-sensitive chemoreceptors are found both peripherally and in the central nervous system (CNS). CO_2-sensitive chemoreceptors in the lungs of birds and reptiles also play a prominent role in ventilatory control, but similar receptors are not found in mammals.

Central Chemoreceptors

The predominant CO_2-sensitive receptors controlling breathing in mammals are the central chemoreceptors, but there is considerable debate regarding their location and cellular identity. Central chemoreceptors sense intracellular and/or extracellular brain pH, indirectly sensing changes in CO_2. Neurons in multiple brain stem regions show CO_2/pH sensitivity (Figure 2), including (1) retrotrapezoid nucleus (RTN) ventral to the medullary facial nucleus, (2) serotonergic and γ-aminobutyric acid (GABA)ergic neurons in the raphe nuclei, (3) noradrenergic neurons of the locus coeruleus, (4) nucleus of the solitary tract (NTS), (5) preBötC, and (6) cerebellar fastigial nucleus. Additional CO_2-sensitive neurons are found in disparate regions, including the caudal hypothalamus and the hippocampus. The relative sensitivity of these neuronal populations to CO_2/pH *in vivo,* and the contribution they make to the hypercapnic ventilatory response are topics of active debate.

One hypothesis is that a single group of central chemoreceptors in a discrete location with highly specialized cells detecting slight changes in CO_2/pH and eliciting robust ventilatory responses dominates the CO_2 chemoreflex; this hypothesis implies that other CO_2-sensitive neurons play different roles related to arousal or behavioral responses. The RTN is one candidate site for a prominent role in the CO_2 chemoreflex; it contains neurons with high CO_2/pH sensitivity with strong projections to the VRC. An alternate hypothesis for the bewildering array of central chemosensitive sites is that different cell groups assume more

Figure 2 Central chemoreceptors are distributed throughout the brain stem and modify respiratory motor output. Left: Phrenic neurogram and integrated phrenic nerve activity during normal and hypercapnic conditions in an anesthetized, vagotomized, and paralyzed rat. Increased CO_2 elevates respiratory drive, largely due to actions of central chemoreceptors. Right: Horizontal (upper) and sagittal (lower) diagrams of rhombencephalon of the rat, showing the location of different regions where chemosensory neurons have been identified. The ventral respiratory column is the gray shaded area of the ventrolateral medulla. In the nucleus of the solitary tract (NTS; purple), the distribution of chemosensitive neurons has not been accurately determined, but includes portions of the ventral and lateral NTS coextensive with the area postrema. In the retrotrapezoid nucleus (RTN; darker blue), chemosensitive neurons are concentrated under the caudal third of the facial nucleus. The caudal raphe nuclei (RMg/RPa/Rob; green) extend from the rostral medulla to the caudal pons and provide inputs to the brain stem and spinal cord. Raphe magnus (RMg) is the main source of medullary serotonergic projections. Other CO_2-sensitive neurons are found in the pre-Bötzinger complex (preBötC; red), the pontine locus coeruleus (LC; yellow), and the cerebellar fastigial nucleus (Fastigial n; turquoise) of the cerebellum. Additional CO_2-sensitive neurons are found in the caudal hypothalamus and hippocampus (not shown), although these regions are not normally thought to be involved in respiratory motor control. The relative role of each chemosensitive site in the hypercapnic ventilatory response is under active debate. 5n, trigeminal nerve; 7, facial nucleus; 7n, facial nerve; A5, lateral pontine A5 noradrenergic neuronal group; AmbC, compact part of nucleus ambiguus; AP, area postrema; BötC, Bötzinger complex; Cb, cerebellum; cVRG, caudal division of ventral respiratory group; icp, inferior cerebellar peduncle; KF, Kölliker–Fuse nucleus; LPBr, lateral parabrachial region; LRt, lateral reticular nucleus; mcp, medial cerebellar peduncle; Med Cb n., medial cerebellar nucleus (also called fastigial nucleus); Mo5, motor nucleus of the trigeminal nerve; pFRG, parafacial respiratory group; Pn, basilar pontine nuclei; Rob, raphe obscurus; RPa, raphe pallidus; rVRG, rostral division of ventral respiratory group; scp, superior cerebellar peduncle; SO, superior olive; sp5, spinal trigeminal tract; vlpons, ventrolateral pontine region. prominent roles in different physiological states, such as during sleep versus during wakefulness. Alternately, central chemoreflexes may reflect the collective input of many neuronal groups, each contributing partially to the overall ventilatory response. Such a distributed chemoreceptor system would more accurately represent average brain CO_2/pH levels versus the limited spatial domain of a single site.

Peripheral Chemoreceptors

In adult mammals, the most important O_2-sensitive chemoreceptors are the carotid body chemoreceptors, located at the bifurcation of the internal and external carotid arteries. Carotid body chemoreceptors also sense changes in arterial CO_2 and pH. Although the mechanism of carotid chemosensory transduction is largely unknown, recent evidence implicates ATP acting through purinergic P2 receptors (particularly P2X2). Carotid body chemoreceptors relay signals concerning arterial O_2 via the carotid sinus nerve to the nucleus of the solitary tract (NTS), where second-order projections diverge to many CNS regions, including the VRC, RTN, cerebellum, and cortex. When increased chemoafferent neuron activity stimulates breathing, the ventilatory response is complicated by feedback interactions with CO_2 chemoreceptors. For example, increased ventilation during hypoxia minimizes the arterial O_2 decrease, but concurrently decreases arterial CO_2. Consequently, CO_2 chemoreceptors are inhibited and restrain the hypoxia-induced increase in breathing.

O_2-sensitive receptors are also found in the aortic arch (aortic body), but these receptors appear to play little role in ventilation under normal conditions; their greater contribution is in cardiovascular regulation. However, aortic body chemoreceptors increase their contribution to ventilatory chemoreflexes if the carotid bodies are removed, particularly during development. Additional O_2-sensitive neurons are found in the CNS, but their role in ventilatory control is not yet clear.

Integrated Responses

Time Domains of the Hypoxic Ventilatory Response

The hypoxic response is a complex interplay amongst multiple neural mechanisms that differ in their direction (facilitation vs. depression), time domain (seconds to years), and expression during versus following hypoxic exposures (see Figure 3). The acute response during hypoxia is an immediate (within one breath) increase in tidal volume and frequency due to the immediate chemoreflex effects of peripheral chemoreceptor stimulation. Following the acute response, tidal volume gradually increases over several minutes, an effect known as short-term potentiation (STP). On termination of hypoxia, the reversal of STP is observed as a slow return to normal tidal volume. The mechanism of STP is not yet clear but may involve presynaptic calcium accumulation in NTS relay neurons or premotoneurons.

Inhibitory mechanisms are also apparent in the hypoxic ventilatory response, such as hypoxic ventilatory decline (HVD) and posthypoxia frequency decline (PHFD). HVD is the 'roll off' in ventilation (primarily tidal volume) when moderate hypoxia is sustained for many minutes at constant CO_2. HVD may result from decreased peripheral chemoreceptor sensitivity and/or inhibitory mechanisms in NTS relay neurons. PHFD is observed following acute hypoxia, and is a transient

Figure 3 Time-domains of integrated ventilatory responses during and following hypoxia. Top: Integrated phrenic motor output in an anesthetized rat challenged with a single episode of 11% O_2 (5 min). The time scale is compressed, merging successive breaths to highlight changes in the amplitude of respiratory motor output. Below the experimental trace are schematized representations of the time-dependent changes in ventilation ($\dot{V}$) and its components – tidal volume (V_T) and frequency (f_R) – during this short-term hypoxic response. The immediate increase and decrease in ventilation at the beginning and end of the hypoxic episode represent the acute hypoxic response (AR). The AR is followed by a relatively slow and progressive increase in VT, an effect known as short-term potentiation (STP). The overshoot and undershoot in respiratory frequency at the beginning and end of hypoxia, respectively, are forms of short-term depression; the off-response is referred to as the posthypoxia frequency decline (PHFD). When hypoxia is presented in an intermittent pattern (third panel from top; three hypoxic episodes, 5 min in duration, 5-min intervals), long-term facilitation (LTF) is revealed as a slow, progressive increase in respiratory amplitude lasting for several hours posthypoxia. LTF is not revealed by a single hypoxic episode of similar cumulative duration (25 min). When hypoxia is sustained for many hours to years (lower trace), a series of ventilatory responses are observed in sequence, including hypoxic ventilatory decline (HVD; 15–60 min), ventilatory acclimatization to chronic hypoxia (VAH; hours to days), and hypoxic desensitization (HD; months or years). Each time domain of the hypoxic ventilatory response arises from unique mechanisms. See text for further explanation.

(minutes) decrease in respiratory frequency below prehypoxic levels. Although the mechanism of PHFD is not clear, it requires neurons in the ventrolateral pons, and is modulated by noradrenergic (α-2) and serotonergic (5-hydroxytryptamine; 5-HT_{2A}) receptor activation. Prolonged hypoxia (days) and intermittent hypoxia induce additional mechanisms representing forms of respiratory plasticity (reviewed later).

Exercise Ventilatory Response: Feed-forward Control

The ventilatory response to mild or moderate physical activity (e.g., walking) is the most frequent and largest ventilatory adjustment during normal life. To preserve arterial CO_2 (and O_2) homeostasis, ventilation must increase in proportion to increased metabolism. Just how that ventilatory response is achieved is one of the fundamental, yet unresolved, questions of respiratory neurobiology. Most mammalian species increase breathing prior to any perceptible arterial CO_2 change (e.g., prior to or during the first step). Indeed, the steady-state ventilatory response to exercise is typically in excess of increased metabolic CO_2 production, slightly decreasing arterial CO_2 from rest to exercise. Thus, the predominant drive to breathe during modest exercise is feed-forward with respect to arterial CO_2 regulation. Chemofeedback provides inhibitory constraints on ventilation in most mammals, preventing excessive decreases in arterial CO_2 during exercise. In contrast to most other terrestrial vertebrates, the CO_2 change during exercise in humans is a function of exercise intensity. During mild exercise, the feed-forward response is slightly inadequate, and arterial CO_2 increases slightly; during moderate exercise, the feed-forward response precisely matches increased metabolic rate, and arterial CO_2 is regulated at its resting level. Speculations concerning the feed-forward exercise stimulus include parallel activation of respiratory and somatic motor output ('cortical irradiation'), or an unidentified receptor in exercising muscles that couples breathing with increased metabolic rate (Figure 4).

Adaptive Control Strategies: Respiratory Plasticity

With repeated or long-lasting perturbations, the neural system controlling breathing exhibits plasticity, an alteration in behavior based on experience. Respiratory plasticity enables adjustments to longer lasting physiological changes, such as ascent to altitude, normal development and aging, changes in weight, pregnancy, etc. Examples of plasticity in respiratory motor control include (1) plasticity induced by hypoxia or hypercapnia, (2) developmental plasticity, (3) modulation and plasticity of the exercise ventilatory response, (4) respiratory plasticity following neural injury, and (5) classical conditioning (e.g., sensitization of gill-withdrawal reflex in *Aplysia*). Hypoxia-induced respiratory plasticity is the most thoroughly studied and best understood form of respiratory plasticity. The specific mechanisms of hypoxia-induced plasticity depend on the pattern, severity, and duration of hypoxic exposure.

Respiratory Long-Term Facilitation following Acute Intermittent Hypoxia

Repetitive hypoxic episodes (seconds to minutes) elicit respiratory long-term facilitation (LTF), a progressive increase in respiratory motor output lasting several hours posthypoxia (Figures 3 and 5). LTF is primarily expressed as increased respiratory amplitude, with small and inconsistent effects on frequency. Motoneurons innervating respiratory pump muscles (e.g., phrenic and inspiratory intercostals) and upper airway muscles (e.g., hypoglossal) exhibit LTF following intermittent hypoxia. LTF is pattern sensitive, since it is observed following intermittent, but not sustained, hypoxia. LTF is frequently studied in respiratory nerve recordings in anesthetized rodent preparations, and ventilation in unanesthetized mammals. Ventilatory LTF in unanesthetized animals is state dependent, since it is more prominent in sleep versus wakefulness.

The cellular/synaptic mechanisms of LTF are under active investigation. Here, we limit discussion to phrenic LTF (pLTF), although similar mechanisms are proposed in other respiratory motoneuron pools. Our working model of pLTF is that intermittent hypoxia triggers intermittent serotonin release onto phrenic motoneurons, thereby activating 5-HT_{2A} receptors and initiating pLTF. 5-HT_{2A} receptor activation stimulates new protein synthesis, including new synthesis of brain-derived neurotrophic factor (BDNF) from existing mRNA. New BDNF synthesis is necessary for pLTF, since translational inhibition of BDNF mRNA via RNA interference with small interfering RNAs abolishes pLTF. Further, BDNF applied to the cervical spinal cord is sufficient to elicit phrenic motor facilitation with a magnitude and time course similar to pLTF following intermittent hypoxia. BDNF activates the receptor tyrosine kinase, TrkB, thereby activating downstream signaling molecules such as extracellular signal-regulated mitogen-activated protein kinases (ERK-1/2) and protein kinase B (Akt). These kinases may phosphorylate glutamate receptor subunits, increasing glutamate-induced currents and strengthening the synapse between medullary premotoneurons and phrenic motoneurons.

Figure 4 Modulation and plasticity of the exercise ventilatory response during mild or moderate physical activity in a nonhuman mammalian species. Left: Ventilation increases linearly with increased metabolic rate during mild to moderate physical activity; however, the ventilatory response is greater than necessary to maintain homeostasis, causing a slight decrease in arterial CO_2 pressure during exercise. During heavy exercise, the ventilatory response increases disproportionately, accelerating the decrease in CO_2. Middle: The primary drive to breathe during exercise results from a feed-forward mechanism, and is restrained by inhibitory chemoreceptor feedback to prevent excessive hypocapnia during exercise. Although the exercise ventilatory response is isocapnic or slightly hypercapnic in humans, these differences appear to be quantitative versus qualitative. The net result in mammals is good (not perfect) regulation of arterial CO_2 during exercise. When conditions are altered, such as with increased respiratory dead space, modulatory neurons (such as raphe serotonergic neurons) are activated, increasing respiratory motoneuron excitability and augmenting the exercise ventilatory response by a mechanism referred to as short-term modulation. Short-term modulation may reflect serotonergic modulation of potassium channels on respiratory motoneurons (detailed in the enlargement of the blue-shaded motoneuron). When exercise and increased dead space are explicitly paired over many exercise trials, long-term modulation, a form of plasticity, causes persistent augmentation of the exercise ventilatory response, possibly by synthesizing new proteins that increase the synaptic strength of inputs to respiratory motoneurons. Since long-term modulation is also serotonin dependent, it may reflect synaptic enhancement similar to long-term facilitation following intermittent hypoxia (see **Figure 5**).

Figure 5 Working model of cellular/synaptic mechanisms underlying respiratory long-term facilitation (LTF). In the schema, inputs from premotoneurons (respiratory drive) form glutamatergic synapses on phrenic motoneuron dendrites (gray shaded region). Raphe serotonergic neurons with varicosities near phrenic motoneurons are coactivated with respiratory drive during intermittent hypoxia, releasing serotonin in an episodic pattern and stimulating postsynaptic 5-hydroxytryptamine ($5\text{-}HT_2$) receptors on motoneurons. Intermittent $5\text{-}HT_2$ receptor activation initiates translation and new protein synthesis of brain-derived neurotrophic factor (BDNF) within respiratory motoneurons (PKC, protein kinase C). Subsequent BDNF release activates presynaptic and/or postsynaptic TrkB receptors, which increase synaptic strength between premotoneurons and phrenic motoneurons through activation of extracellular signal-regulated mitogen-activated protein kinases (p-ERKs) and/or protein kinase B (p-Akt). Increased synaptic strength likely results from increased phosphorylation and trafficking of postsynaptic glutamatergic receptors, although effects on presynaptic glutamate release cannot be ruled out. Phosphorylated ERK and/or Akt may also translocate to the nucleus, initiating transcription and leading to longer lasting forms of plasticity and metaplasticity in respiratory motor control.

In *in vitro* preparations from neonatal rodents, intermittent applications of 5-HT_{2A} receptor agonists or serotonin to hypoglossal and/or spinal respiratory motoneurons elicit long-lasting facilitation of respiratory motor output (*in vitro* LTF). *In vitro* LTF is pattern sensitive, and results from increased α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor currents. AMPA-induced currents in hypoglossal motoneurons are enhanced by episodic serotonin receptor activation in preparations in which action potential generation has been blocked, thus demonstrating (1) that *in vitro* LTF at least partially results from postsynaptic effects in motoneurons and (2) that *in vitro* LTF is an activity-independent form of synaptic plasticity.

Although the physiological significance of LTF remains uncertain, it may stabilize breathing during sleep. Apneas, with consequent hypoxic episodes, are frequent during sleep; if multiple apneas occur in succession, intermittent hypoxia may induce LTF and prevent subsequent apneas by increasing respiratory motor output and stiffening the upper airway. This hypothesis is consistent with the observation that 15–25 s hypoxic episodes are sufficient to elicit LTF – a duration consistent with apnea-induced hypoxia. Regardless of its specific role, LTF indicates the capacity to alter synaptic strength of inputs to respiratory motoneurons. This capacity may impart the ability to shift the balance of motoneuron pools contributing to a breath. For example, during pregnancy, when the growing fetus compromises diaphragmatic function, a shift toward greater activation of accessory inspiratory muscles alleviates functional breathing deficits.

Chronic Intermittent Hypoxia

When intermittent hypoxia is maintained for prolonged periods, as would occur with sleep apnea, additional mechanisms of plasticity are observed. For example, resting breathing and the hypoxic ventilatory response are increased in rats exposed to chronic intermittent hypoxia (CIH). Increased carotid body sensitivity and central neural integration of carotid chemoafferent neurons are both implicated in these forms of plasticity. Another unique form of plasticity revealed in rats pretreated with CIH is sensory LTF. Following acute intermittent hypoxia in normal rats, carotid body activity increases during hypoxic episodes, but returns to baseline activity shortly thereafter; thus, acute intermittent hypoxia does not elicit long-lasting facilitation of carotid chemosensory activity in normal rats. However, acute intermittent hypoxia induces a long-lasting facilitation of carotid chemosensory activity in rats pretreated with CIH (i.e., sensory LTF). Sensory LTF requires reactive oxygen species generation during CIH and is a serotonin-dependent mechanism.

CIH also elicits metaplasticity, or plasticity in the ability to express plasticity. For example, CIH pretreatment attenuates PHFD and enhances phrenic LTF following acute intermittent hypoxia. Enhanced LTF following CIH is a serotonin-dependent mechanism, but different serotonin receptor subtypes are involved; enhanced LTF requires the activation of both 5-HT_{2A} and 5-HT_7 receptors. Enhanced LTF may reflect combined mechanisms of sensory LTF and normal phrenic LTF, although this hypothesis is untested.

Ventilatory Acclimatization to Chronic Sustained Hypoxia

At the start of sojourn to altitude or chronic sustained hypoxia, the acute increase in ventilation is followed by a slow, time-dependent increase over hours to days, a phenomenon known as ventilatory acclimatization to chronic hypoxia (VACH; Figure 3). VACH mitigates the severity of hypoxia at altitude, but the costs are worsening hypocapnia and respiratory alkalosis. The primary mechanism of VACH appears to be carotid body plasticity. During chronic hypoxia, the carotid body hypertrophies and increases its hypoxic sensitivity, contributing to increased ventilation. When hypoxia persists for days to weeks, NTS relay neurons also exhibit plasticity, accentuating an already elevated input from carotid chemoafferent neurons. When normal O_2 is restored following chronic hypoxia, ventilation only gradually returns to baseline levels, with a time course similar to the onset of VACH, most likely reflecting the reversal of VACH.

Developmental Plasticity in Ventilatory Control

Similar to other neural systems, experiences during development can have lifelong impact on ventilatory control. These effects are often unique to a critical developmental period. For example, when newborn rats are exposed to modest hyperoxia (30–60% O_2) during the first 4 weeks of life, normal carotid body development is suppressed, causing (1) carotid body hypoplasia, (2) decreased chemoafferent neuron counts in the carotid sinus nerve, (3) blunted carotid body responses to stimulation, and (4) blunted hypoxic ventilatory responses in adult rats (Figure 6). There is no evidence for abnormal central neural integration of chemoafferent inputs. Long-lasting effects are not observed when adult rats receive similar hyperoxic exposures, demonstrating that the plasticity is unique to development. With time, rats exposed to perinatal hyperoxia experience slow, spontaneous recovery or lifelong functional deficits, depending on the duration of hyperoxic exposure; rats exposed to 1 week of perinatal hyperoxia recover, whereas those

Figure 6 Developmental plasticity of the hypoxic ventilatory response and carotid chemoreceptors in rats exposed to perinatal hyperoxia. Left: The hypoxic ventilatory response is diminished in adult rats that received moderate hyperoxia (60% O_2) during the first four postnatal weeks. Suppression of the adult hypoxic ventilatory response arises from abnormal carotid body chemoreceptor development. Photomicrographs: Carotid bodies in a control rat (middle) and a rat exposed to hyperoxia for the first two postnatal weeks (right; PTR, perinatal treated rat). Images were captured at 200 . Green fluorescence indicates staining for tyrosine hydroxylase, which identifies carotid body glomus cells. Carotid body hypoplasia is associated with decreased axon counts from chemoafferent neurons in the carotid sinus nerve, and diminished carotid sinus nerve responses to hypoxia or intravenous cyanide. Image's provided courtesy of Wang ZY, collected during the study of Wang ZY and Bisgard GE (2005) Postnatal growth of the carotid body. *Respiratory Physiology & Neurobiology* 149: 181–190; graph drawn after Ling L, Olson EB, Vidruk EH, et al. (1997) Developmental plasticity of the hypoxic ventilatory response. *Respiration Physiology* 110: 261–268.

exposed for 4 weeks do not. The mechanism of impaired carotid chemoreceptor development with perinatal hyperoxia is not known, but it does not appear to be overt oxygen toxicity. Suppressed carotid body activity during hyperoxia may suppress the synthesis of neurotrophic factors necessary for developmental cellular hypertrophy and the attachment of chemoafferent neurons to glomus cells.

Modulation and Plasticity of the Exercise Ventilatory Response

The exercise ventilatory response undergoes plasticity. The best studied example is with increases in respiratory dead space, as would occur with impaired pulmonary gas exchange. Increased dead space diminishes alveolar ventilation and, consequently, increases resting ventilation via negative feedback from CO_2 chemoreceptors. However, with the onset of exercise, the ventilatory response is augmented by a mechanism that does not require changes in chemoreceptor feedback from rest to exercise. The augmented exercise ventilatory response is known as short-term modulation, and requires spinal serotonin receptor activation. During exercise with increased dead space, spinal serotonin receptor activation may increase respiratory motoneuron excitability, thereby enhancing the feed-forward exercise stimulus at the level of respiratory motoneurons (Figure 4). If the dead space is removed after a single exercise trial, the exercise ventilatory response reverts quickly to normal. However, with repeated trials of exercise with increased dead space, a form of plasticity known as long-term modulation is observed. Long-term modulation is a prolonged augmentation of the feed-forward exercise stimulus that lasts for many trials (or hours) after the dead space has been returned to normal. Long-term modulation is serotonin dependent, and may reflect a more robust response to the same stimuli initiating short-term modulation.

Age, Sex, and Genetics Influence Ventilatory Control

Important changes occur in ventilatory control from neonatal development through old age, and these changes are modulated by sex hormones. For example, sex hormones modulate resting ventilation and chemoreflexes during pregnancy. Respiratory plasticity is also influenced by sex hormone changes with aging. In female rats, respiratory LTF increases with age, from young adults to middle age, and then decreases in geriatric rats that have become acyclic. In contrast, LTF is greatest in young male rats, but decreases considerably by middle age; this effect appears to result from age-associated decreases in testosterone-derived CNS estrogen levels.

Ventilatory control is also influenced by genetics. Indeed, transgenic and knockout mice often exhibit interesting respiratory control phenotypes. Of particular interest are those with known associations to human disease (e.g., MeCP2, SOD-1, and leptin). Even normal animals exhibit variability in respiratory control. For example, different rodent strains vary in their hypoxic and hypercapnic ventilatory responses and their expression of respiratory plasticity. Genetic influences on the neural control of breathing remain an important area for future research.

Disorders of Ventilatory Control

Ventilatory control disorders have major human health consequences and are the cause of severe morbidity and

mortality. Some disorders are specific deficits in the ventilatory control system. Other ventilatory control disorders are associated with less specific neurological diseases or injury, and may exacerbate their clinical presentation and/or end life.

Sleep-Disordered Breathing

Sleep-disordered breathing is characterized by repetitive periods without breathing (apnea) and may be particularly prevalent during specific stages of development or aging. Morbidities due to intermittent hypoxia associated with sleep apnea include pulmonary and systemic hypertension, insomnia, depression, learning deficits, hippocampal apoptosis, and hyperactivity in children. Apneas during sleep result from (1) central apneas due to lack of effort and (2) obstructive apneas due to upper airway collapse, preventing breathing despite continued effort. While the mechanistic basis of central sleep apnea is unclear, deficits in brain stem respiratory neurons are often indicated. Central sleep apneas result from neurological diseases (e.g., tumors, traumatic brain stem injury, infectious diseases), circulatory disorders (e.g., congestive heart failure, arteriosclerosis), and sleep at altitude. The latter is characteristic of even normal humans and contributes to acute mountain sickness.

Obstructive sleep apnea (OSA) is the most common ventilatory control disorder in both children and adults. Snoring and excessive sleepiness are important clinical signs indicative of OSA; however, most cases of OSA remain undiagnosed. A strong influence of sex hormones is indicated, since OSA occurs in at least twice as many men as women. OSA is most frequent in middle-aged men, postmenopausal women, and children. Although obesity and congenitally narrowed airways are associated with OSA, diminished modulatory influences on upper airway motoneurons may predispose the upper airway to narrowing or collapse.

Developmental Disorders

Apnea of prematurity and sudden infant death syndrome (SIDS) are relatively frequent in the pediatric population. Apnea of prematurity is characterized by both central and obstructive apneas and is due to an immature respiratory control system. SIDS is characterized by a complete cessation of breathing during the first year of life (particularly during sleep) and is strongly associated with abnormalities in the raphe serotonergic system.

Traumatic and Ischemic Neural Injury

Traumatic or ischemic injury may impair neurons or synaptic inputs to the VRC or respiratory motoneurons. For example, spinal injury interrupts descending projections from brain stem premotoneurons to spinal motoneurons or interneurons. Of particular importance, high cervical spinal injuries interrupt the ability of phrenic motoneurons at cervical spinal levels C3–C6 to drive the diaphragm (and other respiratory muscles innvervated by more caudal spinal segments). Thus, patients with high cervical spinal injuries often die of respiratory insufficiency. Patients with spinal injuries below the cervical spinal cord generally have a normal breathing pattern at rest, but may have impaired breathing during increased respiratory drive or in respiratory defense reflexes such as coughing. Since most spinal injuries are incomplete, one goal of current research is to strengthen spared synaptic pathways to induce at least partial functional recovery.

Neurodegenerative Diseases

Ventilatory insufficiency and sleep apnea are significant complications in many neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS), Parkinson's disease, Huntington's disease, multiple sclerosis, multiple system atrophy, and Alzheimer's disease. Motoneuron disease causes the progressive death of respiratory motoneurons, leading to ventilatory failure; to preserve function, surviving motoneurons must carry a greater load. Less frequently appreciated, more than 50% of patients with Parkinson's, Alzheimer's, and other neurodegenerative diseases experience severe sleep apnea.

Genetic Diseases

Patients with congenital central hypoventilation syndrome (CCHS), Rett syndrome, and Down syndrome have severe abnormalities in the control of breathing. CCHS is characterized by poor or complete lack of automatic breathing mechanisms during sleep and is associated with mutations in the homeobox gene, *Phox2B*. Rett syndrome is associated with mutations in MeCP2, a regulator of gene expression (including BDNF). Patients with Rett syndrome experience alternating episodes of hyperventilation and central apneas (i.e., breath holding) during wakefulness. MeCP2 mutations cause abnormalities in noradrenergic neurons, an effect that may explain at least some ventilatory control abnormalities experienced by these patients. Down syndrome is caused by an extra copy of chromosome 21 and is associated with a high (>50%) incidence of OSA, likely due to craniofacial abnormalities and/or deficits in the serotonergic system. Repetitive intermittent hypoxia during development may contribute to learning deficits in these patients.

Psychiatric Disorders

Anxiety hyperventilation disorder is a frequent affliction in the pediatric population (~6%) and in patients with prior psychological stress. Although the mechanisms of anxiety hyperventilation are not known, most treatments are based on manipulation of the serotonergic nervous system. Neonatal stressors, such as maternal separation in rodents, can have a lifelong impact on adult chemoreflexes and ventilatory control.

Ventilatory Control during Lung Disease

During lung and/or chest wall diseases, mechanics of the respiratory system change, requiring major adjustments in respiratory motor output. With increased lung compliance or lower chest wall compliance (e.g., emphysema and scoliosis), shifts in the balance between diaphragmatic and inspiratory intercostal muscle contractions are necessary to achieve adequate ventilation. With increased airway resistance, greater respiratory muscle contractions are necessary. When mechanical disturbances exceed the ability to compensate, ventilatory failure results.

Common Features of Ventilatory Control Disorders

Ventilatory control adjustments during disease require a robust and flexible neural control system. Since similar network and cellular mechanisms compensate during multiple breathing disorders, common therapeutic approaches to seemingly disparate diseases may be possible. For example, respiratory disorders caused by cervical spinal injury, ALS, and OSA share (relative) deficits in respiratory motoneuron output. Since they share a common need for increased motor output to respiratory muscles, therapeutic approaches designed to strengthen synaptic inputs to respiratory motoneurons may be useful. Disorders leading to central apneas suggest defects in respiratory rhythm generation. Thus, drugs that stimulate respiratory rhythm generation may prove useful. Although our understanding of detailed cellular, synaptic and network mechanisms is rudimentary at best for any ventilatory control disorder, an understanding of promising molecular targets may lead to the development of new therapeutic strategies for devastating respiratory control disorders for which there are few effective treatments and no known cures.

Restless Leg Syndrome

S L Clardy and J R Connor, Pennsylvania State University Milton S. Hershey Medical Center, Hershey, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Restless legs syndrome (RLS) is characterized by dysthesias and an irresistible urge to move the lower limbs. RLS sensations generally occur when the sufferer is at rest, and they are relieved by voluntary movement. Attempting to suppress the dysthesias only increases patient discomfort, often making activities such as plane travel or dining out extremely unpleasant. A circadian pattern characterizes RLS, with symptoms worsening in the evening. The prevalence of RLS in Western countries is estimated to be 7.2%, making it a common disorder of the adult population. The prevalence is approximately twice as high for women as for men, and the percentage of the population with RLS increases with age.

RLS can be broadly classified into two categories, as outlined in (Figure 1): primary, with no known relation to another disorder, or secondary, with the symptoms attributable to another medical condition. Major causes of secondary and reversible RLS include pregnancy, iron deficiency, and end stage renal disease both before and after dialysis treatment. Approximately 25–40% of patients with any of these three conditions report RLS, which is approximately three to five times the expected occurrence for adults. Generally, RLS dramatically improves with the effective treatment or resolution of these primary conditions. It is unclear if there is an association between RLS and neuropathy or Parkinson's disease. Some studies also suggest that RLS may be associated with essential tremor in some families. Limited studies have also demonstrated that attention-deficit hyperactivity disorder (ADHD) also appears to be associated with RLS in children and adults and possibly with RLS in the parents of children with ADHD.

Primary RLS onset can occur at almost any age, with symptom onset classified as early onset if symptoms begin before age 45 years and as late onset if symptoms begin after the age of 45 years. When symptoms begin before the age of 45 years, they are generally slowly progressive, with the expression of the most severe symptoms occurring mainly in adults older than age 50 years. The first-degree relatives of patients whose onset of symptoms occurs before age 45 years are five times more likely to have RLS than the general population.

The accepted diagnostic criteria for primary RLS are based on the following clinical symptoms: (1) an urge to move the extremities, usually the legs, frequently accompanied by dysthesias; (2) onset or exacerbation of symptoms when at rest; (3) relief of the urge to move or unpleasant sensations with movement; and (4) symptoms have a marked circadian pattern, becoming worse at night or only occurring at night. The circadian cycle of RLS symptoms is a primary effect and not secondary to more rest activity during the night. Symptom severity varies widely, and for more severely affected patients, the agony of the sensations may eventually continue through both the day and the night (but the worsening at night must have been previously present to meet the diagnostic criteria). Total daily sleep times are often reduced to 5 h or less, with marked reduction of sleep efficiency.

Sleep deprivation is a common feature of the RLS population, an observation consistent with reports of a circadian rhythm to the symptoms onset and severity (e.g., worsening of symptoms at night). Indeed, a significant number of RLS sufferers are initially diagnosed based on interviews with the patient's bed partner. RLS sufferers are sleep deprived not only because they have difficulty in sleep maintenance but also because they generally have a prolonged latency to sleep onset. This delayed sleep onset is not unexpected because attempting to relax triggers symptoms. Some RLS sufferers may also exhibit involuntary jerking movements, commonly of the legs. Such movements are referred to as dyskinesias while awake (DWA) and typically involve flexion of the leg, hip, knee, or ankle. The presence of DWA may be more specific for RLS than periodic leg movements. The majority of individuals with RLS exhibit periodic limb movements of sleep (PLMS). These are repetitive movements that occur during the period of nonrapid eye movement sleep. When severe, PLMS can disrupt sleep. PLMS increase in prevalence with age, and thus a finding of PLMS in a younger patient is more suggestive of RLS than such a finding in an elderly patient. PLMS occur in 70–90% of RLS patients, although at most, only 30% of patients with PLMS will have RLS.

A specific gene mutation has not been found in RLS despite a considerable amount of research in recent years. Three different loci for RLS have been reported on chromosomes 12q, 14q, and 9p and are referred to as RLS-1, RLS-2, and RLS-3, respectively, as outlined in (Figure 2). RLS-1 was mapped to a French–Canadian family assuming a recessive model of inheritance with a possible pseudodominant appearance, whereas RLS-2 (found in a north Italian family) and RLS-3 (discovered in an American family) mapping was based on an autosomal dominant mode of inheritance. The significance of these three loci is not fully

Figure 1 Primary and secondary restless legs syndrome.

understood, and further investigations of different RLS families are needed to confirm the significance of the loci and possibly identify additional loci in RLS. The genetics of RLS are further complicated by reports of RLS in familial forms of other diseases, such as Charcot–Marie–Tooth type 2 and autosomal dominant-type cerebellar ataxia, as well as case reports and studies suggesting a predilection for mother-to-child transmission.

The current clinical data clearly support a role for the dopaminergic system in this disorder. Dopamine antagonists can aggravate RLS or induce a focal akathesia clinically similar to RLS. Early clinical studies indicated that RLS was dopamine responsive. Subsequently, low-dose levodopa treatment was found to be significantly more effective than the relatively high doses of opiates that had previously been used to treat RLS. Levodopa was one of the first drugs to be proven efficacious in placebo-controlled trials. Treatment with levodopa is greatly limited, however, by augmentation of symptoms, including onset of RLS symptoms earlier in the evening compared to pretreatment onset, involvement of other body parts, and/or increased severity. In 2005, the dopamine agonist ropinirole (Requip) became the first Food and Drug Administration-approved medication for the treatment of moderate to severe primary RLS (15 or more episodes monthly). Consistent with the clinical observations, some brain imaging studies of RLS patients have shown striatal dopamine abnormalities. Not all studies have found striatal abnormalities, however, and none of the studies were done in the evening, when subjects are symptomatic. It is possible that variable symptom expression could account for the conflicting findings, underscoring the need for evaluation of subjects during the symptomatic period. An autopsy report has identified the first direct evidence for a dopaminergic involvement in RLS.

Opioids, benzodiazepines, carbamazepine, valproic acid, gabapentin, clonidine, iron, and magnesium have all been reported to be beneficial in the treatment of RLS, but experience with these drugs is limited. Nonpharmacologic treatments include improved nutrition, exercise, and sleep hygiene. Additionally, many patients tend to find that engaging in a mental activity requiring concentration, such as painting or computer programming, alleviates symptoms. Caffeine, antihistamines, and cold preparations have been reported to aggravate symptoms, whereas alcohol may offer a brief reduction in symptoms but with rebound worsening of symptoms.

Figure 2 Genetics and pathophysiology of restless legs syndrome.

Although much of the clinical intervention for RLS has focused on the dopaminergic system, there is a growing body of literature that suggests a significant role for iron. Iron is a cofactor for tyrosine hydroxylase, which in turn is the rate-limiting enzyme for dopamine metabolism. Iron deficiency has been recognized as a significant contributing cause of RLS for approximately 50 years. Oral iron supplementation has been shown to improve symptoms in some RLS patients, but the uptake of iron is limited by the rate of absorption from the gut. Intravenous iron injection eliminates this barrier to absorption, and as shown by Nordlander, multiple, low-dose, intravenous iron therapy brought about complete relief of symptoms in 21 of 22 RLS patients for periods of up to 3–9 months, even though the majority had normal iron status prior to treatment. Earley et al. demonstrated symptomatic improvement for an average of 6 months in a small number of RLS patients after a 1000-mg injection of iron dextran. Furthermore, they demonstrated that repeated infusions of 450 mg iron gluconate provided additional months of relief. The rate of serum ferritin excretion in the subjects was much greater than predicted after the first ferritin injection, but the excretion rate decreased with subsequent injections. The elevated loss of ferritin in RLS patients may suggest part of the mechanism by which iron contributes to the biology underlying this disorder. In support of this idea, a strong negative correlation between serum ferritin levels and RLS symptom severity has been observed.

Low iron in the central nervous system in RLS may be more important than low iron levels in serum in RLS pathophysiology because low central nervous system iron storage may directly result in reduced dopamine synthesis and/or receptor function. Early onset RLS is associated with significant decreases in several iron-related proteins, including whole-molecule ferritin, H-ferritin, L-ferritin, and pro-hepcidin in cerebrospinal fluid (CSF). Late-onset CSF values in RLS subjects, however, are not significantly decreased compared to controls. Analyses of the CSF in RLS have provided compelling evidence for disruption of brain iron homeostasis in RLS.

Additionally, there is a strong correlation between the age of symptom onset and CSF ferritin values such that the earlier the age of RLS onset, the lower the CSF ferritin level at the time of the study. These studies suggest that early and late-onset phenotypes may define two distinct disease processes.

Direct evidence of brain iron deficiency derives from a magnetic resonance imaging analysis that indicates brain iron levels in the substantia nigra are below normal in individuals with RLS. Both the substantia nigra and the putamen showed iron losses in proportion to RLS severity. Histopathological analyses and biochemical studies on autopsy material also provide support that the substantia nigra in RLS is iron deficient. Two autopsy studies have been performed, and neither found histopathological alterations that suggest a structural basis (e.g., plaques and Lewy bodies) for RLS. An intriguing observation is that a neuronal surface protein, Thy1, which is important for maintaining structural integrity of the synapse and promoting interaction of presynaptic vesicles with the synaptic membrane, is decreased in the substantia nigra of individuals with RLS and in animal models of iron deficiency. Thus, the working hypothesis for the biological basis for RLS is that it is a result of a hypofunctionality of the dopaminergic system that stems from insufficient amounts of brain iron. Autopsy studies on the dopaminergic parameters are under way.

A discussion on the biological basis would be remiss in not including the possibility of a spinal origin for RLS. Reports exist that individuals with RLS may have enhanced spinal excitability or diminished central inhibition. Animal experiments have clearly demonstrated that the spinal cord is intrinsically able to generate motor activity without descending input through a central pattern generator (CPG), thus raising the possibility that the pathophysiology of RLS may be independent of the brain. The existence of RLS in paraplegic patients supports the possible role of CPGs in humans. In RLS patients and spinal cord injury patients, there is also lower threshold and greater spatial spread of the flexor reflex. In RLS patients, this difference is more prominent during sleep, perhaps contributing to the nocturnal worsening of symptoms in RLS. Further evidence for spinal cord involvement in RLS derives from studies of task-dependent modulation. Motor activity modifies spinal reflex pathways, and this presynaptic control of sensory afferent inflow outlasts the period of motor activity by a few minutes. This could help to explain the temporary relief of dysthesias in RLS patients after movement. A study that lesioned the A11 dopaminergic diencephalic spinal neurons in rats found an increased number of standing episodes and increased total standing time (behaviors suggestive of RLS in an animal model) and a subsequent reduction in the total standing episodes and standing time in the lesioned animals after intramuscular pramipexole treatment. Within the spinal cord, there is an extensive dopaminergic system with roles in motor functions and sensorimotor integration, although the exact relevance is not fully understood, and thus it is not understood how levodopa and dopamine agonists affect spinal cord networks in RLS.

RLS is a common and likely underdiagnosed disorder that ranges in severity from irritating to debilitating. Current evidence suggests that primary RLS is a consequence of iron- and dopamine-related dysfunction in one or more locations in the central nervous system. Additional research is necessary to elucidate the specific pathophysiologic cause and the primary or initial location of the iron- and dopamine-related dysfunction, as well as the genetic inheritance and chromosomal linkage patterns. Nonetheless, data strongly support a biological basis for RLS and evidence is building against the early notion that RLS is a psychosomatic disorder.

Reticular Activating System

Introduction

Sleep and arousal states are characterized in the electroencephalogram (EEG) by synchronization of slow rhythms during slow-wave sleep and synchronization of fast rhythms during waking and rapid eye movement (REM) sleep. These rhythms are generated by reverberating oscillations between the thalamus, hypothalamus, and basal forebrain and the cortex. The reticular activating system (RAS) serves to modulate these oscillations (ascending inhibition or decreased excitation will serve to slow these rhythms, whereas ascending excitation or disinhibition will speed up rhythms) depending on sensory inputs and ongoing activity. In addition, descending modulation of motor neurons serves to decrease muscle tone during REM sleep (atonia) or prime the system to fight or flee during waking by modulating the startle response.

Wiring Diagram

RAS is composed of three main cell groups: the pedunculopontine nucleus (PPN) (and its medial partner, the laterodorsal tegmental nucleus, both of which are mainly cholinergic), the locus coeruleus (LC; mainly noradrenergic), and the raphe nucleus (RN; mainly serotonergic). RAS receives input from all afferent sensory systems in parallel to primary afferent sensory projections. That is, the 'nonspecific' projection system through RAS relays 'arousal' information via the intralaminar thalamus (ILT) to the cortex. This system functions in parallel with the flow of 'specific' sensory input through the primary sensory thalamic nuclei that is then relayed to the cortex. It is the temporal summation of ILT nonspecific inputs with primary sensory specific inputs at the level of the cortex that is thought to participate in the conscious perception of a sensory event. Disturbances in RAS driving of the ILT and thalamocortical oscillations thus can be expected to lead to disturbances in perception.

RAS also sends descending projections to posture and locomotion systems that act as the 'fight-or-flight' system, simultaneously activating higher centers while priming motor systems to respond appropriately to sudden stimuli. These descending projections modulate the pontine inhibitory area (PIA) that controls the atonia of REM sleep, pontine neurons that generate the startle response (a flexor response that primes the motor system), and reticulospinal systems that drive locomotion. RAS, especially cholinergic, projections to the dorsal subcoeruleus region also trigger the generation of ponto-geniculo-occipital (PGO) waves during REM sleep. This region generates high-frequency bursts of activity (such as those required for long-term potentiation) that have been proposed to participate in sleep-dependent plasticity.

The hypothalamic sleep–wake modulatory system is composed mainly of the tuberomammillary nucleus (TMN; mainly excitatory histaminergic), the lateral hypothalamus (LH; mainly excitatory orexinergic), and the ventrolateral preoptic nucleus (VLPO; mostly inhibitory GABAergic). These hypothalamic systems are thought to help stabilize sleep–wake states. Excitatory LH orexin projections can be thought of as an 'on' switch promoting waking, particularly through activation of excitatory TMN neurons, which are tonically active during waking (and decrease firing during sleep), and of excitatory basal forebrain and RAS neurons. The basal forebrain cholinergic system is mainly active during waking and serves to raise the excitability of the cortex, although acetylcholine release from the basal forebrain is greater during REM sleep than during waking. Inhibitory VLPO GABAergic projections can be thought of as an 'off' switch promoting slow-wave sleep through inhibition of RAS, LH, basal forebrain, and cortex.

Figure 1 outlines the main projections described previously. The dorsal ascending cholinergic (PPN) and monoaminergic (LC and RN) projections from RAS to ILT serve to activate the cortex via thalamocortical projections. There is also a ventral projection system that bypasses the thalamus to terminate diffusely throughout the cortex that originates in RAS (noradrenergic LC and serotonergic RN) and ascending projections from TMN, LH, and VLPO (Figure 1, VP), as well as from the basal forebrain (not shown). In turn, TMN, LH, and VLPO send descending projections to RAS that may act reciprocally to stabilize sleep–wake states.

In addition, adenosine (Figure 1, A; diffusely localized) is a ubiquitous homeostatic factor believed to be involved in sleep–wake regulation. High metabolic activity or prolonged wakefulness leads to a buildup of adenosine, which decreases subsequent to sleep. Adenosine may also modulate sleep–wake states via its inhibitory actions on most cells. Adenosine injections into RAS are known to decrease waking, whereas adenosine levels in the basal forebrain (but not in the thalamus) progressively increase during

Figure 1 Main ascending projections of the reticular activating system. A, adenosine; ILT, intralaminar thalamus; LC, locus coeruleus; LH, lateral hypothalamus; PPN, pedunculopontine nucleus; RN, raphe nucleus; TMN, tuberomammillary nucleus; VP, ventrolateral preoptic nucleus.

prolonged wakefulness and decrease during subsequent recovery of sleep.

Figure 2 shows the connectivity of neurons within RAS and their firing patterns during sleep and waking. RN inhibits PPN and LC, and LC inhibits PPN, whereas PPN activates LC. During waking, all three cell groups are active, but in slow-wave sleep the cholinergic cells decrease firing while monoaminergic cells remain active. However, in REM sleep, the cholinergic cells are highly active while monoaminergic cells decrease their firing rates markedly, thereby disinhibiting cholinergic cell groups. Thus, cholinergic RAS neurons are active during waking and REM sleep (i.e., during synchronization of fast cortical rhythms) but slow their firing during synchronization of slow cortical rhythms in slow-wave sleep.

Intrinsic Properties

Neurons in the region of PPN have been reported to show 'wake-on,' 'REM-on,' and 'wake-REM-on' firing patterns whose properties are implied by their names. It is not clear how these patterns correspond to intrinsic membrane properties. There are three types of PPN neurons based on intrinsic membrane properties: type I have low-threshold spike (LTS) calcium-dependent inward currents, are noncholinergic, and tend to burst especially when released from hyperpolarization; type II have Ia transient outward potassium currents, are mostly cholinergic, and tend to fire slowly and tonically; and type III have both LTS and Ia currents, are mainly noncholinergic, and fire tonically and in bursts. A large proportion of these cells also have hyperpolarization-activated Ih currents that tend to restore the membrane potential following hyperpolarization. Evidence suggests that at least some neurons in PPN, possibly GABAergic, are electrically coupled, promoting ensemble activity. Cholinergic RAS neurons are active tonically during waking depending on the level of depolarization. In a slightly hyperpolarized state, some of these cells show LTS bursts, perhaps corresponding to the bursting activity observed during REM sleep. Then, further hyperpolarization leads to cessation of firing, as in slow-wave sleep. During moderate inhibition, PPN neurons thus may undergo a change from tonic to bursting activity such as that observed in waking versus REM sleep.

LC and RN cells fire relatively slowly during slow-wave sleep, cease firing during REM sleep (disinhibiting PPN cells), and are most active and variable during waking, particularly in response to novel stimuli. LC neurons show electrotonic coupling, which allows them to act as a group. Therefore, a novel stimulus could elicit a synchronized response from this population of neurons. However, recurrent inhibition follows such activation so that the initial response is quickly followed by inhibition of further output. RN cells are similar to LC neurons in that many of the conductances of these neurons tend to limit the firing rate (e.g., long-duration action potential and high-amplitude afterhyperpolarizations). It has been postulated that during waking serotonin inhibits REM-on neurons without affecting wake-REM-on neurons, thereby allowing synchronization of fast rhythms; however, these slow down during REM sleep, thus disinhibiting REM-on, presumably bursting, neurons to promote REM sleep. In general, noradrenergic and serotonergic neurons have high input resistance so that relatively small currents (such as those elicited by marginal inputs) will elicit considerable changes in membrane potential. There are also both excitatory and inhibitory interneurons (GABAergic) and projection (glutamatergic) neurons intermingled within all RAS cell groups.

Descending cholinergic projections to the subcoeruleus region affect several types of neurons, including cells with LTS currents, Ia currents, and LTS and Ia currents – similar to the types found in PPN. Electrical coupling appears to be more common in this region, mainly among GABAergic neurons that are induced to fire rhythmically at theta rhythm by cholinergic agonists. Such rhythmic coherent activation may underlie the mechanism behind REM sleep and perhaps PGO wave generation.

Transmitter	Waking	SWS	REM
Acetylcholine	+− (tonic)	−	+− (burst)
Catecholamine	+−	+	−

Ascending Effects

Waking and the 40 Hz Rhythm

The waking state is characterized by fast EEG oscillations in the 15–60 Hz range. The waking EEG is of low amplitude and composed of synchronization of fast rhythms or of high frequencies >15 Hz. Faster rhythms appear upon arousal and occur mainly in the 35–45 Hz range during selective attention to sensory input, referred to as the '40 Hz rhythm.' This rhythm is thought to be generated by cortical neurons receiving inputs from thalamocortical specific and nonspecific nuclei, such that the specific inputs to cortex provide the content of cognition (via input through primary sensory pathways), whereas the nonspecific inputs provide the context (via ILT), with their coherence providing the temporal binding required for the unity of cognitive experience.

The mechanism behind the 40 Hz rhythm appears to include layer IV cortical inhibitory interneurons, which exhibit a sequential activation of a persistent low-threshold sodium current followed by a subsequent potassium conductance. These cells can transmit the 40 Hz rhythm onto thalamic cells, allowing the entrainment of thalamocortical resonance. This 'ringing' is thought to be the basis of conscious perception so that for a transient sensory input to be perceived or consciously appreciated, it must generate a lasting reverberation or reentrant signaling in thalamocortical systems. RAS modulates these oscillations through its ascending projections (Figure 1).

The process of awakening entails two stages: a rapid (5 min) reestablishment of consciousness that is marked by increases in cerebral blood flow in RAS and thalamus, followed by a slower (15 min) increase in cerebral blood flow, primarily in anterior cortical regions. It should also be noted that cholinergic RAS neurons have some of the highest concentrations of nitric oxide synthase in the brain. Therefore, wherever PPN projects, a corollary effect may include vasodilation and other processes modulated by nitric oxide.

Slow-Wave Sleep

This state is characterized by high EEG with synchronization of low frequencies <15 Hz. These oscillations include spindles (7–14 Hz), delta waves (1–4 Hz), and slow oscillations (<1 Hz). This state is marked by decreases in cerebral blood flow throughout the brain, especially in RAS, thalamus, hypothalamus, and basal forebrain. It is characterized by decreased activity of cholinergic RAS, basal forebrain neurons, LH orexinergic cells, and TMN histaminergic cells.

The main excitatory projection systems decrease their outputs during slow-wave sleep.

Spindles Spindles are present early in sleep and the inhibition they promote basically deafferents the cerebral cortex (primary sensory pathways are gated), which may be a prerequisite for falling asleep. The reticular nucleus of the thalamus is thought to be the main cell group generating spindles, which result from bursting in a syncitium of electrically coupled reticular nucleus neurons that produce synchronized inhibitory postsynaptic potentials in thalamocortical neurons. These lead to postinhibitory rebound bursts that are relayed to cortex, producing slow, rhythmic, excitatory postsynaptic potentials. Spindles begin to occur as brain stem cell groups, particularly cholinergic RAS neurons, diminish their firing rates, disinhibiting reticular nucleus neurons.

Delta waves Delta waves increase gradually as slow-wave sleep deepens. These waves are generated by cortical and thalamocortical neurons that are synchronized by inhibitory reticular nucleus neurons and scattered dorsal thalamic cells. They represent waveforms elicited at a more hyperpolarized membrane potential than spindles so that as slow-wave sleep deepens, the occurrence of spindles decreases, whereas that of delta waves increases. These waves mark the virtual cessation of activity in mesopontine cholinergic cells.

Slow waves Slow waves appear to be generated spontaneously in cortical neurons, but this rhythm is also present in thalamic reticular nucleus neurons. All major classes of cortical cells display slow waves. The slow depolarization of these neurons corresponds to the depth-positive EEG wave, whereas their hyperpolarization corresponds to the depth-negative EEG wave. Because of the widespread synchronization of slow waves in cortical neurons, it is likely that thalamic neurons, specifically inhibitory reticular thalamic cells, help entrain these slow oscillations.

REM Sleep

Every 90 min during sleep, slow rhythms are interrupted by fast oscillations triggered by cholinergic mesopontine cell groups that induce REM sleep. The EEG displays low-amplitude synchronization of fast oscillations identical to those in the waking state. This 'paradoxical' state is accompanied by eye movements, contains most of our dreaming time, and leads to a decrease in skeletal muscle tone or atonia. The atonia is particularly strong on antigravity muscles, whereas the diaphragm and extraocular muscles retain substantial tone. REM sleep is characterized by increased blood flow in RAS, thalamus, anterior cingulate, and other cortical areas, with decreases in blood flow in the dorsolateral prefrontal cortex. It has been proposed that the unregulated (by other RAS nuclei) activity of RAS cholinergic cells is responsible for REM sleep and, via unknown mechanisms, for decreased frontal lobe blood flow. The 'hypofrontality' of REM sleep may account for the lack of critical judgment during dreaming (and during hallucinations).

In advance of and during REM sleep, paroxysmal events called PGO waves can be detected in the brain stem, the lateral geniculate nucleus, and occipital cortex, and they appear to be due to bursting activity in brain stem nuclei, including the PPN and especially the subcoeruleus. Interestingly, the 40 Hz cortical oscillation evident in waking is also present during REM sleep; however, it does not appear to be reset by sensory input, despite the fact that specific primary sensory thalamic systems are not gated. This suggests that the intrinsic activity of the brain does not place sensory input in the context of the functional state being generated by the brain. That is, REM sleep may be a state of intrinsic activity in which external sensory input cannot access thalamocortical reverberation or conscious experience.

It should be noted that transitions in state from waking to slow-wave sleep, or from slow-wave sleep to REM sleep, are gradual. During these transitions, waveforms characteristic of more than one state appear intermingled in the EEG. The frequency of these events increases until the new state is fully expressed. It appears that new states are gradually recruited rather than elicited instantaneously.

Muscle Tone and Locomotion

RAS is a phylogenetically conserved system that modulates fight-or-flight responses. During waking, our ability to detect predator or prey is essential to survival. RAS is linked to the motor system in order to optimize attack or escape. During REM sleep, atonia keeps us from acting out our dreams. Only our diaphragm and eye muscles appear to be acting out dream content. During waking, RAS can modulate muscle tone and locomotion via reticulospinal systems. For example, in a standing individual, there is tonic activation of antigravity, mainly extensor, muscles. Before the first step can be taken, there must be flexion (i.e., a release from extensor bias). The startle response, a rapid response to a supramaximal stimulus, is basically an induced flexor response, placing the body in a 'ready' position. The startle response is composed of a short latency

activation of muscle activity (the ready condition), followed by a brief inhibition (the 'reset' state) and then a long latency activation (the 'go' condition). The intermediate latency inhibition is thought to be part of the modulation of the startle response by cholinergic RAS neurons, and it may represent a 'resetting' of motor programs which allow the subsequent selection of response strategies – the triggering of attack or escape movements.

There appear to be multiple descending pathways by which RAS modulates muscle tone and locomotion. PIA can be activated by cholinergic agonists to induce REM sleep with atonia and PGO waves. Lesions of this region produce an animal exhibiting REM sleep without atonia, although such lesions may damage passing axons. Presumably, outputs from this region activate reticulospinal systems that lead to profound hyperpolarization of motor neurons, which is the mechanism responsible for the atonia of REM sleep. Cholinergic projections to the medioventral medulla appear to elicit increases in muscle tone and controlled locomotion. Outputs from this region activate reticulospinal systems that trigger spinal pattern generators to induce stepping. Electrical stimulation of the pontine and medullary reticular formation is known to induce decreased muscle tone at some sites while producing stepping movements at other sites. This suggests the presence of a heterogeneous, distributed system of muscle tone and locomotor control.

Neuropharmacology of Sleep and Arousal

Alcohol

Direct effects of alcohol on sleep–wake control regions appear to involve potentiation of GABAergic transmission. Significant impairment in motor performance, such as driving, occurs at very low blood alcohol concentrations, an effect potentiated by sleep deprivation or sleep loss. Most alcoholic patients suffer from insomnia, which is clinically important since alcoholism can exacerbate the adverse consequences of insomnia, such as mood changes and anxiety, and because insomnia has been associated with alcohol relapse.

Anesthetics and Sedatives

The proposed mechanisms of action of anesthetics have typically involved a number of cellular effects at different sites. Evidence suggests that the primary site of action of most anesthetics may be the sleep–wake control system. The parallel manifestations between sleep and anesthesia suggest that anesthetics basically 'hijack' the sleep–wake control system to induce anesthesia.

Most anesthetics, including barbiturates, etomide, propofol, neuroactive steroids, and volatile anesthetics, act on $GABA_A$ receptors, among others. Sedation and natural sleep occur mostly as a result of enhanced GABAergic transmission, which in turn affects the release of a number of excitatory transmitters, such as acetylcholine, excitatory amino acids, and histamine. These actions may take place specifically in such regions as RAS, TMN, and basal forebrain (all of which have local circuit GABAergic neurons and receive GABAergic input from VLPO), thereby regulating the level of arousal.

Interestingly, halothane and propofol appear to block gap junctions, and oleamide, which promotes sleep, is also known to block electrical coupling. Anandamide, which enhances adenosine levels to promote sleep, can block gap junctions. Carbenoxolone, a putative gap junction blocker, is known to decrease gamma band oscillations (high-frequency EEG), whereas connexin 36 (the neuronal gap junction protein) knockout mice exhibit low gamma band power. These findings all support a role for electrical coupling via gap junctions in the control of sleep–wake states and their modulation by certain anesthetic agents.

The benzodiazepines act by binding to a site that modulates GABA receptors, especially $GABA_A$ receptors. These agents produce sedative, hypnotic, anxiolytic, and anticonvulsant activities. They act generally by amplifying GABAergic transmission, such that short-acting agents have been used to promote sleep in insomnia patients.

Antihistamines

Pathology and lesions of TMN cause hypersomnia (these neurons are highly active during waking). Histaminergic inputs to RAS suppress slow-wave sleep and promote waking, although they do not affect REM sleep significantly. Administration of antihistamines (histamine receptor blockers) results in sedation due to blockade of histaminergic inputs to RAS, basal forebrain, and/or LH.

Stimulants

The popularity of caffeine is related to its stimulant properties, which are mediated by its ability to reduce adenosine release in the brain. Caffeine appears to block adenosine A1 and A2a receptors, producing a psychomotor stimulant effect.

Amphetamine induces the release of monoamines, especially dopamine, but also blocks reuptake and may have neurotoxic effects on nigral neurons. Methylphenidate does not appear to have such neurotoxic

effects. Amphetamine psychosis occurs in two forms – acute intoxication after a single large dose (characterized by confusion and disorientation) and chronic abuse that produces a schizophrenia-like syndrome. The increased release of dopamine by amphetamine is considered a model of schizophrenia, and it led to the 'dopamine theory' of schizophrenia.

Modafinil is a newer stimulant that does not appear to act through dopaminergic mechanisms, and it has been found to be effective in the treatment of daytime sleepiness in patients with narcolepsy. Modafinil has also been reported to alleviate spatial neglect and to increase vigilance in stroke patients. This suggests that sensory neglect arising from stroke can be treated successfully by 'waking up' the involved cortex, implying that the consequences of stroke may be to decrease activity, blood flow, and/or metabolism, one or more of which modafinil may counteract.

Development

The human newborn sleeps 16 h per day – 8 h in REM sleep and 8 h in slow-wave sleep. Between birth and the end of puberty, there is a developmental decrease in REM sleep such that the adult has 1 h of REM sleep and 6 or 7 h of slow-wave sleep per day. That is, the decrease in REM sleep is replaced by a postpubertal increase in waking. During development, REM sleep may serve to direct brain maturation, providing endogenous stimulation at a time when the brain has little or no exogenous input. However, REM sleep is not essential for survival in the adult. REM sleep suppression does not lead to death or disease. Evidence suggests that a number of transmitter systems change during the developmental decrease in REM sleep and may modulate that decrease. In addition, levels of the gap junction protein connexin 36 are high before the developmental decrease (10 days in the rat) and are considerably lower at the end of the decrement (30 days in the rat). It thus appears that there is a large syncitium of coupled neurons which segregates into distinct functional networks with age; however, the capacity to revert to a developmental condition may be present in the adult, leading once more to increased REM sleep drive.

Arousal and Sleep Disorders

The connectivity of RAS shown in Figure 2 can be used to deduce the potential sites of dysregulation related to hypervigilance and increased REM sleep drive that are evident in depression, anxiety disorder, and schizophrenia.

The treatment of depression previously included tricyclic antidepressants that mainly blocked reuptake of noradrenaline and serotonin and blocked histamine and acetylcholine release, thus accounting for increased sleepiness. The selective serotonin reuptake inhibitors more selectively affect RAS by increasing the inhibition of PPN and LC neurons (Figure 2). It is not clear if the etiology of depression is related to disinhibition of PPN and LC by a decrement in serotonergic tone, although this would seem a likely origin for the sleep–wake disturbances seen in depression.

The treatment of anxiety disorder has involved the use of benzodiazepine amplification of GABAergic inhibition. In addition, the use of the α_2 receptor agonist clonidine produces anxiolytic effects, probably by inhibiting autoreceptors in LC and postsynaptic receptors in PPN, thus downregulating vigilance. The etiology of anxiety disorder has been proposed to include downregulation or degeneration of LC outputs (possibly induced by stress hormones), which would act to disinhibit PPN neurons.

The treatment of schizophrenia previously involved the use of the dopaminergic receptor blocker haloperidol, which induced tardive dyskinesia, among other side effects. Newer antipsychotics appear to block dopaminergic, noradrenergic, and serotonergic receptors. More striking antipsychotic effects resulted from the use of clozapine, which was designed as a muscarinic cholinergic blocker for the treatment of Parkinson's disease. A later generation agent that has maintained anticholinergic activity without this side effect is olanzapine. These agents appear to have partial penetrance at serotonergic, cholinergic, and dopaminergic receptors, basically reducing muscarinic cholinergic activation of the substantia nigra (SN), as well as partially blocking dopaminergic actions in the striatum. The etiology of schizophrenia has been suggested to include increased PPN output, accounting for marked hypervigilance and hallucinations (REM sleep intrusion into waking). Excessive PPN output would overactivate the SN and, in turn, increase striatal release of dopamine, complying with the dopamine theory of schizophrenia.

Disturbances in RAS function are evident in a number of parasomnias that are discussed in other articles in this encyclopedia. Suffice it to say that RAS dysregulation is part of the psychopathology in a host of disorders and may even presage the onset of some of these disorders.

Reticular Formation and the Brain Stem

This article is reproduced from the previous edition © 2004, Elsevier B.V.

The reticular formation of the brain stem is the most ancient part of the brain and the one part that is absolutely necessary to the life of the organism. It consists of large numbers of neurons and fibers and – exclusive of the adjacent cranial nerve nuclei, long ascending and descending tracts, and a few large nuclear masses such as the olives, nucleus ruber, and substantia nigra – it constitutes the core of the brain stem. It is generally thought of as extending from the caudal medulla to the interface between mesencephalon (midbrain) and diencephalon (thalamus–hypothalamus). However, a series of cell masses clustered in the medial portions of the thalamus continues forward, forming the thalamic nonspecific system and, as such, can be thought of as the reticular formation of the thalamus.

In addition, a thin, sheet-like layer of neurons surrounding the lateral surfaces of the thalamus is known as the nucleus reticularis thalami or reticular nucleus of the thalamus. This functionally distinct cell ensemble should not be confused with the others.

Terminology for the system is far from satisfactory. Reticular refers to the net-like pepper-and-salt appearance of these cell-fiber fields as they were visualized in tissue stains prepared by neuroanatomists over a century ago. More recent terms include nonspecific system and ascending reticular activating system (ARAS). The term nonspecific differentiates these cell groups from the specific, earlier-recognized ascending sensory relay systems such as the dorsal column-medial lemniscal systems of the brain stem. Activation refers to the functional capability of significant portions of the system to activate (desynchronize) electrocortical rhythms. The latter is obviously a more functionally meaningful term, based as it is on important experimental studies performed in the 1940s and 1950s. However, presently developing knowledge of the functional repertoire and range of structural patterns argues for the inadequacy of any and all of these names. I suggest the use of the functionally noncommittal term brain stem reticular core, combining, as it does, aspects of geographic position with historical precedent.

Histologic Structure

The core is made up of interneurons of various sizes and shapes, most of which are multipolar in appearance, with radiating, relatively unramified dendrites, a pattern which has been called idiodendritic. No typical short-axoned cells have been identified, although many of the more lateral-lying core neurons have axons with rather limited trajections. The majority of cells send their axons appreciable distances up or down the brain stem and beyond. The range and pattern of these projections provide some measure of the enormous scope of reticular core influence over the remainder of the central nervous system (Figure 1).

A number of subnuclei have been delineated on purely morphologic and cytoarchitectonic grounds. The significance of such structural parcellation is not entirely clear, especially in view of the mutual interpenetration of such cell fields by dendrites from adjacent, or even distant, ensembles. In addition, more meaningful characterization of cell groups on the basis of enzyme or neurotransmitter content and intramembraneous receptor arrays is now possible with fluorescence and immunocytochemical techniques. Selective microstimulation of small cell groups in the unanesthetized animal or in tissue slabs maintained under *in vitro* conditions provides further evidence as to the functional role of cell assemblies in the core. Within this broad frame of possibilities, it seems advisable to review the major cell groups as structurally and chemically identifiable entities, and then to sketch in their functional roles wherever possible.

Small to medium neurons characterize posterior medulla, upper pons, and mesencephalon, whereas large and even giant reticular cells (nucleus reticularis gigantocellularis and nucleus pontis caudalis) are centrally located in the upper medulla and lower pons. These large neurons (somata up to 80 μm diameter) often possess large bifurcating axons whose branches may ascend as far as diencephalon or descend into spinal cord. Scattered cell groups found along the midline of medulla, pons and mesencephalon constitute the raphe nuclei of the reticular core. Although these large bidirectional axon systems are dramatically presented in Golgi silver impregnations, newer retrograde double labelling studies with fluorescent tracers and microelectrode experiments using antidromic invasion techniques indicate that not more than 5% of reticular neurons generate such axon

systems. Many of these cells, which are closely applied to small blood vessels, project their axons to the dorsal horn of the spinal cord, where they are believed to modulate incoming pain stimuli. Cell groups flanking the raphe system at pontine levels and grouped under the general rubric of pararmedian pontile nuclei have been found to enter complex synaptic relationships with the optic tectum (midbrain) and those cranial nerve nuclei (III, IV, and VI) that mediate eye movements. As a substrate for visual tracking behavior, this reticular zone is of obvious importance in maintaining reflex orientation in a rapidly changing world. Operating in a somewhat different physiologic mode, it is also involved in the rapid eye movements characteristic of REM sleep.

A potentially delimitable family of nuclei consists of those whose major axonal projections are directed primarily toward the cerebellum, rather than up and down the brain stem. These include the lateral reticular nucleus of the caudal medulla, the nuclei prepositi hypoglossi of the dorsomedial medulla, and the nucleus reticularis tegmenti pontis of the ventral pons. In view of the widespread distribution of most axonal systems of reticular cells, it seems unwarranted to single out any cell group on the basis of axonal trajectory alone.

Groups of reticular neurons have been characterized chemically at virtually all levels of the reticular core. One group of aminergic nuclei exerts profound effects over the entire neuraxis. Scattered along the midline from caudal medulla to rostral mesencephalon are groups of raphe cells (reticular cell groups B1–B9) rich in the indoleamine serotonin. These neurons, which appear to constitute one of the major central nervous system sources for this neurotransmitter, project widely upon the diencephalon and forebrain. Descending projections to the spinal cord terminate in significant measure on neurons of laminae 1, 5, and 6, where they are believed to exert suppressive influences on incoming pain impulses.

Equally potent ensembles of catecholaminergic neurons (reticular cell groups A1–A12) containing norepinephrine or dopamine are also found at various stations throughout the reticular core from the caudal medulla through the midbrain. High concentrations of dopamine and one of its synthesizing enzymes, tyrosine hydroxylase (TH), are found in neurons of the substantia nigra and in perinigral cells of the surrounding brain stem core, the ventral tegmental area of Tsai (cell groups A9–A10). While nigral neurons project primarily to the corpus striatum, axons of the tegmental cells reach many parts of the limbic system, including the nucleus accumbens septi, nucleus of the stria terminalis, and olfactory tubercle. Highest concentrations of norepinephrine are found in a compact group of deeply pigmented cells, the locus coeruleus, situated in the dorsolateral portion of the pontine reticular core and known as cell group A6. From this relatively small cell cluster (only 30 000 cells per side) a remarkably rich axon system spreads out through virtually the entire central nervous system, including diencephalon, limbic system, parts of neocortex, brain stem, cerebellum, and spinal cord. Significant and largely caudally directed projections tend to characterize the more caudally situated noradrenergic cell groups of the medulla and lower pons. The locus coeruleus has proved of particular interest because of its apparent functional relationship to modulation of cortical activity pattern and behavioral attentiveness and to sensory and motor neurons

throughout the brain stem and spinal cord. Its putative relationship to the capillary bed of the neuraxis, coactively with the dopaminergic and serotonergic systems, has recently become a topic of interest.

Several ascending, acetylcholine (ACh)-rich systems have also been identified within the reticular core. Parent cell clusters in the dorsal midbrain supply much of the tectum, thalamus, and globus pallidus. More ventrally placed cell groups in the midbrain and pons project at least as far rostrally as the thalamus, hypothalamus, preoptic area, and the basal forebrain, the last constituting another significant site of cholinergic neurons. The role of these acetylcholine-rich systems in cortical activation, orientation, and memory processing is receiving increasing attention, especially in light of recent evidence suggesting progressive declines in ACh concentration in aging and more extreme loss of the neurotransmitter in senile and presenile dementias.

Although not strictly located within the reticular core, the histaminergic projection system of the tuberomamillary portion of the hypothalamus should also be included with this group of neurotransmitters because of its apparent conjoint role in cortical activation and arousal.

It seems increasingly likely that the cortical projections of noradrenergic, dopaminergic, and cholinergic systems are bilaterally asymmetric. Dopaminergic and cholinergic projections appear denser in the left hemisphere, whereas noradrenergic systems seem to have greater representation on the right. It is tempting to hypothesize that this type of pattern may be responsible for the now well-recognized affectual depression and concern that usually accompanies cerebrovascular accidents in the left anterior hemisphere compared with the lack of apparent concern and general sense of equanimity that comes with similar episodes in the right hemisphere.

Physiologic Effects of Reticular Cell Activity

From a phenomenologic point of view, it appears that catecholamines such as norepinephrine and dopamine may change the level of gain of cortical cells. Some studies suggest that both act to diminish the responsiveness of pyramidal and stellate cells, with greater decrease being described in 'spontaneous firing' than in evoked discharge. The net result of this would be to improve the signal-to-noise ratio and, accordingly, the fidelity of cortical cell response. Although more work is necessary in this important area, one recent study suggests that dopamine exerts this effect on pyramidal cells and norepinephrine on stellate and granule cells.

The actual cellular mechanisms substrating these effects are also not completely clear. However, there are data that indicate that the 'arousal system' alters activity of thalamic and cortical neurons by blocking potassium conductance. In the process, slow depolarization may be effected and with it a change from burst firing mode to single spike firing. However, it also seems increasingly clear that there is continuous interaction among the multiple neurotransmitters, so that postulation of single cause-and-effect relationships in the intact cortex (as opposed to *in vitro* preparations) may prove overly simplistic. Experimental evidence suggests that neurotrophins operating at a pontine level may also be involved in changing cortical – and therefore behavioral – states.

As one example of neuromodulator interaction, locus coeruleus noradrenergic neuronal activity is usually considered to accompany high attention levels. However, sustained high levels of attention have recently been found to be accompanied by low levels of locus coeruleus activity and enhanced levels of cholinergic activity. It is conceivable that the initial peak of noradrenergic activity accompanying the original arousal component of attention rapidly attenuates as cholinergic activity levels increase to sustain the attentive mode. My colleagues and I suggest that a number of synergistic patterns of this type characterize the interplay of reticular core modulatory systems on the rest of the central nervous system.

Input–Output Patterns

Cell masses of the reticular core receive a broad range of information from impinging collateral and terminal fibers. Microphysiologic analyses of single-cell responses emphasize the heterogeneity of the convergent afferent terminals, which may include ascending somethetic and interoceptive sources and descending cortical and subcortical, visual, auditory, reticular, and cerebellar sources. However, preference patterns for certain afferent inputs have been identified. For instance, the face is the body part most heavily represented in the lower two-thirds of the brain stem, and its distribution pattern is usually ipsilateral. Hindlimbs, trunk, and tail are least frequently represented and are usually found more rostrally and in diffuse patterns with bilateral representation. Reticular neurons also show remarkable adaptive or habituative response to iterative stimuli. Experimental studies of spike responses of single cells to repetitive stimulation of the sciatic nerve, at $2\,\mathrm{V\,s^{-1}}$, show a decline in responsiveness to 10% of initial values within 60s. This type of plastic response contrasts strongly with that of visual cortical cells, which show response habituation patterns of no more than

5–15%. It emphasizes the role of reticular cells in the recognition of the immediacy and relevance of stimulus patterns.

Powerful descending (reticulospinal) fiber systems modulate ongoing activity of spinal (and brain stem) motor neurons. The stimulation studies of Magoun and Rhines identified inhibitory zones in the medial portion of the medulla and facilitatory areas in the dorsolateral medulla and caudal pons. More detailed investigations indicate that stimulation of the pontine reticular formation evokes monosynaptic excitatory postsynaptic potentials in spinal motoneurons, whereas stimulation of the caudal half of the medullary reticular formation results in large, rather long-latency inhibitory postsynaptic potentials in motoneurons. This pontomedullary tissue continuum is a mosaic of functional zones, in that most caudal areas seem to act selectively on axial musculature of the neck and back, whereas more rostral and central zones exert increasingly diffuse effects on spinal motor outflow. Reasonably localized 'centers' for control of respiration, licking, locomotor patterns and 'species-specific calling' have been described.

Ascending reticular projections diverge at the junction of mesencephalon and diencephalon. A dorsal leaf enters the thalamus and terminates among the cell masses of the thalamic nonspecific system and as far rostrally as the nucleus reticularis thalami. The ventral leaf projects through the subthalamus and portions of the dorsal-lateral hypothalamus, reaching the septum and basal forebrain. Approximately 10% of these fibers continue on into the cerebral cortex, terminating in greatest concentration in the anterior third of the cerebral hemisphere. Converging lines of evidence point to the conjoint operation of the dorsal leaf with thalamic nonspecific neurons and their thalamocortical projections as the most likely source of cortical synchronous wave activity, such as the alpha rhythm and spindle waves. Conversely, the ventral leaf seems primarily responsible for driving the cortex at faster rhythms (i.e., low-voltage fast activity characteristic of the attentive conscious state and of REM sleep). Ascending projections from the raphe complex of the reticular formation via the medial septum-diagonal band of Broca exert control over hippocampal theta frequencies and thus can influence hippocampal information processing in response to particular behavioral states.

Thalamic Extensions of Reticular Formation

Surrounding the third ventricle is a central core of thalamic cells with distinctive structural and functional properties that differentiate it from the mass of the surrounding thalamus. The largest and most caudal elements are the paired center median and parafascicular nuclei (CMPF complex), which constitute a prominent landmark of the posterior thalamus. A group of thin, vertically oriented nuclei (the medial and midline nonspecific nuclei) and their dorsolateral wing-like extensions in the internal medullary lamina, the intralaminar nuclei, make up the remainder of the thalamic nonspecific system. Complex synaptic patterns with cerebral cortex, basal ganglia, diencephalon, and brain stem mark these still-enigmatic cell fields. A rather extensive but as yet unsatisfying literature points to their role as pacemaker for thalamocortical electrical patterns and, in a larger sense, for the fine-tuning of conscious states.

The nucleus reticularis thalami, an embryologic derivative of the subthalamus, consists of a thin layer of elongated cells lying within the external medullary lamina along the lateral surface of each thalamus. In this situation, the nucleus sits astride almost all connections between upper brain stem and cortex, and projects its axons back upon mesencephalic and thalamic sources of these fibers. Electrophysiologic and immunocytochemical studies reveal it to be a γ-aminobutyric acid (GABA)-rich feedback system whose facilitation by ascending thalamic volleys results in characteristic high frequency bursts of activity in reticularis cells which, in turn, inhibit the thalamic sources of these volleys. Intrinsic activity of ensembles of reticularis cells appears to serve as source of thalamic spindle bursts consonant with drowsing and light slow wave sleep activity in the organism. The blockade of these synchronized oscillations upon arousal appears to result from increased activity in cholinergic midbrain reticular neurons, which not only stimulate relay and thalamic reticular cells but also suppress depolarizing oscillations of reticularis neurons by inducing long-lasting hyperpolarization associated with enhanced K^+ conductance. Connectional specificity among the mesencephalic, thalamic and cortical loci playing upon this sheet of cells enhances the precision of gating effects exerted by the nucleus reticularis. It is of further interest that the prefrontal cortex also modulates the activity of reticularis neurons by way of the thalamic 'nonspecific' nuclei, thereby providing a putative override at the highest cognitive levels. Here, perhaps, lie mechanisms that enable not only selective focusing of the conscious state, but also the suprarogative control over body functions and painful states achieved at certain levels of concentration, meditation, or hypnosis.

Reticulospinal System

J A Buford, Ohio State University, Columbus, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Overview

The reticulospinal system descends from neurons in the brain stem reticular formation to the spinal cord. The most commonly accepted divisions are the medial and lateral reticulospinal tracts. The medial reticulospinal tracts originate mainly from nucleus reticularis pontis caudalis (NRPc) and pontis oralis (NRPo), and from the dorsal part of nucleus reticularis gigantocellularis (NRGc). The lateral reticulospinal tracts originate mainly from the more ventral parts of NRGc and from nucleus reticularis magnocellularis (NRMc). The general locations of these nuclei in the monkey are illustrated in Figures 1(a) and 1(b). Taken together, these regions are called the pontomedullary reticular formation (PMRF). The reticular formation of the brain stem also includes sections in the rostral pons and mesencephalic reticular formation that project to the PMRF as well as to the cervical spinal cord, although these spinal projections are sparse. The focus of this article is the reticulospinal fibers from the PMRF. These fibers are the main sources of the reticulospinal system's effects on motor control of the neck, trunk, and proximal limb muscles.

As a whole, the reticulospinal system is notable for it influence over whole-body movement patterns. For example, postural responses engaging the trunk and limbs and the ultimate whole-body movement pattern, locomotion, depend heavily on reticulospinal control. Head and neck movements are also heavily dependent on reticulospinal control. In addition, the reticulospinal system is involved in the support of skilled voluntary movements such as reaching. Just as there are widespread outputs from the reticulospinal system, there are also widespread inputs. The cerebral cortex, cerebellum, vestibular system, auditory system, somatosensory systems, and other brain stem nuclei, notably the mesencephalic locomotor region (MLR), are the major inputs to the reticulospinal system.

Anatomy of the Reticulospinal System

Medial and Lateral Reticulospinal Tracts – Origins

The medial and lateral reticulospinal tracts are named for the locations of their descending axons in the white matter of the spinal cord, as illustrated in Figure 1(c). The medial reticulospinal tract is concentrated in the ventromedial funniculus, somewhat ventral to the medial vestibulospinal tracts. The lateral reticulospinal tracts descend in the ventrolateral funniculus, mostly dorsal to the lateral vestibulospinal tracts, and also to some extent in the dorsolateral funniculus. There is not an absolute segregation of the cells of origin for the medial and lateral reticulospinal tracts, but there is general separation. The medial reticulospinal tracts originate mainly from the NRPc and dorsal NRGc, with some from the caudal part of the NRPo. The lateral reticulospinal tracts originate mainly from the ventral part of the NRGc and NRMc. Brodal referred to this latter combination as the nucleus reticularis ventralis and did not specifically recognize the NRMc. Even with these rough designation, the cells of origin of the two tracts are somewhat spread out and overlap with one another in the reticular formation. To state this another way, just as the nuclear boundaries of the parts of the reticular formation such as the NRPc and NRGc are somewhat indistinct, so are the exact origins of the medial and lateral reticulospinal tracts.

Part of the ventromedial system The reticulospinal system is a ventromedial system according to Kuypers's classification. This is a general nomenclature for systems descending in the ventral and medial white matter of the primate spinal cord, in contrast with the lateral descending systems (e.g., the lateral corticospinal tract) descending in the lateral funniculus. Contrasting the general characteristics of the ventromedial versus lateral descending systems provides a useful framework for understanding the reticulospinal tracts.

Consider the lateral systems for a moment. A typical axon of the lateral descending system terminates in a few spinal segments concentrated at a certain level of the spinal cord. Although most descending axons use interneurons, the lateral descending systems tend to make strong contacts on premotor interneurons that are only one synapse away from the motor neurons. In higher primates, lateral systems terminate heavily in the lateral part of the ventral horn, where distal muscles are represented. Monosynaptic contacts from corticospinal and rubrospinal cells of the lateral system are common for the distal muscles of fine control in primates. This gives the lateral systems the anatomical substrate for specific control over individual movement components, such as a relatively independent control of finger movements.

The reticulospinal system is virtually the opposite. Individual reticulospinal axons tend to make contacts at multiple levels of the spinal cord, sometimes including the cervical, thoracic, lumbar, and sacral segments. These terminations tend to be medial in the gray matter

Figure 1 Anatomy of the monkey reticulospinal systems: (a) sagittal view of the brain stem sowing the general locations of the cells of origin for the reticulospinal tracts; (b) frontal sections showing the locations of the key nuclei; (c) the location of descending fibers in the white matter of the spinal cord for the medial reticulospinal tract (MRST) and lateral reticulospinal tract (LRST). These diagrams are from the monkey, but data from the cat are similar. 6, nucleus of 6th cranial nerve (abducens); 7, nucleus of 7th cranial nerve (facial); io, inferior olive; lVe, lateral vestibular nucleus; ml, medial lemniscus; mlf, medial longitudinal fasciculis; mVe, medial vestibular nucleus; n5, 5th nerve; n7, 7th cranial nerve; NRGc, nucleus reticularis gigantocellularis; NRMc, nucleus reticularis magnocellularis; NRPc, nucleus reticularis pontis caudalis; NRPo, nucleus reticularis pontis oralis; Pn, pontine nuclei; PrP, nucleus prepositus; Py, medullary pyramids; Ra, Raphe nuclei; scp, superior cerebellar peduncle; so, superior olive; Sp5, spinal nucleus of 5th cranial nerve; SVe, spinal vestibular nucleus; tz, trapezoid body.

or in the intermediate zone. Although there are some monosynaptic contacts on motor neurons, most reticulospinal contacts tend to be on interneurons, presumably providing polysynaptic control over the motor system. When present, the monosynaptic contacts on motor neurons are probably mostly on the distal dendrites. Hence, the anatomical substrate of the reticulospinal system tends to favor whole-body movement patterns. The muscles around the spinal column (axial muscles) and in the hip and shoulder girdles tend to be most strongly influenced by the reticulospinal systems, but there are also projections affecting muscles of the limbs. Thus, not only can the reticulospinal system contribute to the control of posture, it can also produce movements of the limbs.

Laterality and terminations of the medial versus lateral reticulospinal tracts Before defining the laterality of the reticulospinal tracts, it is important to be clear about what is meant by the laterality of a descending system. Anatomy is typically used to define laterality. If a reticulospinal cell on the left side of the brain stem produces an axon that descends and makes synaptic contacts exclusively on the left side of the spinal cord, the cell is called ipsilateral; however, if those contacts are predominately on interneurons that cross the midline to exert their influence on muscles of the other side, then the functional effects could be contralateral. For the developmental biologist, the anatomical feature may be most important, but for the systems physiologist, the function may be the key issue. Ultimately, when controlling axial muscles, bilateral influences at a functional level are probably the norm for the reticulospinal tracts; it makes little functional sense to regulate muscles on the one side of the spinal column without coordinated control of the muscles on the other side. As the details of anatomical and physiological data are considered, it is important to keep this in perspective.

Medial Reticulospinal Tracts

Neurons contributing to the medial reticulospinal tract make synaptic contacts throughout the spinal cord from the cervical through lumbosacral levels, often making contacts ipsilaterally and contralaterally through axon collaterals that decussate. Cells originating in the pons, especially those originating rostrally, descend ipsilaterally. Those that originate in the caudal pons and rostral medulla can descend either ipsilaterally or contralaterally. Those that descend contralaterally decussate in the medulla around the level of the soma itself. The axons of these neurons have a variety of sizes (3–10 μm) and conduction velocities (10–120 m s^{-1}).

The terminals of the medial reticulospinal tracts are in lamina VII and especially VIII of the spinal gray matter, where axial and proximal limb motor control is concentrated. Many of contacts are on commissural interneurons in the spinal gray. Although cells descending ipsilaterally or contralaterally can both contact commissural interneurons, reticulospinal cells descending contralaterally are somewhat more likely to engage the commissural interneurons. These commissural interneurons decussate and recruit motor outputs on the contralateral side.

Lateral Reticulospinal Tracts

The lateral reticulospinal tract is a bilateral system. Like the medial reticulospinal tract from the NRGc,

neurons of the lateral reticulospinal tract either descend ipsilaterally or decussate in the medulla and descend contralaterally. The lateral reticulospinal tract appears to make more limited contacts at only a few spinal segmental levels at a time. Its contacts are in lamina VI, VII, and VIII. In general, the projections of the lateral reticulospinal tract are slightly more dorsal in the gray matter of the spinal cord, suggesting more indirect control over movement. Axons of the lateral reticulospinal tract are mainly small (<3 μm in diameter) and relatively slowly conducting (10–20 m s^{-1}).

In sum, both anatomically and functionally, the reticulospinal tracts have bilateral influence over motor circuits controlling the axial and proximal limb muscles on both sides of the body. The substrate at a single-cell level on with this system operates is whole-body movement engaging both sides of the body, often engaging the upper and lower limbs at once.

Inputs to the Reticulospinal System

The reticulospinal system receives inputs from the cortical, tectal, somatosensory, vestibular, and cerebellar centers. Thus, vestibular systems can recruit reticulospinal outputs as a part of whole-body movement patterns necessary in postural responses, and tectal influences may use this avenue as part of the head and neck movements associated with gaze control. Midbrain projections to the reticulospinal system also originate from the MLR. Cerebellar influences may also engage trunk and proximal limb control, as well as anticipatory postural adjustments in advance of movement and locomotion. Cortical projections come mainly from the motor and premotor cortical areas. Ascending influences from somatosensory systems are bilateral in origin and are strongest for proprioceptors.

Cortical Inputs

Corticoreticular projections to the reticulospinal system emanate from the primary motor cortex (area 4) and the premotor cortical areas (area 6). Some corticoreticular projections are collateral branches of corticospinal neurons. These collaterals ascend from the pyramids up into the PMRF. Other corticoreticular projections are direct projections that are not part of the corticospinal tract, and these also ascend from the pyramids. In cat and monkey, anterograde labeling indicates that pure corticoreticular projections come from the more rostral parts of the cortical motor areas, with the strongest contributions from area 6 (Figure 2). The area richest with corticospinal neurons' delivering collaterals to the reticulospinal systems appears to be the transitional zone at the rostral boundary of area 4, where the distinction between area 4 and area 6 is sometimes difficult. In the more caudal regions of area 4, where corticospinal control of distal muscles is concentrated, there are fewer cortical projections to the reticulospinal system.

Figure 2 Corticoreticular projections from the motor cortex in relation to corticospinal fibers and cortical motor areas. Area 6 includes the supplementary motor area and the premotor cortex. This area contributes corticospinal fibers and corticoreticular fibers, but these corticoreticular fibers are relatively small and are not usually collaterals of corticospinal fibers. The transition is the region at the rostral end of area 4, the primary motor cortex, and the caudal end of area 6 where the anatomical distinction between these areas can be difficult. Corticospinal tract fibers originating from this transitional area are likely to deliver collaterals to reticulospinal neurons. From the caudal part of area 4 in the monkey, corticospinal fibers tend not to send collaterals to the reticulospinal system. PMRF, pontomedullary reticular formation.

In the most rostral regions of the PMRF, in the NRPo, the corticoreticular projection may be mostly ipsilateral and tends to be from smaller-diameter fibers originating in area 6. But for the majority of the reticulospinal system, in the NRPc, NRGc, and NRMc, corticoreticular projections are bilateral and come from both area 4 and area 6. Projections from the upper limb region of the motor cortex appear slightly more numerous than projections from the lower limb area, suggesting that the corticoreticulospinal system may be somewhat biased in favor of the upper limb. The largest-diameter corticoreticular fibers are collaterals from corticospinal cells, although these collaterals are smaller than their main-stem axons. Direct corticoreticular projections that are not from collaterals of corticospinal cells tend to be the smallest axons of the corticoreticular system. From all sources, the corticoreticular projections terminate mainly on the dendrites of the reticulospinal cells.

Cerebellar Inputs

The cerebellar output to the reticulospinal system mainly originates from the fastigial nucleus and is crossed. These synaptic contacts tend to be closer to the soma and exert strong influences over reticulospinal neurons than corticoreticular projections. As an

output nucleus for the spinocerebellum, where motor control of posture and movement is concentrated, it is not surprising that the fastigial nucleus are a strong source of cerebellar influence over the reticulospinal system. The cerebellar locomotor region appears to work largely through projection to the reticulospinal system, especially to the pontine part, which in turn activates spinal cord central pattern-generator circuitry.

Inputs for Initiation of Locomotion

In addition to the cerebellar locomotor region already described, the MLR and other rostral portions of the brain stem associated with control of locomotion project to the reticulospinal system. These projections are strongest to the more caudal regions of the reticulospinal system, where reticulospinal cells projecting to the lumbosacral spinal cord are more numerous.

Tectal Inputs

The deep layers of the superior colliculus, around the origins of the tectospinal tracts, project to the reticulospinal system, especially the pontine regions. Head and neck movements are easy to elicit from electrical stimulation of the NRPo and NRPc, so it seems likely that these tectal projections to the reticulospinal system are part of the gaze-control system. To the extent that head movements require accompanying postural shifts to maintain stability, integration of control of head movement with control of gross upper limb movements and posture in the brain stem makes sense. Indeed, as any parent of a new teenage driver recognizes, the tendency to move the arms (and hence the steering wheel) when turning the head is a natural reaction that new drivers must learn to suppress.

Somatosensory Inputs

Reticulospinal neurons can be excited by mechanical stimulation of the skin and deep tissues (muscles and tendons) and by electrical stimulation of peripheral nerves. Light stroking of the skin or hair does not seem to affect reticulospinal cells. Proprioceptors such as muscle spindles and Golgi tendon organs (GTOs) sending their signals up the dorsal columns project strongly to reticulospinal neurons. High-threshold cutaneous afferents, particularly nociceptors, appear more effective for exciting reticulospinal neurons than discriminative touch modalities from the skin. Interestingly, just as reticulospinal outputs are bilateral, stimulation of muscle and cutaneous afferents from either side of the body can activate a reticulospinal neuron. In most cases, stimulation of a peripheral receptor results in the excitation of the reticulospinal neuron, but a sizable minority can produce inhibition.

The cutaneous and muscle receptors appear most likely to influence reticulospinal neurons rostrally. We can speculate that these types of inputs are more likely to influence the outputs of the medial reticulospinal tracts, which in turn appear to have more rapidly conducting fibers and more direct connections to the motor outputs. The higher-threshold afferents, including pain fibers that ascend in the spinothalamic tracts, appear more likely to influence reticulospinal neurons more caudally in the brain stem, from the NRGc. Again, this suggests that these more slowly conducting fibers tend to influence the more slowly conducting outputs in the lateral reticulospinal tracts.

Auditory Inputs

The acoustic startle response appears to be mediated through reticulospinal outputs. In response to a loud auditory tone, the head turns toward the sound and a postural adjustment accompanies the response. The NRPc appears to be the most critical part of the reticulospinal system for conveying the acoustic startle.

Functions of the Reticulospinal System

At the level of behavioral neurophysiology, it becomes difficult to distinguish the medial and lateral reticulospinal tracts. Despite the differences in their origins and projections, there is no clear distinction in the literature between the task-related neural activity for these two different kinds of reticulospinal tract neurons.

Initiation and Regulation of Locomotion

Reticulospinal projections to the spinal cord appear to be the principal system for activating the central pattern generators of the spinal cord for initiation and regulation of locomotion. The evidence for this role comes from multiple experimental approaches and multiple species, has been replicated in different labs, and is overwhelming. As already indicated, the reticulospinal system is a primary target of outputs from the MLR and the cerebellar locomotor region. Reticulospinal neurons are active in phase with locomotion and respond to somatosensory inputs that alter the timing of the locomotor cycle. Stimulation of the PMRF during locomotion produces phase-dependent alterations of the step cycle in intact and reduced preparations. Injection of certain neurochemicals into the PMRF can also initiate locomotion. Partial lesions of the spinal cord white matter in the cat are most disruptive to locomotion when they section the ventral funniculus, where the reticulospinal tracts descend. In the rat,

subjects who recover better locomotion after incomplete spinal cord injury have stronger retrograde labeling of reticulospinal cells from sites distal to the spinal cord injury.

During locomotion in the awake, behaving cat, reticulospinal tract neurons show a variety of response patterns. In many cases, these cells have modulation of activity with an increase during swing (or stance) for each limb. In other words, the cells appear to have firing patterns related to both limbs in an integrated way, not just one limb or the other. On a gross time scale, some of these neurons may appear to be muscle related in that their general period of activation mimics the general period for selected limb muscles. However, when techniques such as spike-triggered averaging are applied, the reticulospinal cells with a pattern apparently mimicking that of a certain muscle may not demonstrate a postspike effect indicative of a direct projection to that muscle. This probably indicates that (1) reticulospinal projections are largely mediated by interneurons that, in turn, project to multiple motor pools and (2) surface similarities in long-term activation patterns for neurons in widely separated parts of the brain cannot be taken as evidence of connections, even when there is anatomical and physiological evidence for tracts connecting those two parts of the brain. Nonetheless, reticulospinal neurons are powerfully modulated during locomotion, and their patterns of modulation can be correlated with critical events in locomotion such as swing onset, stance onset, and the bursting of selected muscles important in walking. There can be little doubt the reticulospinal neurons are a key source of brain stem drive to the spinal cord for supraspinal control and coordination of locomotion.

Preparatory and Anticipatory Aspects of Motor Control

Recent evidence from the cat and primate suggests that, in addition to motor patterns related to the control of posture and limb movements during locomotion, reticulospinal neurons are active in relation to skilled reaching. In the cat, two basic patterns of activity have been described. One group of cells begins firing around the time of an anticipatory postural adjustment preceding the lifting of the limb from a quadrupedal stance to reach for food. The other group of cells is best related to the beginning of the reach itself. In this situation, the cat self-selects the timing between the beginning of the weight shift and the beginning of the reach, providing enough difference in onset times for these two components of the behavior to allow recognition of these two patterns of activity.

In a slightly different experimental setup in the monkey, a similar result has been described. Here, the subject receives an instruction for where to reach, but there is a delay before a go cue indicates the reach should begin. This is the instructed delay paradigm popularized in early studies of the premotor cortex. A substantial portion (35–50%) of neurons sampled in the PMRF have activity that begins with the instruction, well before reaching begins. An example of such a cell is illustrated in Figure 3. In this study, it was possible for the monkey to make subtle adjustments in its posture without failing the trial, so it is possible that the preparatory activity was associated with a postural adjustment or contralateral arm movement that was not measured. Nonetheless, hand position on the reaching side was constant during the instructed delay interval. In addition to cells with this kind of preparatory activity, many of the cells had activity that began with reaching, displaying no response to the instruction stimulus.

This dichotomy between cells in the PMRF of the monkey is highly reminiscent of the two kinds of cells described in the cat. Although the tasks are different, the element of motor control associated with anticipatory postural adjustments seem to be a good candidate for the kinds of functions occurring during instructed delay intervals. In other words, it seems reasonable to speculate that the cells in the cat showing activity in association with anticipatory postural adjustments might be in the same class as the cells in the monkey showing instructed delay-period activity. The corticoreticular projections from area 6 and the rostral part of the motor cortex in area 4, where cortical activity associated with preparatory activity is concentrated, are consistent with the finding of this type of activity in the PMRF.

Movements and Muscle Recruitment Evoked by Electrical Stimulation

Application of brief stimulus trains and averaging electromyography (EMG) responses to a series of single-pulse stimuli produces results that are consistent across the years, across research methods, and across species (cat and monkey). Stimulation of the PMRF usually causes the head to turn to the side ipsilateral to the stimulating electrode in the brain stem. In the upper limbs, reticulospinal stimulation facilitates flexors and inhibits extensors in the ipsilateral upper limb and evokes the opposite response in the contralateral upper limb (Figure 4). About 80% of upper limb responses fit this pattern. In the lower limbs, responses are more variable. In some cases, the responses of the lower limbs are in concert with the responses of the upper limbs, such that both ipsilateral limbs flex and both contralateral limbs extend. This pattern is reminiscent of pacing in a quadrupedal gait. In other cases, the pattern is diagonal between the limb girdles, such

Figure 3 Example of monkey neural activity from a neuron in the PMRF located in the NRGc, just ventral to the abducens: (a) average trajectory from the central while the monkey is waiting spot to one of the targets (the monkey was reaching his hand to one of four targets located on a horizontal work surface); (b) average firing rates for three periods in the task and hand speed. In (b), NC marks the time when a neutral cue was given, alerting the monkey to a particular target that was not the target he would reach to, TC indicates presentation of the true cue, the target for reaching, and Move indicates the time of movement to the target. Hand speed is shown at the bottom of (b). The hand only moves during the movement period. Dot rasters show the times of action potentials for each trial, one trial per row. This neurons activity level increased when the monkey saw which target he was supposed to reach for and also when he actually reached. Such activity is called preparatory activity. PMRF, pontomedullary reticular formation; NC, neural cue; NRGc, nucleus reticularis gigantocellularis; TC, true cue.

Figure 4 Bilateral basis for functions of reticulospinal neurons. Single reticulospinal cells, especially those from the NRPc and dorsal/rostral parts of the NRGc, deliver collaterals to multiple levels of the spinal cord and often decussate at the segmental level. This, combined with corticoreticular projections from both sides of the motor cortex, makes the reticulospinal system a bilateral system for motor control and a likely alternate pathway for control of movement when one side of the cortex is damaged by an injury such as a cerebrovascular accident. NRGc, nucleus reticularis gigantocellularis; NRPc, nucleus reticularis pontis caudalis; RSN, reticulospinal neuron.

that the ipsilateral upper limb flexes, the ipsilateral lower limb extends, and the opposite combination occurs contralaterally. Not every stimulating site evokes an effect in all four limbs; there is some degree of separation between sites where upper and lower limb movements can be evoked. Most sites, however, produce effects bilaterally within a limb girdle, and sites evoking responses in three or four limbs are not uncommon.

Evidence from electrical stimulation with stimulus trains (12 pulses at approximately 300 Hz) in the cat suggests that the cells most likely to have bilateral influence originate closest to the midline in the reticular formation. However, this result could be confounded by stimulation of decussated fibers that originated on the other side and then descend medially toward the spinal cord. Retrograde labeling studies indicate that cells with origins ipsilaterally and contralaterally are spread through the nuclei of origin on both sides of the brain stem in similar locations, with no medial concentration of the contralateral cells.

The strongest and most prevalent effects of electrical stimulation are observed in the muscles around the spinal column and in the proximal muscles of the limbs. In the cat, there have not been responses documented in muscles distal to the elbow. In the monkey, some effects have been noted in wrist muscles, but these are much less prevalent than responses in the neck, shoulder, and elbow muscles. Likewise, in the lower limb, reticulospinal outputs are mainly directed to proximal muscles. This is consistent with the termination of the reticulospinal axons in the medial part of the ventral gray matter of the spinal cord, where proximal and axial motor pools are located.

When stimulus trains are used in the cat, latencies from the onset of stimulation to the beginning of the EMG response range from around 7 ms in the neck and upper limbs to around 16 ms in the lower limbs. When single-pulse stimuli are used in stimulus-triggered averaging in the monkey, upper limb EMG

onsets can be observed in as fast as 3 ms. This is consistent with the fastest observed reticulospinal conduction velocities, which are reported in the 100–120 m s^{-1} range.

The gross somatotopic organization of the PMRF in the cat is that sites associated with neck movements are found throughout the PMRF; the upper limb is represented in the dorsal aspects of the PMRF about midway along its rostral–caudal extent, in the region just ventral to abducens; and the lower limb is represented in the ventral regions and at the rostral or caudal ends of the PMRF but not as much in the middle. No results indicate that there is a muscle-by-muscle somatotopic map. Broad regions of the PMRF best associated with effects in the broad regions of the body can be found, as already described, but even this organization includes considerable overlap. This overlap combined with broad output effects provides an intrinsic substrate for whole-body movements.

Although intense electrical stimulation suggests there is an inhibitory region in the caudal and ventral PMRF, around the NRMc, and an excitatory region just lateral to the NRPo, more specific electrophysiological methods such as stimulus-triggered averaging do not reveal separation between the course of inhibition and excitation. Inhibition is probably a consequence of projection to inhibitory interneurons in the spinal cord.

These studies of output effects by electrical stimulation have not distinguished whether the effects were conveyed by the medial or lateral reticulospinal tracts. However, based on the bilateral nature of the responses and the rapid latencies between brain stem stimulation and EMG responses in the muscles, it seems likely that most of the results of electrical stimulation that produce direct responses through stimulus-triggered averaging or brief stimulation trains reflect the output of the medial reticulospinal tracts.

Lesion Studies

Lesions of the ventromedial systems in primates, including the reticulospinal and vestibulospinal tracts, leave the animals profoundly debilitated, unable to maintain their posture or move their limbs away from their body. Although hand movement remained possible, limb movement was so limited by the lack of proximal strength that the hand use was of little functional benefit. Lesions of the corticospinal tract in this species, in contrast, were compensated for by the subjects, who could still move about in the cage and feed themselves, albeit clumsily, with gross motor control of the limbs. This result emphasizes the crucial importance of a stable postural base for the effective use of the limbs in skilled movement.

Summary and Implications

The reticulospinal systems originating from the PMRF are one of the major descending systems for motor control. They can receive inputs from cutaneous, tectal, vestibular, auditory, cerebellar, and cortical sources, often from either side of the body. The MLR also projects to the reticulospinal system. The reticulospinal system's outputs are equally widespread and, to a large extent, produce stereotyped responses. Most studies agree that the prevalent outputs from the reticulospinal system are ipsilateral upper limb flexion and contralateral upper limb extension, with turning of the head to the ipsilateral side. In the lower limbs, responses can match those in the upper limbs or be the opposite. The strongest influences are on axial and proximal limb muscles. These widespread outputs are represented at the level of single reticulospinal axons as well as in the organization (or lack thereof) of reticulospinal neurons within the PMRF.

Hence, the reticulospinal tracts are in a position to integrate influences from all over the nervous system and produce responses throughout the body. As we consider lower animals such as the goldfish and lamprey eel, the reticulospinal system is the principal descending system and is mainly aimed at the initiation and regulation of locomotion (swimming). This role in initiation and regulation of locomotion has been retained in the higher animals, and the reciprocal actions between the limbs and, in some cases, between limb girdles is obviously a motor pattern with its roots in the neural control of locomotion. But, in the higher animals, there is now a new integration required between reticulospinal and corticospinal functions for voluntary movement. An interesting aspect of many skilled movements is that they are preceded by preparatory activity in the premotor cortical areas and by anticipatory postural adjustments prior to movement. The corticoreticular projections engaged in skilled movements seem well suited to produce these early aspects of motor control. Through the proper activation of postural and proximal muscles as a first part of movement, a stable basis can be provided on which to superimpose the skilled distal movements that are so uniquely human and that so capture our imagination. It is difficult to imagine how we could perform any useful movement without the integrated control of posture and proximal limb stability provided by the reticulospinal system.

Interestingly, the typical output pattern resulting from the stimulation of the reticulospinal system mimics the upper limb components of the asymmetric tonic neck reflex. This same pattern of upper limb movements dominates the impaired limb after cerebrovascular accidents affecting the motor cortex in the

human. This supports the long-held idea of the reticulospinal system as an alternative pathway for voluntary control of limb movements after stroke. Through projections from the contralesional cortex to both sides of the PMRF (Figure 4) and with the bilateral nature of output from each side of the PMRF, the corticoreticulospinal system is well positioned to provide for the control of upper limb movement even when the normal outputs from the contralateral motor cortex are damaged. Mechanisms behind this potential route for recovery and the possibilities for extending the movement repertoire possible through this system offer exciting areas for future investigation.

Retina: An Overview

J E Dowling, Harvard University, Cambridge, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

The vertebrate retina is a thin (~0.25 mm) layer of neural tissue lining the back of the eye. It is a true part of the brain displaced into the eye during development. In addition to the light-sensitive photoreceptor cells, the retina contains four basic classes of neurons and one principal type of glial cell, the Müller cell. The neurons are organized into three cellular (nuclear) layers, which are separated by two synaptic (plexiform) layers. Virtually all the junctions (synapses) between the retinal neurons are made in the two synaptic layers, and all visual information passes across at least two synapses – one in the outer plexiform layer and another in the inner plexiform layer – before it leaves the eye.

Analysis of visual information occurs in both plexiform layers of the retina. The outer plexiform layer separates visual information into ON and OFF channels and carries out a spatial-type analysis on the visual input. The inner plexiform layer is concerned more with the temporal aspects of light stimuli. Many cells receiving input in this layer respond with transient responses and respond better to moving stimuli than to static spots of light. The output neurons of the retina, the ganglion cells, reflect the processing of information occurring in either the outer or the inner plexiform layers.

Figure 1 is a light micrograph of a piece of human retina. The photoreceptors are located furthest from the front of the eye, at the top of the micrograph. Light, entering the eye, passes through the transparent retina and is captured by the visual pigment-containing, light-sensitive outer segments of the photoreceptors. Overlying the photoreceptors is the pigment epithelium, which serves to absorb stray light and to prevent backscatter of light into the retina, as well as to play an essential role in the regeneration of the visual pigments after light exposure. The cell bodies of the photoreceptors are located in the outer nuclear layer, whereas the cell bodies of three of the basic classes of retinal neurons – horizontal, bipolar, and amacrine cells – are in the inner nuclear layer. The cell bodies of the ganglion cells make up the most proximal cellular layer. The outer and inner plexiform layers are interspersed, respectively, between the outer and inner nuclear layers and the inner nuclear and ganglion cell layers.

In many primates including humans, and in some birds and reptiles, a small region of the retina is specialized for high-acuity vision. It is called the fovea and is centrally located (i.e., on the visual axis of the eye). The layers of the retina below the photoreceptor inner and outer segments are displaced aside from the fovea so that light can impinge directly on the photoreceptors. Only cones are present in the center of the fovea, and these cones are the thinnest and longest photoreceptors in the retina. In humans, the central rod-free foveal area is approximately 0.3 mm in diameter and contains approximately 10 000 cones.

Photoreceptors

Most vertebrate retinas contain two types of photoreceptors, rods and cones. Rods mediate dim-light vision, whereas cones function in bright light and are responsible for color vision. The light sensitivity of the photoreceptors results from the presence of visual pigment molecules contained within their outer segments. One rod pigment, called rhodopsin, and three cone pigments are in the human retina; nonmammalian species may have four or more cone visual pigments. In humans, there is one type of rod cell and three cone types which absorb light preferentially in the red, green, and blue regions of the spectrum.

All visual pigments have a similar chemistry. They consist of two components – retinal (vitamin A aldehyde), termed a chromophore, bound to a protein called opsin. Different visual pigments have different opsins, and this accounts for the variations in their color sensitivity. The light sensitivity of the visual pigments is due to the retinal chromophore. When a visual pigment molecule absorbs a quantum of light, several conformational (shape) changes occur, first in the chromophore and then in the protein (opsin) part of the molecule, which lead, via a cascade of molecular interactions, to excitation of the photoreceptor cell.

All vertebrate photoreceptors hyperpolarize in response to light (i.e., the inside of the cell becomes more negative) as follows: in darkness, the membrane of the outer segment is permeable (leaky) to Na^+. Because Na^+ levels are higher outside the cell than inside, positively charged Na^+ ions enter the cell in darkness, causing the cell to be partially depolarized (i.e., the cell's inside is more positive than is typically the case for neurons at rest). Light decreases the permeability of the outer segment membrane to Na^+, thereby decreasing the flow of positive ions into the cell and causing the inside of the cell to become more negative (i.e., to hyperpolarize).

Figure 1 Vertical section through the human retina. Micrograph shows an area approximately 1.25 mm from the center of the fovea. In the foveal region of the retina, the inner layers of the retina are pushed aside so that light can impinge more directly on receptors. Thus, around the fovea and for some distance away (as shown here), receptor terminals are displaced laterally from the rest of the photoreceptor cells. From Boycott B and Dowling JE (1969) Organization of the primate retina: Light microscopy. *Philosophical Transactions of the Royal Society of London, series B: Biological Sciences* 255: 109–184.

Retinal Neurons

Cellular Organization

There are four major classes of retinal neurons in the retina; however, there are many morphological subtypes in each major cell class. The focus here is on the major subtypes of cells in the mammalian and primate retinas (Figure 2).

In the outer plexiform layer, two cell classes – horizontal and bipolar cells – receive input from the photoreceptors. The bipolar cells are the output neurons for the outer plexiform layer; all information passes from outer to inner retina via these neurons. Horizontal cells, on the other hand, extend processes (branches) widely in the outer plexiform layer, but their processes are confined to this layer. Their role principally is to mediate lateral interactions within this first synaptic zone.

Bipolar cell terminals provide the input to the inner plexiform layer, and two cell classes – amacrine and ganglion cells – are ultimately activated there. Amacrine cells, like horizontal cells in the outer plexiform layer, spread processes widely in the inner plexiform layer, and their processes are usually confined to this layer. Ganglion cells are the output neurons for the retina; their axons run along the margin of the retina, collect at the optic disc to form the optic nerve, and carry all visual information to higher visual centers.

Outer plexiform layer: Horizontal and bipolar cells
Most mammalian retinas contain two basic subtypes

Figure 2 Major cell types found in primate retina as viewed in vertical sections of Golgi-stained retinas. From Dowling JE (1991) Retina. In: *Encyclopedia of Human Biology*, vol. 6. New York: Academic Press.

of horizontal cells – a cell with a short axon that ends in a prominent terminal expansion and an axonless cell. The axonless cell has not been seen in the primate retina; rather, the second horizontal cell type in primates has a short axon, although its synaptic connections are like those of the axonless cell. In mammalian retinas, the processes of the axonless cell and the proximal dendritic branches of the short axon cell connect exclusively with cone synaptic terminals, whereas the axon terminals of the short axon cell end exclusively in the rod terminals. Why the input to the short axon cells is organized this way is not clear; an appealing suggestion is that this allows for segregation of rod and cone responses in different regions of the cells. In fish, for example, there are separate rod and cone horizontal cells.

In many vertebrates, up to 11 subtypes of bipolar cells have been distinguished. In mammals, one type is exclusively connected to rods and the rest are connected to cones. In other species (i.e., fish), there are bipolar cells that receive input from both rods and cones as well as pure cone bipolar cells. The rod-related bipolar cells in mammals extend their dendrites into the rod synaptic terminals, and their axon terminals end deep in the inner plexiform layer. These rod bipolars contact between 15 and 50 rod terminals depending on eccentricity; more peripherally located rod bipolar cells contact more rods.

Two of the cone-related bipolar cell types in primates contact only a single cone. These cells, called midget bipolar cells, make different kinds of synaptic contacts with the cone terminals. Their axon terminals end at different levels within the inner plexiform layer, and they appear to be related to the generation of either ON or OFF responses to light in the retina. Every cone terminal in the primate retina probably makes connections with both kinds of midget bipolar cells (Figure 2). In addition to the cone midget bipolar cells in primates, there are also bipolar cells that contact several cones, probably as many as six or seven. They are called flat or invaginating bipolars based on the type of connection they make with the photoreceptors.

Inner plexiform layer: Amacrine and ganglion cells

Most amacrine cells have no axons; all their processes look similar. Some amacrine cells do show two kinds of branches emerging from the cell body. The thinner of the two has a wider extent and has been termed an axon. Many such branches can emerge from a single cell body and it is not known whether they have axon-like properties (i.e., generate and conduct action

potentials). Amacrine cells are diverse in terms of the extent and distribution of their processes, and it is possible to describe a large number of amacrine cell subtypes in most species – up to 20–30. Investigators often classify amacrine cells into two major types: diffuse and stratified amacrine cells. Diffuse amacrine cells extend their processes throughout the thickness of the inner plexiform layer, whereas the stratified cells extend their processes on one or a few levels in the layer (Figure 2). This simple classification scheme can be expanded to include narrow- and wide-field diffuse or stratified amacrine cells, depending on how far their processes extend, and mono-, bi-, or multi-stratified cells, depending on whether their processes are confined to one, two, or several levels in the inner plexiform layers.

A cell termed the interplexiform cell deserves special mention. Some investigators classify these cells as a separate class of retinal neuron, but others believe they are a subtype of amacrine cell. Their cell bodies sit among the amacrine cells, but unlike typical amacrine cells, they send processes to both plexiform layers. Input to these cells is in the inner plexiform layer, whereas most of their output is in the outer plexiform layer. Hence, they appear to be mainly a centrifugal type of neuron, carrying information from the inner to the outer plexiform layer.

Ganglion cells, like amacrine cells, are also diverse in their morphology. In some vertebrate retinas, as many as 10–15 morphological subtypes can be distinguished. They are mainly stratified cells. In primates, particularly in the central region of the retina, ganglion cells are observed with limited dendritic fields. These cells, termed midget ganglion cells, receive input from one midget bipolar cell. The dendrites of these midget ganglion cells ramify either in the upper or the lower part of the inner plexiform layer so that they receive input from one or the other of the two midget bipolar cells described previously. This implies that one cone in the central (foveal) part of primate retina can send two separate messages to the rest of the brain via two midget ganglion cells. One cell signals increases in illumination of the cone (i.e., it is an ON cell), and the other signals decreases in illumination (i.e., it is an OFF cell). The midget ganglion cells are the most common ganglion cell subtype found in the primate retina.

The other major ganglion cell subtype in the primate retina is called the parasol ganglion cell. It receives most of its input from the bipolar cells, receiving input from several cones; is stratified, extending its processes in either the ON or OFF laminae of the inner plexiform layer; and is physiologically either an ON or OFF cell.

Ganglion Cells and Receptive Field Organization

As noted previously, ganglion cells signal brightness (ON cells) or darkness (OFF cells) information to the rest of the brain, but they also communicate more. Indeed, two basic kinds of analyses appear to be occurring in the retina – one carried out mainly in the outer plexiform layer and the other in the inner plexiform layer. Ganglion cells convey information to the rest of the brain that reflects these two stages of visual information processing.

Ganglion cells typically respond to illumination of a restricted but relatively large region of the retina. This region is called the receptive field of the cell and is typically approximately 1 mm in diameter. The most common ganglion cell in the mammalian retinas shows evidence of spatial processing of visual information in its responses. Ganglion cells of this type are often called contrast-sensitive cells, and they are subdivided into two mirror image classes: ON-center, OFF-surround cells and OFF-center, ON-surround cells. Each has a receptive field that is organized into two concentric zones that are antagonistic to each other (Figure 3(a)).

Most ON-center cells respond to an increase in the illumination of the receptive field center with a sustained burst of nerve impulses (action potentials), whereas illumination in the surround inhibits the firing of nerve impulses by the cell for as long as the light is on. OFF-center cells respond in the opposite way; illumination of the receptive field center inhibits the cell, whereas surround illumination provides a sustained excitation of the cell. In both cases, the center and surround zones are antagonistic; if center and surround areas are simultaneously illuminated, the cell responds only with a weak response that reflects the central response. Those ganglion cells that respond with sustained responses to appropriately positioned spots of light have relatively small receptive fields, and their responses mainly reflect the processing that occurs in the outer plexiform layer of the retina. In cat, these ganglion cells are termed X cells; in primates, they are termed P cells.

Other types of ganglion cells respond with more transient responses to retinal illumination, regardless of the position of the illuminating spot in the receptive field. These cells typically have large receptive fields and respond with more vigorous responses to moving stimuli than to static spots of light. The receptive fields of some of these cells are organized into antagonistic center and surround regions like the sustained contrast-sensitivity cells described previously. The transient ganglion cells with a center–surround organization are termed Y cells in cat and M cells in

Figure 3 (a) Idealized responses and receptive field maps for ON-center (top) and OFF-center (bottom) contrast-sensitive ganglion cells. Drawings on the left represent hypothetical extracellularly recorded action potential responses to a spot of light presented in the center of the receptive field, in the surround of the receptor field, or in both center and surround regions of the receptive field. +, An increase in firing rate of the cell (i.e., excitation); −, a decrease in firing rate (i.e., inhibition). (b) Idealized responses and a receptive field map for a direction-sensitive ganglion cell. Such cells respond with a burst of action potentials at both onset and termination of a spot of light presented anywhere in the cell's receptive field. This response is indicated by + symbols all over the map. Movement of a spot of light through the receptive field in the preferred direction (open circles) elicits action potentials from the cell that last for as long as the spot is within the field. Movement of a spot of light in the opposite (null) direction (open squares) causes inhibition of the cell's maintained activity for as long as the spot is within the receptive field. From Dowling JE (1991) Retina. In: *Encyclopedia of Human Biology*, vol. 6. New York: Academic Press.

primates. Other ganglion cells, termed ON–OFF cells, give short on–off bursts of impulses to static spots of light positioned anywhere in the receptive field. They respond vigorously to moving spots of light, often have no antagonistic surround, and are particularly numerous in nonmammalian species. Some of these show direction-selective properties (Figure 3(b)). Movement of a light spot in one direction vigorously excites the cell, whereas movement in the opposite direction inhibits the cell.

As noted previously, midget ganglion cells receive input from a single midget bipolar cell, which in turn receives input from a single cone. The center of the receptive field corresponds to this direct pathway and is therefore cone (color) specific. The antagonistic surround responses reflect horizontal and/or amacrine cell activity, and these cells receive input from many cones. The center of the receptive field, therefore, is very small and has a spectral sensitivity different from that of the surround. Such ganglion cells are termed color-opponent cells and are involved in the early stages in color vision processing.

Retinal Synapses

Two types of chemical synaptic contacts are observed in both plexiform layers. One of these is similar in morphology to known chemical synapses seen throughout the brain, and it is termed a conventional synapse. It is characterized by an aggregation of synaptic vesicles in the presynaptic terminal clustered close to the membrane. In the retina, conventional synapses are made by horizontal and amacrine cells. The other type of synapse is characterized by an electron-dense ribbon or bar surrounded by synaptic vesicles and is called a ribbon synapse. The ribbon is thought to act like a conveyer belt, directing and allowing a large number of synaptic vesicles to discharge their contents into the synaptic cleft at the base of the ribbon (Figure 4). Photoreceptor and bipolar cells make ribbon synapses in the retina. Electrical (gap junction) synapses are also observed in both plexiform layers of the retina, and they mediate direct electrical interactions between certain retinal neurons.

Figure 4(a) shows a drawing of a bipolar cell ribbon synapse and an amacrine cell conventional synapse in the inner plexiform layer. Typically, there are two postsynaptic processes at the ribbon synapses of bipolar cells, whereas at conventional synapses only one postsynaptic element is found. In this drawing, the amacrine cell synapse is made back onto the bipolar terminal that is making a synapse on it. Thus, a reciprocal or feedback synaptic arrangement is suggested, which is commonly seen between bipolar cell terminals and amacrine cell processes. Amacrine cell synapses are also made on the processes and cell bodies of ganglion and other amacrine cells.

Photoreceptor cell synapses are particularly complex, and a summary drawing of part of a cone synaptic terminal is shown in Figure 4(b). The synaptic

Figure 4 (a) Schematic drawing of a bipolar cell ribbon synapse (arrowhead) and a conventional amacrine cell synapse (arrow) back onto the bipolar cell terminal. One postsynaptic process at the ribbon synapse is an amacrine cell process (right); the other is a ganglion cell dendrite (left), a typical arrangement at cone bipolar cell terminals in primate. (b) Schematic drawing of synapses made by cone terminals in primates. FB, flat bipolar cell dendrite; FMB, flat midget bipolar cell dendrite; H, horizontal cell process; IMB, invaginating bipolar cell dendrite. From Dowling JE (1991) Retina. In: *Encyclopedia of Human Biology*, vol. 6. New York: Academic Press.

ribbons are found above invaginations of the basal surface of the terminal. Dendrites from horizontal cells and invaginating bipolar cells penetrate into the invaginations. Horizontal cell dendrites lie lateral to the synaptic ribbons, whereas the dendrites of the invaginating bipolar cells are centrally positioned. In addition to the ribbon synapse, the cone photoreceptor terminals make a second, unusual synaptic contact with the flat bipolar cells, called a flat or basal junction. No ribbon or vesicle cluster is associated with this junction, but some specializations of the membranes on both sides of the synapse are seen. The flat midget bipolar dendrites are typically found immediately adjacent to the invaginating midget bipolar dendrites, whereas the dendrites of the other flat bipolar cells are positioned away from the invaginations. Rod photoreceptor terminals do not make basal junctions; all rod bipolar dendrites penetrate into invaginations of the rod terminal.

Figure 5 is a simplified summary diagram of the synaptic organization of the primate retina. Each cone in the primate retina makes connections with two midget bipolar cells, one that makes invaginating-type junctions and another that make flat junctions (Figure 5, left). In the central region of the primate retina, these two bipolar cell types synapse on separate midget ganglion cells. In the periphery of the primate retina, midget bipolar cells synapse on ganglion cells that receive input from a few to many midget bipolar terminals.

All cone terminals in primates also make synapses with other bipolar cell types and the dendrites of horizontal cells. The axonal branches of the horizontal cells usually extend to the rod terminals. Synapses made by the horizontal cells have been observed on bipolar cells in many species but very rarely back onto the photoreceptor terminals. However, there is good physiological evidence for feedback from horizontal cells onto cone photoreceptors in many species. Another interesting feature of the cone photoreceptor terminals is that they make small electrical synapses with each other and with adjacent rod terminals.

Rod bipolar terminals in the mammalian retina do not contact ganglion cells directly (Figure 5, right). Rather, amacrine cell processes are always postsynaptic at the ribbon synapses of the rod bipolar terminals. One of these makes a feedback synapse onto the terminal, whereas the other belongs to a special subtype of amacrine cell, called the AII cell, that makes both electrical and conventional chemical synapses with cone bipolar terminals. These cone bipolar terminals then contact the ganglion cells. Thus, rod information in the mammalian retina usually passes through an amacrine cell before it is transmitted to the ganglion cells via the cone bipolar cells. It is believed that the amacrine cells serve to amplify and quicken the rod signal.

Finally, interplexiform cells receive their input from amacrine cells, and they make some synapses in the inner plexiform layer on amacrine and ganglion cell processes. Most of their synapses, however, are made in the outer plexiform layer on bipolar and horizontal cells.

It should be noted that Figure 5 is highly simplified. No one amacrine cell makes the variety of contacts shown for either of the amacrine cells drawn in the figure.

Figure 6 Intracellular responses from receptor (R), horizontal (H), bipolar (B), amacrine (A), and ganglion (G) cells of the mudpuppy retina. Distal retinal neurons (receptor, horizontal, and bipolar cells) respond to illumination with sustained graded potentials; proximal retinal neurons show both sustained and transient potentials and action potentials. Receptor, bipolar, and ganglion cells respond differently to center (spot) and surround (annular) illumination. Horizontal and amacrine cells usually respond similarly to spot and annular illumination; here, responses to a small annulus (250 μm) are shown that would stimulate both the center and the surround of their receptive fields. The bipolar cell illustrated is a center-hyperpolarizing cell, the amacrine cell shown is a transient amacrine cell, and the ganglion cell responses shown on the left and right are from an OFF-center cell. The ganglion cell response in the center is from an ON–OFF cell. The figure also shows how the receptive field organization of the hyperpolarizing bipolar cells, OFF-center ganglion cells, and ON–OFF ganglion cells may be established. The OFF-center bipolar cell responds to direct central illumination (left) by hyperpolarizing and to annular illumination (right) by depolarizing. Note that the switch from hyperpolarizing to depolarizing potentials along the surround illumination pathway occurs at the horizontal–bipolar cell junction. The OFF-center, ON-surround ganglion cells receive much of their input directly from the bipolar cells, whereas the ON–OFF ganglion cell (middle) receives substantial input from the transient amacrine cell. From Dowling JE (1991) Retina. In: *Encyclopedia of Human Biology*, vol. 6. New York: Academic Press.

Neuronal Responses

The distal retinal neurons – receptors, horizontal cells, and bipolar cells – respond to light with sustained and graded membrane potential (voltage) changes (Figure 6). Unlike most neurons found elsewhere in the brain, they do not generally generate action potentials. This is the case because these neurons have relatively short processes, and they do not need to transmit information over long distances; in other words, passive spread of potential along the cell membrane is sufficient to transmit information from one end of the cell to the other. A second reason that the distal retinal cells may function with graded potentials is that such potentials are capable of discriminating a wider range of signals than can all-or-none events (i.e., action potentials). Many amacrine cells and all ganglion cells, on the other hand, generate action potentials.

Another unusual feature of the distal retinal neurons is that most of them respond to light with hyperpolarizing potentials during illumination; that is, the inside of the cell becomes more negative. Elsewhere in the nervous system, hyperpolarizing

potentials are usually associated with inhibition because they prevent neurons from generating action potentials. In the distal retina, the neurons do not generate action potentials; thus, hyperpolarizing potentials can reflect excitation, and the photoreceptors are a good example of this.

Photoreceptors Both rod and cone photoreceptors only hyperpolarize in response to illumination, but rods are approximately 25 times more sensitive to light than are cones. Why photoreceptors hyperpolarize in response to light and why the membrane potential of the cell is partially depolarized in darkness were discussed previously. A typical resting value for the membrane potential of photoreceptors in the dark is −30 mV, and in response to bright illumination the membrane potential decreases to −60 mV, which is a typical resting potential for most neurons at rest. Thus, in the distal retina, photoreceptors and other neurons behave as though darkness is the stimulus and light turns them off.

As noted previously, there are small electrical synapses between photoreceptors. They may relate to the functioning of the photoreceptors or as a pathway for information flow. For example, they can provide an alternative pathway for rod signals to reach the cone bipolar cells. On the other hand, electrical coupling between photoreceptors can reduce membrane noise and hence improve signal detection. The electrical coupling between photoreceptors does slightly increase the receptive field size of the cell. That is, the receptors respond to illumination over a wider area of the retina than that of a single receptor. Nevertheless, photoreceptors typically have the smallest receptive fields of any of the retinal neurons (Figure 6).

Horizontal cells Horizontal cells, like photoreceptors, have relatively low resting membrane potentials in the dark (−30 mV), and most often they only hyperpolarize in response to light (Figure 6). Some horizontal cells respond with depolarizing responses to certain wavelengths of light and with hyperpolarizing responses to other wavelengths. These cells appear to be involved in color processing and are termed chromaticity (C) cells. Horizontal cells that only hyperpolarize to illumination are called luminosity (L) cells.

The receptive fields of horizontal cells are characteristically large, often several millimeters in diameter. Thus, the receptive field size usually exceeds the dendritic spread of the cells. Horizontal cells typically make extensive electrical junctions with each other, and the large receptive fields of these cells can be explained on the basis of the extensive electrical coupling between horizontal cells.

Bipolar cells Bipolar cells, like receptors and horizontal cells, respond to light mainly with sustained graded potentials (Figure 6). In the mammalian retina, all rod bipolar cells depolarize to light. However, two physiological types of cone bipolar cells are found in all species: those that depolarize in response to central spot illumination (ON-center cells) and those that hyperpolarize to such stimuli (OFF-center cells; Figure 6). Furthermore, the cone bipolar cell receptive field is organized into antagonistic zones such that illumination of the surround antagonizes the response to spot illumination. Thus, cone bipolar cells show a center–surround receptive field organization.

Amacrine cells In most retinas, two basic types of amacrine cell responses – transient and sustained – are observed. Transient amacrine cells usually give ON and OFF depolarizing responses to illumination presented anywhere in their receptive field (Figure 6), but there are also transient amacrine cells that respond only at the onset (ON) of illumination. Transient amacrine cells typically generate action potentials, and these potentials are observed on the transient ON and OFF depolarizations. Often, only one to three action potentials are observed on the transient depolarization, and thus these action potentials may serve more as an amplifying mechanism for the amacrine cell potentials rather than as a signal transmitted along the cell, as is the case for most neurons.

Sustained amacrine cell responses often resemble horizontal cell responses. They may be either hyperpolarizing or depolarizing in polarity, and the amplitudes of the two response types are comparable. Usually, sustained amacrine cells, like transient amacrine cells, give similar responses to spot illumination anywhere in their receptive field. There are also amacrine cells whose responses are a mix of transient and sustained potentials.

Ganglion cells The receptive field properties of ganglion cells were discussed previously, and it was noted that many ganglion cells typically show sustained ON-center, OFF-surround responses or sustained OFF-center, ON-surround responses (Figure 6). These ganglion cell responses resemble bipolar cell responses, the major difference being that ganglion cells fire action potentials when they depolarize. Other ganglion cell responses give transient ON or OFF responses or ON–OFF responses. These ganglion cell responses resemble transient amacrine cell activity.

Functional Organization of the Retina

Figure 6 also suggests in a simplified way how receptive fields of the retinal neurons may be produced

by the synaptic interactions occurring within the retina. The figure correlates the basic connections of the retinal cells with intracellular responses recorded from an amphibian (mudpuppy) with spots or annuli (rings) of light.

Photoreceptors have small receptive fields. They respond well to spots of light centered over them but not to light that does not directly strike the cell (annuli). Bipolar and horizontal cells are both activated by the receptors, and Figure 6 shows that both cell types respond with sustained graded potentials that roughly resemble in waveform the photoreceptor response. The figure further shows that the horizontal cells interact with bipolar cells and that this interaction is opposite in terms of polarity from the receptor–bipolar interaction. In Figure 6, the receptor causes the bipolar cell to hyperpolarize, whereas the horizontal cell causes the bipolar cell to depolarize. Horizontal cells have a much larger lateral extent than do bipolar cells; thus, a center–surround receptive field organization is observed in the bipolar cell response. The center response of the bipolar cell (Figure 6, left) is mediated by direct receptor–bipolar cell interactions, whereas the surround response (Figure 6, right) reflects input to the bipolar cell via the horizontal cells.

How horizontal cells mediate the surround response in bipolar cells is not well understood. In most species, feedback from horizontal cells to cone photoreceptor cells has been observed, and it has been proposed that the surround antagonism is generated in this way. Feedforward inhibition of horizontal cells onto bipolar cells has been seen in some species, and no feedback inhibition has been observed on rod photoreceptor cells. Thus, the surround response of the bipolar cells probably results mainly from feedback interactions, but feedforward interactions may contribute as well. The mechanism underlying feedback interaction is unclear. It may represent classic chemical synaptic inhibition or complex electrical interactions between cells in the outer plexiform layer.

As noted previously, two types of synapses made by the cone terminals have been observed: invaginating and flat junctions. Generally, the flat junctions mediate the center-hyperpolarizing responses (OFF responses) in bipolar cells, whereas the invaginating junctions result in the center-depolarizing bipolar cell responses (ON responses).

The bipolar cell terminals carry the visual signal from the outer to inner plexiform layers. Depolarizing or ON bipolar cell terminals are found in the inner half of the plexiform layer, whereas hyperpolarizing (OFF) bipolar cell terminals are in the outer half of the layer. Thus, there is a division of the inner plexiform layer into ON and OFF laminae. ON responses of amacrine and ganglion cells are generated in the lower part of the layer, whereas OFF responses are generated in the upper part. Thus, ON-center ganglion cells have their processes in the lower or ON layer of the inner plexiform layer, OFF-center cells in the upper or OFF layer, and ON–OFF ganglion cells spread processes in both halves of the layer. In addition to the ON and OFF laminae, there is evidence for as many as 10–12 sublaminae in the inner plexiform layer. The cells contributing processes to these sublaminae have distinct properties with regard to characteristics such as rod or cone dominance, response waveform, and excitatory and inhibitory input. Each sublamina thus appears to process visual information somewhat differently.

The responses of the two basic types of ganglion cells found in the mudpuppy (and other retinas) appear to relate to the responses of the major input neurons to the ganglion cells. The sustained ON- or OFF-center ganglion cells (left and right recordings in Figure 6) receive much of their synaptic input directly from the bipolar cells; their responses resemble those of the ON or OFF bipolar cells, and their receptive fields thus reflect primarily the processing that occurs in the outer plexiform layer. The ON–OFF transient ganglion cells, on the other hand, resemble in their properties the transient amacrine cells, and they receive more of their input from amacrine cells (middle recording in Figure 6). These cells reflect more the processing that occurs in the inner plexiform layer. As noted previously, the transient ganglion cells respond better to moving than to static stimuli, and some of these cells show complex receptive field properties such as direction selectivity. Substantial anatomical evi dence indicates that complex ganglion cell receptive field properties, such as motion and direction sensitivity, are mediated in the inner plexiform layer, predominately as a result of interactions between amacrine and ganglion cells. In species that have many motion- and direction-selective cells, there are more amacrine cell synapses per unit area of the inner plexiform layer than there are in species that have relatively few motion- and direction-selective ganglion cells.

In addition to the two basic types of ganglion cells described here, many ganglion cells have a mix of transient amacrine and bipolar cell characteristics. The Y-type ganglion cell of the cat and M-type primate ganglion cell are examples. They show a center–surround receptive organization like the bipolar cells, but their responses to both center and surround stimulation are quite transient and they are sensitive to moving stimuli. These cells appear to receive more of a mix of bipolar and amacrine cell synaptic input than the more sustained ON-center or OFF-center ganglion cells of the cat and primate – the X and P cells.

Pharmacology

The retina, like other regions of the brain, contains a large number of neuroactive substances. At least 17 substances are believed to be released from retinal neurons during retinal activity (Table 1), and, like in other brain regions, these substances may be classified into two general categories – neurotransmitters and neuromodulators – based on their mode of action. Relatively few substances appear to serve as neurotransmitters in the retina. L-Glutamate and acetylcholine mediate fast excitatory pathways in the retina, whereas GABA and glycine mediate fast inhibitory pathways. The bulk of the neuroactive substances released from retinal neurons appear to be neuromodulatory in nature, although little is known about the action or role of most of these substances, especially the peptides.

Both photoreceptors and bipolar cells employ L-glutamate as their transmitter. L-Glutamate depolarizes both horizontal cells and OFF-center (hyperpolarizing) bipolar cells, whereas it hyperpolarizes the ON-center (depolarizing) bipolar cells. Neurotransmitter is released when neurons are depolarized, and because photoreceptors are maintained in a depolarized state in the dark, they release L-glutamate in the dark. When illuminated, photoreceptors hyperpolarize, and transmitter release is decreased. Thus, the light responses of the horizontal and bipolar cells reflect the withdrawal of transmitter from the cell. Horizontal cells are depolarized in the dark because of a dark release of L-glutamate from the photoreceptors; their light response is a hyperpolarization, reflecting the decrease in transmitter release from the photoreceptors in light. The same explanation holds for the OFF-center bipolar cells. These cells are depolarized in the dark; they hyperpolarize in light as transmitter release from the photoreceptor decreases. The ON-center cell, however, is hyperpolarized in the dark, and it depolarizes in the light in response to the decreased release of L-glutamate from the photoreceptor.

Table 1 Substances released from retinal neurons during retinal activity

Amino acids
γ-Aminobutyric acid (GABA)
L-Glutamate
Glycine
Amines
Acetylcholine
Dopamine
Serotonin
Peptides
Cholecystokinin
Enkephalin
Glucagon
Neurotensin
Neuropeptide Y
Somatostatin
Substance P
Vasoactive intestinal peptide
Unconventional modulators
Nitric oxide
Retinoic acid
Zinc

The amino acids GABA and glycine serve as the main inhibitory neurotransmitter agents in both inner and outer plexiform layers. Many horizontal cells contain GABA, and approximately 80% of the amacrine cells in many retinas contain either GABA or glycine, equally divided. Both GABA and glycine powerfully inhibit ganglion cells by opening channels in the cell membrane that cause hyperpolarization of the cell and inhibition of action potential generation. GABA and glycine act on many retinal neurons, mediating specific inhibitory effects. For example, by blocking the effects of GABA with pharmacological agents, direction-sensitive ganglion cells lose their directional selectivity. Such cells now respond to spots of light moving in any direction across the retina. It is believed, therefore, that direction sensitivity is mediated by GABAergic inhibition in the inner plexiform layer.

Most amines and neuropeptides appear to function as neuromodulatory agents in the retina. The exception is acetylcholine, which functions in the retina as an excitatory neurotransmitter in the inner plexiform layer. Acetylcholine is found in a specific type of amacrine cell, the starburst cell, which provides excitatory input to the transient ON–OFF ganglion cells. Interestingly, the starburst amacrine cells also contain GABA, and both acetylcholine and GABA are released by this neuron. The starburst amacrine cells appear to play a critical role in the generation of direction-selective ganglion cell responses.

The other amines, dopamine and serotonin, and the neuropeptides have also been localized principally to amacrine cells. These cells are relatively rare, accounting for no more than a few percent of the total number of amacrine cells. These cells usually spread their processes widely in the inner plexiform layer, and so they are capable of exerting extensive modulatory effects. It is also the case that coexistence of neuroactive substances occurs in many amacrine cells. It has been reported that two peptides can coexist in the same amacrine cell, that a peptide and a monoamine coexist, or that a peptide or monoamine and an inhibitory amino acid (usually GABA) are in the same cell. The significance of the co-localization of two or more neuroactive agents in a single retinal neuron is not yet understood, although an obvious idea is that it permits multiple effects to be exerted on postsynaptic neurons.

The best-understood neuromodulatory substance in the retina is dopamine, which exerts effects throughout the retina via its action on neurons and synapses. For example, it modulates the strength of electrical and chemical synapses in both outer and inner plexiform layers, resulting, for example, in an alteration in strength of the center–surround interactions in bipolar and ganglion cells. Dopamine also modulates the relative strength of rod and cone pathways in many retinas by altering transmitter-gated and voltage-gated channels in neurons. Dopamine exerts these effects by activating receptors on retinal neurons that are linked to the enzyme adenylate cyclase, which catalyzes the formation of the second messenger cyclic AMP in the cells. Cyclic AMP activates a specific kinase which, via phosphorylation, alters the properties of synaptic channels and receptors. Thus, dopamine does not initiate activity in the retina but, rather, modulates retinal function by altering the properties of the retinal neurons and their synapses.

Conclusion

The retina is a relatively well-understood part of the central nervous system, yet its complexity is overwhelming. Whereas we have long recognized that it consists of just photoreceptors and four major classes of neurons, we now realize that each class of neuron consists of many cell subtypes, perhaps as many as 20–30 in the case of amacrine cells. Furthermore, although we can classify the responses of most retinal neurons as ON-center, OFF-surround cells, OFF-center, ON-surround cells, or ON–OFF cells, and as giving principally sustained or transient responses, we now recognize that a variety of subtle image representations are being sent to the brain via the optic nerve and that this variety reflects complex synaptic excitatory and inhibitory synaptic interactions occurring among various neuronal subtypes at different levels of the retina, particularly in different laminae in the inner plexiform layer. Finally, whereas relatively few substances appear to serve as the principal excitatory and inhibitory neurotransmitters in the retina, a much larger number of neuromodulatory substances are known to exist in the retina, including several unconventional substances that have been shown to have significant effects on the retinal cells. Thus, the responses of individual retinal neurons reflect not only the direct excitatory and inhibitory synaptic interactions between neurons but also an extensive modulation of these synaptic interactions by various substances acting in different ways on the neurons and their channels.

Retinal Amacrine Cells

Introduction

The amacrine cells are the major interneurons in the proximal retina of vertebrates. They form the most diverse type of neuron in the retina, with 20–30 morphological subpopulations described in mammals, based on differences in somatic and dendritic architecture (Figure 1). The dendritic branches of these subtypes stratify within restricted levels of the inner plexiform layer (IPL), indicating selectivity in the synaptic connections made with bipolar cell axon terminals as well as the dendritic processes of neighboring amacrine and ganglion cells. It is believed that the structural diversity within the amacrine cell population reflects an equally large range of physiological properties and the corresponding functional roles played in formulating the retinal output signals expressed by the postsynaptic ganglion cells.

Amacrine Cell Morphology

The amacrine cells were named by Ramón y Cajal after a Greek derivation of 'neurons lacking long fibers,' based on the typically circumscribed space occupied by their dendritic arbors. The morphological classification of amacrine cells has been based on a number of structural parameters, including (1) size, position, and shape of the perikaryon; (2) size and symmetry of dendritic arbors, including the shape and caliber of branches and density of arborization; and (3) the stratification pattern of dendrites within the IPL. Beginning with the Golgi method, a wide variety of techniques have been employed to elucidate the different morphological subtypes of amacrine cell in the retina. It is now clear that 20–30 amacrine cell subtypes exist. A significant number of them are conserved across mammalian species and even show correspondence to amacrine cell subtypes in lower vertebrate retinas. Within a given retina, the amacrine cell subtypes form regular mosaics, but these show tremendous variability in intercellular spacing, indicating differences in their sampling of visuotopic space. It is interesting that any single subtype of amacrine cell forms only a small percentage of the total population. While the AII subtype, which subserves the pathway that carries rod information, constitutes about 13% of all amacrine cells, no other subtype totals more than 5%. This division of amacrine cell subtypes suggests that each plays a separate, yet equally important, role in visual processing.

The somata of amacrine cells lie mainly within the proximal portion of the inner nuclear layer (INL), but those of many subtypes are displaced to the ganglion cell layer (GCL) or lie within the IPL. In some retinas, displaced amacrine cells even outnumber the ganglion cells in the GCL. On the basis of dendritic arbor size, amacrine cells can be divided generally into small-field cells, thought to play a role in local processing and higher acuity vision, and wide-field or long-range cells, involved in more-global retinal processing. Some of these long-range amacrine cells have very e xtensive dendritic arbors that span hundreds of micrometers laterally across the retina. Further, a number of amacrine cell subtypes, described recently in mammals, have very long, narrow, axonlike processes distinct from a conventional dendritic arbor (Figure 2). These fibers show the ultrastructure of typical axons in the central nervous system (CNS), including the expression of high-molecular-weight neurofilament proteins. In contrast to ganglion cells, these so-called polyaxonal amacrine cells bear multiple axonlike fibers that emerge from the soma or dendritic processes and course for several millimeters through the IPL but do not exit the retina via the optic nerve.

The synapses made by amacrine cells are confined to the IPL. Chemically mediated synapses are made with ganglion cell dendrites, bipolar cell axonal processes, or dendrites of other amacrine cells. The dendrites of amacrine cells can maintain both presynaptic and postsynaptic specializations. These synapses can occur juxtaposed along the same dendritic segment to form complex circuits. For example, amacrine cell processes that are postsynaptic to bipolar cells at ribbon synapses can make nearby reciprocal synapses back to the bipolar cell axon. This feedback synapse, which is inhibitory, is thought to modulate the release of neurotransmitter from the bipolar cell. A second type of complex amacrine cell circuit is called a serial synapse; in it, one amacrine cell makes contact with a second amacrine cell, which, in turn, synapses onto a third cell, all within a short distance.

It is interesting that the ratio of the number of synapses that ganglion cells make with amacrine cells and with bipolar cells varies across species. This ratio can also vary for different ganglion cell subtypes within the same retina. It has been suggested that ganglion cells with simple, concentric receptive fields receive synaptic inputs mainly from bipolar cells, whereas those with complex response properties,

Figure 1 Amacrine cell subtypes in the central primate retina. Drawings are of Golgi-impregnated cells in the rhesus monkey retina as they appear in flat mount. The cells designated *s.a.*1, 2, and 3 are different subtypes of amacrine cells with unistratified dendritic arbors in the IPL. The amacrine cells labeled as *d.a.* display diffusely stratifying dendritic arbors. Note the overlapping fields of the different amacrine cell subtypes as well as differences in their intercellular spacing. From figure 96 in Boycott BB and Dowling JE (1969) Organization of the primate retina: Light microscopy. *Philosophical Transactions of the Royal Society B: Biological Sciences* 255: 109–184, with permission.

such as direction or orientation selectivity, receive more amacrine cell synaptic input. This suggests that amacrine cell circuitry in the IPL underlies the processing of complex visual responses seen in some ganglion cells.

Electrical coupling via gap junctions occurs for almost all the subtypes of amacrine cell in mammalian retinas (**Figure 3**). This includes homologous coupling between adjacent amacrine cell neighbors or heterologous coupling between amacrine cells and ganglion cells or bipolar cells. These electrical synapses are thought to play a variety of roles in information processing. For example, AII amacrine cells receive inputs from rod bipolar cells and thereby process information during nighttime vision. The AII amacrine cells are extensively coupled to one another via gap junctions composed of connexin36 protein. The coupling between AII cells is believed to sum synchronous signals and reduce background noise, thus increasing the fidelity of the rod signals they carry. Further, the conductance of these gap junctions is affected by dopamine, which acts as a light-mediated neuromodulator. Thus, the size of the network formed by AII cells changes under different ambient, background light conditions. The result is that AII cell coupling is constantly changing to ensure the highest fidelity of responses to maintain the very sensitive rod signals in the proximal retina (see the section titled 'AII amacrine cells'). In support of this notion, the sensitivity of postsynaptic ganglion cells is reduced by about one log unit of illumination in the connexin36 knockout mouse retina, in which the AII amacrine cells are uncoupled.

Amacrine Cell Neurotransmitters

With one exception, all amacrine cells are inhibitory interneurons and typically use either γ-aminobutyric acid (GABA) or glycine as their neurotransmitter. The responses of virtually all ganglion cells are affected by exogenous application of these transmitters, either directly or through the complex circuitry of the IPL described above. The GABA receptors appear to be segregated, whereby $GABA_A$ and $GABA_B$ receptor subtypes subserve feedforward inhibition of amacrine cells onto other amacrine cells and ganglion cells, and $GABA_C$ receptors mediate the feedback inhibition onto bipolar cell axon terminals. The combination of GABA effects via the different receptors is believed to influence the sustained or transient characteristics of amacrine and ganglion cell responses. In general, glycine is the transmitter used by small-field amacrine cells, whereas GABA is used by medium- and wide-field cells. Acetylcholine-containing amacrine cells, also called starburst amacrine cells, consist of mirror-image pairs with somata in the GCL and INL and dendrites monostratified in the inner and outer IPL, respectively. It is interesting that starburst amacrine cells are found in all vertebrate retinas, suggesting that they play an important role in visual processing (see the section titled 'Starburst amacrine cells'). The acetylcholine release from starburst cells occurs by two methods: a small, tonic release that is independent of calcium and light and a second, larger acetylcholine release that is light dependent. It is interesting that starburst cells also release GABA, and so this neuron has mixed excitatory and inhibitory effects.

Dopaminergic amacrine cells form a distinctive subtype that is also found in all vertebrate retinas. Dopaminergic amacrine cells in the mammal have polyaxonal morphology, consisting of a relatively small dendritic arbor and numerous long axonal processes that extend more than 1 mm. Most processes stratify in the IPL, where they encircle the AII amacrine cells. As discussed below, dopaminergic amacrine cells control the electrical coupling between AII amacrine cells. The axons of some dopaminergic cells, particularly in nonprimate species, extend outward past the INL to terminate in the outer plexiform layer. The dendrites of

Figure 2 Morphology of a subtype of polyaxonal amacrine cell in the rabbit retina. (a) Photomicrograph showing the extensive tracer coupling pattern following injection of Neurobiotin into a type I polyaxonal amacrine cell (asterisk). (b) Somata of tracer-coupled type I polyaxonal amacrine cells and the overlapping thick dendritic processes and thin axonal processes. Arrowheads indicate axonal processes emerging from proximal dendrites. (c) Camera lucida drawing providing a flat-mount view of a type 1 polyaxonal amacrine cell. The dendritic arbor is presented in black, and the axonal arbor and somata of tracer-coupled amacrine cells are shown in gray. Scale bars = 100 μm (a), 25 μm (b), 200μm (c). From figures 1 and 2 in Völgyi B, Xin D, Amarillo Y, and Bloomfield SA (2001) Morphology and physiology of the polyaxonal amacrine cells in the rabbit retina. *Journal of Comparative Neurology* 440: 109–125.

dopaminergic amacrine cells receive most if not all the excitatory synaptic input from bipolar cells, whereas the release of dopamine occurs at varicosities within the axonal arbor. Thus, there is a polarity to the structure of dopaminergic amacrine cells in terms of their input and output synaptic circuits.

Another well-studied subtype is the indoleamine-accumulating or serotonergic amacrine cell. In the mammal, the serotonergic amacrine cells maintain very long and thin dendritic processes with numerous varicosities. Computational models suggest that varicosities act to electrically isolate individual dendritic segments, thereby allowing for independent processing of synaptic inputs. These cells receive input mainly from rod bipolar cells, but rather than transmit the signals forward to ganglion cells, the serotonergic amacrine cells make reciprocal synapses with the same rod bipolar axon terminals. These amacrine cells are thus thought to modulate the release of bipolar cell neurotransmitter under scotopic light conditions. Little is known about the effects of serotonin on ganglion cells, but application of serotonin antagonists appears to reduce the responses of on-center ganglion cells and to increase the responses of off-center cells.

In addition to conventional neurotransmitters, amacrine cells express a large number of neuropeptides, including substance P, enkephalin, somatostatin, neurotensin, glucagon, vasoactive intestinal peptide, neuropeptide Y, and cholecystokinin. The peptidergic amacrine cells have been best studied in the bird retina, in which they show differences in dendritic structure, particularly in the IPL strata they occupy. In the mammal, peptidergic amacrine cells are mainly subtypes of polyaxonal cells, suggesting that peptides are released over large areas of the retina and serve a neuromodulatory role. Many of these peptidergic amacrine cells accumulate or express more than one peptide and/or express the conventional inhibitory transmitters GABA and glycine. Individual amacrine cells may thereby have multiple roles in both local and global visual processing.

There have been relatively few studies of the effects of peptides on the responses of retinal neurons, but they appear to have general excitatory or inhibitory actions. For example, substance P excites retinal ganglion cells in the fish retina, whereas enkephalin appears to inhibit their activity in the amphibian. In mammals, ablation of neuropeptide Y amacrine cells results in a reduction of the receptive field size of certain ganglion cells that

Figure 3 Tracer coupling patterns of amacrine cells in the rabbit retina. respond preferentially to low acuity scenes. This peptide is thus thought to have a role in the circuitry underlying ganglion cell spatial tuning.

Amacrine Cell Physiology

Although there are 20–30 subtypes of amacrine cell in the mammalian retina, the physiology of fewer than ten subtypes has been studied in detail. Nevertheless, it is clear the amacrine cells show an extraordinary variety of response properties. In general, amacrine cells can be divided into transient and sustained categories on the basis of the temporal properties of their responses. In lower vertebrates, the transient cells usually show on–off responses, although transient 'on cells' and transient 'off cells' have been described in a number of species. Most sustained amacrine cells show the center-surround antagonistic receptive field organization displayed by bipolar cells and most ganglion cells. In classic experiments, amacrine cells were shown to be robustly excited by a windmill stimulus, indicating their sensitivity to moving objects.

In addition to the relatively simple center-surround receptive field of most amacrine cells, certain subtypes display complex physiology similar to that of some ganglion cells. These include amacrine cell subtypes with orientation selectivity derived from the spatial organization of excitatory and inhibitory inputs or an asymmetry in their dendritic field architecture (**Figure 4**). Amacrine cells with a response preference for the direction of stimulus motion have been reported. This includes the starburst amacrine cell, which shows a response preference for stimuli moving centrifugally away from the soma (see the section titled 'Starburst amacrine cells').

In contrast to other retinal interneurons, many amacrine cells express voltage-gated sodium channels and display action potentials (**Figure 5**). Spiking has been reported in both transient and sustained amacrine cells and is often seen superimposed atop large excitatory potentials. In addition to large-amplitude somatic spikes, some amacrine cells display all-or-none sodium-mediated spikes similar to microspikes thought to be generated within the dendritic

Figure 4 Orientation-sensitive amacrine cells in the rabbit retina. (a) Responses of an orientation-selective amacrine cell to a rectangular slit of light swept across the retina at four orientations. The cell excited when the stimulus was oriented at 90°, but was inhibited when the stimulus was rotated to 0°. (b) Flat-mount view of orientation-selective cell injected with horseradish peroxidase. Same cell whose responses are shown in Panel. (c) Responses of an orientation-biased amacrine cell to a rectangular slit of light swept across the retina at four orientations. A stimulus oriented at 0° evoked the largest depolarization, whereas a stimulus at the orthogonal orientation of 90° produces little response. Unlike orientation-selective amacrine cells, orientation-biased amacrine cells showed no inhibitory responses. (d) Orientation-biased amacrine cell whose responses are shown in panel (c). Note the asymmetry in the dendritic arbor with the major axis oriented at 0° matching the preferred orientation physiology. Scale bar = 150 (b), 50 μm (c). From figures 1, 5, 8, and 10 in Bloomfield SA (1994) Orientation-sensitive amacrine and ganglion cells in the rabbit retina. *Journal of Neurophysiology* 71: 1672–1691, with permission.

membrane (Figure 5(a)). In wide-field amacrine cells, including the polyaxonal cells, spikes are actively propagated centrifugally to terminal branches. In this scheme, somatic spikes are believed to rapidly invade the entire arbor to produce global signaling and release of neurotransmitter. In contrast, dendritic spikes provide only regional activation resulting in local signaling to postsynaptic cells. In this way, the multifocal impulse-generating capability of certain wide-field amacrine cells provides for a complexity in receptive field properties and integration of synaptic inputs.

The dopaminergic amacrine cells show a pacemaker activity of rhythmic, spontaneous bursts of action potentials (Figure 5(b)). This pacemaker activity is generated intrinsically by voltage-gated sodium channels that slowly depolarize the membrane to threshold levels. Since the polyaxonal dopaminergic amacrine cells act on distant cellular targets, the pacemaker activity likely ensures the tonic release of the neuromodulator. In addition to suprathreshold spiking, many amacrine cells show rhythmic subthreshold oscillations. This idea is supported by the finding that bipolar cell axon terminals display calcium-dependent spontaneous membrane oscillations, which may lead to pulsatile transmitter release and rhythmic activity of postsynaptic amacrine cells. In contrast, the oscillatory activity of some amacrine cell subtypes survives cell isolation in culture and thus must be generated intrinsically. The subthreshold oscillatory activity of bipolar and amacrine cells can produce periodic release of neurotransmitter that, in turn, will produce oscillatory activity in postsynaptic cells, particularly ganglion cells. As at other CNS loci,

Figure 5 Spontaneous large somatic and small dendritic spikes displayed by large amacrine cells. (a) Application of extrinsic current via the recording electrode differentially evokes the small- and large-amplitude spikes in a wide-field amacrine cell in the rabbit retina. Relatively low-amplitude current effectively evokes the large somatic spikes, whereas the smaller dendritic spikes are evoked only with larger currents, suggesting more-distal initiating sites. Asterisks indicate small spikes. (b) Rhythmic, spontaneous bursts of action potentials displayed by a dopaminergic polyaxonal amacrine cell in the dark-adapted mouse retina. Both large and small amplitude are seen, presumably generated at somatic and dendritic sites, respectively.

subthreshold oscillations distributed among a network of cells can result in light-evoked synchronous activity as cells will tend to reach spike threshold together. The spontaneous oscillatory activity of amacrine cells may thereby serve to organize ensembles by coordinating the activity when activated by appropriate visual stimuli. This synchronous activity may serve to increase stimulus efficacy, encode additional information, and/or bind information about local visual features.

Examples of Specific Amacrine Cell Functional Roles

While it is clear that amacrine cells must play a wide variety of roles in visual processing, only a few of the many subtypes have been studied in detail. The physiology and morphology of two subtypes, the AII and starburst amacrine cells, have been extensively studied, and we now have a good understanding of their specific roles in retinal processing of visual signals. The results of these studies are summarized below.

AII Amacrine Cells

In the mammalian retina, rod and cone photoreceptors synapse onto largely different bipolar cells, thereby segregating their signals into different vertical streams. Whereas up to 11 different morphological types of cone bipolar cells have been reported, showing both on- and off-center physiology, only a single type of rod bipolar cell exists. It is interesting that the axons of rod bipolar cells do not directly contact ganglion cells but instead contact mainly the small-field, bistratified AII amacrine cell. In turn, AII cells form sign-conserving electrical synapses with the axon terminals of on-center cone bipolar cells and sign-inverting glycinergic chemical synapses with the axon terminals of off-center cone bipolar cells. In this way, both on- and off-center scotopic signals utilize the cone pathways before reaching the ganglion cells and ultimately higher brain centers.

The gap junctions formed between AII cells and the on-center cone bipolar cells form nonrectifying electrical synapses across which the direction of signal flow changes with stimulus intensity. As mentioned above, rod signals generated under dim, scotopic light conditions move from the AII cells to the cone bipolar cells to be distributed to the ganglion cells. In contrast, under bright, photopic conditions, cone signals move in the opposite direction, from cone bipolar cells to the AII amacrine cells. The interconnecting gap junctions thus do double duty as conduits for both rod and cone signals.

The AII amacrine cells also form gap junctions between one another, forming an extensive electrical syncytium. Computational models suggest that this coupling increases the signal-to-noise ratio of AII cell responses by summing synchronous responses and deceasing asynchronous noise. It is interesting that the conductance of these homologous AII cell–AII cell junctions is affected by light via modulation of dopamine release by changes in dark-light adaptation (Figures 6(a)–6(c)). Under dim, rod-mediated light conditions, the relationship between coupling and ambient light intensity has two phases: AII cells are relatively uncoupled in the dark-adapted retina but

Figure 6 Light-induced changes in the coupling between AII amacrine cells. (a) Tracer coupling pattern of AII cells after injection of one AII cell (asterisk) with Neurobiotin in the dark-adapted rabbit retina. Plane of focus on a group of eight darkly labeled AII cell somata and an outer ring of 10–15 lightly labeled AII cell somata are visible. (b) Plane of focus on tracer-coupled somata of ON cone bipolar cells that lie more distal in the INL. (c) Tracer coupling pattern of AII cells after injection of one cell with Neurobiotin in retina exposed to dim background light. Size of tracer-coupled group has increased dramatically with light exposure. (d) Scatterplot illustrating the similar modulation of tracer coupling and receptive field size of AII cells across a range of background light intensities corresponding to the scotopic and mesopic levels (rod operating range). Each data point illustrates the average and standard error of multiple injections. Well dark-adapted retinas are represented by data point corresponding to 'none' background light intensity. Note that coupling increases dramatically with dim light exposure and then reaches a plateau level over the operating range of rods. Scale bars = 25 μm (a–c). (a, b, d) Adapted from figures 2 and 9 in Bloomfield SA, Xin D, and Osborne T (1997) Light-induced modulation of coupling between AII amacrine cells in the rabbit retina. *Visual Neuroscience* 14: 565–576, with permission. Reproduced (c) from figure 1 in Xin D and Bloomfield SA (1999) Comparison of the responses of AII amacrine cells in the dark- and light-adapted rabbit retina. *Visual Neuroscience* 16: 653–665, with permission.

show a dramatic increase in coupling when dim background stimuli are presented (Figure 6(d)).

What is the function of the light-induced changes in AII cell–AII cell coupling? One idea is that these changes reflect the need for AII cells, as vital elements in the rod pathway, to remain responsive throughout the scotopic-mesopic range. In this scheme, dark adaptation is analogous to starlight conditions, under which rods will only sporadically absorb photons of light. The need, then, is for AII cells to preserve these isolated signals above the background noise. Accordingly, the AII cells are relatively uncoupled in that there are few correlated signals to sum, and so extensive coupling would serve to dissipate and thereby attenuate the few isolated responses rather than enhance them. As dawn approaches, more photons become available. In turn, AII amacrine cells show an increase in coupling, which provides for summation of synchronous activity over a wider area, thus preserving the fidelity of these rod-driven, correlated signals at the expense of spatial acuity. This transition in coupling between dark-adapted retinas and those illuminated with dim background light suggests two basic operating states for AII cells under scotopic/mesopic light conditions: (1) responding to single photon events and (2) summing signals over a relatively large area to sum synchronized events above the background noise. Overall, the AII cell coupling ensures that the most sensitive rod signals are maintained at the ganglion cell level and transmitted to higher brain centers.

Starburst Amacrine Cells

A unique subtype of ganglion cell found in the retinas of many species is the direction-selective (DS) unit. DS cells respond vigorously to stimulus movement in the preferred direction yet show little or no activity following movement in the opposite or null direction. The ON–OFF variety of DS ganglion cell can be divided into four subtypes, each preferring a direction of movement roughly corresponding to the attachment points of the extraocular muscles. The mechanism underlying the computation of direction of motion has been the subject of investigation for more than 40 years. Pharmacologic studies indicate that acetylcholine and GABA can modify the selectivity of DS ganglion cells. In particular, application of GABA antagonists abolishes the direction selectivity of DS ganglion cells, suggesting that asymmetric inhibition resulting from null direction stimulus

movement plays a crucial role. Taken together, these data suggest a role for the starburst amacrine cells, which release both acetylcholine and GABA. As mentioned earlier, starburst amacrine cells are of two mirror-image subtypes. The starburst-*a* cell has a perikaryon in the INL and monostratifies within sublamina-*a* of the distal IPL, whereas the starburst-*b* cell is displaced to the GCL and monostratifies in sublamina-*b*. It is now clear that the dendrites of both the starburst-*a* and -*b* subtypes costratify and are presynaptic to the bistratified processes of ON–OFF DS ganglion cells.

Recent studies have provided compelling evidence that starburst cells indeed play a key role in the generation of direction selectivity. Specific ablation of starburst cells, either through pharmacological manipulation or genetic targeting, abolishes the selectivity of DS cells. Electrophysiological studies have shown that starburst cells provide direct inhibition to DS ganglion cells, suggesting that they provide the GABAergic null inhibition crucial for the direction selectivity of DS cells. Furthermore, the null inhibition from starburst cells is itself direction selective, being stronger for stimulus movement in the null direction.

Taken together, these data suggest that starburst amacrine cells manufacture the direction-selective responses in the retina. In particular, two intrinsic properties of starburst amacrine cells are believed crucial to the generation of DS ganglion cell responses. First, computational and calcium-imaging studies have indicated that the dendritic branches of starburst cells are electrically isolated from one another. This means that single starburst cell dendrites can perform computations independently and simultaneously. Second, light stimulation in the centrifugal direction (away from the soma) produces a greater voltage response than movement in the centripetal direction. It is unclear what establishes these two properties of starburst cells, but potassium channels, calcium channels, chloride ion transporters, and membrane cable properties have all been implicated.

As schematized in Figure 7, centrifugal movement of light along one dendritic branch of a starburst amacrine cell will result in a robust depolarization and the release of GABA onto postsynaptic DS ganglion cells. This provides the null inhibition to the DS cells. Stimulus movement in the opposite, or centripetal, direction will not produce a large response in the starburst cell, and thus no GABAergic inhibition of the postsynaptic DS ganglion cells will be evoked. Thus, the preferred and null directions for a DS

Figure 7 Schematic showing how a starburst amacrine cell generates the direction selectivity of the four ON–OFF direction-selective (DS) ganglion cell subtypes that show different preferred directions: temporal, nasal, superior, and inferior. The dendritic arbor of the starburst amacrine cell (center) can be divided into four parts that are electrically isolated and thus function autonomously. Stimulus movement in the centripetal direction evokes a depolarization of the starburst cell dendritic branch and a release of γ-aminobutyric acid. This produces the null inhibition of the postsynaptic DS ganglion cell. The preferred direction of the DS cell is opposite to the null or centrifugal in the starburst cell dendritic branch. Each starburst cell dendritic branch synapses with a different subtype of ON–OFF DS ganglion cell and thereby produces its preferred direction responses of upward, downward, leftward, and rightward.

ganglion cell are established by the direction of stimulus movement along a starburst cell dendritic branch. Since the dendritic branches of the starburst cell are electrically isolated, each can provide a different directional preference expressed by the four subtypes of ON–OFF DS ganglion cells. In this scheme, each subtype of DS ganglion cell must be postsynaptic to different dendritic branches of a given starburst amacrine cell. Indeed, recordings from DS ganglion cells indicate that while starburst cells lying on the null side of a DS cell provide inhibition, those on the preferred side do not. Likewise, morphological data indicate that DS ganglion cells selectively synapse only with particular starburst amacrine cell processes within their dendritic field.

Conclusions

Amacrine cells form an extensive, heterogeneous group of retinal interneurons that are positioned to modify the output signals carried by the postsynaptic ganglion cells. Despite the large diversity of amacrine cell morphology found in the retina, no one subtype dominates, suggesting each plays a distinct important role in visual processing. This idea is supported by the extraordinary variety of physiological response properties found for amacrine cells, despite the fact that only a few subtypes have been studied so far. These properties include complex receptive fields, including orientation and direction selectivity, somatic and dendritic spiking, pacemaker activity, rhythmic subthreshold oscillations, and electrical isolation of dendritic segments. Further, amacrine cells partake in a variety of complex circuitry that includes both chemical and electrical synapses. In fact, nearly every neurotransmitter, neuromodulator, and neuropeptide found in the CNS has been identified in specific subtypes of retinal amacrine cells. Taken together, these data indicate that the amacrine cells play diverse yet specific roles in the integration of visual signals passing through the retina.

Retinal Bipolar Cells

S M Wu, Baylor College of Medicine, Houston, TX, USA

© 2009 Published by Elsevier Ltd.

Bipolar cells (BCs) are the central neurons of the retina which carry light-elicited signals from photoreceptors and horizontal cells (HCs) in the outer retina to amacrine cells (ACs) and ganglion cells (GCs) in the inner retina. They are also the first postphotoreceptor neurons in the visual pathway exhibiting the center-surround antagonistic receptive field (CSARF) organization, the basic alphabet for encoding spatial information in the visual system. BCs may be on-center with off-surround (named on-center BCs, or depolarizing BCs (DBCs)), or off-center with on-surround (named off-center BCs, or hyperpolarizing BCs (HBCs)). The center input of BCs is mediated by rod and cone photoreceptors which make chemical synapses on BC dendrites. Moreover, BC receptive field centers are often found to be larger than their dendritic fields, suggesting that these cells may be electrically coupled. The surround input to BCs is mediated by interneurons that carry signals laterally from the surround region to the central region of the BCs' receptive field. These interneurons include HCs in the outer retina and ACs in the inner retina. HCs mediate BC surround responses through HC-cone–BC feedback synaptic pathways and/or HC–BC feed-forward (electrical or chemical) synapses, whereas ACs mediate BC surrounds through synapses made on BC axon terminals in the inner plexiform layer (IPL).

In addition to dividing into DBCs and HBCs, BCs are further classified according to their rod/cone inputs. In mammals, rods and cones make synaptic connections with rod and cone BCs separately, and one type of rod BC and 9–10 types of cone BCs have been identified (Figure 1). In fish, small BCs make synaptic contacts with cones and large BCs make contacts with both rods and cones, and in turtle, 11 morphological types of BCs have been found, with some contacting only cones and others contacting only rods. BCs in amphibian retinas contact both rods and cones, but some are clearly rod-dominated whereas others are cone-dominated. Despite these differences between species, BCs in most vertebrate retinas have many common functional and morphological features. It has been established in many vertebrate species, for example, that axon terminals of DBCs ramify in the proximal half (sublamina B) of the IPL, whereas those of the HBCs ramify in the distal half (sublamina A) of the IPL. Axon terminals of rod BCs in mammalian retinas end near the proximal margin of the IPL, and axon terminals of cone BCs ramify in more central regions of the IPL. This agrees with the patterns of BC axon terminal stratification in the salamander: axon terminals of rod-dominated BCs ramify at the two margins of the IPL, whereas those of cone-dominated BCs ramify at central regions of the IPL. Additionally, despite the fact that mammalian rod and cone BCs make segregated synaptic contacts with rods and cones, their light responses are somewhat mixed with rod/cone signals like most BCs in lower vertebrates, partially because rods and cones are electrically coupled and partially because rod BC signals can be transmitted to cone BCs by the AII ACs. Furthermore, although rod HBCs have not been identified anatomically in mammalian retinas, recent physiological evidence suggests that they may exist at least in some mammals. Based on these and other common properties of BCs across vertebrate species, it is reasonable to propose that most vertebrate retinas have six major functional types of BCs: the rod (or rod-dominated), cone (or cone-dominated), and mixed (rod/cone) depolarizing and hyperpolarizing bipolar cells (DBC_R, DBC_C, DBC_M, HBC_R, HBC_C, and HBC_M). Each carries a characteristic set of light response attributes and projects them to the inner retina through axons that terminate at segregated regions (strata) of the IPL. Such stratum-by-stratum projection of light response attributes is exemplified by a large-scale patch clamp study of the salamander BC responses and morphology (Figure 2). This study reveals several rules for the function–morphology relationships of retinal bipolar cells: (1) Cells with axon terminals in strata 1–5 (sublamina A) are HBCs (with outward excitatory cation current (ΔI_C)), and those in strata 6–10 (sublamina B) are DBCs (with inward ΔI_C). This agrees with the sublamina A/B rule observed in many vertebrate species. (2) Cells with axon terminals in strata 1, 2, and 10 are rod-dominated, those in strata 4–8 are cone-dominated, and those in strata 3 and 9 exhibit mixed rod/cone dominance. (3) HBCs exhibit spontaneous excitatory postsynaptic currents (sEPSCs) but DBCs do not. sEPSCs in rod-dominated HBCs are of larger amplitude and higher frequency than those of the cone-dominated HBCs, probably reflecting the fact that the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor kinetics of these two populations of cells are different. (4) Light-evoked ΔI_C at light onset in rod-dominated HBCs and DBCs is sustained, that of the cone-dominated HBCs exhibited a smaller sustained outward current followed by a transient inward current at the light offset, and that of the cone-dominated DBCs exhibited a sustained inward

current followed by a small transient off outward current. (5) Light-evoked inhibitory chloride current (ΔI_{Cl}) in rod-dominated bipolar cells is sustained ON and that in cone-dominated bipolar cells is transient ON–OFF. ΔI_{Cl} in all BCs is outward, and thus is synergistic to ΔI_C in HBCs and antagonistic to ΔI_C in DBCs. (6) Bipolar cells with axon terminals stratified in multiple strata exhibited combined light response properties of the narrowly monostratified cells in the same strata. (7) Bipolar cells with pyramidally branching or globular axons exhibit light response properties very similar to those of narrowly monostratified cells whose axon terminals stratified in the same stratum as the axon terminal endings of the pyramidally branching or globular cells.

In addition to projecting signals to various strata of the IPL, where ACs and GCs gather their inputs, BCs with various light response attributes have different CSARF organizations. A summary diagram of CSARF organization of the DBC_R, DBC_C, HBC_R, and HBC_C is given in Figure 3. The figure illustrates the general synaptic circuitry of the center-surround inputs to BCs and GCs. As discussed later, many new synaptic features, often cell type specific, are not included in this general circuitry scheme. For example, a recent study indicates that in the salamander retina, BCs of the same type are dye coupled, and the receptive field center size is positively correlated with the degree of dye coupling, which varies from one BC type to another. It has also been shown that rabbit cone BCs exhibit CSARFs,

Figure 2 Twenty-two morphologically identified (by Lucifer yellow filling) bipolar cells (BCs) and their light-evoked excitatory cation current (ΔI_C) and inhibitory chloride current (ΔI_{Cl}) recorded from dark-adapted salamander retinal slices. Each cell is named according to their spectral difference (ΔS) and ΔI_C polarity as rod-dominated, cone-dominated, mixed rod/cone hyperpolarizing or depolarizing bipolar cells (HBC_R, HBC_C, $HBC_{R/C}$, DBC_R, DBC_C, or $DBC_{R/C}$). BCs with inward ΔI_C are depolarizing BCs (DBCs) and those with outward ΔI_C are hyperpolarizing (HBCs). The spectral difference, ΔS, is defined as $S_{700} - S_{500}$ (where S_{700} and S_{500} are intensities (in log units) of 700-nm and 500-nm light eliciting responses of the same amplitude). Since ΔS for the salamander rods is about 3.4 and that for the cones is about 0.1, BCs with $\Delta S > 2.0$ are rod-dominated (HBC_R or DBC_R), those with $\Delta S < 1.0$ are cone-dominated (HBC_C or DBC_C), and those with $1.0 < \Delta S < 2.0$ are mixed rod/cone cells ($HBC_{R/C}$ or $DBC_{R/C}$). HBC_C displaced: HBC_Cs with somas displaced in the outer nuclear layer. Modified from Pang JJ, Ga20 F, and Wu SM (2004) Stratum-by-stratum projection of light response attributes by retinal bipolar cells of Ambystoma. *Journal of Physiology* 558: 249–262, and Maple BR, Zhang J, Pang JJ, Gao F, and Wu SM (2005) Characterization of displaced bipolar cells in the tiger salamander retina. *Vision Research* 45: 697–705.

Figure 3 Summary schematic diagram of major synapses that mediate center-surround antagonistic receptive field (CSARF) of bipolar cells and ganglion cells in the retina. The left portion shows the on or depolarizing bipolar cell (DBC) pathway and the right portion shows the off or hyperpolarizing bipolar cell (HBC) pathway. The upper trace in each cell is the voltage response to center illumination, and the lower trace is the response to surround illumination. Plus signs (+) are sign-preserving chemical synapses, minus signs (–) are sign-inverting chemical synapses, and jagged lines (WW) are electric synapses. Neurotransmitter color code: blue, glutamatergic; red, GABAergic; green, glycinergic; yellow, unknown. R, rod; C, cone; H, horizontal cell; HBC_R, HBC_C, DBC_R, and DBC_C, rod- and cone-dominated bipolar cells; A_{ON}, sustained on amacrine cell; A_T, transient on-off amacrine cell; A_{OFF}, sustained off amacrine cell; IPC, interplexiform cell; G_{ON}, sustained ON ganglion cell; $G_{ON\text{-}OFF}$, ON–OFF ganglion cell; G_{OFF}, sustained OFF ganglion cell; OPL, outer plexiform layer; IPL, inner plexiform layer. whereas rod BCs do not have antagonistic surround responses. Additionally, double color-opponent BCs (red off-center/on-surround and green on-center/off-surround) have been reported in the fish retina. Therefore, different sets of synaptic circuitry must be involved in mediating the center and surround inputs of different functional types of BCs.

Synapses mediating BC center inputs are glutamatergic. Glutamate is released from photoreceptors in darkness and causes a conductance decrease in DBCs and a conductance increase in HBCs. Postsynaptic responses of DBCs are mediated by the metabotropic L-AP4 receptors coupled with a second messenger cascade, and postsynaptic responses of HBCs are mediated by ionotropic receptors. Recent studies have shown that different subtypes of ionotropic glutamate receptors may be used by different types of HBCs in mediating rod versus cone and transient versus sustained signals. Glutamate release from photoreceptors and BCs is mediated by calcium-dependent vesicular processes. Calcium entry into photoreceptor and BC synaptic terminals triggers exocytosis of glutamatergic vesicles and releases packages of glutamate, each of which activates a number of glutamate receptors and initiates discrete transient EPSCs. EPSCs occur spontaneously (sEPSCs) at high rates in darkness, and the rate decreases in the presence of light. sEPSCs are seen in most HBCs, but analogous (but sign-inverted) sEPSCs are not observed in DBCs. This probably reflects a difference in the kinetics of the glutamate receptors in DBCs and HBCs, as metabotropic glutamate receptors are significantly slower than the ionotropic receptors and thus the fast sEPSCs are largely 'filtered' in the DBCs.

BC surround responses are mediated by HCs in the outer retina, through the feedback synaptic pathway (HC→cone→BC) and/or the feed-forward synapses (HC→BC). Three synaptic mechanisms have been proposed for the HC feedback actions on cones. The first is that HCs release an inhibitory neurotransmitter (γ-aminobutyric acid (GABA) in several species) in darkness that opens chloride channels in cones, and surround light hyperpolarizes the HCs, suppresses feedback transmitter release, depolarizes the cones, and results in depolarization in HBCs and hyperpolarization in DBCs. The second mechanism is that surround light hyperpolarizes HCs, resulting in an outward current through hemichannels in their dendrites near the cones, charging the cone membrane and modulating calcium currents in cones, and increases their calcium-dependent glutamate release, which depolarizes the HBCs and hyperpolarizes the DBCs. The third mechanism is that surround-induced HC hyperpolarization elevates the pH in the HC-cone synaptic cleft, leading to an increase of calcium current in cones and a higher rate of glutamate release, which depolarizes the HBCs and hyperpolarizes the DBCs. It is possible that different species under different conditions favor different feedback synaptic mechanisms, and/or different types of HC-cone synapses in the same animal may use one or more of these three HC-cone feedback mechanisms. This idea is supported by a recent study demonstrating that the responses of salamander GCs to dim surround stimuli are sensitive to GABA blockers and those to bright surround stimuli are sensitive to carbenoxolone, a gap junction/hemichannel blocker.

Properties of the feed-forward synapses are less well understood. Results from salamander retina suggest that HC→DBC feed-forward synapses may be functional. However, application of GABA on BC dendrites in Co^{2+} Ringer's solution does not elicit any response, indicating that if feed-forward synapses are chemical, the neurotransmitter is not GABA. Histochemical evidence suggests that only about 50–60% of the HCs in the salamander retina are GABAergic, and the identity of neurotransmitter(s) in the rest of the HCs is unknown (but unlikely to be glycine). Recent studies on the rabbit and salamander retinas have shown that HCs and subpopulations of BC are dye coupled. This raises the possibility that HC-BC electrical coupling may be involved in mediating the HC-BC feed-forward synapses for DBC surround responses (which does not work for HBC surround because HC-HBC coupling gives hyperpolarizing surround signal in HBCs). A systematic investigation on this issue is needed.

In addition to HC inputs in the outer retina, BC surround responses are also mediated by ACs through their feedback synapses made onto BC axon terminals in the inner retina. The majority of ACs use GABA or glycine as their neurotransmitter. GABA receptors on ACs and GCs are largely $GABA_A$, and those on BC axon terminals are largely $GABA_C$. Glycine receptors have been localized in ACs, GCs, and BC dendrites and BC axon terminals. Receptors in the IPL are postsynaptic to glycinergic ACs, and those in the OPL are postsynaptic to glycinergic interplexiform cells. Voltage clamp experiments reveal that ΔI_{Cl} in all BCs is outward. This suggests that GABA/glycine-mediated ΔI_{Cl} may be responsible for DBC hyperpolarizing surround responses, but not the HBC surround responses which are depolarizing (inward current).

In the *Xenopus* retina, GABA suppresses the surround responses of the DBCs but only slightly reduces the surround of the HBCs, and glycine suppresses the surround responses of both DBCs and HBCs. In the tiger salamander, one study shows that GABA reduces the surround responses of a subpopulation of HBCs, but another report reveals that application of picrotoxin and strychnine does not affect the surround responses of either DBCs or HBCs. Recent studies in the primate retina indicate that the HC feedback signal to cones as well as the surround responses of GCs are not sensitive to GABAergic or glycinergic agents, but are sensitive to carbenoxolone, suggesting that the surround responses in GCs are mainly mediated by HC actions on BCs in the outer retina, not by GABAergic or glycinergic AC actions in the inner retina. The reasons for these differences in GABA/glycine actions on surround responses are unclear. It is evident, however, that the surround responses of different functional types of BCs are mediated by different combinations of synaptic circuitries: HC→cone (GABA/hemichannel/pH) →BC, HC→BC (chemical/gap junction), and AC→BC (GABA/glycine). It is conceivable that the surround responses of different BCs/GCs from different animals under different conditions are sensitive to different synaptic blockers. The wide variation of synaptic circuitries underlying surround responses of various functional types of BCs allows the flexibility for function-specific modulation of BC-receptive fields and contrast sensitivity by various lighting conditions. Systematic studies on detailed synaptic pathways/mechanisms underlying surround responses for each type of BCs are needed.

Retinal Color Mechanisms

N W Daw, Yale University School of Medicine, New Haven, CT, USA

© 2009 Elsevier Ltd. All rights reserved.

In order to see color, one needs at least two classes of photoreceptors with different spectral sensitivities, and differential connections to cells higher in the system. Usually, this means two classes of cone photoreceptors, feeding into color-coded horizontal, bipolar, and ganglion cells in daylight at a level where the rod photoreceptors are not active. However, humans see color in circumstances where only the rods and red-absorbing cones are active. Moreover, frogs have two types of rods with different spectral sensitivities, and could presumably use them to see color, although the point has never specifically been tested. But these are exceptions. In this review, we will follow the conventional terminology, and classify color vision into categories according to the number of cone types that a species has.

Color Vision Varies with Species

Humans have three types of cones: red-absorbing, called L for long-wavelength cones; green-absorbing, called M for medium-wavelength cones; and blue-absorbing, called S for short-wavelength cones. Normal humans are thus known as trichromatic, and can match the color of any object with a mixture of three well-chosen red, green, and blue wavelengths. Old World monkeys such as macaque and chimpanzee also tend to be trichromatic, while New World monkeys such as squirrel and owl monkey tend to be either dichromatic, so that they only need two wavelengths to match the color of an object, or to have somewhat deficient trichromatic vision. Cats, rabbits, dogs, and ground squirrels are dichromatic, goldfish are tetrachromatic, and pigeons are at least trichromatic, and possibly tetrachromatic. Many other species have been shown to have color vision, but the nature has not been fully pinned down.

The photoreceptor pigments of most animals are based on vitamin A_1, with a rod pigment that is called rhodopsin, which has a spectral sensitivity peaking around 500 nm. These animals include mammals, birds, reptiles, amphibians, and marine fish. Some freshwater fish such as carp and goldfish have pigments based on vitamin A_2, with a rod pigment called porphyropsin, which has a spectral sensitivity peaking around 522 nm. The spectral sensitivity of the cone pigments is correspondingly shifted toward longer wavelengths, as a result of which goldfish can make discriminations at higher wavelengths than humans.

Some species, particularly turtles and pigeons, have oil droplets through which the light passes between the lens and the pigment in the photoreceptor. The droplets appear to the human to be either red, orange, or yellow, and cutoff short wavelengths from reaching the photoreceptor pigment. Thus, in theory, these species, which tend to have three classes of photoreceptors, could be more than trichromatic, by using a photoreceptor in combination with different classes of oil droplets. However, tests have not been completed to test whether this is the case or not.

Opponent Color and Double Opponent Responses in Fish

Thomas Young, elaborated by Herman von Helmholtz, was the first to suggest that human color vision is trichromatic, with three classes of cone photoreceptors. Ewald Hering in the nineteenth century came out with an alternative formulation of color vision, emphasizing that red and green are mutually exclusive colors and so are yellow and blue. Hering implied that these opponent color processes exist in the photoreceptors. A number of stage theorists in the early twentieth century pointed out that these alternative theories can be reconciled, if the three classes of photoreceptors feed into a second stage, some with excitatory connections and others with inhibitory connections, to produce opponent color cells. This was shown to be true in the 1960s by Russell de Valois in the macaque monkey, and by Ted MacNichol and Gunnar Svaetichin in a variety of fish.

MacNichol and Svaetichin showed further that the first cells in the fish retina after the photoreceptors, the horizontal cells, may be opponent color cells (Figure 1). Some horizontal cells hyperpolarize to light of all wavelengths: this is a luminance response. Some hyperpolarize to short wavelengths and depolarize to long wavelengths with a neutral point near 550 nm: these were named yellow–blue (Y–B) chromaticity or opponent color cells. Others hyperpolarize to short wavelengths and depolarize to long wavelengths with a neutral point near 600 nm: these were named red–green (R–G) chromaticity or opponent color cells. Fish in deep waters tend to have one type of opponent color horizontal cell, while fish in shallow waters tend to have both. In particular, goldfish and carp have both types of opponent color cells.

There is further processing of color in goldfish and carp retinas. Most ganglion cells are double opponent, that is, opponent for both color and space (Figure 2).

Figure 1 Responses from horizontal cells from various species of fish. Amplitude of response is plotted against wavelength, with hyperpolarization plotted downward and depolarization plotted upward. (1) Lutianidae gave only luminance responses. (2) Serranidae gave both luminance and Y–B responses. (3) Centropomidae gave luminance and R–G responses. (4) Mugilidae gave all three types of response. Reprinted from MacNichol EF and Svaetichin G (1958) Electric responses from the isolated retinas of fishes. *American Journal of Ophthalmology* 46: 26–46.

In the example given, the cell was excited by green light in the center of its receptive field, inhibited by red light in the center, excited by red light in the surround, and inhibited by green light in the surround. The reverse is also found. Excitation and inhibition tend to cancel each other out, so that these cells give little response to red or green light covering the whole receptive field and little response to white light in either center or surround. They respond maximally to color contrast. Moreover, the response to a gray spot in a red surround is similar to the response to a green spot in a gray surround, so that the response of the cells corresponds to simultaneous color contrast. Daw first showed that most ganglion cells are double opponent: subsequently Kaneko and Tachibana also found some double opponent responses in bipolar cells.

The connections for the double opponent surround of the bipolar and ganglion cells are provided by the horizontal cells in the outer plexiform layer, and the amacrine cells in the inner plexiform layer. The horizontal cells have terminals that are inserted into the cone pedicles, so that a feedback response can be recorded in individual cones. This tends to have a broad spectral sensitivity. Signals from cones and horizontal cells then feed forward onto the bipolar cells. It is not clear how far the responses of the bipolar cells would be double opponent if the inner retina was removed. However, amacrine cells contact the axon terminals of the bipolar cells, where contacts with ganglion cells are also made, and chloride channels sensitive to γ-aminobutyric acid (GABA) are found. Thus, it is not surprising that GABA antagonists affect the surround of double opponent responses.

These results show that considerable processing of information for color takes place in the retina in goldfish and carp. This is probably true for other vertebrate species, although the details have not been worked out as they have in goldfish and carp, but is not true in mammals. Double opponent cells are first found at the level of the lateral geniculate nucleus in ground squirrel and cat, and at the level of

Figure 2 Response of a green on center double opponent ganglion cell from goldfish retina. Note that the size of the center of the receptive field for red is larger than that for green, consequently some responses were ON–OFF rather than pure ON or pure OFF.

the visual cortex in the macaque. However, other complications arise in the retinas of these species due to the presence of a fovea or visual streak.

Color Vision in Primates

We will now turn to the retinas of the human, and of the macaque, since vision in this species is close to that of humans. Both are trichromatic, with pigments peaking at close to the same wavelengths. In the human, there are several L cone pigments, peaking between 550 and 560 nm. There are also several M cone pigments, peaking between 530 and 536 nm. People with normal color vision will have one of the L cone pigments and one of the M cone pigments. There is less variation in the S cone pigment, which peaks around 415 nm.

The L and M cones are not arranged in a regular array (Figure 3). In some retinas, the arrangement is random. In others, there appears to be a clumping of cones with the same pigment, more than one would expect from a random arrangement. The ratio of L cones to M cones also varies considerably from retina to retina, between 1.1:1 and 16.5:1. The ratio can also vary from one location to another in the same retina. The ratio is correlated with their contribution to the electroretinogram, which is an electrical potential recorded from the whole retina that varies from individual to individual. Interestingly, in spite of these variations, the perception of the wavelength that produces a unique yellow does not vary. The clumping of L and M cones explains why subjects routinely misjudge the color appearance of tiny flashes of monochromatic light. The S cones, which are a small percentage (5–6%) of the total, form a more regular mosaic interspersed between the L and M cones.

Thirteen types of ganglion cell have been identified in the macaque retina that project to the lateral geniculate nucleus. Most types come in pairs, with two varieties, one of which arborizes in the inner part of the inner plexiform layer, and responds when light is turned on, the other of which arborizes in the outer part of the inner plexiform layer, and responds when the light is turned off. The midget ganglion cells are known to be color coded. Near the fovea they connect to a single bipolar cell which connects to a single cone. The bistratified cells are also known to be color coded, and so are the giant sparse monostratified cells. The parasol cells are not color coded. The large sparse, broad thorny, and narrow thorny cells have not yet been characterized.

Yellow/Blue Color Vision

The most clearly defined color-coded pathway within the primate retina is the blue ON yellow OFF pathway, represented by the small bistratified ganglion cell. To stimulate these cells, Dacey and Lee employed a red + blue stimulus alternating sinusoidally with a green stimulus, which produced no response in red/green color-coded cells, or cells that were not

Figure 3 False color images showing the arrangement of L (red), M (green), and S (blue) cones in the retinas of different human subjects with normal color vision. Reprinted from Hofer H, Carroll J, Neitz J, Neitz M, and Williams DR (2005) Organization of the human trichromatic cone mosaic. *Journal of Neuroscience* 25: 9669–9679. Copyright 2005 by the Society for Neuroscience.

color coded. This stimulus produced a vigorous response in small bistratified cells. A flickering blue stimulus gave a response when the light was on, and a flickering yellow stimulus gave a response when the light turned off (Figure 4(c)).

This cell receives input from a cone bipolar cell that contacts the S cones in the outer plexiform layer, and arborizes in the inner part of the inner plexiform layer, explaining the blue ON response (Figure 5). It also receives input from two types of diffuse cone bipolar cells that contact L and M cones in the outer plexiform layer and arborize in the outer part of the inner plexiform layer, explaining the yellow OFF response. The spatial extent of the blue ON and yellow OFF responses is similar. However, this is not the whole story: if one applies AP4, which is a drug that interrupts transmission between the S cones and the S cone bipolar, much of the L + M cone response in the ganglion cell is abolished, as well as the S cone response. Thus, there must be a blue ON/yellow OFF response in the S cone bipolar. The OFF response probably comes from the H2 horizontal cell, which gets input from L, M, and S cones and makes lateral connections in the outer plexiform layer. Its receptive field is small – about the right size for the yellow OFF response of the small bistratified cell. Thus, there is one set of connections for the blue ON response and two sets of connections for the yellow-OFF response.

The large sparse bistratified ganglion cell also has a blue ON/yellow OFF response (Figure 4(b)). Its receptive field is larger than that of the small bistratified cell, corresponding to its larger dendritic arborization,

Figure 4 Responses from three types of blue/yellow opponent color ganglion cell in macaque retina. The large sparse monostratified cell giving an ON response to yellow and an OFF response to blue. The large sparse bistratified cell giving an ON response to blue and an OFF response to yellow. The small bistratified cell giving an ON response to blue and an OFF response to yellow. Scale bar = 50 μm. Reproduced from Dacey DM and Packer OS (2003) Colour coding in the primate retina: Diverse cell types and cone-specific circuitry. *Current Opinion in Neurobiology* 13: 421–427, with permission from Elsevier.

but otherwise the response is similar. The connectivity has not been worked out in detail, as has the connectivity of the small bistratified cell, but it could well be similar.

The blue/yellow system is phylogenetically older than the red/green system. Mammals that are dichromatic – that is, most mammals – have S cones and either M or L cones. It is only in recent evolution that both L and M cones have been developed. There is a long history of recordings in the mammalian retina showing blue ON responses but few or no blue OFF responses. All the blue/yellow color-coded cells recorded in cat and rabbit retinas are blue ON. Some early recordings of macaque ganglion cells showed some blue OFF cells, but most blue/yellow cells recorded there have also been blue ON. Thus, there seems to be an asymmetry in the system – either the blue ON cells are larger, so that they are recorded more frequently, or they are more numerous.

The macaque blue OFF cells have now been identified, with a variety of receptive field structures, including the large and giant sparse monostratified cells (Figure 4(a)).These cells also come in two types, ramifying at the extreme inner and outer borders of the inner plexiform layer, but do not have the usual dichotomy into ON and OFF, since they are all blue OFF. They have large receptive fields corresponding to their dendritic arborization. Their connectivity has not yet been established, since no blue OFF bipolar cells have been identified. The giant cells code for luminance over both night and daylight vision, also contain melanopsin, and give a slow response when all input from photoreceptors is abolished. Thus, one might expect that they have to do with some subcortical function such as the pupillary response or circadian rhythms, but they also project to the lateral geniculate nucleus.

Red/Green Color Vision

The red/green system is represented by the midget ganglion cells. As pointed out above, these are contacted by a single bipolar cell and a single cone in the

Figure 5 Wiring for the blue ON/yellow OFF small bistratified ganglion cell, and for the green ON, red OFF midget ganglion cell (left). Lateral input to the midget system from both horizontal and amacrine cells (right). Reprinted from Chalupa LM and Werner JS (eds.) *The Visual Neurosciences*, 2 vols, figures 64.4, 64.12, and 63.1, © 2003 Massachusetts Institute of Technology, by permission of the MIT Press.

fovea (Figure 5, left). There are four types – with responses in the center giving red ON, green ON, red OFF, and green OFF. Following the usual rule, the ON types ramify in the inner part of the inner plexiform layer, and the OFF types in the outer part. For each type there is a corresponding midget bipolar cell. The surround response of the midget ganglion cells is larger than the center, of opposite color and opposite polarity (e.g., red ON center and green OFF surround). The surround response could be brought in by horizontal cells, or by amacrine cells (Figure 5, right). The horizontal cells that make lateral connections to the midget system are the H1 cells, which receive input from both L and M cones, and if they are the sole pathway for the surround response, then it should not be specific for red or green alone. The amacrine cells that make lateral connections to the midget system also appear not to discriminate between L and M systems. The S cone input to this system is comparatively minor.

The midget ganglion cells project to the lateral geniculate nucleus where again there is a 1:1 connection between ganglion cell and geniculate cell. In the geniculate, measurements of the surround response suggest that it is specific to either the L or M cones. There is therefore a mystery as to how this system gets a surround response that is specific to a single type of cone, which has not yet been resolved. Some possibilities are (1) that foveal H1 horizontal cells receive a more specific input than those further out in the retina (not many foveal H1 cells have been recorded); (2) that some amacrine cells receive an input from the L or M cone systems alone (the study suggesting that amacrine cells associated with the midget system get input from both L and M cones was an electron microscope study, with a limited number of examples); or (3) that there are lateral connections within the lateral geniculate nucleus bringing in a specific surround response. Further experiments will be needed to resolve this conundrum.

To summarize, there is a red/green opponent color system with a center responding to one color, and a surround responding to the other, represented by the midget system. There is a blue/yellow opponent

Figure 6 L and M cone pigments. Genes shown at top. Shaded and unshaded arrows represent L- and M-photopigment genes, respectively. Spectral sensitivities are shown at bottom. color system, with the spatial extent of the two color responses being the same, represented by the bistratified cells and the sparse cells. Horizontal cells are not opponent color, as they are in the fish. Ganglion cells and bipolar cells are opponent color, but not double opponent, as they are in goldfish and carp.

Color Vision in the Periphery of the Retina

So far the discussion has concentrated on the area near the fovea, where color vision is most acute. However, there are considerable variations in color vision across the retina in primates that have a fovea. There is a small area (about 1/8°) in the center of the fovea in humans where there are no S cones, so that blue is not perceived. Vision is trichromatic for 20–30° out from this. Red/green vision becomes deficient further out, requiring larger stimuli to see color, to 70–80° from the fovea, where the system is color blind. As one brings a red object in from the far periphery, it is seen first as salmon pink or yellow, then eventually as red.

The red/green deficiency beyond 20–30° from the fovea is probably due to a different connectivity of the midget ganglion cells. In this region there are midget bipolar cells that are connected to a single L or M cone, but the midget ganglion cells receive input from several of both types of bipolar cell. Interestingly, the L and M input to the midget ganglion cells varies in the peripheral retina, but this is believed to be due to the clumping of L and M cones. The L and M input to parasol ganglion cells and H1 horizontal cells also varies, and is similar for the three types of

cell in the same part of the retina, from experiments by Dacey and his colleagues. These results suggest that the midget ganglion cells are no more color selective than the parasol cells or the H1 cells in the same part of the retina. Martin and his colleagues, on the other hand, have recorded opponent color responses in midget ganglion cells from peripheral retina, and suggest that the color capability of these cells may even exceed that seen in psychophysical experiments. However, more recent work from this group shows that there is a variety of responses from midget ganglion cells in the periphery, with some showing no color opponency at all. Further experiments will be needed to clarify the situation.

Color Blindness in the Retina

Most color blindness is a retinal defect. There is one of six different L cone pigments in L cones, and one of five different M cone pigments in M cones (Figure 6). People with normal color vision will have one of the L cone pigments, and one of the M cone pigments. People with defective protan vision have none of the L cone pigments, and may have only one of the M cone pigments (protanopes) or two of them in separate cones (protanomalous). People with defective deutan vision have none of the M cone pigments, and may have only one of the L cone pigments (deuteranopes) or two of them in separate cones (deuteranomalous). Thus, protanopes and deuteranopes can match any color with a mixture of two wavelengths, while protanomalous and deuteranomalous people require three. The genes for the L and M cone pigments are on the X chromosome, and this form of color blindness is quite common in males, adding up to about 8% of the population. People missing the S cone pigment (tritanopes) are much more rare, and it is not X-linked. What difference these deficits make to the connections of the cones to horizontal, bipolar, and ganglion cells is not known, but there seems to be little reason why there should be any change.

Retinal Development: An Overview

Ontogenesis and Organization of the Vertebrate Retina

Development of the vertebrate eye involves the paired bulging of the forebrain to form optic vesicles. Each optic vesicle extends laterally where it contacts the surface ectoderm. Reciprocal inductive signals between the surface ectoderm and optic vesicle result in invagination of the optic vesicle to form the optic cup. The inner layer of the optic cup is then patterned to form the neural retina distally and the ciliary body and iris more proximally (Figure 1(a)).

Cell Types of the Retina

The vast majority of cells in the mature neural retina develop from neuroepithelial progenitor cells of the optic cup, the exceptions being vascular cells and some types of immune cells. When fully differentiated, the neural retina is a highly ordered, laminar structure comprising six major neuronal cell types (retinal ganglion cells, amacrine cells, bipolar cells, horizontal cells, and rod and cone photoreceptors) and one intrinsic glial cell type (Müller glial cells) (Figure 1(b)). Laminar organization of the retina facilitates the initial steps in processing visual information. Achieving this exquisite cytoarchitecture requires intricate signaling during development. Coordination of proliferation, cell cycle exit, cell type determination, directed cellular migration, and cellular morphogenesis enables the appropriate numbers, correct laminar organization, and proper synaptic connections within the mature retina.

Proliferation of Retinal Progenitor Cells

Interkinetic Nuclear Migration

During development of the vertebrate retina, the optic cup neuroepithelial cells undergo rapid, proliferative expansion. This proliferative phase is marked by several intriguing cellular behaviors that have been hypothesized to provide cell fate information to the multipotent progenitor cells. One remarkable proliferative cell behavior is known as interkinetic nuclear migration (Figure 2(a)). This is the process in which the nuclei of neuroepithelial cells migrate in an apical–basal manner and in phase with the cell cycle. M phase and cytokinesis are confined to the apical surface near the retinal pigment epithelium (RPE), whereas G_1, S, and G_2 phases occur at more basal locations. This process is heterogeneous among neuroepithelial cells. Variation has been observed in the time required to progress through one round of interkinetic nuclear migration (which equals the cell cycle period), as well as in the distance of nuclear migration. Studies suggest interkinetic nuclear migration aids in the selection of progenitors that will produce neurons in the next mitosis. This is achieved by establishing asymmetry between neuroepithelia with regard to cell body position during critical 'neurogenic' windows of the cell cycle.

Oriented Cell Divisions

A second heterogeneous cell behavior associated with progenitor cell proliferation is regulated mitotic division plane orientation. Although neuroepithelial cell divisions are confined to the apical ventricular zone near the RPE, the orientation of cleavage axis can vary among progenitors (Figure 2(b)). Typically, retinal progenitor cells divide in either an apicobasal or a horizontal manner. Genetic and imaging studies in invertebrates have indicated that mitotic division plane in neural progenitors, and other proliferate cells, is important for symmetric versus asymmetric cell fate outcomes. Symmetric cell divisions create daughter cells that assume the same fates, whereas asymmetric cell divisions produce daughters of different fates. Symmetry in cell fates is subject to definition. For example, symmetry may relate to cell cycle exit and neurogenesis. In this case, symmetric cell divisions produce two daughter cells where both remain proliferative or both leave the cell cycle and become neurons. Alternatively, symmetry can also relate to cell type fate; for example, divisions that produce two ganglion cells or equivalent daughters of other cell types. Studies on cell division orientation in the developing vertebrate retina indicate that this cell behavior influences cell type choice. Mechanistically, it appears that the plane of cell division can equally (symmetrically) or differentially (asymmetrically) partition fate determinants to daughter cells. In the vertebrate retina, a modulator of the Notch signaling pathway, the Numb protein, is the flagship example of this phenomenon. Numb associates with the apical surface of retinal progenitor cells and immunocytochemistry has shown that this protein can differentially segregate between daughter cells. Interestingly, and in contrast to invertebrates, no other examples of vertebrate retinal cell fate determinants have been shown to partition asymmetrically between daughter cells.

Figure 1 Development of the eye and neural retina. (a) Vertebrate eye development initiates with the paired extension of the forebrain to form optic grooves (og). Each groove extends laterally to form an optic vesicle (ov), which contacts the surface ectoderm and induces the formation of a lens placode (lp). Reciprocal inductive events lead to the invagination of the optic vesicle and lens placode to form the optic cup (oc) and lens vesicle (lv), respectively. c, cornea; L, lens; nr, neural retina; rpe, retinal pigment epithelium; on, optic nerve. (b) Histological cross sections of 24 hpf and adult zebra fish neural retinas with schematic representations of the retina at these stages. At 24 hpf, the retina is a pseudostratified neuroepithelium. The adult, laminated retina can be divided into the outer nuclear layer (onl), which includes rod (R) and cone (C) cell bodies; the inner nuclear layer (inl), which includes horizontal (H), bipolar (B), and amacrine (A) cell bodies; and two plexiform or synaptic layers – the outer plexiform layer (opl), which separates the nuclear layers, and the inner plexiform layer (ipl). M, Müller glia.

Figure 2 Cell behaviors of the proliferative neuroepithelium. (a) Interkinetic nuclear migration (blue nucleus) is schematized in one retinal neuroepithelial cell over the course of the mitotic cycle. M phase occurs at the apical region adjacent to RPE cells, whereas G_1, S, and G_2 phases take place at more basal locations. (b) Regulated mitotic division plane orientation is modeled for either an asymmetric or a symmetric division. Note that polarized fate determinants associated with either the cell surface (red molecules) or localized intracellularly (green molecules) can be equally or differentially segregated based on the plane of cytokinesis.

Molecular Regulation of Retinal Cell Proliferation

The factors that promote and regulate cell proliferation in the vertebrate retina are beginning to be discovered. Secreted growth factors such as Fibroblast growth factor (FGF), Hedgehog, and Wnt family members, as well as transmembrane proteins such as Notch function in part to control cellular proliferation, but they control other cellular processes as well. Surprisingly, secreted amino acids such as glutamate or nucleotides such as ATP also promote cell proliferation in retinal progenitors cells. In addition to extrinsic influences, specific transcription factors expressed in retinal neuroepithelia regulate parameters of the mitotic cycle. Proliferative roles for both homeodomain- and basic helix–loop–helix (bHLH)-type transcription factors have been demonstrated for retinal progenitor cells. Thus, both extrinsic and intrinsic influences converge to exert an effect on core cell cycle machinery such as the cyclins, cyclin kinases, and cyclin inhibitors. This is a common theme in development: the balance and interactions between intrinsic cell programs and extrinsic influences. This concept of complex signal integration is discussed in more detail later in the context of the competency model for retinogenesis. Specifically for retinal proliferation, however, regulatory molecules influence both

the kinetics of cell cycle progression (how fast cells pass through the various phases of the cell cycle) and neurogenic decisions (whether to remain in the cell cycle or exit mitosis and initiate migration and differentiation).

Spatial Control of Retinogenesis

The overall process of retinogenesis, from cell cycle exit to cellular differentiation, is coordinated in space and time. The first cells to exit the mitotic cycle do so at the center of the optic cup, although dorsal or ventral biases in where this process begins can vary between species. The initiation of retinogenesis, however, appears to always depend on FGF expression in the neuroepithelium. The patch of FGF expression is regulated in part by adjacent midline mesoderm-derived signals. From this central FGF organizing center, cell cycle exit proceeds in a wavelike manner toward the periphery of the optic cup. At any point within the wave, however, only a subset of progenitor cells are selected to produce postmitotic progeny. The remaining cells stay in the cell cycle to produce late-born cell types. Why some cells remain mitotic and others begin neurogenesis is an active area of research.

Lineage and Birth Date Relationships

Experiments *in vivo* and in cell culture from all vertebrate species studied have demonstrated the multipotency of retinal neuroepithelial cells. Lineage-tracing experiments using either tagged replication incompetent retroviruses or microinjection of nontransferable markers have shown that single neuroepithelial cells can divide to produce all six neuron types and Müller glia. Another evolutionarily conserved feature of retinogenesis is the link between birth date and cell type (Figure 3). Although subtle differences exist between species in the exact order of cell types generated over developmental time, retinal ganglion cells genesis is normally followed by the differentiation of horizontal cells, cone photoreceptors, and amacrine cells, followed by bipolar cells, rod photoreceptors, and Müller glia. This birth order is also reflected by clonal analyses from lineage studies. Clonal descendents from neuroepithelia labeled at early stages of development ('early' progenitors) are biased to produce ganglion cells, amacrine, horizontal cells, and cone photoreceptor cells. Progeny from 'late' progenitors are biased to produce bipolar cells, rods, photoreceptor cells, and Müller glia. Despite the trend of birth order, different cell types can and do differentiate simultaneously (Figures 3 and 4). Finally, lineage studies and cell culture experiments have suggested that the majority of retinal neuroepithelia remain multipotent until the last cell cycle prior to terminal mitosis or, for some cell types, just following cell cycle exit. Overall, observations from lineage and birth order studies, as well as data from other experiments, suggest that the timing of cell cycle exit, intrinsic lineage bias, and influences from adjacent cells all function in cell fate determination.

Competency Model for Retinogenesis

The competency model has emerged as a general paradigm for retinogenesis and posits that retinal neuroepithelia progress through temporal states in which the progenitor is competent to generate only a subset of retinal cell types (Figure 4). This bias in cell type competency is influenced by both determinant intrinsic and modulatory extrinsic factors, each of which are dynamic in nature. In other words, within the developing retina, the type, levels, and expression domain of secreted factors change with time and exert differential influences depending on the changing intrinsic state of the neuroepithelial cell. The compentency model is applicable to two interrelated cell fate decisions that neuroepithelia make during their maturation process: (1) when to exit the cell cycle and (2) what cell type to become. Although

Figure 3 Birth orders for cell types of the mammalian retina; schematic showing the timing of cell cycle exit (birth date) for classes of retinal cells. The areas under the curves represent the relative proportions of cell types typically found in nocturnal (rod-dominated) rodents. Subtle differences exist in the exact birth orders between various species. Note the overlapping timing for genesis of multiple cell types and the relative clustering of 'early' and 'late' cell types.

Figure 4 Competency model for retinal cell fates. As retinal progenitor cells divide and give rise to other proliferative progenitor cells (colored, elongated neuroepithelial cells), the intrinsic cellular competency to differentiate to particular classes of postmitotic cells (labeled ovals) changes. The changing colors represent changes in cellular competence. Postmitotic cells have been grouped into early cell types (pink ovals) or late cell types (green ovals). Note that multiple cell types can be generated at the same time of development and that single cells give rise to complex combinations of differentiated cell types.

general in nature, some of the molecules and signaling pathways underlying intrinsic and extrinsic components of the competency model have been discovered.

Atoh7 and Regulation of Cellular Competence

The bHLH transcription factor Atoh7 (previously known as Ath5) serves as a specific example of the molecular underpinnings of cellular competence for cell cycle exit and cell type fate determination. Atoh7 was first discovered based on its striking expression pattern and loss-of-function phenotype. The expression of *atoh7* is specific to the neural retina and commences in neuroepithelial cells in their last cell cycle preceding a neurogenic cell division (where one or both daughter cells exit the cell cycle and differentiate as neurons). Disruption of *atoh7* in mouse, frog, and fish results in a dramatic loss of retinal ganglion cells. Careful analysis of *atoh7* mutants showed that in addition to the loss of retinal ganglion cells, there was a marked decrease in the proportion of progenitor cells leaving the cell cycle. Importantly, *atoh7* linage-marking studies demonstrated that *atoh7* is expressed transiently, just before cell cycle exit in multiple cell types, but not all cell types. These data suggest that Atoh7 is required for cell cycle exit and biases cells toward particular cell type fates. The exact cell type depends on the co-expression of other transcription factors. Interestingly, ectopic expression of *atho7* alone does not drive cell cycle exit. This is consistent with Atoh7 as important for neurogenic competency, while also providing influence to eventual cell type fate. The initial expression of *atoh7* appears to be established at a time much earlier than its actual expression. This 'clock-like' mechanism is probably set by signals provided at the earliest stages of optic vesicle formation by cells associated with the embryonic midline axis. However, termination of *atoh7* expression is regulated in part by extrinsic proteins. GDF11, a secreted growth factor, has been shown to extrinsically influence the expression of *atoh7*. Mice with deletions in *gdf11* show an extended expression of *atoh7* and a concomitant increase in early born retinal cell types. Therefore, GDF11 regulates the temporal window during which retinal progenitors retain competence to produce distinct neural progeny. Other factors, both autonomous and non-autonomous, interact to provide the complete regulatory network that enable the appropriate numbers and cell types to be generated during retinal development.

Postmitotic Cell Migration

Modes of Migration

Following terminal mitosis at the apical surface, newborn retinal cells migrate to their appropriate laminar position within the retina. Classic histological and more recent time-lapse experiments have demonstrated that the various cell types of the retina employ multiple strategies during postmitotic cell migration. The modes of cell migration can be classified as guided cell migration, somal translocation, and unconstrained migration (Figure 5). These are not necessarily mutually exclusive forms of motility, and some cells may use multiple strategies while migrating. Direct evidence exists for the latter two modes of cell positioning. Within the retina, somal translocation has been demonstrated for retinal ganglion cell and bipolar cell precursors. Some newborn amacrine cells have been shown to move using unconstrained migration, in which dynamic and nonpolarized processes appear to sample the local environment

Figure 5 Modes of cell migration. Postmitotic cells (red) can migrate to their appropriate laminar position in the retina in one of three ways. (a) In guided migration, postmitotic cells use adjacent neuroepithelial cells as a scaffold to move from the apical surface toward their final destination. (b) Somal translocation occurs independently of adjacent cells. After its terminal mitosis a newly formed neuron extends processes to both the apical and the basal cell surfaces. Subsequent to this, the cell body translocates along this process until reaching its appropriate position within the retina, where it then retracts its processes. (c) In unconstrained migration, newly formed neurons migrate independently of other cells or cell processes, often extending neuritis in an 'exploratory' manner.

en route to the inner nuclear layer. It is likely that neuroepithelial-guided cell migration is utilized, to some extent, for both nuclear translocation and free migration. This form of guided cell migration is similar to that in the developing cerebral cortex, where glial cells, instead of adjacent neuroepithelia, provide the substrate and cues for cell positioning.

Within the retina, all forms of migration are restricted primarily to the radial direction along the apical–basal axis. However, clonal analysis using various progenitor cell marking techniques has demonstrated subtle lateral (or tangential) displacements of ganglion cells, horizontal cells, cone photoreceptors, and amacrine cells. This tangential displacement is thought to ensure an even 'planar' distribution of specific classes of cell subtypes and facilitate appropriate synaptic partnering. Although migration is largely restricted to the radial direction, migration is not restricted to one direction because some postmitotic cells show bidirectional movements. For example, some horizontal cells migrate first to the basal surface and then return to their appropriate outer retinal position.

Importance of Cell Polarity and Basement Membranes

Although much has yet to be discovered regarding the mechanisms and regulation of cellular migration in the retina, some important molecules and signaling pathways have been identified. One important class of molecules are those associated with apical cell junctions of neuroepithelia. The apical junctional complex includes the proteins Pard3, Pard6, Prkci, Mpp5, and Crb. Mutations in genes encoding these proteins result in cell positioning defects. Interestingly, studies *in vivo* have demonstrated that the apical junctional complex functions noncell autonomously in the retina for cell migration. This suggests that this signaling complex either regulates the adhesion between cells or facilitates polarized secretion of guidance molecules. In addition, some of these mutants result in disruptions to the RPE, exposing Bruch's membrane, which is the basement membrane of RPE cells. Basement membranes are distinct, thin sheets of extracellular matrix, rich in specific isoforms of collagens and laminins. In these mutants, ganglion cells become misdirected and migrate apically rather than basally. Guidance cues associated with the exposed Bruch's membrane may lead to these migration errors. Direct experiments have demonstrated the importance of the retinal basement membrane in directed cell migration. For example, transient disruption of the basement membrane in chick embryos results in lamination defects. Similarly, mutations in laminin α_1 in zebra fish cause migration defects for cone photoreceptors. Detailed characterizations for how the basement membrane translates into intracellular responses are limited. However, it is likely, based on cell culture work, that membrane-bound receptors such as dystroglycan and integrins, as well as their intracellular associated signaling molecules such as integrin-linked kinases and focal adhesion kinases, mediate directed cell migration.

Regulation of Cellular Differentiation

Coordination of Differentiation

Once a retinal cell reaches its appropriate laminar position, differentiation and morphogenesis begins. However, overt cellular differentiation does not always commence immediately. In addition to the spatial–temporal waves of cell cycle exit, cellular morphogenesis also progresses from central locations to the periphery in a wavelike manner. This wavelike progression of cellular morphogenesis is not a simple consequence of birth date. For example, in mice, expression of rhodopsin and other markers of rod photoreceptor differentiation are independent of birth date. Because rod genesis is very protracted over the course of retinogenesis, adjacent photoreceptor cells can have birth dates that differ by days. Despite differences in the time of terminal mitosis, differentiation and morphogenesis still occurs at approximately

the same time for adjacent cells. Two studies suggest signaling pathways important for coordinated differentiation. The SOCS3 protein (suppressor of cytokine signaling 3) has been shown to regulate and coordinate the timing of photoreceptor signaling by modulating the STAT signaling pathway. More generally, downregulation of the Notch pathway is important for multiple retinal cell types to begin morphogenesis.

Chromatin Remodeling

Chromatin remodeling factors are a diverse class of molecules that may be regulated by differentiation transducers such as the STAT and Notch pathways to coordinate differentiation programs within cells. Genetic analysis of the Brahma chromatin remodeling complex has revealed an essential role in cellular differentiation for all retinal neurons. The Brahma complex is part of the SWI/SNF group of chromatin remodeling complexes. These are large macromolecular complexes that use the energy of ATP to slide nucleosomes and create local alterations in chromatin. In addition to opening chromatin, Brahma subunits can also bind to gene-specific transcription factors and coordinate ocular differentiation programs. Other chromatin remodeling factors with demonstrated roles in global retinal cell differentiation are Dnmt1 (a DNA methyl transferase), Suv39h1 (a histone methyl transferase), and Hdac1 (a histone deacetylase).

Cell Type-Specific Differentiation

In addition to these global coordinators of retinal cell differentiation, a multitude of cell type-specific transcription factors has been shown to regulate particular differentiation programs. Many of these 'cell type-specific' transcription factors, however, are dynamic in expression and function in combination with other factors to control multiple steps of retinogenesis. The homeodomain transcription factor Ceh10 (also known as Chx10) serves as a prime example of the pleiotropy found in retinal differentiation factors. At the optic cup stages, *ceh10* is expressed in all proliferative neuroepithelia. This protein is required for normal proliferation. Following cell cycle exit, *ceh10* is downregulated in most cells but upregulated in differentiating bipolar cells. When *ceh10* is deleted, progression through the mitotic cell cycle is very slow and bipolar cells are missing. In wild-type bipolar cells, Ceh10 binds promoters of bipolar cell-specific target genes to positively regulate gene transcription. Within these same cells, Ceh10 also binds rod photoreceptor cell-specific promoters to inhibit their expression. Genetic complementation using Ceh10 pathway mutants demonstrated that the functions of Ceh10 in proliferation and differentiation are distinct. Interestingly, ectopic expression of *ceh10* in retinal progenitors promotes bipolar cell fates at the expense of rod photoreceptor cells. Cumulatively, these studies demonstrate that Ceh10 functions not only in cellular differentiation but also in cell proliferation and cell type fate decisions. Other factors that regulate specific cell differentiation pathways show similar complexity in function.

Protein Trafficking and Cellular Differentiation

In addition to transcriptional regulation during cell differentiation, protein complexes that drive cell differentiation and morphogenesis are beginning to be resolved. One of the most dramatic examples of cellular morphogenesis is that of retinal photoreceptors. Newly postmitotic photoreceptors are nearly spherical in shape and reside at the apical surface of the retina. However, as photoreceptors begin to differentiate, significant shape changes take place, including the dramatic growth of outer segments. Outer segments are elongated stacks of membranous disks and folds that contain components for phototransduction. Among the first features of photoreceptor morphogenesis is the establishment of the connecting cilium. The connecting cilium is a primary cilium composed of microtubules arranged in a 9 + 0 array. Because no protein synthesis occurs in the outer segment, an elaborate protein/membrane transport mechanism exists to both build and maintain photoreceptor outer segments. Trafficking of outer segment components occurs through the connecting cilium and along the backbone microtubules. The transport process is shared with other cilia-based cell appendages and is known as intraflagellar transport (IFT). IFT was discovered through genetic and biochemical studies of *Chlamydomonas* (green alga) and found to be the mechanism responsible for establishing and maintaining flagella. In photoreceptors, IFT particles composed of two macro-multiprotein complexes nucleate at the base of the connecting cilium where the basal body resides. IFT particles docked at the basal body and loaded with outer segment cargo are assembled onto kinesins, plus end-directed microtubule-based motors, to enable outward movement of the building blocks for the outer segment. Dyneins, minus end-directed microtubule-based motors, return the cargoless IFT particles, as well as the kinesin motors, to the basal body. Many questions remain regarding the details of IFT in photoreceptors, but it is certain that this process is essential for photoreceptor outer segment differentiation.

Neuronal Process Outgrowth and Synaptogenesis

Another obvious consequence of cell differentiation in the retina is the formation and elaboration of neuronal processes. Much of our knowledge of axon and dendrite development in the retina has been derived from serial electron microscopy analyses. Now, time-lapse experiments in mammalian slice culture and in zebra fish are revealing much of the complexity of process outgrowth and synaptogenesis. Multiple approaches have revealed that even before postmitotic neurons reach their final laminar position, process outgrowth initiates. Like retinogenesis as a whole, elaboration of axons and dendrites is dependent on both intrinsic and extrinsic cues. The initial orientation of ganglion cell axons, for example, relies on positional information provided by the retinal basal lamina. Retinal ganglion cells also depend on intrinsic factors such as Brn3b, a POU-domain transcription factor, which is essential for retinal ganglion cells to extend axons. Deletion of *brn3b* in mice results in retinal ganglion cells that prefer to generate dendrites at the expense of axons. Although analysis of process outgrowth and differentiation of individual cell types is ongoing, a general model is supported in which retinal neurons first extend processes in fields more extensive than their final arbors (Figure 6). In the synapse-refinement phase of process differentiation, cell–cell and cell–matrix communication appears to be very important. Similar to organization of neuronal cell bodies into lamina, final axon and dendrite arbors are stereotyped and highly specific. Retinal plexiform layers are organized so that specific subtypes of neurons synapse with each other in specific 'sublamina' or zones. For example, cells comprising the 'on-center' or 'off-center' pathways to light stimulus show sublaminar synaptic organization.

Figure 6 Sublamination of the inner plexiform layer. Early in development, as amacrine cell (A) and ganglion cell (G) dendrites first interact, process outgrowth is broad and relatively unstratified (left synaptic partners). Amacrine cells appear to guide 'on' and 'off' sublamination of the inner plexiform layer (ipl), which becomes strikingly polarized and stratified in the mature retina (right synaptic partners).

The on-center and off-center pathways can be distinguished by bipolar cells, which depolarize or hyperpolarize, respectively, when the photoreceptors from which they receive input are stimulated. On and off bipolar cells synapse with on and off ganglion cells in different substrata of the inner plexiform layer. Modulatory amacrine cells also specifically target their dendrites to either the on or off sublamina. In fact, amacrine cells play a central role in directing sublamination of the on and off circuits. Initially in development, the contacts between on and off cell processes are distributed throughout the inner plexiform layer. Over time, these synapses segregate so that off cells interact in a very discrete region apical to the synapses of on cells. This remodeling of ganglion cell synapses requires synaptic activity from amacrine cells. Interestingly, amacrine cell sublamination does not require ganglion cells or their dendrites at all and instead relies in part on cues from adjacent amacrine cells. Other sublamina, in addition to the on and off zones, exist in both the inner and the outer plexiform layers.

Cell Adhesion and Synapse Partnering

In addition to the activity-based mechanisms of synapse refinement, initial targeting of axons and dendrites to the appropriate lamina also depends on the expression of specific cell-associated guidance molecules. These molecules mediate both attractive and repulsive activities to potential synaptic partners. Based on gene expression and results from the spinal cord, various forms of the Protocadherin and Sidekick families of cell adhesion molecules have been proposed to facilitate initial axon/dendrite targeting within the retina. As with other processes of retinal development, our understanding of neuronal process differentiation and synaptogenesis is rudimentary, and much more research is required for a deeper understanding.

Conclusions

Normal retinal development occurs through a series of continuous refinements in which a simple pseudostratified epithelium is specified and patterned to form a highly organized sensory neuroepithelium. The underlying genetics and cellular interactions that drive retinogenesis are necessarily intricate and subjected to complicated feedback regulatory mechanisms. Current models of retinal development are still general, but our understanding of the gene networks and signaling factors that facilitate retinogenesis is increasing. Many important questions remain to be solved. For example, how is the cell cycle precisely controlled in progenitors, and how are cell type fate determinants integrated with regulation of

cell cycle exit? What are the cues that guide postmitotic cell migration in the retina, and what cues inform cells to stop migrating and begin morphogenesis? What are the factors that mediate the necessary cytoskeletal rearrangements required for both cell migration and morphogenesis? How are the spatial waves of neurogenesis and cell differentiation coordinated? What mechanisms work to allow neurons to find each other and form functional circuits? These and other questions are motivating hard work, driving technological advances, and pushing the creativity of many inspired retinal biologists.

Retinal Development: Cell Type Specification

F L A F Gomes and M Cayouette, Institut de Recherches Cliniques de Montréal, Montreal, QC, Canada

The vertebrate retina is a thin layer of light-sensitive neural tissue lining the back of the eye. It comprises seven major cell classes harmoniously organized in three cellular layers (Figure 1). The outer nuclear layer (ONL) contains the cell bodies of rod and cone photoreceptors, whereas the inner nuclear layer (INL) contains the cell bodies of bipolar cells, amacrine cells, horizontal cells, and Müller glial cells. Finally, the ganglion cell layer (GCL) contains the cell bodies of retinal ganglion cells (RGCs), the projection neurons of the retina, as well as those of displaced amacrine cells. Finally, the inner and outer plexiform layers are synaptic layers located between the GCL and the INL, and between the INL and ONL respectively.

The seven major classes of retinal cells are generated in an evolutionary conserved, overlapping birth order. Generally, in vertebrates, the RGCs, cones, and horizontal cells are among the first cells to be generated, followed closely by amacrine cells, and finally by rods, Müller glia, and bipolar cells, which are among the last cell types to be generated (Figure 2).

Multipotency of Retinal Progenitor Cells

Pioneering lineage studies used retroviral vectors or injection of tracers to label retinal progenitor cells (RPCs), which made possible the identification of the entire progeny of individual RPCs, often referred to as their 'clone' (Figure 3). Some of these clones were composed of all the major retinal cell types, when the ancestor cell was labeled early during retinogenesis, indicating that at least some RPCs are multipotent at some point during retinal development. However, this does not preclude the possibility that a subset of progenitor cells may have restricted fate choices. Consistent with this idea is the finding that certain clones were composed of only one cell type, even when the RPC was labeled early in retinogenesis, suggesting that some RPCs might be constrained to generate one cell type. Whether such restricted progenitors have a characteristic 'molecular fingerprint' remains unknown, but recent gene expression profiling of RPCs should help address this issue. Interestingly, the homeodomain transcription factor Pax6 was recently shown to be required to confer the multipotent state of RPCs. Indeed, specific inactivation of Pax6 in RPCs, at the beginning of retinogenesis, prevented the generation of all retinal cell types except amacrine cells. Thus, it appears that Pax6 function in RPCs, at least early in development, is required to confer the multipotent character to RPCs.

To try to reconcile the finding that at least some RPCs are multipotent, together with the finding that different retinal cell types are generated in a strict chronological order, it has been proposed that RPCs undergo changes in their competence to generate particular cell types as development proceeds. Thus, early embryonic RPCs are competent to generate early-born retinal cell types, whereas more mature, postnatal RPCs have lost the competence to generate early-born cell types and gained the competence to generate late-born cell types. These changes in competence appear to be largely intrinsically driven. This was first suggested by the fact that the proliferative capacity and the timing of differentiation of early embryonic RPCs cultured *in vitro* do not change, even in the presence of a 50-fold excess of older postnatal retinal cells. In these mixed-age cultures, postnatal RPCs proliferated less and gave rise to rods much sooner than did embryonic RPCs, suggesting that early and late RPCs are intrinsically different. In addition, when early embryonic RPCs are cultured *in vitro* they can generate RGCs, whereas older postnatal RPCs, placed in the same *in vitro* conditions, generate mostly rods, even when mixed with an excess of early retinal cells. Moreover, isolated late RPCs, cultured at clonal density in serum-free and extract-free medium, can give rise to clones of the same general birth order, size, and composition as clones generated *in vivo*. The presence of a particular retinal cell type within such isolated clones did not appear to be required for the generation of any other retinal cell type, suggesting that instructive environmental signals from previously differentiated cells are not necessary for normal cell fate decisions, at least in late RPCs. Nonetheless, negative environmental signals most likely operate in such clonal density cultures, as well as *in vivo* (see below).

Coordinating Cell Fate and Proliferation

Of particular importance during retinal development is the coordination of proliferation and cell fate specification. Indeed, if RPCs exit the cell cycle too early during retinal development, the number of early-born cells increases at the expense of late-born cells. Thus, the decision to withdraw from the cell cycle must be coordinated with cell fate specification to guarantee that the correct proportion of each neuron and glia

Figure 1 Organization of the vertebrate retina. The seven major retinal cell types are drawn on top of an actual histological section of rat retina (blue nuclei). Retinal ganglion cells (RGC) are found in the ganglion cell layer (GCL). Amacrine (Am), Müller (Mu), horizontal (H), and bipolar (Bi) cells are located in the inner nuclear layer (INL). Rod (R) and cone (C) photoreceptors are located in the outer nuclear layer (ONL). The inner plexiform layer (IPL) and outer plexiform layer (OPL) form the synaptic layers.

cell type is generated. But how does a cell know when to exit the cell cycle? Recent evidence suggests that there are mechanisms that connect cell cycle to fate determination. For example, subsets of RPCs express different types of cyclin-dependent kinase (CDK) inhibitors, suggesting that subpopulations of RPCs might use different components of the cell cycle machinery to control cell cycle exit. Such factors that direct cell cycle arrest may also specifically regulate cell fate determination pathways. Indeed, recent work has shown that the cyclin kinase inhibitor p27Xic1 promotes both cell cycle exit and Müller cell fate through distinct domains of the p27Xic1 protein.

Environmental Factors in Retinal Cell Fate Decisions

As retinal development proceeds, the microenvironment changes as a result of various retinal cell types being generated, raising the possibility that signals secreted by differentiated cell types act on progenitor cells to influence their fate. While the evidence for environmental signals directly instructing RPCs to produce particular retinal cell types *in vivo* is weak, the evidence for feedback inhibition signals that act to prevent the production of certain cell types is convincing. Perhaps the best-studied case of feedback inhibition concerns the RGCs. Young embryonic chick progenitors are inhibited in their ability to produce RGCs when cultured adjacent to old retinal cells, and depletion of the ganglion cells from the old retinal cell population abolishes this inhibition, indicating that signals from RGCs prevent the generation of too many RGCs. Since RGCs are generated first, one possibility is that they might also secrete signals that are required for progenitors to generate the other retinal cell types (instructive signals). This question was recently addressed using a transgenic mouse that expresses diphtheria toxin under the regulatory elements of Brn3b, a key transcription factor required for generation of RGCs. In this mouse, the toxin rapidly kills RGCs as they are born, thereby producing an RGC-depleted retina. Although the retinas of these animals showed reduced proliferation, there were no differences in the relative proportions of the various retinal cell types generated. Taken together, these results suggest that although environmental signals secreted from RGCs are important for normal RPC proliferation and to prevent RPCs from generating too many RGCs, they do not appear to be necessary to positively instruct the generation of other retinal cell types.

To determine how negative feedback signals could influence the production of RGCs in the retina, progenitors expressing green fluorescent protein (GFP) under the regulatory elements of ath5, a transcription factor required for the generation of RGCs, were imaged. In a wild-type retina, the ath5-positive cells systematically divided once to generate a RGC and another cell type (see below). However, when transplanted into a mutant retina, which lacks RGCs, these same progenitors often generated two RGCs, directly demonstrating that the lineage of RPCs can be modified by feedback inhibitory environmental signals.

What might these feedback signals be? Recent studies show that the conditional ablation of Sonic Hedgehog (Shh), which is expressed by RGCs in the mouse retina, causes a rapid depletion of the progenitor pool due to precocious cell cycle exit and neuronal differentiation. Moreover, progenitors are apparently biased to generate RGCs in the Shh knockout mouse, which contains increased number of RGCs. These results suggest that Shh provides feedback inhibition signal in the developing mouse retina. In addition, there is evidence that Shh signaling from RGCs is required for the normal laminar organization in the vertebrate retina, most likely by promoting normal Müller glial cell development. Negative feedback

Figure 2 Chronological order of cell birth in the rat retina. The different retinal cell types are born in a strict but overlapping chronological order from around embryonic (e) day 10 to postnatal (P) day 10. Ho, horizontal cells; CPr, cone photoreceptors; RGC, retinal ganglion cells; Am, amacrine cells; RPr, rod photoreceptors; Bi, bipolar cells; Mu, Müller cells. This diagram is based on published results from Rapaport DH, Wong LL, Wood ED, Yasumura D, and Lavail MM (2004) Timing and topography of cell genesis in the rat retina. *Journal of Comparative Neurology* 474: 304–324.

Figure 3 An example of a clone obtained by labeling a retinal progenitor cell at P0 with a GFP-expressing retroviral vector. The clone contains several photoreceptors, which are located in the outer nuclear layer (ONL), and a bipolar cell, which is located in the inner nuclear layer (INL).

signals may also affect the timing of differentiation. In the mouse retina, the growth differentiation factor 11 (GDF11) is a key regulator of RGC genesis. Evidence suggests that GDF11 acts by regulating the temporal window during which progenitors are competent to produce RGCs.

Another interesting group of environmental cues are the ligands of Notch. Constitutive stimulation of the Notch signaling pathway in rat RPCs biases the development of Müller glia at the expense of neurons, probably by interfering with the function of proneural bHLH transcription factors. At the same time, Notch clearly affects cell cycle exit. Experiments in *Xenopus* retina indicated that the Notch signaling pathway controls when a progenitor can differentiate. When cells are released from the inhibition mediated by the Notch pathway, basic helix–loop–helix (bHLH) transcription factors act as intrinsic factors that bias neuroblasts toward particular fates and histogenically appropriate cell cycle exit (see below).

Intrinsic Factors in Retinal Cell Fate Decisions

bHLH and Homeodomain Transcription Factors

As in other regions of the central nervous system, there are a number of transcription factors that intrinsically influence several facets of cell fate specification in the retina. The two major classes of transcription factors involved in cell fate identity comprise the bHLH and the homeodomain (HD). A bHLH motif consists of a short α helix connected by a loop to a second, longer α helix, whereas HD transcription factors constitute a special family of helix-turn-helix DNA-binding proteins, constructed from two α helices connected by a short extended chain of amino acids, which constitute the turn. These two classes of transcriptions factors bind to regulatory DNA sequence

either alone or via a complex with other transcriptions factors. In some cases binding triggers or enhances transcription, while in other cases it reduces or blocks transcription of developmental genes.

There are two functionally distinct groups of bHLH genes: repressors and activators. bHLH repressors (e.g., Hes1 and Hes5) are expressed in progenitors and inhibit neuronal differentiation. These repressors help maintain the undifferentiated state in the embryonic phase of retinogenesis, whereas they appear to promote gliogenesis in the postnatal retina. Misexpression of Hes1 in embryonic retina prevents differentiation and maintains the RPC fate. On the other hand, in Hes1 knockouts, progenitors show decreased proliferation, resulting in small-eye phenotype. In mice, the lack of Hes1 upregulates the expression of Mash1 (bHLH activator) resulting in increase of early-born types of neurons at the expenses of late-born cell types. Double mutation experiments have shown that another member of the Hes family, Hes5, acts cooperatively with Hes1 to regulate the maintenance of RPCs. Upon stimulation by Notch ligand from adjacent cells, Hes1 and Hes5 expression is increased, leading to the repression of bHLH activators genes, which in turns inhibits neuronal differentiation.

The role of bHLH and homeodomain transcription factors has been extensively studied in the retina. Here, we summarize the general results for the different retinal cell types, but it is beyond the scope of this article to describe in detail the function of these genes in retinal cell specification.

Müller glial cells In the postnatal retina, Hes1 and Hes5 are expressed in differentiating Müller glial cells and in RPCs. Misexpression of either Hes1 or Hes5 in postnatal RPCs increases Müller glia cell fate. Because both Hes1 and Hes5 are Notch effectors, these data indicate that activation of Notch signaling induces glial fate determination at the expense of other fates. Consistent with these results, constitutive activation of Notch signaling in postnatal RPCs increases the generation of Müller glial cells.

Interestingly, several lines of evidences suggest that progenitors and Müller glia cells are more closely related to each other than was previously thought. First, both cell types express the same transcriptions factors (Hes1, Hes5, and rax). Second, they are morphologically very similar, and lastly, Müller glia cells have been shown to have progenitor-like potency such as the capacity to self-renew and the ability to give rise to neurons and glia cells after retinal injury.

Bipolar cells It has been demonstrated that for bipolar cell fate specification two bHLH activators genes, Mash1 and Math3, and the HD factor Chx10 are required. Misexpression in RPCs of either Mash1 or Math3 alone mostly increases photoreceptor generation, whereas misexpression of Chx10 alone increases generation of Müller glia or undifferentiated cells, but not mature bipolar cells. In contrast, co-expression of Mash1 or Math3 with Chx10 in RPCs predominantly forces the generation of bipolar cells. Knockout mouse experiments have shown that Mash1/Math3 double mutants have no bipolar cells, whereas the number of Müller glial cells is increased. Loss of Chx10 function also prevents bipolar cell genesis but, in contrast to the Mash1/Math3 double mutant, is not accompanied by an increase of Müller glia cells, suggesting that Chx10 and Mash1/Math3 have distinct roles in specification of the bipolar cell fate.

Amacrine cells Two bHLH genes, NeuroD and Math3, are transiently expressed in differentiating amacrine cells. A mutation in either NeuroD or Math3 alone does not significantly affect amacrine cell development, but mutation in both NeuroD and Math3 severely decreases amacrine cell genesis, while increasing ganglion cell production.

Although NeuroD and Math3 are expressed during amacrine cell development, misexpression of each gene alone does not increase amacrine cell genesis, but significantly increases photoreceptor cell production. These results indicate that other genes may be required for amacrine cell development. Two homeodomain genes, Pax6 and Six3, are also expressed in amacrine cells. Although misexpression of each gene alone does not lead to increased amacrine cell production, concomitant expression of Pax6 or Six3 with NeuroD and Math3 significantly increases amacrine cell numbers. Thus, as in bipolar cell genesis, the co-expression of the bHLH and homeodomain genes influences the fate of amacrine cells.

Ganglion cells Math5, another member of the atonal bHLH activator gene, plays an important role in ganglion cell genesis. Math5 appears to directly activate the expression of the POU domain transcription factor Brn3b, which in turn is required for terminal differentiation of RGCs. In mice, it has been shown that a Math5 null mutation causes a dramatic decrease in RGC production and an increase of amacrine cells. These results, as stated earlier, are contrary to those of NeuroD/Math3 double mutants, which favored ganglion cell genesis at the expenses of amacrine cell production. It is plausible that NeuroD/Math3 and Math5 antagonistically control each other for amacrine versus ganglion cell fate specification. However, the mechanism for this regulation remains unknown.

Photoreceptor cells The homeodomain genes Crx and Otx2 have been shown to be required for photoreceptor cell development. In humans, mutations in Crx are associated with retinal diseases leading to photoreceptor degeneration and vision loss, such as cone–rod dystrophy-2, retinitis pigmentosa, and Leber's congenital amaurosis. Crx is expressed specifically in photoreceptor cells, where it is thought to regulate the expression of photoreceptor-specific genes such as rhodopsin and cone opsins. Overexpression of Crx in RPCs results in an increased generation of photoreceptor cells, and Crx knockout mouse photoreceptor cells do not elaborate outer segments and lack normal electrophysiological activity.

While Crx activity regulates the differentiation of both rods and cones, other factors specifically control the production of rod photoreceptors. The protein neural retina leucine zipper (Nrl) is a basic motif–leucine zipper transcription factor that is preferentially expressed in rod photoreceptors, where it is thought to act synergistically with Crx to regulate rhodopsin expression. Mutations in human NRL have been associated with autosomal dominant retinitis pigmentosa, which is characterized by rod photoreceptor degeneration. Interestingly, deletion of Nrl in mice results in the complete loss of rod function and an increase in cone function. Histological analysis of the Nrl knockout retina revealed that rod photoreceptors do not develop, whereas cone photoreceptors are overproduced. Thus, it appears that Nrl acts as a binary molecular switch during rod photoreceptor development by modulating rod-specific genes and inhibiting the cone differentiation pathway.

Another important regulator of rod photoreceptor development is the retinoblastoma (Rb) gene. During postnatal retinal development, Rb is expressed in proliferating RPCs and in differentiating rod photoreceptors. In the absence of Rb, RPCs continue to divide, and rods do not differentiate normally, as judged by abnormal inner and outer segments and disrupted pedicles. Based on these results, it has been proposed that Rb functions to regulate cell cycle exit of RPCs and rod differentiation.

Horizontal cell It was recently shown that coexpression of the homeodomain genes Pax6 or Six3 with the bHLH gene Math3 promotes primarily horizontal cell formation, in addition to amacrine cells. However, Math3 null mice develop horizontal cells normally, indicating that other genes may be compensating for Math3 function in horizontal cells.

The HD Prox1 is another essential gene for horizontal cell development. During retina development, Prox1 is expressed in differentiating horizontal cells, bipolar cells, and a subtype of amacrine cells. RPCs lacking Prox1 are less likely to stop dividing, and ectopic expression of Prox1 forces RPCs out of the cell cycle. In Prox1 knockout mice, horizontal cells are absent and misexpression of Prox1 in postnatal RPCs promotes horizontal cell production. Thus, it appears that Prox1 is both necessary and sufficient for RPC proliferation and horizontal cell fate determination in the vertebrate retina.

Asymmetric Cell Divisions in Retinal Cell Fate Decisions

Increasing evidence suggests that the asymmetric inheritance of cell fate determinants during an RPC division is an important mechanism regulating cell fate specification. In vertebrates, a number of studies have now provided evidence that the orientation of cell division is correlated to symmetric and asymmetric outcomes in various organs in different animals (Figure 4). Specifically, in the developing retina, the process of symmetric and asymmetric division has been most studied in terminal divisions that generate two postmitotic daughter cells. Upon terminal division, most RPCs divide with their mitotic spindle oriented parallel (horizontal) to the plane of the neuroepithelium, but a substantial minority divides with their spindle oriented perpendicular (vertical) to the plane of the neuroepithelium, along the apico-basal axis. A mammalian homolog of Numb (m-Numb), a natural antagonist of Notch signaling, is asymmetrically localized at the apical pole of the dividing RPCs and thus would be presumably asymmetrically inherited by the apical daughter cell of vertical divisions, whereas it would be symmetrically inherited by both daughter cells of horizontal divisions. Live imaging experiments of retrovirally labeled rat RPCs demonstrated that the two daughter cells of terminal divisions with a horizontal spindle tend to become the same cell type, whereas the two daughter cells of divisions with a vertical spindle tend to produce daughters that become different cell types. Moreover, overexpression of m-Numb in RPCs resulted in more daughter cell pairs of the same cell type and fewer daughter cell pairs of different cell types. Thus, the plane of cell division can apparently influence cell fate choice in the developing rat retina, presumably by controlling the asymmetric segregation of cell fate determinants such as m-Numb.

In the zebra fish retina, the orientation of cell division also appears to be correlated with cell fate. Although no apical–basal divisions are found in the zebra fish retina, some RPCs reorient their mitotic spindle within the plane of the neuroepithelium and divide either along the central to peripheral axis or along the circumferential axis. As development proceeds, the orientation of RPC divisions switches from

Figure 4 Different possible outcomes of symmetric and asymmetric cell divisions. RPCs undergo mitosis at the apical side of the neuroepithelium and segregate cell fate determinants (blue) asymmetrically at the apical pole of the cell cortex. In a symmetric division (left panels), the RPC divide parallel to the plane of the neuroepithelium, and cell fate determinants are inherited symmetrically by both daughter cells. The outcome of the division is two daughter cells of the same type, which can be two progenitors (P + P) or two neurons (N + N). In an asymmetric cell division (right panels), the RPC reorients its mitotic spindle to divide perpendicular to the asymmetric concentration of cell fate determinants at the apical pole of the cell cortex. This leads to asymmetric inheritance of cell fate determinants by the daughter cells. The outcome of the division is two daughter cells of different types, which can be two progenitors with different intrinsic potential (PA + PB), a progenitor and a neuron (P + N), or two neurons of different types (NA + NB).

being mostly central-peripheral to being mostly circumferential, suggesting that changing the orientation of cell division may contribute to particular cell fate decisions. Recent live imaging studies in the zebra fish retina support this possibility. In these experiments, it was shown that ath5:GFP RPCs in a wild-type retina divide along the circumferential axis to give rise to a RGC and another cell type, most likely a photoreceptor, whereas when these ath5:GFP RPCs are grafted in a RGC-depleted environment, they tend to divide along the central-peripheral axis to give rise to two RGCs, indicating that the orientation of cell division can predict the outcome in terms of the fate adopted by the daughter cells. It remains to be determined whether cell fate determining proteins are asymmetrically inherited by the daughter cells of circumferential divisions in the fish retina, but proteins involved in the establishment of planar cell polarity are certainly good candidates.
