Introduction

Ganglion cells are the projection neurons of the vertebrate retina, conveying information from other retinal neurons to the rest of the brain. Their perikarya are the largest of any retinal neurons and are located along the inner margin of the retina, in the ganglion cell layer. Their axons run in a separate layer on the inner surface of the retina, collect at the optic disk, and then exit the eye as the optic nerve. Ganglion cells are the first type of neuron to differentiate, appearing earliest in the central retina and later in the periphery.

Ganglion cell dendrites extend into the inner plexiform layer (IPL), a neuropil located on the outer side of the ganglion cell layer. The ultrastructure of ganglion cell dendrites is typical of dendrites seen elsewhere in the central nervous system, and they usually do not contain synaptic vesicles or any other presynaptic specializations. Ganglion cells receive inputs from bipolar cells, which convey signals from photoreceptors to the IPL, and from amacrine cells, which branch in the IPL (**Figure 1**).

The presynaptic bipolar cell axon terminals contain specialized synaptic structures called ribbons that are surrounded by synaptic vesicles. There are two postsynaptic processes opposite each ribbon, and these synapses are called dyads. One postsynaptic process is usually a ganglion cell dendrite, and the second postsynaptic process is typically from an amacrine cell. At dyads, the amacrine cell process can make a reciprocal synapse back onto the bipolar cell, a feed-forward synapse onto the ganglion cell dendrite, or both. Amacrine cells also make chemical and electrical synapses onto ganglion cell dendrites at other sites, and they influence ganglion cells indirectly via synapses onto other bipolar cells and onto other amacrine cells.

The classical receptive field of a ganglion cell is defined as the area of the retina where stimulation with a small spot of light produces a change in ganglion cell firing rate. Ganglion cells are classified into three basic types based on their responses to light stimuli presented in the centers of their receptive fields. ON ganglion cells depolarize and fire action potentials to increments in light intensity, and OFF cells depolarize and fire action potentials to decrements in light intensity. Illumination presented in the region surrounding the receptive field center typically generates a response opposite in sign to that generated by central illumination. ON–OFF cells depolarize and fire action potentials to both increments and decrements in light intensity; they may or may not have antagonistic surrounds.

There are two common types of ganglion cells in typical vertebrate retinas, one type with relatively small dendritic arbors and sustained light responses and another type with larger dendritic arbors and more transient light responses. In addition, there are a number of other, less common types with more complex light responses. In all, vertebrate retinas have 10–20 types of ganglion cells, distinguishable by their morphology, synaptic connections, and light responses. The perikarya of each type are distributed across the retina in a regular array.

The light responses of ganglion cells are generated by direct, excitatory inputs from bipolar cells mediated by the neurotransmitter L-glutamate (**Figure 2(a)**). Axon terminals of ON-type cone bipolar cells contact the dendrites of the ON retinal ganglion cells in the inner half of the IPL. OFF-type cone bipolar cells terminate in the outer half of the IPL, where they contact the dendrites of OFF ganglion cells. ON–OFF ganglion cells receive input from both types of bipolar cells. For the most part, the chemical synapses made by amacrine cells are inhibitory, using either γ-aminobutyric acid (GABA) or glycine as neurotransmitters, but one type of amacrine cell, the starburst cell, releases acetylcholine and excites ganglion cells via nicotinic receptors. Some types of ganglion cells also make electrical synapses with amacrine cells or with other ganglion cells of the same type.

In mammals, there are rod bipolar cells with dendrites that receive input exclusively from rod photoreceptors; they depolarize in response to increments in light intensity (**Figure 2(b)**). The axon terminals of these rod bipolar cells make excitatory synapses onto two types of amacrine cells, A17 and AII cells. The A17 cells make reciprocal, inhibitory synapses back onto the rod bipolar cell axons. Signals from the AII cells are conveyed to the cone bipolar cells via two different pathways. The AII cells excite ON cone bipolar cells via gap junctions, and they also make glycinergic inhibitory synapses onto OFF cone bipolar cells. Signals also flow directly from rods to cones through gap junctions; however, this second rod pathway is less sensitive to light. In some mammals, there is a third rod pathway in which the dendrites of one type of OFF cone bipolar cell receive input directly from rods. Thus, signals originating in both rods and cones reach the ganglion cells through the same bipolar cells.

The focus of this article is on the anatomy of retinal ganglion cells in primates. The three most common

Figure 1 A large OFF parasol ganglion cell dendrite receives synapses from an amacrine cell process at a conventional synapse (open arrowheads) and a bipolar cell axon at a dyad synapse (arrow). The bipolar cell axon receives a reciprocal synapse (solid arrowheads) from an electron-lucent amacrine cell process. The parasol cell was from a macaque retina and was labeled by intracellular injection of neurobiotin. Scale bar = 1 μm.

types of ganglion cells in primates are called midget cells, parasol cells, and small bistratified cells, and together they comprise approximately 70% of all ganglion cells. The remaining ganglion cells are quite heterogeneous, but because they all have larger dendritic arbors, compared to the three common types, they are called wide-field cells. The wide-field ganglion cells of primates closely resemble the ganglion cells described in other mammalian retinas in their size and in morphology. Because primates have many more ganglion cells than other mammals have, the number of wide-field ganglion cells in primates is roughly the same as the total number of ganglion cells in typical mammalian retinas. In those instances where the light responses or synaptic connections have been studied, the wide-field ganglion cells of primates are similar to their homologs in other mammals in these respects, as well.

Midget Cells

Midget cells are the most common type of ganglion cells in primate retinas. In the central retina, approximately 70% of ganglion cells are midget cells, but in the peripheral retina the proportion decreases to 50%. Midget cells are also known as P cells because they project to the parvocellular layers of the lateral geniculate nucleus (LGN). In the central 6–7° of visual angle, they generally receive excitatory synapses from a single midget bipolar cell, which, in turn, receives input from a single long-wavelength (L) or middle-wavelength (M) sensitive cone. The dendritic fields of midget ganglion cells become larger with increasing eccentricity, and these peripheral midget ganglion cells receive input from two or more midget bipolar cells. Another difference in the peripheral retina is that rod signals reach midget ganglion cells via contacts between AII amacrine cells and midget bipolar cells, whereas the midget ganglion cells in the central retina receive only cone input.

Midget ganglion cells also receive synaptic input from amacrine cells, this comprises approximately half of their input in the central retina and a larger proportion in the peripheral retina. GABAergic amacrine cells receiving input from midget bipolar cells at dyads with midget ganglion cells often make reciprocal synapses onto the bipolar cell, feed-forward synapses onto the ganglion cell, or both. Amacrine cells containing glycine contact both midget bipolar cells and midget ganglion cells. Another amacrine cell type synapses only onto the midget ganglion cells. Interactions between amacrine cells in the neural circuit providing input to midget ganglion cells are seen very frequently in studies of serial sections using electron microscopy.

Midget ganglion cells with dendrites in the inner half of the IPL have ON center responses; that is, they are excited by increments in the intensity of white light in their receptive field centers and inhibited by that stimulus in the receptive field surround. Midget ganglion cells branching in the outer half of the IPL have the opposite, or OFF center, responses, and they have smaller dendritic fields than do the ON subtype at a given eccentricity. Because their dendritic fields are small and there is no overlap between dendrites of the same type, midget ganglion cells are well suited for high-acuity vision.

Most central and midperipheral midget ganglion cells have responses of opposite polarity to stimulation of the L and M cones, and thus they also mediate red–green color vision. When either L or M cones are stimulated selectively, midget ganglion cells respond as though their receptive field centers are driven by a single subtype of cone, and their surrounds are driven by the opposite type. Cone-selective centers and surrounds such as these are optimal to detect differences in color, although this is achieved at the expense of sensitivity to differences in brightness. Despite 40 years of research, it is unclear how the neural circuit providing input to midget ganglion cells generates these cone-selective responses.

Figure 2 In mammals, the rods and cones differ in their connections with horizontal cells and contact different sets of bipolar cells. (a) Cone pathways: In the outer plexiform layer (OPL), cones (C) provide input to ON and OFF cone bipolar cells (BP) and horizontal cells (HC) in the inner nuclear layer (INL). In the inner plexiform layer (IPL), bipolar cells make excitatory, ribbon synapses onto ON and OFF ganglion cells (GC) (GCL, ganglion cell layer; OFL, optic fiber layer). The bipolar cells also synapse on amacrine cells (AC), which make inhibitory synapses back onto bipolar cells and forward onto amacrine cells and ganglion cells. (b) Rod pathways: Rods (R) provide input to rod bipolar cells (RBP), which synapse onto bistratified AII amacrine cells and A17 amacrine cells. A17 cells make inhibitory, feedback synapses onto rod bipolar cells. AII amacrine cells relay the rod signal to OFF ganglion cells via inhibitory synapses onto OFF cone bipolar cells and to ON ganglion cells via gap junctions with ON cone bipolar cells. Rods also make gap junctions with cones.

In the central 6–7°, the input from a single midget bipolar cell might account for the cone specificity of the excitatory input. However, there are small gap junctions between neighboring L and M cones, and the signal from one cone subtype has a contribution from the other. Cone-selective receptive field centers might also arise by chance in the midperipheral retina. Because L and M cones are randomly arranged and tend to form clusters of a single type, the midget bipolar cells presynaptic to a peripheral midget ganglion cell might receive input from the same subtype of cone. This would not account for the large proportion of color opponent peripheral midget ganglion cells, however.

There is no obvious anatomical explanation for the cone-selective inhibitory input in any part of the retina. Horizontal cells, neurons that branch in the outer plexiform layer (OPL), are unselective in their contacts with L and M cones, and their light responses indicate that the input from both cones is of the same polarity. Amacrine cells that contact midget ganglion cells receive input from all types of bipolar cells within their dendritic fields. Thus, the anatomical studies suggest that the light responses of midget ganglion cells simply reflect the distribution of L and M cones in their receptive fields. The apparent contradiction between the anatomical and physiological findings can be reconciled if interactions between local circuit neurons generate cone-specific responses.

All other mammalian retinas have ganglion cells that mediate high-acuity vision. These ganglion cells have brisk, sustained light responses and linear summation of light responses within their receptive field centers. None are as highly specialized as the midget ganglion cells in the central primate retina, but they resemble peripheral midget ganglion cells in many respects. These ganglion cells are not electrically coupled, and they have a high spatial density. Their dendritic arbors are small in diameter, relatively dense, and broadly stratified within the IPL.

Parasol and Other Cells with Brisk Transient Responses

Parasol cells are another major type of ganglion cell in primates, comprising approximately 5% of all ganglion cells in the central retina and 15% in the peripheral retina. Parasol cells are also known as M cells because they project to the magnocellular layers of the LGN. Parasol cells contribute to many aspects of

vision, particularly to the perception of motion. They are more sensitive to luminance contrast than midget cells are, and they also respond more transiently to light stimuli. They have a greater absolute sensitivity to light than midget cells have, because they collect from a larger area of the retina and receive more input from the rod pathway. Unlike midget cells, parasol cells are also responsive to certain types of stimuli outside the classical receptive field, and thus they convey information about global as well as local stimulus properties.

At any given eccentricity, parasol cells have much larger dendritic fields than do midget cells; their dendrites are also more narrowly stratified and ramify closer to the center of the IPL. There are two types, ON cells with branches in the inner half of the IPL, and OFF cells with branches in the outer half. As with midget cells, each type of parasol cell forms a regular array across the retina, and the dendritic field size increases with eccentricity. An important difference between midget and parasol cells is that the dendrites of adjacent parasol cells of the same type overlap extensively. The spacing between perikarya of neighboring parasol cells is roughly half of their dendritic field diameters, and thus, the dendritic coverage is three. As a result, a small spot stimulus would excite three neighboring parasol cells of the same subtype.

Many other differences between parasol cells and midget cells are attributable to the neurons that provide their input. Parasol cells receive excitatory synapses from diffuse bipolar cells, which, in turn, receive input from several cones. Two different types of diffuse bipolar cells provide input to OFF parasol cells. Diffuse bipolar cells are also presynaptic to ON parasol cells, but they have not been identified. The classical surround responses of parasol cells originate from the summed surround responses of the diffuse bipolar cells, which are generated in the OPL by horizontal cells.

Parasol cells also receive input from multiple types of amacrine cells, and the proportion of input from amacrine cells increases with eccentricity. Unlike amacrine cells in the pathway providing input to midget ganglion cells, the amacrine cells presynaptic to parasol cells rarely make reciprocal synapses with the bipolar cells providing input to the parasol cells, and they do not contact other amacrine cells in the vicinity of the parasol cell. Nevertheless, it is clear that interactions between amacrine cells are important in the pathway providing input to parasol cells. All the amacrine cells known to be presynaptic to parasol cells receive inputs from other amacrine cells. In addition, the GABA antagonist picrotoxin attenuates the light responses of parasol cells, a finding suggesting that GABAergic amacrine cells inhibit other amacrine cells in the pathway.

These interactions between amacrine cells take place on a spatial scale too large to detect in serial electron microscopic reconstruction studies of parasol cells, however. For example, some amacrine cells receive input from other amacrine cells at their dendrites and convey the signals to parasol cells via their axons, which extend for several millimeters. These inputs from axon-bearing amacrine cells presumably enable parasol cells to respond to stimuli outside their classical receptive fields. Another reason why interactions between amacrine cells in the neural circuit providing input to parasol cells are difficult to unravel is that some presynaptic amacrine cells receive synapses in one part of their dendritic trees and make synapses in another part. The starburst amacrine cell is one such amacrine cell. Its dendrites costratify with those ON and OFF parasol cells and synapse onto both types.

Dendrites of parasol ganglion cells make gap junctions with large, axon-bearing amacrine cells, and they are coupled indirectly to other parasol cells of the same subtype (**Figure 3**). As a result, neighboring parasol cells of the same subtype tend to fire synchronously, and when the signals from neighboring parasol cells converge in the brain, they are particularly effective in depolarizing their target cells. Midget ganglion cells, on the other hand, do not make gap junctions or fire synchronously, and they act independently when their signals converge in the brain. The gap junctions with amacrine cells might also enhance the sensitivity of parasol cells to luminance contrast. Because the amacrine cells coupled to parasol cells also make inhibitory synapses onto other parasol cells, neighboring parasol cells indirectly inhibit one another. At a border, parasol cells on the unstimulated side are inhibited, and this relieves parasol cells on the stimulated side from tonic inhibition. The gap junctions do not enlarge the receptive fields of parasol cells, however; the diameters of parasol cell receptive field centers are the same as their dendritic field diameters.

Primates also have wide-field ganglion cells very similar to ganglion cells known as alpha cells in other mammals. That is, they are large, monostratified ganglion cells with brisk, transient responses to light. The alpha-like cells comprise 2–3% of all ganglion cells, and they project to both the LGN and the superior colliculus. Like parasol cells, the alpha-like cells are electrically coupled to amacrine cells. In addition, their dendrites have a characteristic, radiate branching pattern and are narrowly stratified on either side of the center of the IPL. In some other

Figure 3 A large ON parasol cell dendrite receives a conventional synapse from an amacrine cell (arrow) and makes a gap junction with another amacrine cell (arrowheads). (a) Both synapses are found on a large dendrite, ~1.2 μm in diameter (30 000×). (b) The amacrine cell making the gap junction is cut in cross section (50 000×). (c) The junction is shown at higher magnification (150 000×). The parasol cell was injected with neurobiotin in a baboon retina.

mammals, there are also two types of alpha-like ganglion cells, although the differences between the two types are not as pronounced as those between alpha-like cells and parasol cells of primates.

Cells Responding Selectively to Short Wavelengths

Small bistratified cells make an important contribution to blue–yellow color vision. They depolarize and fire action potentials when short-wavelength (S) cones are stimulated and are inhibited when either L or M cones are stimulated; with 500 nm light stimulation, they do not respond at all. Small bistratified cells also depolarize and fire action potentials in response to decrements in long- and middle-wavelength light; this is called an OFF response. They have two sets of dendrites, one near the inner border of the IPL and another near the outer border. Their dendritic arbors increase in size with eccentricity and are roughly the same size as those of neighboring parasol cells. The small bistratified cells are arranged in a regular array, and their dendritic coverage is approximately two. Small bistratified cells are the third most common type of primate ganglion cells, comprising approximately 5% of all ganglion cells. They project to koniocellular layers 3 and 4 in the LGN.

The bipolar cells that provide the major excitatory input to small bistratified ganglion cells are called blue cone bipolar cells because they receive input exclusively from S cones. The horizontal cells in this pathway, the H2 type, contact all three cone types and particularly S cones. There is a second, much smaller excitatory input from diffuse bipolar cells in the outer half of the IPL that also hyperpolarize when L and M cones are stimulated. However, most of the OFF response originates in the H2 horizontal cells and is conveyed to the small bistratified ganglion cells by the blue cone bipolar cells.

Small bistratifed ganglion cells are electrically coupled to narrow-field amacrine cells and, indirectly, to neighboring small bistratified cells. In the central retina, small bistratified cells receive 30% of their input from amacrine cells, and the proportion increases to 80% in the peripheral retina. In this respect, the small bistratifed ganglion cells are typical of primate

ganglion cells; all three major types receive more input from amacrine cells in the peripheral retina. This may explain the greater responsiveness of primate ganglion cells to moving and other rapidly changing stimuli in the peripheral retina.

Several types of wide-field cells also contribute to blue–yellow color vision. Large bistratified cells comprise approximately 3% of all ganglion cells and project to the LGN. They have two sets of dendrites near the borders of the IPL, and they are excited by increments in short-wavelength light and decrements in long and middle wavelengths. However, they have considerably larger dendritic arbors than do the small bistratified type. There are two types of sparse, monostratified ganglion cells, one with dendrites near the outer border of the IPL and the other with dendrites near the inner border. Together, the two subtypes of sparse monostratified cells comprise approximately 3% of all ganglion cells, and they project to the LGN. The cells branching near the inner border have OFF responses to short wavelengths and ON responses to long and middle wavelengths.

The giant cells that contain the photopigment melanopsin also have OFF responses to short wavelengths and ON responses to long and middle wavelengths with bright stimuli. The light responses of giant ganglion cells are atypical in two other respects, however. Despite the fact that many of the giant cells have dendrites branching in the outer IPL, all of them have ON responses to dim lights that stimulate only the rods. A slow, sustained component of their light responses mediated by melanopsin enables the giant cells to transmit information about the absolute intensity of light stimuli to their targets in the brain. They comprise approximately 0.2% of all ganglion cells, and they project to the olivary nucleus of the pretectum, the suprachiasmatic nucleus of the hypothalamus, and the LGN.

Most mammals have only two cone types, S and M, and therefore have dichromatic color vision. All species studied to date have a distinctive type of ON bipolar cell that contacts S cones exclusively and ramifies in the innermost stratum of the IPL. Some mammals also have ganglion cells that costratify with the axon terminals of the blue cone bipolar and ganglion cells with color opponent responses. However, the color opponent ganglion cells have only been identified morphologically in primates. All mammals also have ganglion cells with extremely large dendritic arbors that express the photopigment melanopsin and are intrinsically sensitive to light. It is uncertain whether they also have color opponent light responses like the giant cells of primates.

Other Wide-Field Cells

A number of other types of wide-field ganglion cells have been described using anatomical techniques in primates (Figure 4). Only the most abundant types are described here. Two types of wide-field ganglion cells resemble direction-selective ganglion cells of other mammals, cells that respond vigorously to stimuli moving in one direction but not to stimuli moving in the opposite direction. They project to the superior colliculus and, together, comprise 6% of all ganglion cells. Thorny ganglion cells have fine, tortuous branches with many small branches and spines, and they resemble local edge detectors of other mammals. They project to the LGN and comprise 4% of all ganglion cells. To determine how these wide-field cells contribute to vision in primates, it will be essential to characterize each type by intracellular recording and dye injection.

Conclusions

An important goal for future research is to determine how amacrine cells contribute to the light responses of each type of ganglion cell. The classical receptive field centers and surrounds of ganglion cells can be explained in large part by synaptic interactions in the OPL. However, most of the synapses in the IPL are made by amacrine cells, and all types of ganglion cells receive a major input from amacrine cells. Ganglion cell types differ in the patterns of excitation and inhibition that they receive during the response to light, and many of these differences are attributable to amacrine cells. However, it is uncertain which types of amacrine cells provide input to most types of ganglion cells. The amacrine cells are quite diverse in their morphology and synaptic connections, but aside from the starburst cells and the two cells in the rod pathway, very little is known about their roles in visual information processing.

In primates, the different morphological types of retinal ganglion cells develop in a proscribed-sequence, and this may provide insight into their evolutionary history. Wide-field cells, which closely resemble ganglion cells in other mammals, are the first types to develop. In the central nervous system, as a rule, phylogenetically old structures develop early. Taken together, these findings suggest that wide-field cells were the retinal ganglion cells in the common ancestors of mammals, nocturnal animals having only S and M cones. It will be a challenge for the future to determine the precise sequence of developmental events that generates the morphological

Figure 4 An artist's conception of the ganglion cell types described to date in macaque retinas, as they would appear in vertical sections. The five strata of the inner plexiform layer (IPL) are indicated by shading, S1 being closest to the inner nuclear layer (INL) and S5 being closest to the ganglion cell layer (GCL).

differences between the various types of wide-field cells, but these processes are likely to be similar in all mammalian retinas. Midget ganglion cells are the next to develop, followed by the parasol cells. These later developing cells presumably evolved more recently and, among mammals, may be unique to primates.

Retinal Ganglion Cells: Receptive Fields

J B Troy, Northwestern University, Evanston, IL, USA

Introduction

One can trace the term receptive field to Sherrington, who used it to name the region of a sensory surface from which a stimulus can evoke a neural response. Sherrington applied the term to a group of neurons, but today the term receptive field more commonly means the sensory region where a stimulus evokes a response from a single cell. In the visual system, one may consider the retina to be the sensory surface where receptive fields are located, but descriptions of receptive fields are more often presented in terms of the optical projection of the retina out into the world, the construct we call the visual field. Hence, for the retinal ganglion cell, the receptive field could be either a small region of retina or a small region of the visual field. Since descriptions of receptive field in the latter case incorporate an additional component due to optical blurring, which increases with decreasing light level as the pupil dilates, the two usages are not completely equivalent.

Throughout the years, the receptive field concept has taken on a meaning greater than just a spatial region over which sensory stimuli can influence neural activity. Usage of the term receptive field has come to include also a description of the configuration of the optimal stimulus for the field. For example, ever since Kuffler provided the classical description of receptive fields for mammalian retinal ganglion cells, we have come to speak of center-surround receptive fields, which are divided into two subtypes: those with off-centers and on-surrounds and those with on-centers and off-surrounds. In subsequent years, many varieties of retinal ganglion cell have been discovered in vertebrate retina, and the classification into physiological types is predicated on differences in receptive field properties. There are ganglion cells with different varieties of center-surround receptive field, some of which can be differentiated by size. In a particular retinal location, there will be some retinal ganglion cells with on-centers that are markedly larger than those of neighboring retinal ganglion cells with on-center/off-surround receptive fields. A difference in the time course of response to visual stimulation has also been used to differentiate ganglion cell types. Although one might argue that the term receptive field should be reserved for descriptions in the spatial domain, this is not followed, and perhaps with good reason. Individual neurons can represent just one spatial location since all the information they convey is carried by a single spike train. A receptive field description incorporating how the spatiotemporal distribution of light and dark and, in some cases, wavelength modulates the distribution of spikes in the spike train is richer from a functional perspective. Thus, the term receptive field encompasses both a spatial area and how the sensory stimulus should be configured over that area spatially, temporally, and spectrally to most effectively drive the cell's discharge.

By taking on this added dimension, the concept of receptive field has become one of the cornerstones of sensory physiology. We have come to view change in receptive field structure as one moves up the chain of neurons in a sensory pathway as an indicator of the processing that occurs at each stage. The spatiotemporal and spectral structure of the receptive field tells us the operation performed on the visual input by the optical and neural elements that precede spike initiation and thus what controls the neuron's discharge.

Classification of Retinal Ganglion Cell Types

No consensus exists on how to relate ganglion cell types across species and, even within a species, different terminologies coexist. Hence, the classification of mammalian ganglion cells is confusing, particularly to the nonexpert. One might hope that genetic fingerprinting will lead to a clearer classification, but the extent to which ganglion cells can be separated on the basis of gene expression remains unclear. At best, it seems that differentiation into types will require analysis of genetic expression in multidimensions. With few exceptions (perhaps the melanopsin ganglion cell), it does not seem that single gene markers could be used to identify a type of ganglion cell.

Physiological cell typing is something of an art, in that the characterization of receptive field properties depends on the skill and insight of the experimenter. An approach that some have used is to employ a spot of light (or dark) as the visual stimulus. By adjusting the position where one flashes the spot within the receptive field, one might assume that one can faithfully map the receptive field's response to the spot and thus reveal the receptive field structure. By adjusting the spectral properties of the spot, one could reveal chromatic receptive field properties and the temporal nature of the response should inform the observer

about the temporal properties of the receptive field region probed. There are many reasons why this approach to receptive field mapping is problematic. First, the sensitivity of the retina to light is not constant but, rather, varies as a function of its space- and time-averaged illuminance. The structure of the receptive field measured from darkness is not the same as the structure measured against a background of higher luminance. Second, some visual adaptation in the retina occurs locally. Thus, the light in a stimulus spot might adapt the retinal region being stimulated and thus affect the response of the cell to that stimulus. This is particularly likely when stimulating regions of a receptive field with low sensitivity. In such circumstances, one has the choice between applying a weak stimulus and obtaining a weak response or applying a stronger stimulus (a more intense light) to obtain a bigger response. The latter will produce more adaptive effect and so one might want to avoid this choice. The former runs afoul of the third difficulty faced in receptive field mapping, namely discharge noise. Repeated presentations of the same stimulus do not result in the same response from a ganglion cell; responses are noisy. Hence, in order to determine the response in the presence of this noise, one must collect and average responses to repeated presentations of the stimulus to improve signal-to-noise. The smaller the response, the more averaging is required and the longer the data collection period. Given that physiological experiments are of limited duration, the experimenter must weigh expediency against rigor. A fourth problem with the use of spots as stimuli is that the time courses of light and dark adaptation are different, so spots of significant but equal light and dark contrast will not produce exactly inverse responses. Another pitfall of reliance on single spot stimuli is that there are ganglion cell receptive fields responsive to the direction of movement of the visual stimulus. This property cannot be revealed with a flashing spot stimulus.

Cathode ray tube technology permitted the mapping of visual receptive fields with more complex stimuli. The pioneering work was done by Enroth-Cugell and Robson. They used sinusoidal luminance gratings and other two-dimensional patterns (e.g., edges) in which luminance is modulated along one of the two dimensions to map ganglion cell receptive fields. The cat was the animal subject and, in this species, they discovered two varieties of Kufflerian center-surround receptive field, one of which they ascribed to X cells and the other to Y cells. Both X and Y cells occur with on-center/off-surround and off-center/on-surround subtypes. What differentiated X cells from Y cells in Enroth-Cugell and Robson's view was the fact that the responses of X cells could be largely explained in terms of the linear spatial summation of light within their receptive fields, whereas the responses of Y cells could not. Subsequent work has shown that Y cells have significantly larger receptive field centers than X cells of the same retinal locale and that their morphologies differ. When viewed in whole mounts, Y cells have α cell morphology and X cells have β cell morphology. This difference in morphology is also related to the difference in receptive field center size, in that the spread of the dendritic tree is highly correlated with center size.

Receptive Field Modeling

The application of sinusoidal luminance gratings to the study of visual neural responses led naturally to application of the Fourier transform to the analysis and modeling of receptive fields. Essentially coincident, but using different approaches to studying ganglion cell receptive fields, Rodieck and Enroth-Cugell and Robson developed the first quantitative model of ganglion cell receptive fields. The model is the difference of Gaussians receptive field, which provides a very good quantitative description of center-surround properties. In the model, both center and surround mechanisms are assumed to have Gaussian weighting for their sensitivity to light (for on-center mechanisms) or dark (for off-center mechanisms), with the spread of the surround Gaussian being significantly broader. The central points of the two Gaussians are coincident, and it is the difference between the signals generated by the two mechanisms that accounts for the cell's response. Rodieck's model was based on measurements of ganglion cell responses for stimuli in the spatial domain, whereas Enroth-Cugell and Robson's derivation of the model relied on ganglion cell responses made for stimuli in the spatial frequency domain. The Fourier transform can be used to equate models developed in the two domains and the fact that the results were consistent demonstrated the validity of the model. This model has dominated modeling of center-surround receptive fields since, although some modifications of the original model have proven necessary. It was assumed originally that the center and surround mechanisms had circular symmetry, but later work indicated a small degree of ellipticity to the center mechanism at least. It has also been found that the midpoints of center and surround may be slightly offset and, most important, that the time course of response for center and surround mechanisms is not the same. The effect of the last observation is that the spatial structure of the receptive field is dependent on the temporal properties of the stimulus, with less surround antagonism as

temporal frequency increases. A consequence of this is that the spatial frequency tuning of the ganglion cell shifts from band-pass at low temporal frequencies to low-pass at high temporal frequencies. A similar shift from band-pass to low-pass tuning with increasing temporal frequency has long been known to occur for contrast sensitivity versus spatial frequency measurements made on human subjects psychophysically.

The difference of Gaussians receptive field model cannot explain nonlinear receptive field properties. It is a linear model. The first nonlinear receptive field model was probably that proposed by Barlow and Levick to account for the directional selective receptive field of a variety of rabbit retinal ganglion cell. Similar directionally selective receptive fields have been found in many mammalian retinas subsequently and are believed to be present in all mammals. Hochstein and Shapley developed a nonlinear receptive field model for the cat Y cell. It was built on the classical difference of Gaussians receptive field model to account for the center-surround receptive field of these cells, but with an added mechanism to account for the Y cell's nonlinear responses. The new mechanism was an extensive field of subunits, each of which sums light over a small retinal region and then feeds a rectified version of this signal as its input to the Y cell. The Y cell discharge is therefore governed by a signal that is a sum of the signal coming from the nonlinear subunits and the signal coming from the linear difference of Gaussians field. This model was found to provide a good description of Y cell responses to sinusoidal luminance gratings, whether drifted across the receptive field or held stationary, with contrast modulated in time.

Varieties of Retinal Ganglion Cells

As noted previously, the grouping of retinal ganglion cells into different types is still something of an art form and disagreements over classification have become heated at times. The current dogma holds that each type of retinal ganglion cell will have

1. unique receptive field properties;
2. a distinct dendritic tree morphology, when viewed in a retinal whole mount; and
3. a unique pattern of dendritic stratification in the retina's inner plexiform layer.

The sites of axonal projection in the brain may be another factor that helps in ganglion cell differentiation. It also seems likely that, in time, differences in gene expression will be found to correlate with receptive field phenotypes and, as the art of ganglion cell typing develops, it will come to be another basis on which to group ganglion cells. If this transpires, classification of ganglion cell types will come to be considered more scientific and less artful. Correspondences between ganglion cell types in different species will then become a less contentious issue, and one may presume that the confusing proliferation of names that currently exists will cease and there will be retrenchment with more general agreement on nomenclature.

The physiological classification of ganglion cell-types has seen its greatest advance in the cat and, hence, the naming of ganglion cell types in this species has been largely responsible for the names given to ganglion cell types in other mammalian species. Overall, the naming of cell types has fallen into two camps. There are those who prefer names that carry no implication about the physiological properties of the receptive field or other ganglion cell properties and those who wish to impart with the name some sense of what distinguishes one ganglion cell type from others. From the former camp came the terminology X and Y cells. From the latter came the terms sustained and transient cells, which were intended to reflect their temporal response properties. Both classification schemes applied to cells with Kufflerian center-surround receptive fields. The latter scheme was soon found to have problems. It was discovered that there were different types of ganglion cells with temporal response properties that could be separated into the limited binary division sustained and transient. Hence, there was a further division made along an also binary dimension into brisk and sluggish types, chosen to indicate a somewhat qualitative sense of the nature of the cell's discharge. Thus, the names brisk-sustained, brisk-transient, sluggish-sustained, and sluggish-transient cells were created. It is now generally accepted that the brisk-sustained cell and the brisk-transient cell correspond to the X and Y cell, respectively.

The use of names for ganglion cell types that carry some sense of presumed function has been more widely followed than naming on the basis of letters of the alphabet, and the brisk-sustained, etc. terminology has been carried over to other mammals more frequently than the X and Y terminology. In fact, the use of the alphabetic naming scheme for cat ganglion cells has fallen out of favor. This was probably precipitated by the unfortunate introduction of the term W cell. The axons of Y cells are larger than those of X cells, with the result that electrical stimulation of the optic nerve results in a compound action potential showing an early peak reflecting the summed response of Y cell action potentials and a later peak reflecting the summed response of X cell action potentials. A third, slower and more diffuse, peak is also observed, reflecting the summed response of

action potentials discharged by ganglion cells with smaller axons still than those of X cells. Thus emerged the term W cell, which corresponds to all ganglion cell types but the X and Y cells. That W was the letter preceding X in our alphabet made the letter sequence consistent with increasing spike conduction velocity. Unfortunately, the term W cell has limited utility since we now know that it includes many varieties of ganglion cells which have very different functional properties sharing just one, namely a slower rate of action potential conduction. With the introduction of the W cell, the advantage of an alphabetic naming scheme – 26 letter choices and no implication of function – was dealt a major blow. A letter had been used to signify a group of cell types and, at the same time, it carried meaning. To my knowledge, the use of alphabetic names has been employed only once since for a physiological type of cat ganglion cell. The name Q cell was used by Enroth-Cugell et al. for what is almost certainly the cat sluggish-sustained cell.

The classification of ganglion cell types of primate retina, although influenced by work in the cat, has occurred somewhat independently. Ganglion cells with center-surround receptive fields were divided first into tonic and phasic varieties, corresponding roughly to the sustained and transient divisions of cat ganglion cells. A later division was made between ganglion cells whose axons project to the magnocellular layers of the primate lateral geniculate nucleus and those whose axons project to its parvocellular layers. These ganglion cells were given alphabetic names – M cell for the magnocellular projecting and P cell for the parvocellular projecting ganglion cell. Linking a functional aspect with the letter had the same downside as the use of W cell for cat ganglion cells. It is now believed that multiple ganglion cell types provide input to the magnocellular and parvocellular layers of the primate lateral geniculate nucleus, so linking nomenclature with a nonunique cellular property in this way leads to confusion. However, the terms M and P cell have obtained a status that transcends their original meaning. The M cell is a physiological cell type whose receptive field is largely achromatic and has a center-surround organization. These cells have both off-center and on-center subtypes and are linked to a distinct dendritic morphology, the parasol cell. Their responses are also phasic, and thus these cells likely correspond to the classical phasic ganglion cells of primate. The P cell is a physiological cell type whose center-surround receptive field shows spectral opponency. Old World primates have three varieties of cone: the long-wavelength sensitive L cone, the middle-wavelength sensitive M cone, and the short-wavelength sensitive S cone. There are P cells with L cone-dominated on-centers and M cone-dominated off-surrounds, P cells with L cone-dominated off-centers and M cone-dominated on-surrounds, P cells with M cone-dominated on-centers and L cone-dominated off-surrounds, and P cells with M cone-dominated off-centers and L cone-dominated on-surrounds. All four physiological cell types exhibit the midget cell morphology. The responses of these cells are tonic; thus, the P cell and the classical tonic ganglion cell of primate are probably one and the same. The term K cell has been used by some to refer to the ganglion cells whose axons terminate in the koniocellular layers of the primate lateral geniculate nucleus, but again this was not a good choice because it includes a number of ganglion cell varieties. For the most part, the naming of non-M and P ganglion cell types of primate and other ganglion cells of other mammalian species has been made on the basis of presumed receptive field function.

At approximately the same time that X and Y cells were discovered in cat, it became clear that other ganglion cell types lacking center-surround receptive fields existed. Barlow and Levick had described the directional selective receptive field of a ganglion cell of rabbit retina. We now know of two types of directionally selective ganglion cell of mammalian retina. One is the on–off directionally selective cell and the other is the on directionally selective cell. The latter cell type responds with an on response to light shone over the center of its receptive field. The former type gives an on–off response to this form of stimulation. Both exhibit a pronounced preference for the direction of stimulus movement across the receptive field, and the on–off directionally selective cell has a preference for spatially restricted stimuli. Movement of large field stimuli across its receptive field, even in the preferred direction, evokes little or no response from the cell. Rodieck reported another ganglion cell receptive field whose discharge was interrupted when either light or dark contrast was introduced to its receptive field. This cell type was colorfully named the suppressed-by-contrast cell. It has been suggested that there may be more than one type of such receptive field, and others have called these uniformity detectors and edge-inhibitory off-center cells. Another ganglion cell type that was discovered early was the on–off cell. As its name implies, this cell responds to both the onset and the offset of a stimulus within the receptive field. These cells have also been called excited-by-contrast cells, phasic on–off cells, local-edge detectors, and impressed-by-contrast cells. There is also a cell with a receptive field showing spectral opponency between S cone and the L/M cones and another ganglion cell which is inherently light sensitive. This has come to be known as the

melanopsin cell. Ganglion cells with many of these receptive field properties have been found in the retinas of primate, rabbit, ground squirrel, guinea pig, mouse, and rat. It is suspected that all are present in all mammalian retinas.

Conclusion

The receptive field has become a most useful concept in sensory physiology, indicating the operation performed on the sensory stimulus by the processing stages preceding spike generation. It informs us what sensory information is transmitted and what is discarded. The presence of multiple receptive field types for retinal ganglion cells indicates that the visual image is broken into packets for transmission to the brain. Since the axonal destinations of different classes of ganglion cell differ, one can presume that the function of this packaging in part at least reflects its usefulness for the brain centers where it is destined. In the case of some simple functions (e.g., control of pupil diameter as a function of mean light level), we have a good sense of how and why the message is packaged in the way that it is. For most ganglion cell types, the nature of packaging is less obvious. Segregation of sensory messages into packets with different cell types carrying separate components seems to be a common design feature. Hence, what we learn about parallel processing in the visual system will help us to understand parallel processing in sensory systems generally. Thus, characterization of receptive field properties for ganglion cells should lead to a better overall understanding of sensory processing. We have entered a period in which it is reasonable to suppose that all ganglion cell receptive field types of mammals will be known and their properties characterized. When this has been accomplished, we will be in a better position to understand how visual information is encoded in the retina and, thus, what information reaches the next stages in the visual pathways. Obviously, we need this understanding to determine what processing takes place at each of these higher visual centers. It has long been appreciated that the characterization of ganglion cell receptive fields is foundational for an understanding of visual information processing. As our knowledge of ganglion cell properties has grown, so has an appreciation of the complex nature of the visual message sent from the retina to the brain. We have moved beyond the simplistic view of ganglion cell receptive fields with few varieties to one in which we accept that there are many varieties. In the not too distant future, we can expect that all varieties will be known along with their receptive field properties.

Retinal Glia

E A Newman, University of Minnesota, Minneapolis, MN, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Glial cells outnumber neurons in the central nervous system (CNS) by ~10 to 1. Traditionally, glia were believed to provide only passive structural and metabolic support for neurons. Recent work has demonstrated, however, that glial cells in the retina as well as in the brain interact actively with neurons and have many essential functions.

There are three principal types of glial cells in the mammalian retina: Müller cells, astrocytes, and microglial cells. Müller cells are the most prominent retinal glial cell. They are a specialized form of radial glia which span nearly the entire depth of the retina. Astrocytes, the second type of retinal macroglial cell, are present only in species having a retinal circulation and, in these species, are restricted largely to the nerve fiber layer at the inner boundary of the retina. Microglia, the third type of retinal glial cell, are present in the nerve fiber layer and the inner and outer plexiform layers of the retina. Oligodendrocytes, the glial cells that form the insulating sheath of myelinated axons in the CNS, are completely absent from the retina, except in those species, including rabbit and guinea pig, possessing myelinated axons in the nerve fiber layer.

Retinal Glial Cell Development and Morphology

Müller Cells

Müller cells differentiate from progenitor cells at the outer margin of the retinal neuroepithelium during the second phase of cell differentiation, following the birth of ganglion cells, horizontal cells, and cones. The developing Müller cells migrate toward the vitreous humor and extend processes towards the inner and outer retinal margins. Their radial processes serve to guide migrating neurons during subsequent retinal development.

In the mature retina, Müller cell somata lie in the middle region of the inner nuclear layer (Figure 1). Single or multiple radial processes extend inwards toward the vitreous and end in enlarged structures termed endfeet. A second cell process extends outward to the outer limiting membrane, where apical microvilli project into the subretinal space. Secondary Müller cell processes project from the main trunk of the cell, surrounding neuronal somata and processes in all retinal layers. Müller cell endfeet terminate at the vitreal border of the retina as well as onto blood vessels, both at the vitreal surface and within the retina.

Müller cells contain numerous glycogen granules which represent the main retinal glucose store. They also contain numerous mitochondria and intermediate filaments, composed both of vimentin and glial fibrillary acidic protein (GFAP). GFAP distribution is normally sparse in Müller cells but is dramatically upregulated following retinal injury.

Astrocytes

Astrocytes migrate into the developing retina from the optic nerve and advance across the retinal surface as the retina matures. The distribution of astrocytes over the surface of the retina is determined by a 'contact-spacing' interaction between cells.

In the mature retina, astrocytes are restricted largely to the nerve fiber layer (Figure 2). They are closely associated with blood vessels and are only present in species having a retinal circulation. Their processes are confined largely to the plane parallel to the retinal surface, although processes sometimes follow blood vessels into deeper retinal layers. Astrocyte processes are terminated by endfeet which contact superficial retinal blood vessels. Astrocytes contain glycogen granules and dense bundles of intermediate filaments composed of GFAP.

Microglia

Microglia are the resident macrophages of the retina. They are derived from blood monocytes and enter the retina along with blood vessels during development. Microglia are normally present in the retina in their dormant state and are found principally in the nerve fiber layer and the inner and outer plexiform layers. They have small somata and short, irregular processes. The cells are normally flat in appearance and have slender hair-like extensions protruding from their processes.

Microglial cells proliferate following retinal injury and differentiate into macrophage-like cells that remove degenerating retinal neurons by phagocytosis. Microglia also phagocytose neurons that die during the course of normal retinal development.

Glial Induction and Guidance of Retinal Blood Vessels

Glial cells induce the formation of blood vessels and guide their growth into the retina. During development, astrocytes migrate into the retina from the

Figure 1 Drawings of Golgi-stained Müller cells from the retinas of several species. Retinal layers, indicated to the right of the frog Müller cells, are (a) outer nuclear layer; (b) outer plexiform layer; (c) inner nuclear layer; (e) inner plexiform layer; (f) ganglion cell layer; (g) nerve fiber layer. The basal endfeet of the Müller cells are seen as enlargements of the processes in the nerve fiber layer. From Ramon y Cajal S (1972) *The Structure of the Retina*. Springfield, IL: Thomas, C.C.

optic nerve, first appearing at the optic disk and then advancing outwards across the retinal surface. Retinal blood vessels, which also originate from the optic nerve, grow along newly formed astrocyte processes, which function as templates for angiogenesis. Vessel growth is stimulated by the secretion of vascular endothelial growth factor (VEGF), which is released by glial cells in response to hypoxic conditions generated by neuronal activity. Astrocytes serve as guides for developing vessels as they grow across the inner surface of the retina while Müller cells serve as templates for vessel growth into the retina and across the inner nuclear layer.

Retinal Glial Cell Membrane Properties

Retinal glial cells possess many of the same voltage-gated ion channels and neurotransmitter receptors that are expressed in neurons. These glial channels and receptors play a key role in mediating glia–neuron interactions in the retina. Most research on retinal glial cell properties has been conducted on Müller cells and the following discussion will focus on the properties of these specialized glial cells.

Ion Channels

Müller cells have a high membrane permeability to K^+, which results in a negative resting membrane potential of –80 to –90 mV, near the K^+ equilibrium potential of the cell. Expression of Kir4.1, an inwardly rectifying K^+ channel, is largely responsible for this K^+ membrane permeability. In Kir4.1 knockout animals, which lack Kir4.1 channels, Müller cell input resistance increases from a wild-type level of 25 to 310 MΩ, demonstrating that Kir4.1 channels account for over 90% of the cell membrane conductance. Kir4.1 channels are not distributed uniformly over the cell surface but rather are localized to cell endfeet, which terminate at the vitreal surface of the retina and on retinal blood vessels. The dystrophin–dystroglycan complex plays a critical role in the clustering of K^+ channels to cell endfeet. As discussed below, clustering of K^+ channels contributes to Müller cell clearance of excess K^+ from the retina.

In addition to Kir4.1, Müller cells express a number of other voltage-gated ion channels, including Ca^{2+}-activated K^+ channels, fast inactivating K^+ channels, Ca^{2+} channels (which share some of the properties of L-type Ca^{2+} channels), and Na^+ channels. Müller cells also express aquaporin-4 (AQP4). These water-permeable channels are co-localized with Kir4.1 at Müller cell endfeet. Together, Kir4.1 and AQP4 make up a macromolecular complex that can be visualized in freeze-fracture electron

micrographs of endfoot membranes as orthogonal arrays of particles (OAPs).

Müller cells and astrocytes are extensively coupled to each other by gap junctions, composed of connexin43 and 45 in Müller cells and connexin30 and 43 in astrocytes. Gap junctional coupling imparts both electrical and chemical tracer coupling to these networks of glial cells. Coupling is stronger between astrocytes than between astrocytes and Müller cells. Coupling is very weak (or may not exist) between Müller cells, except in amphibians. Interestingly, coupling between astrocytes and Müller cells, as assessed by tracer spread, is asymmetric, with tracer passing from astrocytes to Müller cells more freely than from Müller cells to astrocytes. In rabbit, astrocytes are coupled to oligodendrocytes as well as to Müller cells.

Neurotransmitter Receptors

Retinal Müller cells and astrocytes express a number of neurotransmitter and neuromodulator receptors. The most prominent among these are P2Y purinergic receptors. Amphibian Müller cells express $P2Y_1$, $P2Y_2$, $P2Y_6$, and $P2Y_{11}$ purinergic receptors. Müller cells of different species also express a number of glutamate receptors, including AMPA (GluR4), NMDA, and metabotropic types. $GABA_A$, acetylcholine, dopamine, noradrenaline, adenosine (A_{2B}), thrombin, and lysophosphatidic acid receptors as well as several neuroactive peptides receptors are expressed. Activation of many of these receptors evokes glial Ca^{2+} increases (see below). Interestingly, in the mammalian retina, glutamate is largely ineffective in evoking Ca^{2+} increases in Müller cells or astrocytes. In contrast, glutamate evokes large Ca^{2+} increases in astrocytes in brain slices and in culture. The insensitivity of retinal glial cells to glutamate may be a specialization to conditions in the retina, where glutamate is released continuously from neurons.

Receptors to a number of growth factors, including basic fibroblast growth factor (bFGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and nerve growth factor (NGF) are expressed. The effects of these factors are varied, and include the stimulation of DNA synthesis, mitosis, and cell proliferation, expression of cytoskeletal filaments, and the modulation of ion channels. $Endothelin_B$ receptors are expressed in Müller cells and are upregulated following retinal injury.

Transporter systems

The high-affinity glutamate/aspartate transporter (GLAST, also named EAAT1) is present in Müller cells and serves to maintain a low concentration ($<1\ \mu M$) of glutamate in extracellular space. It utilizes the gradients of Na^+, K^+, and H^+ across the plasma membrane to transport glutamate into cells. A high-affinity GABA transporter of the GAT-3 type is also present in Müller cells.

Several acid/base transport systems are expressed in Müller cells. The transporters regulate intracellular pH (pH_i) and can influence extracellular pH. An electrogenic Na^+/HCO_3^- co-transporter is preferentially localized to the basal endfoot of Müller cells. A Na^+/H^+ exchanger and a Cl^-/HCO_3^- anion exchanger are also present in Müller cells. The anion exchanger is of the AE3 type and is localized to the cell endfoot. Intracellular as well as membrane-bound forms of the enzyme carbonic anhydrase (CA) are also expressed in Müller cells at high activity levels. The enzyme contributes to pH and CO_2 regulation in the retina (see below).

Calcium Signaling in Retinal Glial Cells

Calcium Waves

Activation of P2Y and other metabotropic receptors on Müller cells and astrocytes results in the release of Ca^{2+} from internal stores and to increases in intracellular Ca^{2+}. Calcium increases can also be evoked by mechanical or electrical stimulation of glial cells. Stimulation of a single glial cell often leads to the generation of propagated Ca^{2+} waves that travel through many astrocytes and Müller cells (Figure 3). Propagated Ca^{2+} waves travel at a velocity of approximately $23\ \mu m\ s^{-1}$ and can extend outwards for distances as great as $180\ \mu m$.

Glial cell-to-glial cell signaling during Ca^{2+} wave propagation is mediated by two mechanisms: by movement of the intracellular messenger IP_3, which diffuses through gap junctions coupling glial cells together; and by release of ATP, which functions as an extracellular messenger. Calcium wave propagation between astrocytes is mediated by both IP_3 diffusion and by ATP release while signaling between astrocytes and Müller cells and between Müller cells occurs solely by ATP release. The component of glial Ca^{2+} waves mediated by ATP release is blocked by purinergic antagonists.

Light-Evoked Ca^{2+} Signaling

In addition to agonist-evoked Ca^{2+} signals, Müller cells generate spontaneous, transient increases in Ca^{2+} in the absence of any applied stimulus. These endogenously generated Ca^{2+} increases occur at a frequency of 4.6 transients per cell per 1000 s in mammalian Müller cells. The transients range from 2.5 to 6 s in duration and are similar to those observed in astrocytes in the brain.

Figure 3 A Ca^{2+} wave propagated through retinal glial cells. Pseudocolor images of Ca^{2+} fluorescence within astrocytes (larger cells) and Müller cells (smaller spots) at the vitreal surface of the retina are shown. The Ca^{2+} wave is evoked by a mechanical stimulus applied to a single astrocyte. The wave is initiated at the stimulated cell (panel 2) and propagates outwards through neighboring astrocytes and Müller cells. Elapsed times following stimulation in panels 1–6 are 0, 0.2, 1.5, 3.5, 5.5, and 9.5 s, respectively. Scale bar = 50 μm. From Newman EA, unpublished.

Neuronal activity, evoked by light flashes, increases the frequency of Ca^{2+} transient generation in Müller cells by 28% (Figure 4). Signaling from activated neurons to Müller cells is mediated by release of ATP from the neurons and activation of glial P2Y purinergic receptors. Light-evoked Ca^{2+} increases are blocked by suramin, a purinergic antagonist, and by apyrase, which hydrolyzes ATP. Light-evoked Müller cell Ca^{2+} increases are also blocked by TTX, indicating that only retinal neurons that generate action potentials, amacrine and ganglion cells, are signaling to glial cells. Light-evoked increases in Müller cell Ca^{2+} transients are greatly potentiated by adenosine, which is a degradation product of ATP. Adenosine potentiation of neuron-glia signaling is of clinical interest as adenosine levels increase in certain pathological states.

Functions of Retinal Glial Cells

Regulation of the Extracellular Microenvironment

One of the principal functions of retinal glial cells is to regulate the composition of the fluid in which neurons are bathed. Neuronal activity results in changes in neurotransmitter, K^+, and H^+ levels in the extracellular space, all of which can, in turn, influence subsequent neuronal excitability. Müller cells play a major role in regulating these extracellular constituents.

Regulation of neurotransmitters Glutamate released from the synaptic terminals of photoreceptors and bipolar cells is removed from extracellular space primarily by uptake into Müller cells, mediated by GLAST, the high-affinity glutamate transporter. Glutamate, once taken up by the glial cells, is converted to glutamine and recycled back to the neuronal terminals where it serves as a substrate for the synthesis of additional neurotransmitter. Glutamate uptake by Müller cells influences the efficacy of synaptic transmission. When the Müller cell transporter GLAST is blocked, the magnitude of bipolar-to-ganglion cell synaptic transmission increases dramatically. Müller cells also express a high-affinity GABA transporter that removes this inhibitory transmitter from extracellular space following release from horizontal cell and amacrine cell synaptic terminals.

Regulation of pH Müller cells contribute to the regulation of extracellular pH (pH_o) in the retina. Neuronal activity results in the alkalinization of the extracellular space, which can dramatically alter the efficacy of synaptic transmission and neuronal excitability. The magnitude of this alkalinization may be reduced by the action of the Müller cell Na^+/HCO_3^- co-transporter. Müller cell depolarization, induced by neuronal activity, generates an acid efflux through the Na^+/HCO_3^- co-transporter, countering the alkalinization generated by the neurons. Müller cells may also regulate pH_o through the action of carbonic anhydrase, which is expressed by Müller cells in both cytoplasmic and membrane-bound forms. Carbonic anhydrase contributes to pH buffering by catalyzing the conversion of H^+ and HCO_3^- to CO_2

Figure 4 Light-evoked Ca^{2+} signaling in Müller cells. (a) Calcium fluorescence measured simultaneously in eight Müller cells. The retina was exposed sequentially to a uniform dim light, a bright flickering light, and a dim light (the light stimulus protocol is shown at the bottom in (a) and (b)). Calcium transients are more likely to be generated during the flickering light stimulus than during periods of constant illumination. (b) Mean Ca^{2+} fluorescence averaged over 84 trials. The flickering light evokes both a transient and a sustained increase in Ca^{2+} in Müller cells. From Newman EA (2005) Calcium increases in retinal glial cells evoked by light-induced neuronal activity. *Journal of Neuroscience* 25: 5502–5510.

Figure 5 Müller cell regulation of K^+. (a) Light-evoked depolarizations recorded from a Müller cell of the mudpuppy. A 4 s light flash (bottom trace) evokes increases in extracellular K^+ concentration at light ON and OFF, resulting in K^+ influx into Müller cells and to cell depolarization. (b) Potassium siphoning in Müller cells. Active neurons release K^+ into the inner plexiform layer (IPL). The increase in extracellular K^+ concentration evokes a K^+ influx into Müller cells. The resulting cell depolarization generates an equal efflux of K^+ from other cell regions, into the vitreous humor, the subretinal space (SRS) and onto blood vessels. This K^+ current flowing through Müller cells reduces the initial K^+ increase in the IPL. (a) From Karwoski and Proenza (1977) Relationship between Müller cell responses, a local transretinal potential and potassium flux. *Journal of Neurophysiology* 40: 244–259. (b) From Newman (1966) *Neuroscientist* 2: 110–119.

and H_2O. Blocking the action of the enzyme leads to increases in the light-evoked pH_o alkalinization.

Regulation of potassium Müller cells play a key role in regulating extracellular K^+ ($[K^+]_o$) within the retina. Light-evoked neuronal activity results in increases in $[K^+]_o$ in the inner and outer plexiform layers and to a $[K^+]_o$ decrease in the distal retina. These $[K^+]_o$ variations will change the membrane potential of retinal neurons, altering their excitability. The $[K^+]_o$ variations are buffered by K^+ currents flowing through Müller cells, a process termed 'K^+ siphoning,' which is a specialized form of K^+ spatial buffering. Potassium released from active neurons results in an influx of K^+ into Müller cells. The K^+ influx depolarizes Müller cells (Figure 5(a)) and drives out an equal quantity of K^+ from other cell regions, primarily from cell endfeet, which have a high K^+ conductance. Potassium is released from basal endfeet into the vitreous humor, which acts as a large K^+ sink, and from apical processes into the subretinal space, where it counters the light-evoked $[K^+]_o$ decrease generated in this region (Figure 5(b)).

The influx and efflux of K^+ in Müller cells during the K^+ siphoning process occurs largely through Kir4.1 inwardly rectifying K^+ channels. The voltage- and K^+-dependent properties of these channels enhance the K^+ siphoning process; channel conductance increases with increased $[K^+]_o$, resulting in greater siphoning currents and a more rapid transfer of K^+ to the vitreous humor and the subretinal space. When Müller cell Kir4.1 channels are blocked by Ba^{2+}, the siphoning current is interrupted and $[K^+]_o$ regulation in the retina is compromised.

Generation of the electroretinogram A consequence of K^+ current flow through Müller cells is the generation of extracellular field potentials within the retina. These light-evoked potentials can be recorded with an electrode on the cornea as components of the electroretinogram (ERG). For many years, the b-wave, the most prominent component of the ERG, was believed to be generated by K^+ current flow through Müller cells. However, if K^+ siphoning is prevented by blocking Müller cell Kir channels with Ba^{2+}, or if the channels are eliminated by employing Kir4.1 knockout animals, the b-wave is not reduced. These experiments demonstrate conclusively that Müller cells do not generate the ERG b-wave. The b-wave is generated, instead, by bipolar cells, as originally suggested by Tomita.

Other components of the ERG are generated by light-evoked K^+ current flow through Müller cells, however. The slow PIII response, the retinal component of the ERG c-wave, is generated by Müller cell K^+ current flow established by a decrease in $[K^+]_o$ in the distal retina. Müller cells also generate the scotopic threshold response, a rod-driven response generated at the ON of light in mammals, and the M-wave, a negative response with prominent ON and OFF components. Both responses are generated by K^+ current flow through Müller cells established by $[K^+]_o$ increases in the inner plexiform layer.

Modulation of Neuronal Activity

In recent years, it has become clear that glial cells in the CNS modulate neuronal activity by releasing gliotransmitters. In the retina, stimulation of Müller cells results in changes in light-evoked spiking of ganglion cells. Spike activity can either be potentiated or depressed following glial cell stimulation and the initiation of Ca^{2+} waves in retinal glial cells. It is likely that Müller cells, in particular, modulate neuronal activity by several different mechanisms, two of which are described below.

Inhibition of ganglion cells Selective stimulation of Müller cells by agonist ejection evokes large Ca^{2+} increases in these cells and subsequent hyperpolarization of adjacent ganglion cells (Figure 6(a)). The hyperpolarization can be sufficiently strong to completely block the generation of action potentials (Figure 6(b)). The ganglion cell hyperpolarization is mediated by ATP release from the Müller cells. Released ATP is rapidly converted to adenosine by ecto-ATPases and ecto-nucleotidases. Adenosine, in turn, activates A_1 adenosine receptors on the ganglion cells, leading to the opening of K^+ channels and to cell hyperpolarization.

Figure 6 Glial cell inhibition of action potential generation in ganglion cells. (a) Ejection of ATPγS onto the retinal surface evokes a Ca^{2+} increase in glial cells (glial Ca^{2+}). This Ca^{2+} increase is associated with a hyperpolarization (neuron voltage) and an outward current (neuron current) in a neighboring ganglion cell. (b) ATPγS stimulation of glial cells hyperpolarizes a ganglion cell and blocks the generation of action potentials in the cell. From Newman EA (2003) Glial cell inhibition of neurons by release of ATP. *Journal of Neuroscience* 23: 1659–1666.

Figure 7 Glial cell-evoked dilation of a neighboring blood vessel. (a–c) Fluorescence images showing Ca^{2+} concentration within retinal glial cells. (d–f) Infrared differential interference contrast (IR-DIC) images showing the arteriole within the region indicated in (a). Photolysis of caged-Ca^{2+} in the glial cell indicated by the circle in (a) evokes a Ca^{2+} increase that propagates from the stimulated cell into neighboring glial cells surrounding the blood vessel (a–c). Glial cell stimulation results in the dilation of the adjacent arteriole (d–f). From Metea MR and Newman EA (2006) Glial cells both dilate and constrict blood vessels. A mechanism of neurovascular coupling. *Journal of Neuroscience* 26: 2862–2870.

D-serine regulation of NMDA receptors Müller cell stimulation may also lead to the release of D-serine and to potentiation of NMDA receptor neurotransmission in the retina. Müller cells contain D-serine, an endogenous NMDA receptor co-agonist, and serine racemase, the synthetic enzyme for D-serine. Stimulation of brain astrocytes results in D-serine release and a similar release of D-serine may occur in retinal Müller cells.

Regulation of Blood Flow

Light stimulation results in an increase in blood flow in retinal arteries, bringing increased oxygen and nutrients to activated neurons. Müller cells mediate neuron to blood vessel signaling, a process termed neurovascular coupling. When Müller cells are selectively stimulated, neighboring arterioles either dilate or constrict (Figure 7). Vasodilation is mediated by production of EETs while vasoconstriction is mediated by production of 20-HETE. Both vasoactive agents are metabolites of arachidonic acid. Light stimulation also evokes either vasodilation or constriction by generation of the same two arachidonic acid metabolites. When neuron to Müller cell signaling is blocked by a purinergic antagonist, light-evoked vasomotor responses are also blocked, indicating that Müller cells mediate neurovascular coupling.

Metabolic and Trophic Support of Neurons

Müller cells play an active role in supporting neuronal metabolism. Glucose is metabolized in Müller cells to lactate, which is then transferred to neurons where it serves as a primary energy source for oxidative metabolism. Müller cells also contain large reserves of glycogen, which serve as a source of glucose during times of high metabolic activity.

Retinal glial cells secrete a number of growth factors which have trophic effects on retinal neurons and blood vessels. Basic fibroblast growth factor (bFGF), which promotes photoreceptor survival, is synthesized by Müller cells and retinal astrocytes. Müller cells also secrete a number of other growth factors including brain-derived neurotrophic factor, NGF, neurotrophin-3, neurotrophin-4, and glial cell line-derived neurotrophic factor. Both Müller cells and astrocytes synthesize VEGF, which plays an essential role in the development of the retinal vasculature.

Retinal Horizontal Cells

I Perlman and E Weiner, Technion – Israel Institute of Technology, Haifa, Israel

Morphological Characteristics of Horizontal Cells

Horizontal cells are second-order neurons interconnecting photoreceptors laterally across the retina at the first synaptic layer. They are wide-spreading, horizontally oriented neurons with dendrites that connect with the synaptic endings of photoreceptors. The morphological forms of horizontal cells found in vertebrate retinas are shown in Figure 1. Through Golgi staining, intracellular marking, and immunostaining techniques we have learned of the various morphologies horizontal cells can adopt in different vertebrate species (Figures 1–3).

There are at least two types of horizontal cells in the majority of vertebrate retinas, B-types, which have axons, and A-types, which are axonless (Figures 1 and 3(c)). In general, the cells bodies and dendritic ends of horizontal cells contact cone pedicles of cone photoreceptors (Figures 2(a) and 2(b)), while the axonal terminals (when present) contact rods. In nonmammalian species, horizontal cells come in several axonless subtypes with color-specific cone connections (Figure 1). Rod-dominated, nonmammalian retinas (such as those found in fish) also have a horizontal cell type devoted solely to the rods, while in rod-dominated, mammalian retinas the axonal terminal portions of the B-type cells that connect with rods act essentially independently from the cone-connected cell bodies.

B-Type horizontal cells are only concerned with light intensity changes and shaping adaptation and spatial responses of vertical pathway neurons. They are the luminosity-type horizontal cells that will be discussed later. B-Type cells can often be identified with antibodies against calcium-binding proteins (Figure 2(a)) and γ-aminobutyric acid (GABA) neurotransmitter. In turtle retina, acetylcholine has been located to H1-type horizontal cell dendrites where they invaginate the cone pedicles (Figures 2(b) and 3(a)). A-Type horizontal cells in mammals are purely cone connecting (most species have only green and blue cones). They have no connections with rod photoreceptors at all. Even in the case of the H2 cells of the trichromatic primate retina, where one or more dendrites are elongated and axonlike, their connections are with cones, and interestingly enough with blue cones (Figure 1). This may be a general theme for mammalian axonless horizontal cells that is only now being realized. In certain big cats (not yet confirmed in domestic cats), the elongated dendritic tips of A-type cells contact blue cones, while the dendrites closer to the cell body are in contact with both green cones and blue cones. In horses the A-type cell is apparently only connected to blue cones (Figure 1).

In turtles, birds, and fish, species with excellent color vision, type H2 and type H3 horizontal cells are large, stellate cells lacking axons, and are concerned solely with cone pathways (Figure 1). They are the chromaticity (C-type) horizontal cells that will be described later. Thus, in turtle (pentachromats) and fish (trichromats or tetrachromats), H2 horizontal cells connect to green and blue cones, and H3 cells connect to blue cones (Figure 1). The C-type horizontal cells of the turtle can be labeled with antibodies to nitric oxide synthase and calcium-binding proteins, suggesting a role for NO in their functioning (see later section).

Horizontal cells always interact with photoreceptor terminals at their knoblike dendritic terminals (Figure 2(b)) that invaginate the photoreceptor synaptic complex as lateral elements at a presynaptic ribbon (Figure 3(a)). The postsynaptic receptors at the lateral elements are ionotropic glutamate receptors (iGluRs). Retinal horizontal cells in all species are also connected to their homologous neighbors, by areas of gap junctions between their dendrites (Figure 3(b)) and their axon terminals, and occasionally between their dendrites and cell bodies. These areas of gap junction can be extremely large, appearing as plaques of electrical junction (Figure 3(b)).

Gap junctions are formed at closely applied plasma membranes (2–4 nm gaps) of the two horizontal cell structures (Figure 3(b)). Each half of the cell supplies connexons, or hemichannels, to complete the gap junction channel. These channels can consist of homomeric or heteromeric connexons, thus allowing a huge variety of gap junctions with slightly different properties to exist between various neurons of the nervous system. Each connexon channel contains six connexins (Cx) surrounding the channel pore. In fish and turtle retinas Cx43 and Cx26 have been demonstrated to comprise the horizontal cell gap junction connexons. Procion Yellow dye can diffuse through the gap junctions and label the horizontal cell syncytium, as seen in Figure 3(c). In this figure, the central horizontal cell is brightly stained, and the neighboring horizontal cells are faintly stained, by dye diffusion through the gap junctions. Not only dye molecules but also ion and cytoplasmic molecules of

Figure 1 The morphologies of different types of horizontal cells and their known connectivities with rod and cone photoreceptors. The cells, Golgi stained or visualized using neurobiotin-filled staining techniques, are viewed in flat, whole-mounted preparations. B-Type cells with axons and axonless cell types exist in most vertebrate retinas. The physiological types that have been proved to be associated with the morphological types are indicated (i.e., luminosity, blue-yellow, and color-opponent types). Red dots represent red cones; green dots represent green cones; blue dots represent blue cones; black squares or shaded gray areas represent rod inputs.

small size can pass through the connexon pores of the gap junction, changing horizontal cell activities and ionic properties.

Horizontal cells are among the earliest neurons to develop in the vertebrate retina. They develop at about the same time as amacrine cells and ganglion cells. The horizontal cells emit processes and are at first oriented vertically like all the primordial neurons of the retina (Figure 4(a); P3). At first, horizontal cell dendrites stretch in many directions, as they seek a point of contact with cone terminals. But once they have found their cone contacts they become flattened and assume the more adult form of a horizontally running neuron with dendrites on one plane in the outer plexiform layer (Figure 4(a); P12). Horizontal cell axonal processes assume their contacts with rod photoreceptors a few days later in development.

Like during development, horizontal cells undergo bizarre morphological and structural changes after retinal detachment or retinal degenerations whereby the photoreceptors are lost. When the rods and cones are degenerating they retract their axons and become autolysed. The horizontal cells degenerate with strange transformation of their dendritic and axonal processes (Figure 4(b)). Some horizontal cell outgrowths are fairly thick processes while others are thin, often beaded cylindrical processes (Figure 4(b); red processes). These ascending ribbonlike processes occupy the subretinal space along with massive numbers of hypertrophied Müller cell processes (Figure 4(b); green processes). It is as though loss of

Figure 2 (a) Section of monkey retina immunostained with anticalbindin (red) and antiparvalbumin (green). The cone photoreceptors stain in their entirety and their pedicles contact the dendrites of horizontal cells (hc; green). Some horizontal cells co-localize parvalbumin and calbindin (yellow). (b) Section of turtle retina immunostained with anticalbindin (green) and anticholine acetyltransferase (red). The cones and horizontal cell structures (hc) are making synaptic contacts at the horizontal cell dendrites. The tips of the horizontal cell dendrites contain acetylcholine (red semicircles, arrows). Micrographs courtesy of Nicolas Cuenca.

photoreceptor contacts in retinal degenerations is the reverse of the morphological changes that occur in development. Thus, horizontal cells of the vertebrate retina can become highly plastic under abnormal retinal conditions.

Physiological Types of Horizontal Cells

The first light-evoked electrical responses that were recorded with intracellular microelectrodes from nerve cells in the vertebrate retina were called S-potentials. At that time, neurons were believed to be depolarized (inside becoming more positive relative to outside) by excitatory synaptic inputs. If the depolarization was of sufficient amplitude, action potentials, or nerve spikes, were generated to transfer signals down the length of the axon. The S-units, however, responded to light with graded hyperpolarization (Figure 5). Intracellular marking techniques, in which dyes were injected from the electrode tips into the cytoplasm of the recorded neurons, revealed the horizontal cells to be the source of the S-potentials. Since first described in fish retinas, S-potentials have been recorded from retinal horizontal cells in all vertebrate classes studied (Figure 5).

Horizontal cells are separated into two major physiological types based upon their responses to chromatic light stimuli, luminosity-type and chromaticity-type horizontal cells.

Luminosity-Type Horizontal Cells

Luminosity-type (L-type) horizontal cells are found in every retina that has been studied. Figure 5 shows the photoresponses of L-type horizontal cells from turtle, rabbit, and monkey retinas. These cells respond with graded hyperpolarization of amplitude and duration, depending upon the intensity and duration of the light stimuli. The relationship between peak response amplitude and stimulus intensity fits a generalized hyperbolic function,

$$V = V_{\max}[I^n/(I^n + \sigma^n)] \qquad [1]$$

where V and $V_{\max}$ are the amplitudes of the responses to a stimulus of intensity I and to a stimulus of supersaturating intensity, respectively. The parameter σ is the semisaturation constant and equals the stimulus intensity needed for response amplitude of half-maximum, and n is an exponent that depends upon the steepness of the curve. In L-type horizontal cells the exponent n ranges from 0.7 to 1.2, depending upon species and upon state of adaptation. The response–intensity relationship of retinal neurons is not linear and saturates at bright intensities.

In some species, two classes of L-type horizontal cells can be identified according to their anatomical structure and physiological properties. In the turtle retina, the L1- and L2-types are similar in their spectral sensitivity, but differ in receptive field size and in the kinetics of their photoresponses to red and green light. Anatomically, these two L-type horizontal cells are, respectively, the soma and axon terminal of the H1 horizontal cell (Figure 1). In the mammalian retina, type A and B luminosity horizontal cells differ in morphology and in their major excitatory input, but respond similarly with graded hyperpolarization to light stimuli.

In primate retina, horizontal cells also only occur as luminosity types. Some of these cells receive synergistic signals from long- and medium-wavelength

Figure 3 (a) Electron micrograph of a triad synapse in a rod photoreceptor spherule in the monkey retina. The horizontal cell processes (HC) form lateral elements of the triad of processes at the single synaptic ribbon (R). The central process (CP) is a bipolar cell dendrite (DJ, distal junction; J, junction). (b) High-magnification electron micrograph of a gap junction between two horizontal cell dendrites in the cat retina. (c) An A-type horizontal cell (A-hc) in the rabbit retina has been intracellularly stained with neurobiotin (yellow). All of the surrounding A-type horizontal cells have also become more faintly yellow stained because the stain has passed through gap junctions linking neighboring horizontal cell dendrites. (a) From Lasansky A (1972) Cell junctions at the outer synaptic layer of the retina. *Investigative Ophthalmology* 11: 265–275. (c) From Mills SK and Massey SC (1994) Distribution and coverage of A-type and B-type horizontal cells stained with Neurobiotin in the rabbit retina. *Visual Neuroscience* 11: 549–560.

cones (red and green cones), while others receive synergistic input from all three spectral types of cones: long-, medium-, and short-wavelength (red, green, and blue) cones. Anatomically, H1-type horizontal cells tend to avoid the pedicles of blue cones, and are therefore not responsive to blue light stimuli physiologically. On the other hand, many dendrites of H2-type horizontal cells make synaptic contacts with blue cone pedicles, and they are, therefore, very sensitive physiologically to the blue end of the spectrum physiologically.

Chromaticity-Type Horizontal Cells

In 1958, Svaetichin and MacNichol first reported on a class of S-units, responding with graded depolarization to long-wavelength stimuli and with graded hyperpolarization to short-wavelength stimuli. These S-units were called chromaticity-type (C-type) horizontal cells. C-Type horizontal cells have been extensively studied in cold-blooded vertebrates (e.g., fish, turtle, toad, salamander), but were not found in mammals and primates. C-Type horizontal cells are identified by the number of wavelengths at which response polarity reverses (one reversal, biphasic cells; two reversals, triphasic cells), and by the wavelength of response reversal. In the bowfin retina, response reversal for the biphasic cells is around 640 nm, while for the triphasic cells one response reversal occurs in the region of 500–530 nm and the other in the region of 650–670 nm. The biphasic and triphasic C-type horizontal cells of the fish retina are identified morphologically as types H2 and H3, respectively (Figure 1).

In the turtle retina, two classes of biphasic C-type horizontal cells have been described. For the turtle *Mauremys caspica*, typical photoresponses of C-type horizontal cells to light stimuli of different wavelength and intensity are compared in Figure 6 to

Figure 4 (a) The appearance of horizontal cells during the course of development in the neonatal mouse retina. At postnatal day 3 (P3) the horizontal cells (hc; arrows) are irregular in shape, with dendrites pointing in all directions, and have not reached the plane of the outer plexiform layer. By P12 the cells are regularly arranged and form a horizontally organized layer of cells at the outer plexiform layer. (b) After a retinal detachment whereby the photoreceptors are no longer in contact with the pigment epithelium, the retina undergoes significant remodeling. The horizontal cells (hc; red) become dysplasic and their dendrites develop strange growth modes. They appear to be searching for contacts, with dying photoreceptor terminals. Müller cells (green) also become filled with intermediate filaments and vimentin (green) and grow abnormally extensive. those of an L1-horizontal cell. The L1-horizontal cells (Figure 6, top row) respond with graded hyperpolarization to light stimuli of any wavelength and are characterized by action spectra with peak sensitivity in the red range of the visible spectrum (640–650 nm). Red/green C-type horizontal cells (Figure 6, middle row) respond with graded depolarization to red light stimuli and with graded hyperpolarization to yellow, green, and blue stimuli. Response reversal occurs at wavelengths from 600 to 620 nm. Yellow/blue horizontal cells (Figure 6, bottom row) respond with graded depolarization to red and yellow light stimuli and with graded hyperpolarization to blue light stimuli. In these cells, response reversal occurs in the range 540–560 nm. The red/green and yellow/blue C-type horizontal cells of the turtle retina are identified morphologically as types H2 and H3, respectively (Figure 1).

Figure 6 Photoresponses of L-type and C-type horizontal cells in the turtle retina were elicited by light stimuli of different wavelength and intensities From Perlman I, Kolb H, and Nelson R (2003) Anatomy, circuitry, and physiology of vertebrate horizontal cells. Synaptic Transmission between Photoreceptors and Horizontal Cells

Feed-Forward Excitatory Synapse

Photoreceptors make excitatory (sign-conserving) synapses onto horizontal cells. In darkness, the photoreceptors continuously release, in a calcium-dependent manner, an excitatory neurotransmitter that opens cationic channels with a reversal potential close to 0 mV. Therefore, the horizontal cells are maintained at a relatively depolarized potential in darkness. When the photoreceptors are hyperpolarized by a light stimulus, transmitter release is reduced. The concentration of the neurotransmitter in the synapse reduces, the postsynaptic ligand-gated channels close, and the horizontal cells hyperpolarize toward the potassium equilibrium potential.

L-Glutamate is the excitatory neurotransmitter mediating light-evoked signals from the photoreceptors to second-order neurons (horizontal cells and bipolar cells), as supported by pharmacological experiments. Exposing the retina to L-glutamate causes depolarization of the horizontal cell and loss of its photoresponses. This is consistent with the notion that exogenous application of the neurotransmitter saturates the receptor sites in the horizontal cells causing further depolarization and preventing the effects of endogenous light-induced changes in neurotransmitter release from affecting the horizontal cell. This conclusion is supported using kainic acid, an agonist of L-glutamate. In contrast, kynurenic acid, a nonselective antagonist of excitatory amino acids receptors, induces the opposite effects; the horizontal cell hyperpolarizes and loses its photoresponses.

Immunostaining techniques and pharmacological analysis of the properties of the glutamate-gated channels in horizontal cells have revealed the cells to be of the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid/kainic acid (AMPA/KA) type. They are specifically activated by AMPA or KA and are antagonized by 6-cyano-7-nitroquinoxaline (CNQX) or *cis*-2,3-piperidinedicarboxylic acid (PDA).

Feedback Inhibitory Synapse

Horizontal cells are postsynaptic to the photoreceptors, but are also presynaptic to them. The effects of these pathways can be revealed with intracellular recordings from cone photoreceptors, while adjusting the spatial properties of the light stimuli. In turtle retina, a stimulus composed of large spot of red light can elicit a depolarizing response in the medium-wavelength cone, while a green stimulus of the same dimensions elicits a hyperpolarizing response. Reducing the size of the illuminated retinal area reduces the differences between the responses to red and green light stimuli.

The negative feedback pathway from horizontal cells to cones is thought to take place through the horizontal cell lateral elements invaginating the photoreceptor terminal at the triad ribbon synapse. The exact mechanism(s) underlying the negative feedback pathways from horizontal cells to cone photoreceptors is still under debate. GABA was suggested as the candidate for the inhibitory feed back neurotransmitter. This notion was supported by experiments demonstrating GABA-induced currents in the terminals of red-sensitive and green-sensitive cones isolated from the turtle retina. Furthermore, color opponency in fish C-type horizontal cells could be eliminated upon exposure to GABA or its antagonists. However, other studies in other species failed to show GABA effects that were supportive for a role of GABA as the inhibitory neurotransmitter of the horizontal cell. A recent theory suggested that large extracellular currents flowing into the horizontal cells through hemi-gap-junction channels, at their lateral elements in the triad synapse, change the potential difference across the plasma membrane of the photoreceptors at the terminal region. Any change in this current will change the potential difference and thus the activation of voltage-dependent calcium channels in the

photoreceptors' terminals. According to this theory, neurotransmitter release from the photoreceptors can be altered by the biophysical properties of the horizontal cells.

Receptive Field Properties of Horizontal Cells

Gap junctions between neighboring horizontal cells are permeable to dyes that can be used to assess the size of the horizontal cell syncytium. Dye coupling, using Neurobiotin, for turtle H2 cells and for rabbit A-type horizontal cells is shown in Figure 7(a). It is clear that the entire field of view represents one large syncytium that is composed of cells with similar morphology. The gap junctions between neighboring horizontal cells are also highly permeable to small ions, allowing lateral spread of electrical signals within the horizontal cell layer. This leads to the genesis of large homogeneous receptive fields that spread to retinal regions outside the range of the immediate dendritic fields of the individual horizontal cells.

Different procedures have been used to characterize the receptive fields of horizontal cells. The most common experimental procedures have been the application of a series of concentric spots of increasing diameter but fixed intensity, or moving a narrow slit of light across the retina. Figure 7(b) shows an

Figure 7 (a) Neurobiotin-coupling of H2 horizontal cells in the turtle (left) and of A-type horizontal cells in the rabbit retina (right). (b) Receptive field properties of L-type horizontal cell in the turtle retina. Photoresponses to light stimuli of constant intensity but different spatial pattern, as seen above each response (dots), were recorded with an intracellular microelectrode. (c) The relationship between peak response amplitude and radius of the illuminated retinal region reveals the extent of the receptive field. Scale bar = 50 μm (a). (b, c) Reproduced from Perlman I and Ammermüller J (1994) Receptive-field size of L1 horizontal cells in the turtle retina: Effects of dopamine and background light. *Journal of Neurophysiology* 72: 2786–2795, used with permission from the American Physiological Society.

experiment in which the receptive field of turtle L1-type horizontal cell was assessed using a series of concentric spots of different radii. The photoresponses, elicited by light stimuli of fixed intensity and wavelength (650 nm) but different diameters, are characterized by a gradual reduction as the size of the illuminated retinal area is reduced (Figure 7(b)). This occurs because nonilluminated peripheral horizontal cells shunt the response of the central cell. With full-field illumination, all of the horizontal cells are evenly illuminated and are equipotential, and therefore no current flows between them.

The dimension of the horizontal cell receptive field can be quantified by the diameter of the spot that elicits a response that does not differ from that elicited by a full-field illumination or by the two-dimensional length constant (λ). The latter parameter can be determined by applying a mathematical model to the relationship between response amplitude (normalized to the response to full-field stimulation) and spot radius (Figure 7(c)). The horizontal cell syncytium cannot be described by a simple array of resistors interconnected by coupling resistors. The resistances of the horizontal cell layer, reflecting glutamate-gated conductances, voltage-dependent conductances, leak channels, and gap junctions, constantly change with time due to changes in ambient illumination and in the chemical composition of the extracellular space. Therefore, the size of the horizontal cell receptive field (magnitude of length constant) changes with time and with changes in environmental conditions.

Modulation of Horizontal Cell Physiology and Morphology

The properties of horizontal cells are modulated by a variety of chemicals that are released by retinal cells during changing conditions of illumination. These chemicals, generally referred to as neuromodulators, are believed to alter the modes of information processing in order to adjust retinal function to any new state of adaptation. To date, three candidates have been studied for their effects on vertebrate horizontal cells: dopamine, nitric oxide, and retinoic acid.

Dopamine

Dopamine-containing neurons reside in the amacrine cell layer of the retina in most species. In some species (e.g., fish), dopaminergic cells are interplexiform cells (IPCs), which send long processes to the outer plexiform layer to make synaptic contact with horizontal cells. In other species (e.g., turtle, mammals), the dopaminergic cells are amacrine cells, and therefore dopamine has to reach the horizontal cells by diffusion through the inner nuclear layer.

Dopamine (DA) has several influences on horizontal cells – some are general and some species dependent.

1. The size of the receptive field is reduced, as shown by dye coupling and by electrophysiological determination of receptive field size (Figure 8(a)). Here, the length constant, λ, was calculated for L-type horizontal cells using light stimuli of different intensities under control conditions and in the presence of dopamine. For each light intensity, the receptive field is narrowed (small λ) by dopamine. This effect reflects a reduction of gap junction conductance induced by activation of adenylate cyclase (AC) by dopamine at D1-type receptors (Figure 8(d)).
2. In fish horizontal cells, dopamine induces the formation of spinules in a manner similar to that seen with bright light background illumination.
3. In some species (e.g., fish), the interaction between L-glutamate and its receptors on the horizontal cell membrane is modulated by dopamine so that the amplitude of the photoresponse is reduced to any given light stimulus. This does not happen in the turtle retina (Figure 9(a)).
4. Dopamine changes the balance between rod and cone inputs to horizontal cells in *Xenopus* retina, in order to augment the rod contribution in the dark-adapted state and the cone contribution in the light-adapted state.

Nitric Oxide

Cells containing the enzyme nitric oxide synthase (NOS) have been demonstrated in all retinas studied, indicating potential synthesis of nitric oxide (NO). In all species NOS occurs in amacrine cells, but reports of NOS in photoreceptors, horizontal cells, bipolar cells, and Müller cells have been published. In the turtle retina, NOS was reported in horizontal cell processes at the photoreceptor ribbon synapses, in the inner segments of the photoreceptors, in H2 and H3 cells, and in Müller cells. In the rabbit retina, nicotinamide adenine dinucleotide phosphate (NADPH) diaphorase activity in horizontal cells was shown to depend upon the state of adaptation and the activity of glutamatergic pathways. It is increased in the dark-adapted state or by the activation of AMPA/KA-type receptors. Thus, NO can be synthesized in the distal retina to modulate the physiology of distal neurons including horizontal cells.

NO reduces the size of the horizontal cell receptive field (Figure 8(b)), reflecting direct action of NO upon guanylate cyclase (GC; Figure 8(d)). NO also modulates the horizontal cells' photoresponses. Raising the retinal level of NO by adding

Figure 8 Modulation of horizontal cell receptive field by (a) dopamine (DA), (b) nitric oxide (from donor sodium nitroprusside (SNP)), and (c) retinoic acid (RA). For each drug, the length constant was measured using light stimuli of different intensities under control conditions and during superfusion with the experimental drug. Each drug lowered the dimensions of the horizontal cell respective field, probably by different mechanisms, as illustrated schematically in (d). (d) Dopamine acts on a dopamine receptor (DR) to activate the cyclic adenosine monophosphate (cAMP) pathway. Nitric oxide (NO) diffuses into the cell to activate the cyclic guanosine monophosphate (cGMP) pathway and retinoic acid probably acts directly on receptor sites on the gap junction proteins (AC, adenylate cyclase; PKA, protein kinase A; GC, guanylate cyclase; PKG, protein kinase G). Figure 9 The effects of (a) dopamine (DA), (b) nitric oxide (from donor sodium nitroprusside (SNP)), and (c) retinoic acid (RA) upon the responsiveness to light of L-type horizontal cells in the turtle retina. The photoresponses were elicited in the dark-adapted states with light stimuli of different intensities under control conditions and during superfusion with the experimental drug. The response–intensity relationships were derived and fitted to the generalized hyperbolic function (eqn [1]) (continuous curves). It is clear that dopamine did not affect the photoresponses, that nitric oxide caused response augmentation, and that retinoic acid caused response diminution.

its precursor, L-arginine, or adding an NO donor such as sodium nitroprusside (SNP) leads to response augmentation (Figure 9(b)), while lowering the NO level leads to response diminution. The actions of NO on processing of visual signals in the distal retina of the turtle mimic the effects of background light. In darkness or in low NO, synaptic transmission from cone photoreceptors to L1-horizontal cells is nonlinear, with high gain for small signals, while in the presence of background light or high NO level, synaptic transmission becomes linear and of low gain.

Retinoic Acid

Retinoids are of great importance in the eye, having roles in photopigment cycle and in development. Retinoic acid (RA) is produced in the pigment epithelium as a side effect of the rhodopsin phototransduction process. Retinoic acid induces synaptic plasticity at the terminal dendrites of horizontal cells and promotes the growth of spinules in fish in a pattern similar to that induced by background lights or by dopamine. It exerts a pronounced effect on the electrical coupling between horizontal cells in mammalian and nonmammalian retinas, and reduces the receptive fields of the horizontal cells (Figure 8(c)), probably by acting directly on the gap junctions (Figure 8(d)). Intracellular recordings demonstrate retinoic acid-induced changes in horizontal cells' responsiveness to light. Retinoic acid augments the amplitudes of the horizontal cell photoresponses to full-field stimuli in the fish retina, but reduces them in the turtle retina (Figure 9(c)).

Functional Roles of Horizontal Cells

Spatial Information Processing

The major functional role of horizontal cells in the vertebrate retina is creating spatially opponent receptive field organization in postreceptoral retinal cells (bipolar, amacrine, and ganglion cells). Bipolar cells are the first visual neurons exhibiting spatial organization of their receptive fields. They respond with opposite polarity to light stimuli illuminating the center or the surround portions of their receptive field. The simplest model explaining the spatial properties of bipolar cells includes direct input from photoreceptors contributing to the central response and opponent inputs from horizontal cells forming the surround response. The spatial organization of the bipolar cell's receptive field is transmitted to ganglion cells, and then to higher visual centers in the central nervous system (CNS) for further processing, eventually leading to pattern recognition. In experiments in which horizontal cell membrane potentials are directly polarized by injections of current through an intracellular microelectrode, ganglion cells respond in a manner characteristic for 'surround responses.' This current-evoked response can reflect the negative feedback pathway from horizontal cells to cone photoreceptors and/or direct inputs from horizontal cells to bipolar cells. Evidence for both possibilities has been reported in different species.

Color Information Processing

Horizontal cell feedback probably serves to generate color opponency in bipolar cells and, therefore, in

ganglion cells in species having color vision, and where color opponent pathways exist in the retina. In the retina of cold-blooded vertebrates, color opponency in C-type horizontal cells is most likely generated by excitatory feed-forward and negative feedback inputs between horizontal cells and cone photoreceptors. Direct excitatory inputs from long-, medium-, and short-wavelength-sensitive cones to L-type horizontal cells, from medium- and short-wavelength-sensitive cones to red/green C-type horizontal cells, and from short-wavelength-sensitive cones to yellow/blue C-type horizontal cells determine the hyperpolarizing responses of the horizontal cells. A negative input from L-type horizontal cells onto medium-wavelength-sensitive cones provides the pathway for long-wavelength depolarizing photoresponses in turtle red/green C-type horizontal cells. Negative feedback pathways from both L-type horizontal cells and red/green C-type horizontal cells onto short-wavelength-sensitive cones underlie the depolarizing responses in turtle yellow/blue C-type horizontal cells. This is the best example of how a simple neuronal network between three spectral types of cone photoreceptors and three types of horizontal cells gives rise to color opponency channels. In mammals and primates, color opponency is observed only in bipolar cells or ganglion cells, and the role of the horizontal cells is unclear.

Photoreceptor Modulation under Different Lighting Conditions

The negative feedback pathways from horizontal cells to cone photoreceptors also provide modulation of photoreceptor activity during changing conditions of illumination, thus affecting signal transmission from photoreceptors to bipolar cells and eventually to higher visual centers. In the simple model of horizontal cell feedback onto cone photoreceptors, horizontal cells modulate the transmembrane potential of the cone pedicle, thus affecting the rate of transmitter release. This effect serves, at an early stage of the visual process, to reset the activity of visual neurons during changing conditions of illumination in a manner that will increase sensitivity and will shift the dynamic range of responsiveness to higher levels of illumination. The end result is that the visual system is insensitive to the level of constant illumination but is very sensitive to changes in illumination.

Retinal Models

G T Kenyon, Los Alamos National Laboratory, Los Alamos, NM, USA

Published by Elsevier Ltd.

Introduction

Computational models of the retina have targeted a range of biological scales, from mathematical formulations of the phototransduction cascade to biophysical models of reconstructed ganglion cells and large-scale simulations of heterogeneous networks. As with computational studies of other central nervous system (CNS) structures, retinal models have been used to investigate emergent phenomena in systems of interacting elements in order to better understand the contribution of each component to the collective behavior. Quantitative models have also been used to describe robust experimental phenomena using elegant mathematical relationships characterized by a small number of parameters. The retina has also provided a test bed for the application of information theoretic techniques to the analysis of simultaneously recorded spike trains. Finally, the retina represents an extraordinary example of biological adaptation over a vast range of operating conditions. The retina may be the first CNS structure to be completely described by biophysically detailed computational models able to account for functionally significant aspects of the system. Potential applications of such models include the computer-aided design of retinal prosthetics, the improved interpretation of the electroretinogram (ERG), and even the development of next-generation computer vision systems.

Unique Advantages of Retinal Models

As a target system for the development of computational models, the retina offers a number of distinct advantages relative to other CNS structures. Sections of intact retina can be removed and studied *in vitro*, permitting external stimuli to be controlled very precisely while recording simultaneously from multiple retinal output neurons, or ganglion cells, under effectively normal physiological conditions. With the exception of birds, the vertebrate retina receives only diffuse modulatory feedback from higher brain areas and thus to a good approximation can be studied as a stand-alone circuit. The input/output function of the retina can therefore be characterized to a much greater resolution than is possible for other CNS structures and with a minimum of confounding factors related to experimental manipulations or state of arousal. Over short distances, retinal circuitry is roughly translationally invariant and coverage of the visual space – with the exception of certain direction-selective neurons – is approximately isotropic. The connections to and from a representative retinal neuron of a given type can thus serve as a template for all such cells of the same type (to within biological variation), thereby greatly reducing the number of free model parameters. In addition, the gross anatomical structure of the vertebrate retina is largely conserved, allowing model developers to use general circuit motifs where data from a particular species may be lacking. Multiple independent evolutions of retinal-like structures may even allow some aspects of model development to be guided by universal visual processing principles. Despite these distinct advantages from the standpoint of model construction, the retina is nonetheless a highly complex structure for which a complete specification of the underlying anatomy and physiology is not available. However, emerging technologies for automating the reconstruction of neural processes from thin electron microscope sections may soon unveil retinal circuitry in unprecedented detail. Moreover, once a nearly complete specification of the retinal input/output function has been obtained – a prospect that seems increasingly plausible for several vertebrate species – it may be possible for model developers to uniquely infer the remaining unknown physiological parameters necessary to fully account for the retinal code.

Differences with Respect to Classical Models

Probably no structure in the CNS is purely classical in the sense that all of its dendrites and axons have strictly input or output functions and all of its synapses are activated solely by action potential-mediated transmitter release. The retina, however, deviates substantially from such classical neural circuits and includes several specializations that must be taken into account in the development of biophysically detailed models. Most prominently, photoreceptors possess unique transduction mechanisms and light/dark adaptation properties that drive the light responses of all retinal neurons (except for a class of photosensitive ganglion cells not discussed here). Fortunately, both the phototransduction cascade and Ca^{2+}-mediated negative feedback are relatively well understood, and detailed models of the underlying biochemical processes are actively being developed. A relatively complete mathematical characterization of the photocurrents in rods and cones is thus increasingly feasible, potentially

allowing photoreceptor responses to light flashes of varying duration and intensity and under a range of adaptation conditions to be modeled with a high degree of accuracy (Figure 1).

Retinal circuitry also involves several unconventional, or graded, synaptic contacts that do not require the generation of action potentials to mediate functional interactions, including feed-forward excitatory ribbon synapses at photoreceptor and bipolar cell terminals, dendrodendritic and dendroaxonic synapses – particularly between amacrine cells and their feedback projections onto bipolar cells – extensive gap junction coupling, as well as evidence for nonvesicular neurotransmitter release from some retinal neuron types. Indeed, conventional synapses that require action potentials for the release of chemical neurotransmitters are more the exception in the retina than the rule. Vesicular release at graded synapses can be modeled as a stochastic process whose rate depends on the presynaptic membrane potential or, if greater accuracy is required, on the concentration of intracellular calcium. Additional terms are necessary to account for reductions in gain during sustained light responses and for saturation at high intensities. Nonvesicular release, which uses voltage-dependent transporter mechanisms, can be approximated by empirically determined functions giving the change in the postsynaptic conductance produced by shifts in the presynaptic membrane potential. Mathematically, gap junctions can be effectively described as simple ohmic resistances linking coupled cells. Unlike conventional synapses, however, graded synapses and gap junctions must be accounted for – and the associated currents updated – on every time step, not just when an action potential is generated, which may significantly increase the computational load. Retinal interneurons also release a number of neuromodulators, such as dopamine, which in turn affect retinal connectivity and excitability, creating feedback loops that can operate over much longer timescales than typical light responses.

Survey of Retinal Models

Quantitative Models

Linear systems In the late 1950s, Hartline and Ratliff extended the application of linear models to the analysis of delayed, lateral inhibition between individual ommatidia in the compound eye of *Limulus*, accounting for Mach bands (enhancement of light/dark boundaries at a high contrast edge) and for amplified responses to a sinusoidally varying light intensity, the latter occurring near a resonance

Figure 1 Reaction scheme and model for the generation of photocurrent in human cones. (a) Photopigment R is converted by light I into activated photopigment R*, which is inactivated with rate constant $1/\tau_R$. R* activates a G-protein (transducin), which subsequently forms an activated complex with PDE. The activated transducin–PDE complex is inactivated with rate constant $1/\tau_E$; it hydrolyses cGMP with rate constant β. Cyclic nucleotide-gated (CNG) channels in the membrane, opened under control of cGMP, admit an ionic current I_{chan}, part of which is carried by Ca^{2+} ions. Ca^{2+}, which is removed with rate constant $1/\tau_{Ca}$, regulates the production rate α of cGMP via guanylyl cyclase (GC). Ca^{2+} also exerts a direct inhibitory influence on the CNG channels. Part of the ionic current I_{chan} charges the membrane of the cone outer segment (with membrane time constant τ_m), yielding the output photovoltage, V. (b) The boxes with $\tau_{(\cdot)}$ represent first-order low-pass filters. The rate constant of cGMP hydrolysis consists of a dark rate constant, $1/\tau_D$, plus a light-dependent component with scaling determined by the gain factor k_β. The nonlinear differential equation describing cGMP hydrolysis can be understood as a static nonlinearity $1/\beta$ followed by a low-pass filter with time constant $\tau_\beta = 1/\beta$. The calcium feedback loop is governed by n_X, the apparent Hill coefficient of cGMP activation of the CNG channels (including the effect of a local calcium feedback, indicated by the dashed line), and by n_{cyc}, the Hill coefficient of GC deactivation; a_{cyc} is a scaling constant. Reproduced from Van Hateren JH and Lamb TD (2006) The photocurrent response of human cones is fast and monophasic. *BMC Neuroscience* 7: 34, with permission.

frequency at which the recurrent inhibition lags the excitatory center response by approximately one-half of a stimulus cycle. In 1965, Rodieck used linear systems theory, exploiting the principles of superposition and separability, to predict the responses of cat ganglion cells to arbitrary stimuli (Figure 2). The center-surround receptive field organization was modeled as a difference of Gaussians and the time dependence of the step response treated as a separate multiplicative factor with both transient and sustained components. Generalizing the Rodieck model so that the surround could be activated with a slower time course than the center, Enroth-Cugell and colleagues were able to account for the responses of cat ganglion cells to drifting sinusoidal gratings across a range of spatial and temporal frequencies. Such models continue to be widely employed as quantitative descriptions of the linear receptive field properties of retinal neurons.

Nonlinear effects In the late 1970s, computational models were developed to account for nonlinear aspects of ganglion cell responses. In a series of papers, Shapley and Victor employed a cascade of low- and band-pass temporal filters, the latter representing negative feedback, to quantify the increased selectivity of cat ganglion cells to rapidly varying stimuli as a function of luminance contrast – a phenomenon they termed contrast gain control. Such models were able to express the primary action of contrast gain control in terms of a single parameter characterizing the product of the gain and natural frequency of the negative feedback loop. Descriptions based on a cascade of temporal filters have become a standard technique for quantifying nonlinear changes in receptive field dynamics as a function of center and/or surround stimulation.

Linear–nonlinear models A linear–nonlinear model refers to a technique most commonly used to account for the responses of retinal ganglion cells to naturalistic stimuli. Unlike ganglion cell responses to very simple inputs, such as stationary spots or drifting gratings, the spike trains evoked by video clips of natural scenes are often highly reproducible from trial to trial, with temporal spreads as narrow as a few milliseconds. Linear–nonlinear models use reverse correlation methods to reconstruct spatiotemporal receptive fields via spike-triggered averaging, with the firing activity in response to a random checkerboard used to build up the average stimulus at each time point preceding a spike. The reconstructed spatiotemporal receptive field is then treated as a linear kernel that can be convolved with an arbitrary input pattern to produce a subthreshold generator potential. To account for the firing threshold, the generator potential is passed through an expansive nonlinearity. The output of the nonlinear filter is used to modulate the instantaneous rate of a stochastic

Figure 2 Analytic representation of the receptive field of a cat ganglion cell. Assuming separability, the response to a step change in illumination over a small retinal patch can be expressed as the product of separate spatial and temporal factors: $f(x, y, t) = f(x, y) \cdot h(t)$. The temporal factor is characterized by a maintained change in firing rate of amplitude M and a transient, exponentially decaying component of amplitude T. The spatial factor can be approximated as the sum of two Gaussian functions, one of which is wider and reversed in sign. The total response to any uniform stimulus is given by the integral of $f(x, y, t)$ over the bounding contour. For a uniform bar of arbitrary width moving with constant velocity perpendicular to either axis, the solution can be written analytically in terms of error functions. The response curve, which estimates the change in firing rate, is triphasic. The predicted responses of both center-activated (CA) and center-suppressed (CS) cells are shown after adding a nonzero baseline and truncating negative firing rates to zero. For these, the width of the center Gaussian = 0.59°, the ratio of the total center to surround strengths = 0.8, the ratio of surround to center widths = 3, $T/M = 4$, exponential decay constant = 40 ms, and bar velocity = 10° s^{-1}. Reproduced from Rodieck RW (1965) Quantitative analysis of cat retinal ganglion cell response to visual stimuli. *Vision Research* 5: 583–601, with permission from Elsevier.

Poisson or renewal processes, yielding a predicted output spike train in response to any given input. Model parameters, particularly those characterizing the threshold nonlinearity, are adjusted to produce the best fit to experimental data. For testing purposes, a novel naturalistic stimulus – one not used for optimizing model parameters – is presented multiple times, allowing the experimentally measured peristimulus time histogram to be compared with the prediction of the linear–nonlinear model. Such linear–nonlinear models have been used to quantify changes in the intrinsic gain of retinal ganglion cells in response to contrast increments or decrements (contrast adaptation) and can be generalized to incorporate functional interactions based on pairwise correlations between ganglion cell spike trains.

Biophysical Models

Voltage-gated channels Computational models of single retinal neurons have been used to synthesize diverse sets of experimental data, providing insight into how different mixtures and distributions of voltage-gated ion channels, in combination with realistic dendritic and axonal morphology, act collectively to shape measured input/output properties. In the salamander retina, Miller and colleagues used multicompartmental reconstructions to explore how the distribution of voltage-gated conductances in ganglion cell dendrites modulates somatic responses to injected currents. In the absence of voltage-gated currents, such models predict that capacitive charge stored in the dendritic membrane would trigger somatic spikes much more rapidly than is actually observed. Computational models of nonspiking retinal neurons further suggest that voltage-gated currents may help to maintain the membrane potential within an optimal dynamic range for modulating graded release. There can be little doubt that biophysically detailed models will continue to reveal important functional roles for the variety of voltage-gated currents present in all retinal neuron types.

Nonlinear subunits In the cat retina, α ganglion cells contain nonlinear subunits that respond asymmetrically to step changes in light intensity – a feature that increases the overall sensitivity of these neurons to moving textures, for example, by ensuring that responses to a leading edge are not canceled by an opposite response to a trailing edge. Computational models have shown that the rectification of transient inputs from both cones and bipolar cells can quantitatively account for the formation of nonlinear subunits. Because nonlinear subunits are present in a variety of mammalian retina, although not in the majority of primate ganglion cells, computational models will continue to play an important role in determining to what extent a common mechanism for nonlinear subunits has been conserved across vertebrate species.

Direction selectivity Computational models have been used extensively to investigate the synaptic mechanisms underlying the direction-selective responses of certain ganglion cells. A direct consequence of the principle of superposition is that the total integrated response of any linear system must be independent of the direction of stimulus motion, mandating that direction-selective responses must involve some essential nonlinearity. Correlation-based motion detectors were used by Reichardt in the late 1950s to account for direction-selective responses in insect visual systems, and biologically plausible circuits that could explain the main properties of directional-selective ganglion cells in the rabbit retina were proposed by Barlow and Levick in 1965. Using computational models, in 1983, Koch and Poggio investigated the role of nonlinear shunting inhibition on the dendrites of direction-selective ganglion cells, exploiting the fact that an excitatory synaptic input would be more strongly attenuated by a current shunt placed more proximally relative to the site of action potential initiation. Subsequently, in 1991, Borg-Graham and Grzywacz developed a computational model to examine the generation of direction-selective responses at the distal ends of starburst amacrine cell dendrites, which extend radially from the cell body and provide a natural axis for differentiating null and preferred directions. Computational models continue to be used to test theories of direction selectivity at both pre- and postsynaptic sites.

Network Models

Ultimately, the most interesting consequences of retinal processing are likely to arise from network-level interactions. Carver-Mead pioneered the use of analog VLSI technology (aVLSI) to physically emulate a retina-like circuit based on feedback inhibition of photosensitive elements and feed-forward inhibition of second-order neurons reminiscent of horizontal cell interactions with cones and bipolar cells. Similar to recurrent lateral inhibition in *Limulus*, the silicon retina exhibited both enhanced spatial and temporal contrast and thus was able to reproduce an essential aspect of retinal processing. By the late 1980s, computational resources had advanced to the point that network-level models were feasible. Smith and colleagues constructed some of the first biophysically detailed computer simulations of large-scale retinal networks, including models of the bipolar cell input to a reconstructed cat α ganglion cell and of the

inhibitory feedback from horizontal cells onto cone terminals. Subsequently, Werbin and coworkers developed a comprehensive circuit model based on the salamander retina that included contributions from all of the major cell classes. Implemented on a specialized parallel architecture called the PIPE, individual neurons were implemented as nonlinear filters that summed weighted activity across locally defined neighborhoods consisting of distinct presynaptic cell populations. The integrated synaptic input was then combined with a blur function to account for lateral electrical coupling. The model included explicit descriptions of various retinal interneurons, including sustained and transient bipolar cells of both ON and OFF types and of narrow and wide-field amacrine cells, providing one of the first experimentally based simulations of retinal processing stretching from cones to ganglion cell membrane potentials. Boahen and colleagues have since developed a functionally complete model of the mammalian retina configured for real-time implementation in aVLSI that accounts for contrast gain control and the spatial and temporal frequency tuning curves measured from cat ganglion cells. Models of functionally complete retinal networks are fast becoming a reality, with the incorporation of additional biophysical detail likely to proceed as the underlying anatomy and physiology become better understood.

Retinal Code

On the order of 7 million cones and more than 100 million rods converge down to 1 million fibers in the optic nerve, including both ON and OFF types. The human retina thus contains far fewer total output pixels than do modern digital cameras. Trial-to-trial variability in the responses of individual retinal ganglion cells further reduces the precision of the local visual signals conveyed by each optic nerve fiber, in part resulting from evolutionary pressure to reduce the number of impulses transmitted to the brain and thus the total metabolic cost. The resulting information bottleneck suggests that far from serving as a passive relay, the retina employs a sophisticated spatiotemporal code in order to support the perceived acuity of visual experience. Understanding the nature and origins of the retinal code, and how it maintains operational fidelity over a range of ambient light intensities covering nearly 12 orders of magnitude, represents an exciting goal of computational modeling studies.

Ensemble Activity

Population codes As the ability to record simultaneously from multiple retinal neurons becomes more widely available, computational models will be increasingly used to investigate how stimulus properties are represented by the ensemble of evoked activity. Chichilnisky and coworkers developed techniques for recording simultaneously from a nearly complete mosaic of parasol ganglion cells in the primate retina. To analyze such enormous data sets, they employed computational models to quantify how precisely a population code could be used to estimate the velocity of a moving bar. Spike trains from ganglion cells at different retinal locations were time shifted by an amount proportional to the delay in their peak activation by the moving stimulus. Estimates of bar velocity based on a population code greatly exceeded that available from any given pair of ganglion cells, demonstrating the importance of averaging over ensemble activity in order to obtain precise estimates of stimulus parameters. In the future, computational models are likely to remain essential for interpreting population-coded signals.

Correlations The spike trains generated by pairs of retinal ganglion cells are often correlated, especially when their receptive fields partially overlap. Pairwise correlations are categorized into three functional classes: (1) correlations due to stimulus coordination, which are all but inevitable when both ganglion cells respond to the same stimuli; (2) noise correlations, defined as the residual correlations remaining after the effects due to stimulus coordination have been subtracted; and (3) background correlations, which persist regardless of the stimulus condition. Of particular interest is whether the noise correlations are synergistic, providing additional information about the stimulus beyond that conveyed by the cells individually, or redundant, such that the total information transmitted is less than would have been the case if the two spike trains were statistically independent. From a computational standpoint, such issues are commonly addressed using information theory. A small time bin, usually on the order of 1 ms, is used to digitize the recorded spike train segments, typically as binary patterns in which a '1' and a '0' denote the presence and absence of an event in the corresponding bin, respectively. The information conveyed by a suitably digitized pattern of spikes in response to a particular stimulus, regardless of whether the pattern includes one or more cells, is proportional to the logarithm of the conditional probability for that pattern to occur (measured as a fraction of all patterns observed in response to the same stimulus), divided by the logarithm of the *a priori* probability for the same pattern to occur regardless of what stimulus is present. By averaging over all stimuli and over all observed patterns, a measure of the mutual information, which

quantifies how much information the digitized spike train transmits about a given set of input stimuli, is obtained. Elegant techniques have been developed for applying information theory to spike train data, along with strategies for handling finite data artifacts, for eliminating stimulus coordination effects, and for extrapolating results to the limit of infinite temporal precision and/or infinite record lengths.

Nirenberg, Latham, and coworkers used information theory to analyze noise correlations between pairs of ganglion cells in the mouse retina responding to video clips of natural scenes. Formally, they used the Kullback–Leibler distance to estimate the information lost, on average, when pairwise correlations were ignored. Under the conditions of their protocol, the information conveyed by correlations was determined to be less than 10% of the total, leading to the conclusion that retinal ganglion cells are largely independent encoders. On the other hand, the existence of high-frequency oscillatory potentials in the ERGs of humans and other primates, as well as direct measurements of oscillatory responses between 60 and 120 Hz in a variety of vertebrate species, suggests a potential mechanism for coordinating the activity of retinal ganglion cells over long distances with millisecond precision. The main properties of coherent, high-frequency oscillations were reproduced in a computational model developed by Kenyon, Marshak, and coworkers, which employed long-range inhibitory feedback from a class of axon-bearing amacrine cells that were electrically coupled to neighboring ganglion cells. Berry, Bialek, and colleagues used Ising models to estimate the consequences of realistic pairwise correlations among large numbers of retinal ganglion cells. They reported that even weak pairwise interactions can have a profound collective effect on the overall state of the network, analogous to the spontaneous alignment of local domains in a ferromagnetic material below the Currie temperature. Although the nature and origins of the retinal code remain to be elucidated, computational models will provide an indispensable complement to experimental investigations.

Models of Light/Dark Adaptation

Quantitative Models

The retina evolved to maintain contrast sensitivity across visual environments ranging from diffuse starlight to direct sunlight. Under laboratory conditions, responses can be recorded to test flashes superimposed on steady backgrounds whose combined luminance spans nearly 12 orders of magnitude. Quantitatively, many essential aspects of light adaptation are described by the Naka–Rushton equation, which in simplified form can be written as follows:

$$V/V_{\mathrm{T}} = I/(I+\sigma)$$

where $V = V_{\mathrm{T}} + V_{\mathrm{B}}$, $I = I_{\mathrm{T}} + I_{\mathrm{B}}$, such that V_{T} is the response, measured relative to a stable baseline V_{B}, to a test flash of intensity I_{T}, presented on a mean background of luminance I_{B}, and the maximum response is given by V_{m}. When the absolute intensity of the test flash, either positive or negative, is much less than the half saturation value, σ, the Naka–Rushton equation predicts that responses will be linearly proportional to the stimulus amplitude, $V_{\mathrm{T}} \sim I_{\mathrm{T}}$, or

$$V_{\mathrm{T}}/V_{\mathrm{m}} \approx I_{\mathrm{T}}/(I_{\mathrm{B}}+\sigma)$$

For very large increments in light intensity, however, the Naka–Rushton equation predicts that responses will saturate at $V \approx V_{\mathrm{m}}$, or $V_{\mathrm{T}} \approx V_{\mathrm{m}} - V_{\mathrm{B}}$.

The Naka–Rushton equation can be written more generally as

$$V/V_{\mathrm{m}} = I^n/(I^n+\sigma^n)$$

with the Hill coefficient, n, typically falling between 0.7 and 1.0. Within these limits, the generalized Naka–Rushton equation predicts that at a fixed background luminance, the dynamic range of retinal light responses, including both positive and negative flashes, covers approximately four orders of magnitude, corresponding to changes in contrast of $\pm 100\%$. The dynamic range of retinal light responses is thus consistent with the range of contrasts typically encountered in natural scenes. However, four orders of magnitude is not nearly enough to account for the shifts in mean background luminance produced, for example, by the transition from moonlight to sunlight. Adaptation mechanisms are thus required to maintain contrast sensitivity across a wide range of background light levels.

Within the framework of the Naka–Rushton equation, adaptation is modeled by allowing σ to vary as a function of the mean background intensity, with the average luminance taken over time intervals ranging from fractions of a second to tens of minutes, depending on the underlying physiological process. Generally, light adaptation is faster than dark adaptation since the latter may require additional time for bleached rod and/or cone photoreceptors to recover. In practice, the half saturation value measured under light-adapted conditions, σ_{L}, can most easily be evaluated in terms of the experimentally measurable quantities, $V_{(+)}$ and $V_{(-)}$, representing the maximum positive and negative responses to light increments and decrements, respectively, with the total response range given by $V_{\mathrm{m}} = V_{(+)} + |V_{(-)}|$. Assuming that the generalized Naka–Rushton equation remains valid,

Figure 3 Silicon retina. Each pixel (vertex) represents a triad synapse (circular window) in the outer vertebrate retina, consisting of a conductance (G) that links the photoreceptor output (P) to the resistive network, a parasitic capacitance (C) arising from the interface with the silicon substrate and that provides temporal integration analogous to biological membranes, and an amplifier that takes the difference between P and the local voltage on the resistive network, implemented as a hexagonal array. All resistors are made of transistors, allowing the effective resistance to be controlled by an external input and which forces the current–voltage relation to saturate outside the linear operating range, thus limiting the potential damage from failed circuit components. The primary phototransducer is a vertical bipolar transistor whose output is logarithmic over four or five orders of magnitude, covering a similar range of light intensities to vertebrate cones. The output of the silicon retina, in analogy to bipolar cells, is sensitive to contrast, or the difference between the local receptor output and the space–time average of the surrounding elements. Reproduced from Mead CA and Mahowald MA (1988) A silicon model of early visual processing. *Neural Networks* 1: 91–97, with permission from Elsevier.

it is straightforward to solve for the value of σ_L that reproduces the measured responses range for any given mean luminance:

$$\sigma_L = I_B[\gamma/(1-\gamma)]^{1/n}$$

where $\gamma = V_{(+)}/V_m$ is the range compression factor, which equals 1 in the fully dark-adapted state and approaches 0 as light responses saturate at sufficiently large background levels.

The previous expression predicts that as a result of light adaptation, the half saturation value remains proportional to the mean background intensity, $\sigma_L \sim I_B$. For small test flashes, it follows that $V/V_m \sim I_T/I_B$, and thus that the responses to weak stimuli will be proportional to contrast. This property of light adaptation, which ensures that a 1% increment in light intensity always produces the same fractional responses regardless of the background luminance, is known as Webber's law.

The generalized Naka–Rushton equation has also been used to predict the results of threshold versus intensity (TVI) experiments. As a function of the mean background luminance, a TVI curve gives the amplitude of a test flash that is just sufficient to produce a given response, which may be measured either electrophysiologically or psychophysically, with the latter corresponding to a behavioral criteria specifying the fraction of trails on which a test flash can be successfully detected against an adapting background.

Defining ΔI_L as the minimum flash intensity required to produce a criterion response, δ, at a mean background luminance level, I_B, relative to the flash intensity required to produce the same criterion response in the dark-adapted state, ΔI_D, the generalized Naka–Rushton equation predicts that

$$\Delta I_L/\Delta I_D = I_B(1/\gamma)[1/(1-\gamma)]^{1/n}(\delta/V_B)^{n-1/n}$$

where it is assumed that $\delta \ll V_m$, V_B. As γ goes to zero as a function of increasing background luminance, the associate TVI curves diverge as $1/\gamma$, a result that is independent of the value of the Hill coefficient, n.

Remarkably, the generalized Naka–Rushton equation can accurately describe the responses of retinal neurons to test flashes presented against steady backgrounds as well the changes in both electrophysiological and psychophysical thresholds over essentially the entire range of natural visual stimuli, despite the enormous variety of biochemical and physiological processes involved. An example of the application of quantitative models to the analysis of light/dark adaptation in primate cones is presented in Figures 4 and 5.

Biophysical Models

A number of existing biophysical retinal models exhibit some form of light/dark adaptation, encompassing a wide range of underlying mechanisms. Detailed models of the phototransduction process (Figure 1) have successfully accounted for light/dark adaptation in both rod and cone photoreceptors across the entire span of naturally occurring light levels. Because light flashes produce hyperpolarizing responses by turning off a persistent depolarizing dark current, the saturation of photoreceptor responses arises naturally from the fact that the fraction of light-sensitive channels that can remain open, regardless of the flash intensity, cannot fall below zero. Adaptation in such models is governed primarily by a calcium-mediated negative feedback loop, which acts to reopen the same light-sensitive ion channels, thereby desaturating the response to large step changes in background light levels and thus partially restoring overall sensitivity. At the network level, following a step change in light intensity, both center-surround antagonism (Figure 2) and inhibitory feedback (Figure 3) contribute to light/dark adaptation by restoring the membrane potentials of retinal neurons nearer to their baseline resting levels. Electrophysiological experiments indicate that under both scotopic and photopic conditions, light/dark adaptation involves a combination of cellular processes intrinsic to individual photoreceptors as well as network-level mechanisms in both the inner and the outer retina. Typically, network-mediated mechanisms are more important when the response of individual photoreceptors is weak and thus relatively noisy, conditions under which signals from many rods and

Figure 4 Quantitative model of light/dark adaptation in primate cones. Extracellular potential drop measured along cone outer segments in the primate fovea plotted as a function of flash intensity. The adapting background luminance is indicated by the number to the left of each curve (log td). The small horizontal lines indicate the background response level, V_B, at each background luminance. Solid curves are solutions to the generalized Naka–Rushton equation with $n = 0.74$, with the half-saturation value evaluated from the maximal positive and negative responses, measured relative to V_B. Figure 5 Threshold versus intensity (TVI) of primate cones. Thresholds at each background (ΔI_L) are measured relative to the dark-adapted threshold (ΔI_D). Data points (crosses) were obtained by determining for each background the amount of light necessary to elicit a criterion response ($\delta = 35\,\mu V$). The light-adapted half-saturation level, σ_L, was expressed as a product of three factors – σ_D, σ_{photo}, and σ_{bleach} – corresponding to the dark-adapted value, σ_D, multiplied by a factor due to adaptation in the phototransduction cascade, σ_{photo}, and a separate factor due to pigment bleaching, σ_{bleach}. Both σ_D and σ_{bleach} can be measured independently, allowing the various contributions to the light-adapted threshold to be identified. Reproduced from Valeton JM and Van Norren D (1983) Light adaptation of primate cones: An analysis based on extracellular data. *Vision Research* 23: 1539–1547, with permission from Elsevier.

cones are more likely to be pooled, whereas mechanisms intrinsic to the photoreceptors become more prominent as light levels increase.

Retinal Pharmacology: Inner Retinal Layers

P D Lukasiewicz, Washington University, St. Louis, MO, USA

© 2009 Elsevier Ltd. All rights reserved.

The inner retina is composed of bipolar, horizontal, and amacrine cell interneurons, which process visual information that is received from photoreceptors, and ganglion cells that form the outputs of the retina (Figure 1). The optic nerve, which is comprised of ganglion cell axons, relays visual information to the brain. Because, on average, each ganglion cell receives input from 300 photoreceptors, the optic nerve is a potential transmission bottleneck for visual information. The inner retina processes and compresses the information received from hundreds of photoreceptors into a more compact form that can be sent to the brain by the ganglion cell axon, avoiding the bottleneck dilemma. The inner retina is involved in the complex spatial and temporal processing of visual information that is accomplished by synaptic interactions in the inner plexiform layer (IPL), the second synaptic layer of the retina. A diverse array of neurotransmitters, receptors, and transporters participates in visual processing in the IPL. The retina is an excellent model for the study of CNS synaptic pharmacology because it can be isolated intact and it can be physiologically activated with natural visual stimuli.

To understand inner retinal pharmacology, a basic knowledge of retinal circuitry is necessary (Figure 1). The retina is a layered structure that is composed of six classes of neurons. The fundamental classes of neurons and basic circuitry of the retina are well characterized. Rod and cone photoreceptors form the inputs to the retina, their somata are found in the outer nuclear layer (ONL) and they are the only photosensitive neurons involved in visual information processing in the retina. The retinal outputs are formed by ganglion cells, whose somata are found in the ganglion cell layer (GCL). Recently, a few percent of ganglion cells were found to be intrinsically photosensitive. These ganglion cells are not involved in visual processing. Instead, they provide inputs to parts of the brain that control circadian rhythms and pupillary reflexes. The retinal interneurons that process the visual signals as they flow from photoreceptors to ganglion cells are found in the inner nuclear layer (INL). Bipolar cells are important relay neurons that convey information through the vertical signaling pathway comprised of photoreceptors, bipolar cells, and ganglion cells (Figure 1, yellow neurons). Photoreceptors synapse onto bipolar cells in the first synaptic layer, called the outer plexiform layer (OPL) and bipolar cells synapse onto ganglion cells in the second synaptic layer, called the IPL. At least 10 types of bipolar cells have been described that convey different aspects of the visual signal from photoreceptors to ganglion cells, and form parallel signaling pathways. The somata of horizontal cell and amacrine cell interneurons are also located in the INL. At the OPL, horizontal cell processes make synaptic contacts with photoreceptors and bipolar cells. Horizontal cells modulate signaling from photoreceptors to bipolar cells. At the IPL, amacrine cell processes make synaptic contacts with bipolar cells and ganglion cells to modulate signaling between these two elements of the vertical signaling pathway.

Synaptic communication in the retina is mainly mediated by three neurotransmitters. Glutamate mediates fast excitation, whereas glycine and γ-aminobutyric acid (GABA) mediate fast inhibition. When bound to their receptors, all three neurotransmitters gate ion channels. Other substances released by retinal neurons act as neuromodulators. These substances do not directly excite or inhibit neurons. Instead, they modulate the effects of fast transmitters and voltage-gated channels, to fine-tune neuronal signaling. Amines and neuropeptides, and also glutamate and GABA, can act as neuromodulators.

Glutamate

Distinct Glutamate Receptors Mediate Excitatory Light Responses in ON and OFF Bipolar Cells

In the vertical signaling pathway, glutamate is the neurotransmitter utilized by both photoreceptors and bipolar cells. ON and OFF visual signals are formed at the first retinal synapse between cone photoreceptors and bipolar cells. Applied glutamate depolarizes or excites OFF bipolar cells, and hyperpolarizes or inhibits ON bipolar cells. In darkness, photoreceptors tonically release glutamate, which depolarizes OFF bipolar cells via a sign preserving synapse, and hyperpolarizes ON bipolar cells via a sign reversing synapse. Light decreases the glutamate release from photoreceptors, causing OFF bipolar cells to hyperpolarize and ON bipolar cells to depolarize. These opposite synaptic responses in OFF and ON bipolar cells are attributed to different glutamate receptor types on the dendrites of these two cell types (Figure 2). The excitatory glutamate responses of OFF bipolar cell are produced by the activation of ionotropic α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and

Figure 1 This schematic illustrates a cross section of the retina and the positions of the major neuronal cell types. The retina is a layered structure composed of three nuclear layers. The outer nuclear layer (ONL) contains the somata of rod (R) and cone (C) photoreceptors. The inner nuclear layer (INL) contains the somata of the retina interneurons, horizontal cells (HC), bipolar cells (BC) and amacrine cells (AC). The ganglion cell layer (GCL) contains the somata of ganglion cells, the retinal output neurons. The retina has two synaptic or plexiform layers, where most synaptic connections occur. The outer plexiform layer (OPL) is the first synaptic layer and it is where photoreceptors make synaptic contacts with horizontal cells and bipolar cells. The inner plexiform layer (IPL) is the second synaptic layer and it is where bipolar cells make synapses with amacrine and ganglion cells. The vertical signaling pathway (yellow neurons) consists of photoreceptors, bipolar cells and ganglion cells. This is the most direct signaling pathway through the retina. Horizontal cells synapse onto photoreceptors and bipolar cells and modulate signaling along the vertical pathway in the OPL. Amacrine cells synapse onto bipolar cells and ganglion cells and modulate signaling along the vertical pathway in the IPL.

kainate (KA) subtypes of glutamate receptors. Different subtypes of OFF bipolar cells have distinct synaptic response timecourses that are attributed to the predominance of either AMPA or KA receptors. The inhibitory glutamate responses of ON bipolar cells are produced by the activation of metabotropic, type 6 glutamate receptors (mGluR6), which stimulate a second messenger that closes cation channels. The mGluR6 receptors are members of group III metabotropic glutamate receptors (mGluRs) and are activated by the group-selective agonist L-amino-phosphonobutyric acid (l-AP4). These ON and OFF signaling pathways that are generated in bipolar cells are preserved throughout the visual system; they are then relayed to ON and OFF ganglion cells and then to higher visual processing centers in the brain. The locations of the major retinal glutamate receptors are summarized in Table 1 and illustrated in Figure 2.

Glutamate is the Main Excitatory Transmitter of the Inner Plexiform Layer

ON and OFF bipolar cells both release glutamate in the IPL to communicate with amacrine and ganglion cells. Bipolar cells are slow potential neurons that do not fire action potentials and tonically release glutamate when depolarized. ON bipolar cells release glutamate in response to increments of illumination and OFF bipolar cells release glutamate in response to decrements of illumination. Bipolar cell inputs to ganglion and amacrine cells activate postsynaptic AMPA and *N*-methyl-D-aspartate (NMDA) subtypes of glutamate receptors (see Figure 2 and Table 1). The AMPA receptor-mediated component of ganglion cell responses has a fast onset and rapid decay, while the NMDA receptor-mediated component has a slower onset and decay. NMDA receptor-mediated currents are also voltage dependent (unlike AMPA receptors) because at negative potentials their cation channels are blocked by magnesium, but at more positive potentials this block is relieved. NMDA receptors also differ from AMPA receptors because they are more sensitive to glutamate and require the binding of both glutamate and the coagonist glycine for activation. Glycine and D-serine, which also act as a coagonist, are abundant in the retina. Pharmacological studies suggest that extracellular levels of glycine and D-serine may be modulated to regulate NMDA receptor activation and the excitability of amacrine and ganglion cells.

The combination of AMPA and NMDA receptors may enhance the range of signaling between bipolar and ganglion cells. This is because NMDA receptor activation is voltage dependent and contributes more

to excitation at positive potentials. In contrast, AMPA responses are reduced at positive potentials. Signaling is enhanced at positive potentials because increased NMDA receptor contributions balance the reduced AMPA receptor contribution. In addition, the kinetics of excitatory synaptic signaling also depends on the relative proportions of AMPA and NMDA receptors on the postsynaptic amacrine or ganglion cell. Some amacrine cell synapses possess only AMPA receptors, while other amacrine cells and all ganglion cell synapses possess both AMPA and NMDA receptors. Thus, a single bipolar cell that contacts two postsynaptic neurons may elicit different postsynaptic responses that depend on the complement of NMDA and AMPA receptors.

Figure 2 The locations of the major glutamate receptors in the vertical pathway are shown. In the outer plexiform layer, metabotropic, mGluR6 receptors are located on the dendrites of ON bipolar cells, and AMPA and/or kainate ionotropic glutamate receptors are located on the dendrites of OFF bipolar cells. These two distinct classes of receptors respond differently to photoreceptor synaptic input; ON bipolar cells depolarize to light increments and OFF bipolar cells depolarize to light decrements (see text). In the inner plexiform layer, bipolar cells make excitatory synapses onto ganglion cells and amacrine cells (not shown here). The glutamate receptors on the dendrites of both ON and OFF ganglion cells are similar, AMPA and NMDA ionotropic glutamate receptors.

As noted above, ON and OFF retinal pathway signaling is determined by the presence of different postsynaptic glutamate receptors on the dendrites of ON and OFF bipolar cells. Since ON and OFF bipolar cells both release glutamate that activates NMDA and AMPA receptors, ON and OFF ganglion cell synaptic responses to increments and decrement of illumination, respectively, are generally considered to be equivalent. Recent work suggests that glutamate signaling at ON and OFF ganglion cells synapses may be asymmetric. This has been attributed to differences in presynaptic inhibition of ON and OFF bipolar cell terminals (see below) and to differences in the locations of AMPA and NMDA receptors at ON and OFF ganglion cell synapses. In ON ganglion cells, AMPA receptors are located synaptically near the glutamate release sites. In contrast, NMDA receptors are located perisynaptically away from the glutamate release sites, and are activated only when sufficient glutamate is released and diffuses to perisynaptic NMDA receptor locations, a process called spillover. In OFF ganglion cells, AMPA and NMDA receptors are both located synaptically and are readily activated by even small amounts of released glutamate. The distinct locations of AMPA and NMDA receptors at ON and OFF ganglion cell synapses produce asymmetric ON and OFF visual signaling in the IPL. This asymmetry produces a larger dynamic response range in ON ganglion cells, compared to OFF cells.

Synaptic Mechanisms Shape Excitatory Signaling in the IPL

Since glutamate release from bipolar cells is tonic, prolonged increases in synaptic glutamate levels present a number of signaling challenges not found in other parts of the CNS. In other parts of the CNS glutamate is released in brief pulses in response to action potentials exciting synaptic terminals. Also, elsewhere in the CNS, glutamate responses are unaffected by receptor desensitization, are limited by agonist unbinding (deactivation), and are terminated

Table 1 Locations of major retinal glutamate receptors

Neuron type	*Synaptic layer*	*AMPA receptors*	*Kainate receptors*	*NMDA receptors*	*mGluR6*
OFF bipolar cells	OPL	Yes	Yes	No	No
ON bipolar cells	OPL	No	No	No	Yes
Rod bipolar cell	OPL	No	No	No	Yes
Amacrine cells	IPL	Yes	No	Yes	No
Ganglion cells	IPL	Yes	No	Yes	No

by rapid diffusion from the synapse. But when glutamate release is tonic, postsynaptic receptor desensitization may occur and clearance of glutamate from the synapse may be slowed. Physiological and pharmacological studies show that the clearance of glutamate from ganglion cell synapses depends upon glutamate uptake by transporters. Pharmacological blockade of glutamate transporters, located on neighboring glial cell and bipolar cell terminals, enhances and prolongs excitatory light-evoked responses in ganglion cells, suggesting that transporters normally limit the amplitude and duration of excitatory synaptic responses.

AMPA receptors rapidly desensitize to maintained activation by glutamate. Because glutamate release from bipolar cells is sustained and glutamate clearance by uptake is slow, elevated synaptic glutamate levels may desensitize AMPA receptors. Pharmacological studies suggest that AMPA receptor desensitization shapes light-evoked responses in ganglion cells. Ganglion cell responses were enhanced when AMPA receptor desensitization was pharmacologically blocked by cyclothiazide or reduced by depolarization, suggesting that AMPA receptor desensitization normally limits ganglion cell excitatory responses.

Autoinhibitory mechanisms can also modulate excitatory transmission in the IPL by limiting glutamate release from bipolar cells. Glutamate released from bipolar cells may limit release by activating mGluRs located on bipolar cell terminals. In addition to glutamate, protons are also released from vesicles. Increased extracellular proton levels also limit glutamate release, but they do so by inhibiting calcium influx into bipolar cell terminals.

mGluRs are also found on the dendrites of amacrine and ganglion cells, where they are thought to modulate synaptic signaling in the IPL. Group I, II, and III mGluRs are found on amacrine and ganglion cell processes, where they act postsynaptically to modulate synaptic transmission. Often mGluRs are found only on one of the two processes postsynaptic to the bipolar cell, suggesting that these receptors selectively modulate transmission. The group I receptor member, mGluR1, is located on amacrine cell processes and modulates the release of GABA to control the strength of feedback inhibition to bipolar cell terminals. However, the physiological roles of most of the mGluRs in the IPL remain unknown.

GABA

Inhibitory signaling in the IPL is mediated by amacrine cells, which comprise the most diverse class of retinal interneurons. Amacrine cells are morphologically and functionally distinct, possessing different sets of neurotransmitters and receptors.

Table 2 Locations of inner retinal GABA and glycine receptors

Neuron type	*$GABA_A$ receptor*	*$GABA_B$ receptor*	*$GABA_C$ receptor*	*Glycine receptor*
OFF bipolar cells	Yes	?	Yes	Yes
ON bipolar cells	Yes	?	Yes	No
Rod bipolar cell	Yes	?	Yes	Yes
Amacrine cells	Yes	Yes	No	Yes
Ganglion cells	Yes	Yes	No	Yes

Approximately 50% of all amacrine cells are GABAergic and are a major source of fast inhibitory signaling in the IPL. The population of GABAergic amacrine cells is composed of multiple subtypes that share the common feature of possessing wide field processes that extend laterally but not vertically within the IPL. Thus, GABAergic amacrine cells signal within specific layers of the IPL, but they do not signal between layers. Wide field, GABAergic amacrine cells mediate lateral inhibition between distant excitatory signaling pathways, modulating bipolar to ganglion cell transmission. GABAergic amacrine cells also mediate local feedback inhibition that controls glutamate release from bipolar cells, as described below.

GABA receptors are found throughout the IPL and are located presynaptically on bipolar cell terminals and postsynaptically on amacrine cell and ganglion cell dendrites. There is a diversity of GABA receptors in IPL that includes ionotropic $GABA_A$ and $GABA_C$ receptors and metabotropic $GABA_B$ receptors. Table 2 summarizes the locations of these GABA receptor subtypes.

$GABA_A$ and $GABA_C$ Receptors

The retina is atypical in the CNS because it possesses two distinct types of ionotropic GABA receptors, $GABA_A$ and $GABA_C$. Both receptor subtypes gate chloride channels, but they are composed of distinct molecular subunits and have different biophysical properties. $GABA_C$ receptors are more sensitive to GABA than $GABA_A$ receptors, and $GABA_C$ receptors mediate more sustained responses.

The pharmacology of $GABA_A$ and $GABA_C$ receptors is distinct. $GABA_A$ receptors are antagonized by bicuculline and gabazine and potentiated by barbiturates and benzodiazepines. $GABA_C$ receptors are unaffected by these $GABA_A$ receptor-specific agents, but their function is blocked by the selective antagonist (1,2,5,6-tetrahydropyridin-4-yl)methylphosphinic

acid (TPMPA). $GABA_A$ receptors are located throughout the IPL on amacrine, bipolar, and ganglion cells and have both pre- and postsynaptic locations (Figure 3). Anatomical and molecular studies suggest that multiple subtypes of $GABA_A$ receptors exist in the IPL. However, subunit-specific antagonists are not yet available to confirm the functional significance of this diversity of $GABA_A$ receptors. In contrast, $GABA_C$ receptors have very specific locations in the retina; they are only found on bipolar cell terminals, where they mediate presynaptic inhibition (Figure 3).

Ionotropic GABA receptors in the IPL control communication between bipolar cells and their postsynaptic targets. GABA released from amacrine cells activates $GABA_A$ receptors on the dendrites of amacrine and ganglion cells, mediating postsynaptic inhibition that limits excitation. GABA release also activates $GABA_A$ and $GABA_C$ receptors on bipolar cell terminals, limiting glutamate release. Both local and lateral forms of GABAergic inhibition occur. Lateral inhibition contributes to the antagonistic receptive field surround in ganglion cells. Local inhibition occurs at pre- and postsynaptic synapses, where excitatory input from bipolar cells causes local GABA release from amacrine cells that activates presynaptic $GABA_A$ and $GABA_C$ receptors on bipolar cell terminals or postsynaptic $GABA_A$ receptors on amacrine and ganglion cell dendrites.

Presynaptic inhibition contributes to the temporal processing of visual information by controlling the time course of ganglion cell excitation and by limiting glutamate release from bipolar cells. Distinct combinations of fast $GABA_A$ and slow $GABA_C$ receptors are found on different bipolar cells, suggesting that presynpatic inhibition is temporally filtered for specific bipolar cell pathways. Pre- and postsynaptic lateral GABAergic inhibition affects the spatial processing of visual information and contributes to the receptive field organization of ganglion cell types.

Figure 3 The presynaptic and postsynaptic locations of ionotropic GABA receptors in the IPL are illustrated. Presynaptic $GABA_A$ (blue) and $GABA_C$ (green) receptors are located on the terminals of all classes of bipolar cell. The relative proportion of each receptor class varies with bipolar cell type. Postsynaptic $GABA_A$ (blue) receptors are found on the dendrites of ganglion cells and the processes of amacrine cells (not shown here). As noted in the text, $GABA_A$ and $GABA_C$ receptors have different functional properties and are thought to mediate temporally distinct forms of inhibition. $GABA_A$ receptors mediate fast inhibition, while $GABA_C$ receptors mediate a slower form of inhibition.

$GABA_B$ Receptors

The G-protein-coupled $GABA_B$ receptors are found on amacrine and ganglion cells, where they have been shown to modulate voltage-gated potassium and calcium channels. There is no anatomical evidence for $GABA_B$ receptors on bipolar cell terminals, but physiological and pharmacological evidence from cold blooded animals suggests that they limit glutamate release from bipolar cells. The $GABA_B$ receptor agonist baclofen has been reported to enhance transient excitatory light responses, but suppress sustained, excitatory light responses in ganglion cells. However, the effects of $GABA_B$ receptor antagonists upon ganglion cells are relatively weak. Thus, there is some evidence for the presence of $GABA_B$ receptor in the inner retina, but it is unclear what the precise roles of this class of receptor are in retinal information processing.

Glycine

Glycine is the other major fast inhibitory neurotransmitter of the inner retina, and approximately one-half of all amacrine cells are glycinergic. Glycinergic amacrine cells are distinct from GABAergic amacrine cells because their processes have narrow fields that do not extend laterally. Unlike GABAergic amacrine cell processes, glycinergic cell processes extend vertically within the IPL and mediate signaling between different IPL layers. These distinct morphological features suggest that these two classes of inhibitory amacrine cells have different functional roles. The glycinergic, AII or rod amacrine cell is the best example of this principle; it receives input in the ON layers of the IPL and sends output in the OFF layer of the IPL. Glycine receptors are found presynaptically on the terminals of OFF cone and rod bipolar cells, and postsynaptically on the dendrites of amacrine and ganglion cells. Immunocytochemical labeling of receptor subunits suggests that there is a diversity of glycine receptors expressed in the inner retina, which may mediate distinct responses. However, additional physiological and pharmacological studies are needed to show that distinct glycine receptors play different roles in retinal signal processing.

There is strong evidence indicating that glycinergic inhibition plays several critical signaling roles in the retina. Glycine-mediated presynaptic inhibition from AII amacrine cells of OFF cone bipolar cells plays a critical role in rod-mediated signaling in the mammalian retina. Blocking this pathway with the specific antagonist strychnine eliminates rod-mediated OFF signals. Glycine also mediates change-sensitive surround inhibition in the retinas of lower vertebrates, which is distinct from the stationary surround inhibition, mediated by GABAergic amacrine cells.

Acetylcholine

Starburst amacrine cells are the main cholinergic neuron in the retina and they play a role in directionally sensitive (DS) responses, recorded in some ganglion cells. These cholinergic amacrine cells make synaptic contacts with directionally sensitive ganglion cells, other amacrine cells and some bipolar cell terminals via nicotinic acetylcholine (ACh) receptors. The inhibitory neurotransmitter GABA is co-localized with ACh in starburst amacrine cells. The genetic ablation of starburst amacrine cells eliminates DS responses. However DS responses are relatively unaffected when Ach receptors are blocked, suggesting that GABA signals from starburst amacrine cells may be more important for DS responses. Muscarinic ACh receptors are also found on various inner retinal neurons, but the function of these receptors is unclear.

Dopamine

Dopamine is the best-studied neuromodulator in the vertebrate retina. It is found in a small population of amacrine cells, which stain positively for the dopamine synthetic enzyme, tyrosine hydroxylase. Although the population of dopaminergic amacrine cells is small in number, their processes are wide ranging and tile or cover the entire retina. The fast inhibitory transmitter GABA is co-localized with dopamine in this class of amacrine cells. Dopamine receptors are found on most retinal neurons. In many species, dopamine acts as a paracrine substance that is released into the extracellular space to affect both local and distant targets. Dopamine is a chemical mediator of light adaptation in the retina. It acts in the outer retina to reduce signaling through rod pathways and enhance signaling through cone pathways. Dopamine also affects a number of inner retinal processes. Increased dopamine levels uncouple the electrical synapses between AII amacrine cells, reducing rod-mediated signaling. Dopamine may also modulate fast synaptic signaling by increasing the $GABA_A$ receptor mediated responses in amacrine cells and enhancing Ach release from cultured amacrine cells. In salamander retina, dopamine reduces $GABA_C$ receptor-mediated presynaptic inhibition of bipolar cell terminals, enhancing the excitatory drive to ganglion cells. Finally, dopamine affects the balance of center and surrounds receptive field inputs through its actions in the outer retina, where it reduces electrical coupling between horizontal cells.

Neuropeptides

A number of neuroactive peptides have been localized to specific populations of amacrine cells with immunocytochemistry. In other parts of the CNS, neuropeptides have modulatory roles and affect the actions of fast excitatory and inhibitory transmitters or the activity of voltage-gated channels to alter the excitability or transmitter release properties of neurons. Different populations of amacrine cells contain the following neuroactive peptides: neuropeptide Y, somatostatin, vasoactive intestinal polypeptide, and enkephalins. Calcium imaging studies suggest that both neuropeptide Y and somatostatin inhibit calcium currents in rod bipolar cell terminals. Presumably, these actions will limit glutamate release and reduce excitation in the rod signaling pathway. The precise mechanisms by which neuropeptides modify visual information processing in the retina remain unknown.

In summary, the inner retina is critical for visual processing. Information processing occurs in the second synaptic layer, the IPL. Glutamatergic, bipolar cells provide the excitatory input to the IPL and ganglion cells form the output. Excitatory signaling is shaped by postsynaptic AMPA and NMDA receptor properties, glutamate uptake and presynaptic inhibition. GABAergic and glycinergic inhibitory amacrine cells also shape the synaptic signaling between bipolar and ganglion cells. Together, these complex excitatory and inhibitory synaptic interactions mediate the temporal and spatial processing of visual information in the inner retina. Neuromodulators are thought to fine-tune fast excitatory and inhibitory signals. However, with the exception of dopamine, we still know relatively little about how these neuromodulators affect visual processing.

Retinitis Pigmentosa

E L Berson, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Retinitis pigmentosa has a prevalence of about 1 in 4000 worldwide. About 50 000–100 000 people are affected in the United States. Affected patients typically report night blindness in adolescence, loss of mid-peripheral vision in young adulthood, and loss of far peripheral and then central vision in middle life. Clinical findings on ophthalmoscopy include intraretinal pigment around the mid-peripheral retina for which the condition is named, attenuated retinal vessels, and waxy pallor of the optic disks. Histologic examinations of autopsy eyes have shown that loss of vision is due to degeneration of both rod and cone photoreceptor cells across the retina.

This group of diseases can be inherited by an autosomal dominant, autosomal recessive, X-linked, digenic, or mitochondrial mode of transmission; uniparental isodisomy has also been rarely reported. Assuming most isolate cases (i.e., cases with no relatives known to be affected) are inherited by an autosomal recessive mode, it is estimated that some 30–40% of cases are inherited as an autosomal dominant trait, 50–60% as an autosomal recessive trait, and 10–15% as an X-linked trait. Some 15% of all cases have associated partial hearing loss (Usher syndrome, type II) and another 2–6% have associated profound congenital deafness and vestibular ataxia (Usher syndrome, type I). About 1% of patients with retinitis pigmentosa have adult-onset hearing loss with or without ataxia (Usher syndrome, type III).

Retinitis pigmentosa can be detected in early life by electroretinographic testing. Electroretinograms (ERGs) are recorded in response to flashes of light with a contact lens electrode placed on the topically anesthetized cornea; responses are electronically amplified and displayed on an oscilloscope. Patients with early retinitis pigmentosa typically have reduced rod and cone ERG responses which are delayed in their peak implicit times (i.e., time interval between stimulus flash onset and the peak of the corresponding response). Abnormal ERGs have been detected in asymptomatic children years to a decade before diagnostic changes are seen on routine ocular examination. ERG amplitudes become smaller as the disease progresses (Figure 1). Most patients with remaining vision have detectable responses when ERGs are recorded with computer averaging and narrow bandpass filtering. Patients aged 6 and older with normal ERGs in families with retinitis pigmentosa have not been observed to develop this condition at a later time.

More than 100 gene loci that cause retinitis pigmentosa have been identified or mapped; an updated list of genes causing this condition is maintained on the RetNet website. Genes so far identified as causes of nonsyndromic retinitis pigmentosa as well as Usher syndrome are given in Table 1. Molecular genetic analyses have revealed defects in genes encoding proteins involved in the phototransduction cascade (see Figure 2), the retinoid cycle, maintenance of photoreceptor cell structure, cell–cell interactions, RNA intron-splicing factors, intracellular transport of proteins, regulation of carbon dioxide/bicarbonate balance, phagocystosis, and in yet-to-be-defined functions in the photoreceptors or retinal pigment epithelium. About 50–60% of cases of retinitis pigmentosa have known molecular genetic abnormalities.

Variability of clinical expression has been observed both within and between families among patients with the same gene defect, leading to the hypothesis that some factor or factors other than the gene defect itself contributes to the pathogenesis of disease. Light exposure, nutritional factors, and/or modifying genes have been proposed as possible risk factors that might contribute to severity of disease at a given age. More than 100 mutations have been found in the rhodopsin gene alone and severity of disease has been correlated with the region of the opsin molecule affected by a given mutation; for example, patients with a mutation near the C-terminus (e.g., rhodopsin, Pro347-Leu) have more severe disease at a given age than patients with a mutation near the N-terminus (e.g., rhodopsin, Pro23His). Mutations in the peripherin/RDS gene have been associated with retinitis pigmentosa, retinitis punctata albescens, and retinal degenerations primarily involving the macula, showing that abnormalities in the same gene can be associated with different phenotypes.

A severe form of retinitis pigmentosa is called Leber congenital amaurosis. Mutations in at least ten genes have been implicated as causes of this recessively inherited condition; these genes are GUCY2D, CRB1, IMPDH1, RPE65, AIPL1, RPGRIP1, RDH12, CRX, TULP1, and LRAT. Affected children are typically born with little, if any, vision, nystagmus, and hyperopia. Optical coherence tomography has revealed that patients with little vision may still have some remaining photoreceptor nuclei that might be amenable to treatment. Promising results in restoring retinal

Figure 1 ERG responses recorded in 1967 (a) and 1977 (b) from a normal subject and from four affected members of a family with a dominant form of retinitis pigmentosa transmitted over six generations. Pedigree number and age at time of testing are indicated for each patient. One to three responses to same stimulus are represented. For (a) and (b), rod-isolated responses to single flashes of blue-green light are illustrated in the left column; mixed cone–rod responses to single flashes of white light are illustrated in the middle column; and cone-isolated responses to 30 Hz white flickering light are illustrated in the right column. Calibration symbol for 1967 responses designates 50 ms horizontally for columns 1 and 2, 25 ms for column 3, 50 μV vertically for column 1, and 100 μV vertically for columns 2 and 3. Calibration symbol for 1977 responses designates 60 ms horizontally and 100 μV vertically for all tracings. Reproduced from Berson EL and Simonoff EA (1979) Dominant retinitis pigmentosa with reduced penetrance: Further studies of the electroretinogram. *Archives of Ophthalmology* 97: 1286–1291, with permission from American Medical Association. function have been achieved with a viral-mediated subretinal injection of the RPE65 gene in a canine model and the RPGRIP gene in a murine model of this group of diseases when treatment is initiated at a time when these models have remaining photoreceptors. It remains to be established whether viral-mediated gene therapy is safe and effective in humans with the early stages of Leber congenital amaurosis.

Retinitis pigmentosa has been associated not only with hearing loss but also with polydactyly, mental retardation, truncal obesity, and hypogonadism (Laurence–Moon–Bardet–Biedl syndrome). Some clinicians have subdivided this syndrome into two disorders; polydactyly is found primarily in patients with the Bardet–Biedl form, and neurological abnormalities are found usually in patients with the Laurence–Moon form. Variability of clinical expression is well known and some patients may have this condition without mental retardation or polydactyly. Mutations in at least nine genes have so far been identified (i.e., BBS1, BBS2, ARL6, BBS4, BBS5, MKKS, BBS7, TTC8, and PHTB1). Renal disease occurs in some cases; therefore, patients should have their blood pressure and urine checked periodically. No treatment is known for the retinal degeneration observed in some 90% of patients with this syndrome.

Retinitis pigmentosa is also found in association with anosmia, ataxia, dry skin, and EKG abnormalities with elevated serum phytanic acid (Refsum disease); malabsorption, acanthocytosis, ataxia, and abetalipoproteinemia (Bassen–Kornzweig syndrome); and adult-onset ataxia, dysarthria, hyporeflexia, decreased proprioception, decreased vibration sense, and low serum vitamin E levels (Friedreich-like ataxia with retinitis pigmentosa). These uncommon recessively inherited conditions are treatable as follows: a low phytol/low phytanic acid diet (excluding animal fats, milk products, and dark green leafy vegetables) in the case of Refsum disease; a low-fat diet plus supplementation with vitamin A, vitamin E, and vitamin K in the case of Bassen–Kornzweig syndrome, and vitamin E supplementation in the case of Friedreich-like ataxia associated with retinitis pigmentosa.

The common forms of retinitis pigmentosa have also yielded to treatment. In a randomized, controlled double-masked trial among 601 patients aged 18–49, the course of retinal degeneration as monitored by the ERG was slower on average among patients taking a daily supplement of vitamin A palmitate, 15 000 IU day^{-1}, than among those not on this dose. Furthermore, the course appeared to be faster on average among patients taking a daily supplement of 400 IU day^{-1} of vitamin

Table 1 Estimated proportions of cases of retinitis pigmentosa (RP) caused by Identified genes (excluding syndromic RP except for Usher syndrome)

Inheritance pattern/gene	*Percent of all RP (including Usher syndrome)*
Autosomal dominant (~40% of all cases of retinitis pigmentosa)	
1. RHO (rhodopsin) (3q)	10%
2. RP1 (8q)	2.2%
3. PRPF31 (19q)	2.0%
4. PRPF3 (1q)	1.6%
5. peripherin/RDS (6p)	~1%
6. FSCN2 (fascin) (17q)	~1%
7. PRPF8 (17p)	0.8%
8. IMPDH1 (7q)	0.8%
9. NRL (14q)	0.4%
10. CRX (19q)	0.4%
11. CA4 (carbonic anhydrase) (17q)	? frequency in USA (~2% in UK)
12. PAP1 (7p)	<1%
13. SEMA4A (semaphorin) (1q)	<1%
Autosomal recessive (~50% of all cases of retinitis pigmentosa, including isolates)	
14. usherin (1q)	~10% (Usher IIA)
15. rod PDEβ (4p)	2%
16. rod PDEα (5q)	1.5%
17. CNGA1 (rod channel α (4p)	1%
18. RPE65 (1p)	1%
19. myosin VIIa (11q)	~1% (Usher IB)
20. LRAT (4q)	<1%
21. NR2E3 (15q)	<1%
22. MERTK (2q)	<1%
23. harmonin (11p)	<1% (Usher IC)
24. CDH23 (10q)	<1% (Usher ID)
25. PCDH15 (10q)	<1% (Usher IF)
26. MASS1 (5q)	<1% (Usher IIC)
27. clarin-1 (3q)	<1% (Usher IIIA)
28. SAG (arrestin) (2q)	~0.5%
29. CRALBP (15q)	~0.5%
30. RHO (rhodopsin) (3q)	~0.5%
31. TULP1 (6q)	~0.5%
32. ABCA4 (i.e., ABCR) (1p)	<1%
33. RGR (10q)	<1%
34. CRB1 (1q)	<1%
35. CERKL (2q)	<1%
36. CNGB1 (rod channel β) (16q)	<1%
37. SANS (17q)	<1% (Usher 1G)
38. RP1 (8q)	<1%
X-linked (~10% of all cases of retinitis pigmentosa)	
39. RPGR (Xp21.1)	8% (RPGR and RP2 combined account for 1%
40. RP2 (Xp11.3)	~90% of XLRP)
Digenic (only a few families)	
41. ROM1 (11q) and peripherin/RDS (6p)	<1%
Mitochondrial (only one family)	
42. MTTS2	<1%

Percentages are approximate and are based on the breakdown of RP cases according to genetic type reported by Fishman (*Archives of Ophthalmology* 96: 822–826, 1978), Macrae (*Birth Defects: Original Article Series* 18: 175–185, 1982), and Bunker et al. (*American Journal of Ophthalmology* 97: 357–365, 1984) and on the assumptions that all isolate cases are autosomal recessive and that about one-third of cases of Usher syndrome type I (approximately 6% of all cases of RP) are caused by defects in myosin VIIa. The values are calculated based on frequency of cases in a published series multiplied by the proportion of RP with that inheritance pattern (e.g., dominant rhodopsin mutations were found in 90/363 cases of ADRP; ADRP accounts for about 40% of all cases of RP; accordingly, the percentage of cases caused by dominant rhodopsin mutations is $90/363 = 24.8\% \times 0.4 = 9.92 \approx 10\%$).
A current referenced list of genes causing retinitis pigmentosa and allied retinal diseases can be accessed on the world wide web at: http://www.sph.uth.tmc.edu/Retnet/sum-dis.htm.

Figure 2 Schematic representation of some proteins normally found in the rod photoreceptor outer segment, interphotoreceptor matrix, and retinal pigment epithelium. Genes encoding these proteins are considered candidate genes that could cause retinitis pigmentosa because mutations in them could result in compromise of the phototransduction cascade or the mechanism by which vitamin A is transported between the photoreceptors and the pigment epithelium with consequent photoreceptor cell degeneration. IRBP, interphotoreceptor retinoid binding protein; CRBP, cellular retinol-binding protein; CRALBP, cellular retinal-binding protein; PDE, phosphodiesterase; ROM1, rod outer segment membrane protein 1; cGMP, cyclic guanosine monophosphate. E than those not on this dose. This has led to the recommendation that most adult patients with the common forms of retinitis pigmentosa should take a daily supplement of 15 000 IU of vitamin A in the palmitate form under the supervision of their physician and avoid high-dose supplementation with vitamin E. Since doses of $>25\,000\,\mathrm{IU\,day^{-1}}$ of preformed vitamin A can be associated with liver disease when taken over the long term, patients should have a fasting serum vitamin A and liver function profile before commencing this treatment and measures of these parameters annually thereafter while on this supplement. Beta-carotene is not predictably converted to preformed vitamin A and therefore should not be considered as a substitute for treatment with vitamin A palmitate. Sources of the appropriate dose of vitamin A palmitate are maintained on the website of the Foundation Fighting Blindness.

No toxic effects have been observed in adults with retinitis pigmentosa in good general health on this supplement of vitamin A who have been followed for up to 12 years. Because of the increased risk of birth defects associated with high-dose vitamin A supplementation, women who are pregnant or planning to become pregnant should not take this supplement. Long-term vitamin A supplementation has been associated with a decrease in bone density and up to a 1% increase in risk of hip fracture; therefore, postmenopausal women and men aged 49 and above with retinitis pigmentosa taking vitamin A should have their bone health monitored periodically by their family doctor. Since patients under age 18 were not included in this trial, no formal recommendation can be made for patients with retinitis pigmentosa under this age.

A second randomized, controlled, double-masked trial for retinitis pigmentosa revealed that docosahexaenoic acid (DHA) supplementation in a dose of $1200\,\mathrm{mg\,day^{-1}}$ did not, on average, provide benefit for adults also taking vitamin A $15\,000\,\mathrm{IU\,day^{-1}}$. However, a subgroup analysis revealed that those taking vitamin A who ate two or more 3-ounce servings of oily fish per week (i.e., salmon, tuna, herring, mackerel, or sardines) of which DHA is a major constituent showed a 40–50% slowing of annual decline in visual field sensitivity. It has been estimated that the combination of vitamin A palmitate $15\,000\,\mathrm{IU\,day^{-1}}$ and a diet rich in oily fish could result in almost 20 years of additional visual preservation. The average patient who starts this regimen in his or her thirties would be expected to retain some useful vision until about age 80 in contrast to an

untreated patient who would be expected to be virtually blind by age 60.

Night vision devices are available that amplify light and thereby allow patients with retinitis pigmentosa and night blindness to use their remaining cones to function under dim daylight, moonlight, or even starlight conditions. The best candidates for these devices are patients with best corrected vision of better than 20/200 in at least one eye and a central visual field diameter of >20° in that eye. For patients with reduced visual acuity, a closed circuit television for reading is helpful in some instances. Patients with retinitis pigmentosa should avoid exposure to bright sunlight outdoors until more is known about whether exposure to sunlight affects the course of this condition. Since no particular type of sunglass has been shown to alter the course of retinal degeneration, patients should select sunglasses for outdoor use that provide maximal protection from sunlight without compromising vision.

The precise cellular mechanisms that lead to photoreceptor cell death are under study. Among the questions remaining to be answered are why rod-specific gene defects lead to cone photoreceptor cell death and whether the process of apoptosis (or genetically programmed cell death) can help to explain pathogenesis. Efforts to replace degenerated photoreceptor cells through transplantation of healthy photoreceptor cells in the subretinal space have so far proved unsuccessful as the implanted photoreceptors have not formed functional connections with the proximal retina necessary for the transmission of visual information to the brain. Light-sensitive microchips implanted on or under the retina are under study but their value remains to be established. Studies are in progress to rescue remaining photoreceptor cells with ciliary neurotrophic factor (CNTF), gene therapy, or other nutritional supplements. A multidisciplined approach combining biochemistry, electrophysiology, molecular and cell biology, and ophthalmology would appear to have the greatest chance of making new discoveries that will benefit patients with this group of diseases.

Retinoic Acid Signaling and Neural Patterning

Retinoic Acid Signaling Plays a Role in Patterning of the Posterior Central Nervous System

During gastrulation, the rostral–caudal axis of the mammalian central nervous system (CNS) is progressively laid down in an anterior to posterior fashion as primitive ectoderm in the epiblast differentiates into neuroectoderm. Various signaling pathways direct specific regions of the neuroectoderm to adopt forebrain, midbrain, hindbrain, or spinal cord fates. One of these signals is retinoic acid (RA), a lipid derived from metabolism of vitamin A (retinol). RA is not synthesized during early gastrulation, when the forebrain and midbrain fields are established (embryonic day E6.5–E7.5 in mouse embryos). However, at E7.5, RA synthesis begins specifically in the posterior paraxial mesoderm (presomitic mesoderm). From E7.5 to E8.5, mesoderm provides RA in a paracrine fashion to nearby neuroectoderm fated to become hindbrain and spinal cord, but RA does not reach the forebrain or midbrain. RA regulation of gene expression in the hindbrain helps define its patterning along the anteroposterior axis into discrete units called rhombomeres. In addition, RA control of gene expression in spinal cord neuroectoderm is required for dorsoventral patterning events leading to formation of motor neurons ventrally. Thus, RA is required for patterning of the posterior CNS (hindbrain and spinal cord), but not the anterior CNS (forebrain and midbrain).

Spatiotemporal Aspects of RA Signaling in Early Mouse Embryos

The establishment of when and where RA signaling occurs in mouse embryos has been instrumental in defining the role of RA in neural patterning. One approach has been to establish the identity and expression patterns of RA receptors and enzymes that may synthesize RA. RA serves as a ligand for three nuclear RA receptors (RARs) that bind DNA as heterodimers with retinoid X receptors (RXR). Under physiological conditions (normal dietary sources of vitamin A), RA is found only in the form known as all-*trans*-RA, which binds to RAR but not RXR, but under pharmacological conditions (vitamin A excess), the isomer 9-*cis*-RA is formed and can bind to both RAR and RXR. However, several studies have demonstrated that physiological RA signaling requires only binding of all-*trans*-RA to the RAR component of RAR/RXR heterodimers. During early stages of mouse development, expression of RARα and RARγ is widespread throughout the developing CNS, but RARβ expression is limited to hindbrain and spinal cord. Thus, RA signaling could potentially occur throughout the CNS because of the presence of RARα and RARγ. However, the location of RA signaling will also depend on the location of RA synthesis, which is not as widespread as RAR expression.

RA synthesis is a two-step process in which retinol is reversibly oxidized to retinaldehyde, followed by irreversible oxidation of retinaldehyde to RA. Several members of the alcohol dehydrogenase and short-chain dehydrogenase/reductase enzyme families catalyze oxidation of retinol to retinaldehyde in many tissues in an overlapping fashion such that it is essentially ubiquitous. In contrast, oxidation of retinaldehyde to RA is carried out by three nonoverlapping, tissue-specific retinaldehyde dehydrogenases encoded by *Raldh1*, *Raldh2*, and *Raldh3* (*Aldh1a1*, *Aldh1a2*, and *Aldh1a3* in the Mouse Genome Informatics database). These three *Raldh* genes are conserved in human, mouse, and several lower vertebrates. It has been demonstrated that *Raldh* genes determine where RA signaling occurs as mouse embryos carrying the *RARE–lacZ* RA-reporter transgene plus a null mutation of *Raldh1*, *Raldh2*, or *Raldh3* selectively lose *RARE–lacZ* expression in the location where that *Raldh* gene is normally expressed. *RARE–lacZ* expression is first observed at E7.5 in the posterior mesoderm (where *Raldh2* is expressed), as well as the adjacent posterior neuroectoderm and endoderm. As *Raldh1* and *Raldh3* are not expressed until E8.5 and E9.5, respectively, only *Raldh2* is involved in generating RA for early CNS patterning. Also, studies of null mutant embryos indicate that *Raldh1* and *Raldh3* generate RA for eye morphogenetic movements but not for CNS patterning.

Raldh2 is the only source of RA for CNS patterning, but not the only determinant of where RA signaling can occur. Selective RA degradation by P450 enzymes encoded by the *Cyp26* family has been found to limit how far anteriorly and posteriorly RA can travel from its site of synthesis by *Raldh2* in the posterior mesoderm (presomitic and somitic). Thus, RA signaling does not occur throughout the CNS during early neural patterning but only in the hindbrain and spinal cord (**Figure 1**).

Figure 1 Retinoic acid (RA) signaling in early mouse embryos. (a) The *RARE–lacZ* RA-reporter transgene demonstrates that RA signaling activity in the central nervous system (CNS) at the six-somite stage is limited to the posterior hindbrain and spinal cord; no activity is observed in the forebrain or midbrain. (b) The only source of RA for the CNS at the six-somite stage is *Raldh2* expressed in the somitic and lateral plate mesoderm; *Raldh2* functions in a paracrine fashion by synthesizing RA in mesoderm which diffuses to the hindbrain and spinal cord neuroectoderm. fb, forebrain; hb, hindbrain; lpm, lateral plate mesoderm; mb, midbrain; ps, primitive streak; s, somite; sc, spinal cord.

RA Is Not Required for Neural Induction

In amniote vertebrate embryos, the primitive ectoderm (epiblast) consists of a pluripotent embryonic stem cell population which differentiates during primitive streak formation (gastrulation) to produce the three primary germ layers (embryonic ectoderm, mesoderm, and endoderm). As development proceeds, the primitive streak stem cell zone regresses posteriorly, and ectodermal cells emerging from the primitive streak differentiate into either neuroectoderm or epidermis in the process of neural induction. Neural induction has been found to require bone morphogenetic protein (BMP) antagonists produced in underlying mesoderm generated in the primitive streak as well as fibroblast growth factor (FGF) produced in the primitive streak. As the body axis extends, anterior neuroectoderm (forebrain/midbrain) becomes differentiated from posterior neuroectoderm (hindbrain/spinal cord) at an early stage. Posterior expansion of the hindbrain and loss of the forebrain on administration of exogenous RA to amphibian, avian, and mammalian embryos suggested that RA may be a factor normally needed to define the posterior CNS. However, as RA treatment of embryonic stem cells stimulates differentiation to neuroectoderm, it was unclear for some time whether RA is normally needed for neural induction. As ectoderm emerges from the primitive streak, *Sox1* and *Sox2*, encoding high-mobility group transcription factors, are expressed in ectoderm that has undergone neural induction to form neuroectoderm; expression occurs all along the CNS, from the forebrain to the spinal cord. *Sox1* and *Sox2* expression differentiates neuroectoderm from nonneural ectoderm, which will form epidermis. Studies on *Raldh2*$^{-/-}$ embryos has demonstrated that expression of *Sox1* and *Sox2* is not changed in the absence of RA signaling. Thus, although exogenous RA treatment has been reported to increase *Sox1* expression in mouse embryonic stem cells, endogenous RA is not required for normal induction of *Sox1* in the mouse embryo neural plate. These findings indicate that RA is not required to generate neuroectoderm. RA does, however, play a role in patterning the neuroectoderm as discussed in the section titled 'Role of RA in spinal cord dorsoventral patterning.'

Role of RA in Hindbrain Anteroposterior Patterning

During early CNS development, the hindbrain is patterned along the anteroposterior axis into segments known as rhombomeres. Studies on vitamin A-deficient quail embryos reported that a loss of the precursor for RA results in loss of rhombomeres 4–8 (r4–r8) and that the remaining hindbrain consisted of an enlarged r1–r3 joined to the anterior spinal cord. A similar phenotype was also observed in *Raldh2*$^{-/-}$ mouse embryos, vitamin A deficient rat embryos, and chick embryos treated with an RA receptor antagonist. Markers of r4 were also lost, including expression of *Hoxb1* encoding a homeobox gene and *Cyp26c1* encoding an RA-degrading enzyme.

Neural expression of *Hox* genes is limited to the posterior CNS, where these genes play essential roles in rhombomere formation. Several members of the vertebrate *Hox* gene family are direct targets of RA signaling during hindbrain development, including *Hoxb1*, whose anterior-most expression domain is in r4, located in the middle of the hindbrain. The mouse *Hoxb1* gene is regulated by an RA response element (RARE) located 3′ to the promoter that is required for early widespread induction in the posterior hindbrain up to the presumptive r3–r4 boundary, as well as another RARE located 5′ to the promoter

that has been demonstrated to be required for repression of *Hoxb1* in r3 and r5 to provide restricted expression in r4. However, *Hoxb1* r4 expression is also repressed by the homeodomain protein encoded by *vHnf1* (*Tcf2*), which is expressed in the spinal cord and posterior hindbrain up to the r4–r5 boundary. It is interesting that *vHnf1* is also inducible by RA. Studies using the *RARE–lacZ* RA reporter transgene have shown that rhombomere 3 is the anterior-most location of RA signaling during early CNS patterning but that RA activity is very transient in r3 and r4, lasting only a few hours. Transient RA activity in r3 and r4 has been found to be due to expression of RA-degrading P450s in the hindbrain. Three RA-degrading P450s encoded by *Cyp26a1*, *Cyp26b1*, and *Cyp26c1* are expressed in dynamic patterns during hindbrain development. It is now clear that the RA signal initially travels from the presomitic mesoderm (where *Raldh2* is expressed) to r3, forming a boundary next to the r2 expression domain of *Cyp26a1*. After *Hoxb1* induction, the RA boundary quickly shifts to r4–r5, coincident with induction of *Cyp26c1* in r4. Thus, during a brief period in development, RA is present in r4 to induce *Hoxb1*. Analysis of *Raldh2*$^{-/-}$ embryos has provided support for a direct role of endogenous RA signaling in *Hoxb1* induction up to r4 and repression in r3–r5 through earlier described 3′ and 5′ RAREs. Also, *Raldh2*$^{-/-}$ embryos have demonstrated that endogenous RA induces *Cyp26c1* in r4 as well as *vHnf1* posterior to the r4–r5 boundary. As *vHnf1*$^{-/-}$ embryos exhibit ectopic expression of *Hoxb1* in r5, this has provided evidence for an indirect role of RA in *Hoxb1* repression via RA induction of *vHnf1*.

It is important to note that these studies have demonstrated the existence of shifting RA boundaries in the hindbrain, as opposed to an RA gradient. *Raldh2* and *Cyp26* generate at least two distinct boundaries of RA activity along the anteroposterior axis of the hindbrain, first at r2–r3 and then at r4–r5, such that r3–r4 receives a short pulse of RA and r5–r8 receives a long pulse of RA. These two pulses of RA activity provide patterning by establishing expression of *Hoxb1* and *vHnf1* on opposite sides of the r4–r5 boundary.

Role of RA in Spinal Cord Dorsoventral Patterning

RA is required for early dorsoventral patterning of the spinal cord to generate motor neuron progenitors and later for specifying motor neuron subtype identity. RA also plays a role in assignment of positional identity of motor neurons along the anteroposterior axis of the spinal cord to generate unique neurons that innervate forelimbs, trunk, and hindlimbs. Anteroposterior effects of RA along the spinal cord are mediated primarily by regulation of *Hox* genes, similar to the role of RA in the hindbrain. In contrast, dorsoventral patterning of the spinal cord involves several different transcription factors, including the homeobox transcription factors *Pax6* and *Nkx6.1*, which are expressed dorsally and ventrally, respectively. In the region where overlapping expression of *Pax6* and *Nkx6.1* occurs (future ventral horns), the basic helix–loop–helix transcription factor *Olig2* is expressed. Genetic studies in the mouse have demonstrated that *Olig2* is required for spinal cord motor neuron differentiation. Secreted signals important for establishing spinal cord dorsoventral patterning include *Shh* expressed ventrally, *Bmp* expressed dorsally, and RA synthesized in the adjacent somitic mesoderm. A lack of RA synthesis in *Raldh2*$^{-/-}$ mouse embryos results in a loss of *Pax6* and *Olig2* expression in the spinal cord, whereas *Nkx6.1* expression remains, suggesting that *Nkx6.1* does not require RA for expression. This requirement for RA during spinal cord patterning is conserved between mammalian and avian embryos, and studies on avian embryos suggest that *Pax6* and *Olig2* are both direct targets of RA action. RA is thus needed as an additional trigger, along with *Pax6* and *Nkx6.1*, to allow induction of *Olig2*, which then stimulates undifferentiated spinal cord neuroectoderm to acquire a ventral motor neuron cell fate.

Early studies in avian embryos suggested that *Raldh2* may be responsible for synthesizing RA needed for spinal cord motor neuron differentiation as *Raldh2* is expressed in somitic mesoderm adjacent to the neural tube. Genetic studies have now shown that *Raldh2* is responsible for all RA detected posteriorly in mouse embryos at E8.5 and that *Raldh2* is necessary for *Olig2* expression in the spinal cord. The extent of RA distribution from sites of *Raldh2* expression during spinal cord development has been examined in mouse embryos. *RARE–lacZ* RA–reporter expression is observed in trunk mesoderm and throughout the dorsoventral axis of the spinal cord, demonstrating that RA synthesized by *Raldh2* in the somites can travel to all portions of the spinal cord. These findings provide evidence that RA functions exclusively in a paracrine fashion during early spinal cord patterning. As RA is not localized to any particular region of the spinal cord, this may explain its ability to induce not only *Olig2*, which is limited to the developing motor neuron domain located ventrally, but also *Pax6*, which is expressed more widely across the dorsoventral axis of the neural tube.

Development of *Raldh2*$^{-/-}$ embryos can be substantially rescued by a low-dose maternal dietary RA

supplement that returns embryonic RA levels to approximately the same level observed in wild-type embryos. Such treatment can rescue *Olig2* expression in *Raldh2*$^{-/-}$ embryos. It is interesting that *RARE–lacZ* expression in rescued *Raldh2*$^{-/-}$ embryos occurs throughout the spinal cord and posterior hindbrain, similar to wild-type, but unlike wild-type, there was no detection of *RARE–lacZ* in the somitic mesoderm, which is normally the source of RA. This phenomenon is clearly dose dependent as large doses of exogenous RA will induce *RARE–lacZ* in all cells of the embryo. These findings suggest that the low dose of exogenous RA entering the embryo was not distributed evenly. RA may be preferentially sequestered in the posterior CNS as it is known that cellular RA binding protein II (*Crabp2*) is expressed highly in the spinal cord and hindbrain but not in mesoderm. As the normal site of RA synthesis in the somitic mesoderm did not exhibit RA signaling activity in *Raldh2*$^{-/-}$ embryos under these rescue conditions, it may be that RA does not need to perform an additional function in the mesoderm during spinal cord dorsoventral patterning; the somitic mesoderm is simply acting as a source of RA. The rationale for such RA signaling may be to coordinate motor neuron differentiation with mesodermal differentiation along the anteroposterior axis as cells emerge from the primitive streak.

Many of the above observations were made possible through the use of mouse embryos carrying the *RARE–lacZ* transgene, which enables one to follow where endogenous RA signaling activity occurs in wild-type embryos and where RA signaling occurs in *Raldh2*$^{-/-}$ embryos rescued by maternal RA treatment. Such experiments have not been possible in avian, amphibian, or fish embryos because of lack of a transgene that can serve as an RA reporter during the early stages of neural development. This highlights the importance of the mouse in studies designed to understand the mechanism of RA action in the CNS.

RA Antagonism of *Fgf8* Expression in the Primitive Streak Controls Posterior Patterning

FGF signaling controlled by *Fgf8* is particularly important in the mouse as it is necessary for neural induction in the posterior CNS as well as generation of mesoderm during gastrulation. Early studies suggested that presomitic mesoderm emerging from the primitive streak provides another signal needed for differentiation of the posterior CNS, that is, a signal that antagonizes posterior FGF signaling mediated by *Fgf8*. Recent studies in avian, mouse, and zebra fish embryos indicate that RA generated by *Raldh2* is the presomitic mesodermal factor that antagonizes *Fgf8* action. The concept of embryonic tissue differentiation occurring in regions of opposing RA and FGF signals was originally proposed in studies of proximodistal outgrowth of chick limb buds where *Raldh2* and *Fgf8* also function to generate opposing RA and FGF signals.

Fgf8 is normally expressed in the primitive streak, but its expression is extinguished anteriorly as cells exit the streak. Studies in avian, mouse, and zebra fish embryos indicate that RA functions as an antagonist of posterior *Fgf8* expression. In particular, RA functions to limit the anteroposterior extent of *Fgf8* expression and confines it to the primitive streak or tailbud. Whether this reflects a direct effect of RA on the *Fgf8* gene remains to be determined, but a conserved RARE is found in the promoter regions of human, mouse, and rat *Fgf8* genes. This function is consistent with the observation that *RARE–lacZ* expression in mouse embryos is high in tissues anterior to the primitive streak, then progressively much weaker in the primitive streak itself. Primitive neuroectodermal cells thus exist in a zone of high FGF8 and low RA signaling, but on exiting the primitive streak anteriorly, these cells enter a zone of high RA emanating from the directly adjacent somitic mesoderm, which downregulates *Fgf8* and stimulates neuronal differentiation.

RA also controls left–right patterning of somite pair formation, and this is proposed to function via antagonism of *Fgf8* expression in neuroectoderm. RA synthesized in presomitic mesoderm by *Raldh2* is required to maintain bilateral symmetry between the left and right somite columns; for instance, loss of RA can result in embryos displaying 11 somites on the left side but only nine somites on the right side. Presomitic mesoderm in mouse *Raldh2*$^{-/-}$ embryos displays left–right asymmetric expression of *Hes7* and *Lfng*, required for periodic mesodermal segmentation, suggesting that a loss of RA allows left–right asymmetry to occur in presomitic mesoderm, where it normally does not occur. On the other hand, lateral plate mesoderm (where left–right asymmetry normally occurs) still maintains left–right asymmetry of key genes, including *Nodal* and *Pitx2* in *Raldh2*$^{-/-}$ embryos. RA thus acts as a buffer to prevent left–right asymmetry from occurring in presomitic mesoderm. In the 'clock and wavefront' model of somitogenesis, a moving wavefront of *Fgf8* gene expression in the primitive streak regresses posteriorly as the body axis extends, and mesodermal segmentation occurs just anterior to the *Fgf8* expression domain. FGF8 signaling also plays a required role in the node, a structure located anteromedially in the primitive streak that produces

left–right asymmetry in the lateral plate mesoderm. As *Fgf8* mRNA is not detected in the node, nearby cells in the epiblast ectoderm that do express *Fgf8* mRNA evidently secrete FGF8 that travels to the node. A hypothesis for how RA functions to prevent somite left–right asymmetry states that by limiting the anterior extent of *Fgf8* expression in the ectoderm, RA ensures that FGF8 signaling in the node is not excessive.

RA signaling monitored with *RARE–lacZ* exhibits no left–right difference in presomitic or lateral plate mesoderm at early somite stages, and RA activity extends from the posterior neural plate into node ectoderm, where it meets the *Fgf8* expression domain in the epiblast (primitive ectoderm) and then fades out. Although RA activity exists in presomitic mesoderm, it is absent in node mesoderm. Thus, it appears that RA functions in node ectoderm during somite left–right patterning. *Raldh2*$^{-/-}$ embryos exhibit a bilateral anterior shift of *Fgf8* expression into node ectoderm and neural plate, where it normally is not expressed. It is important to note that a loss of RA does not result in an anterior advance of *Fgf8* expression in presomitic mesoderm (which normally expresses *Fgf8* at a lower level than that seen in primitive ectoderm), and no ectopic *Fgf8* expression is observed in node mesoderm. These findings have provided evidence that the site of RA action during control of left–right asymmetry is the node ectoderm and adjacent neural plate.

Somite left–right patterning defects in *Raldh2*$^{-/-}$ embryos can be rescued with low-dose maternal dietary RA supplementation. It is interesting that RA provided to only the six-somite stage rescues somite patterning defects until at least the 25-somite stage. Thus, RA is needed only during a short time frame early in somitogenesis. Studies on rescued *Raldh2*$^{-/-}$ embryos carrying *RARE–lacZ* have provided further evidence that the site of RA action during control of left–right asymmetry is the node ectoderm and adjacent neural plate. Examination of such embryos at somite stages 2–10 revealed no *RARE–lacZ* expression in somitic or presomitic mesoderm (normally the source of RA), but *RARE–lacZ* was expressed in posterior neural plate and node ectoderm. As mentioned earlier, selective action of RA in neuroectodermal tissues may be due to expression of *Crabp2* that functions to sequester RA.

The limited time frame needed for RA action to correct somite left–right asymmetry is likely due to a transient RA requirement in the node as the node regresses after the ten-somite stage. At the two-somite stage, *Raldh2* is expressed in posterior presomitic mesoderm lying lateral to the node, whereas at the ten-somite stage, *Raldh2* is no longer expressed in presomitic mesoderm but remains in somites. Consistent with this observation, *RARE–lacZ* expression is present in the posterior neuroectoderm and node ectoderm during early stages but later retracts anteriorly such that by the ten-somite stage, there is no longer RA activity in the posterior neuroectoderm adjacent to the presomitic mesoderm; RA activity remains in neuroectoderm adjacent to the somites that have formed. These findings provide evidence that after the node regresses, RA is no longer needed to limit *Fgf8* expression posteriorly.

RA Acts in a Paracrine Fashion to Regulate Posterior CNS Patterning

As *Raldh2* and *RARE–lacZ* are normally expressed in presomitic and somitic mesoderm, it was initially presumed that RA functions locally in these mesodermal tissues during somite formation as well as in the adjacent neuroectoderm, where *RARE–lacZ* expression is also observed. However, studies on RA-rescued *Raldh2*$^{-/-}$ embryos demonstrate that RA needs to function only in the adjacent node ectoderm and neural plate to regulate early somite patterning, plus in the neuroectoderm of the hindbrain and spinal cord to regulate posterior CNS patterning. Thus, RA generated by *Raldh2* in mesoderm may function solely as a paracrine signal as no autocrine function has been uncovered.

Retinomotor Movements

Nature and Occurrence

In many species, photoreceptors and retinal pigment epithelium (RPE) undergo positional rearrangements, called retinomotor movements, in response to changes in ambient light conditions and to circadian signals. Retinomotor movements are achieved by elongation and contraction of rod and cone photoreceptors and by migration of melanin pigment granules (melanosomes) within the apical projections of the RPE (Figure 1). In the light, cones shorten, rods elongate, and pigment granules disperse into the long apical projections of the RPE cells, thus positioning the cones closest to incoming light and burying the rod outer segments in the shielding pigment of the RPE. In the dark, these movements are reversed: RPE pigment granules aggregate to expose the rod outer segments and rods shorten to move their outer segments in front of those of the elongating cones. Thus in the dark (night) the retina is morphologically optimized for dim light reception with rods contracted to position their outer segments first in line for detection of incoming light, while in the light (day) the retina is optimized for bright light vision with cone outer segments first in line and rod outer segments protected from bleach by RPE pigment.

Though the cones of some fish may elongate and contract as much as 80 μm, most cone length changes range from 15 to 40 μm. Rod length changes are usually more modest. Since rates of elongation and contraction are in the 1–4 $\mu m\ min^{-1}$ range, the transition from light-adapted to dark-adapted positions and vice versa are relatively time consuming, requiring as much as 60 min in species with extensive movements. This slowness may explain why mammals deploy the more agile strategy of pupillary movement for adapting the eye to differing light intensities. Though faster, the pupillary movement strategy forfeits the use of the entire light capture area of the retina for both photopic (cone) and scotopic (rod) vision.

Because these dramatic morphological changes can be easily detected by light microscopy of sectioned retinas, many of the earliest studies of retinal morphology concerned the properties and species distributions of retinomotor movements, the first by Kühne in 1856. The late eighteenth and early nineteenth century produced an astonishingly large literature describing retinomotor movements among the vertebrate groups. Modest or nonexistent in mammals, urodeles, and reptiles, retinomotor movements are more robust and common in anurans and birds, and most elaborate and widely distributed in fishes with duplex retinas. In the pure cone retinas of early fish larvae and in the pure rod retinas of benthic fishes, retinomotor movements are absent.

Retinomotor movements are not only regulated by light but also by an endogenous circadian rhythm. When animals are maintained in constant darkness, retinomotor movements persist at expected dawn and dusk. In constant illumination, the cycles of retinomotor movements are abolished. In most species circadian cone movements mimic those of the diurnal cycle at reduced amplitude, but in some species they are more variable. Circadian retinomotor movements of cones have been observed in most fish species studied; circadian retinomotor movements of rods and RPE are considerably less common. In all species so far studied, cones contract to assume their light-adaptive retinomotor positions in anticipation of expected dawn; thus for the fish in their natural environment, circadian signals appear to be more important regulators of cone contraction than light.

Mechanisms of Force Production for Retinomotor Movements

Many of the early studies of retinomotor movement grappled with whether retinomotor movements required energy or were passive accommodations of other forces. Subsequent studies with isolated cells have made it clear that rod, cone, and RPE retinomotor movements can each occur in the absence of other cell types and indeed in the absence of the rest of the retina; thus, force production for cell elongation, contraction, and for pigment migration appears to be autonomous for each cell type.

The Photoreceptor Cytoskeleton and Force Production for Elongation and Contraction

Contraction and elongation take place in the inner segment, that is, the part of the photoreceptor between the photopigment-bearing outer segment and the junctional complexes of the outer limiting membrane, where the photoreceptors are attached to the supportive Müller cells of the retina. Thus, the motile portions of the photoreceptors protrude into the subretinal space between the retina and the RPE,

Figure 1 Retinomotor positions of rods, cones, and RPE in light- and dark-adapted fish retinas (drawn from the green sunfish *Lepomis cyanellus*). (a) In dark-adapted retinas, cone myoids are long, rod myoids are short, and pigment granules are aggregated to the base of the RPE cell near Bruch's membrane. (b) In light-adapted retinas, cone myoids are short, rod myoids are long, and pigment granules have migrated into the long apical projections (ap) of the RPE. cos, cone outer segment; ce, cone ellipsoid; ros, rod outer segment; e, rod ellipsoid. Scale bar = 10 μm. Reproduced from Burnside B and Nagle B (1983) Retinomotor movements of photoreceptors and retinal pigment epithelium: Mechanisms and regulation. In: Osborne N and Chader GJ (eds.) *Progress in Retinal Research,* vol. 2, pp. 67–109. Oxford: Pergamon, with permission from Elsevier.

where they interdigitate with the long apical projections of the RPE cells (Figures 1 and 2). The interphotoreceptor matrix filling the subretinal space thus lubricates, or at least permits, the shear produced by rods and cones moving in opposite directions. The photoreceptor inner segment is composed of the distal ellipsoid, containing a mass of aggregated mitochondria, and the more proximal myoid, so named because of its ability to contract in lower vertebrates. Almost all of the retinomotor shape change is mediated by changes in length of the myoid. In fish retinas, cone photoreceptors are generally considerably larger than rod photoreceptors and exhibit greater excursions of retinomotor movement.

Rod and cone photoreceptors have a relatively consistent cytoskeletal organization characterized by axially aligned actin filaments and microtubules (Figure 2). From the distal end of the inner segment, microvillus-like calycal processes cup the base of the outer segment. Paraxial bundles of cross-linked actin filaments form the cores of the calycal processes, continue through the peripheral cytoplasm of the ellipsoid and then splay out in the myoid into a less tightly cross-linked, but still longitudinally oriented actin filament array. Thus, the contractile myoid region is rich in paraxially aligned actin filaments. These polarized actin filaments of the ellipsoid and myoid are oriented with fast-growing (plus) ends toward the outer segment. The polarity of actin filaments plays a critical role in actin-based motility, since each type of myosin motor protein is constrained to walk in only one direction along the actin filament. Thus a plus-end directed myosin motor would walk along the photoreceptor inner segment actin bundles toward the outer segment, while a minus-end directed motor would walk toward the nucleus. Actin filaments are also highly concentrated at the outer limiting membrane, where they form the submembrane actin densities of the adherens junctions found there.

The microtubule cytoskeleton of the photoreceptor consists of two distinct microtubule populations with different properties: the highly stable $(9+0)$ ciliary axoneme of the outer segment, and the more labile paraxially aligned cytoplasmic microtubules of the photoreceptor cell body. Relatively parallel microtubules populate the sleeve of cytoplasm surrounding the mitochondrial mass in the ellipsoid and extend throughout the myoid and axon. As with actin, microtubule polarity and the orientation of the

Figure 2 Schematic illustration of cell shape and thin filament distribution in dark- and light-adapted teleost rods. Not shown are ellipsoid and myoid microtubules that are also present in both states. Scale bar = 10 μm. Reproduced from *Journal of Cell Biology*, 1981, 89, pp. 517–524, by copyright permission of The Rockefeller University Press.

microtubules within a cell play critical roles in microtubule-based motility, since microtubule-based motors are also constrained to walk one direction along a microtubule. The polarity of the inner segment and axonal microtubules is quite uniform, with virtually all microtubules oriented with their slow-growing (minus) ends toward the outer segment. Thus in a photoreceptor, a minus-end directed microtubule motor like dynein would walk toward the outer segment, while a plus-end directed microtubule motor like kinesin would walk toward the synapse.

Cytoskeletal inhibitors have been used to ascertain the roles of microtubules and actin filaments in teleost rod and cone retinomotor movements. In cones, dark-adaptive myoid elongation is microtubule dependent while light-adaptive cone myoid contraction is actin dependent. Myosin II, a cytoplasmic myosin capable of forming bipolar filaments, is highly concentrated in cone myoids, suggesting that a muscle-like sliding filament model of actin–myosin interaction might mediate cone contraction. In rods, myoid elongation and myoid contraction are both actin dependent; neither elongation nor contraction requires intact microtubules. Actin inhibitor studies of rod elongation suggest that force production for rod elongation is provided by actin assembly and/or cross-linking.

The RPE Cytoskeleton and Force Production for Pigment Granule Dispersion and Aggregation

The advancement and retraction of shielding pigment in the RPE results from the translocation of individual melanin pigment granules within the long apical projections of the RPE cells. The membrane-bound melanosomes migrate out into the long apical projections in the light and aggregate back into the RPE cell body in the dark. The apical projections extend from the RPE cell apical surface into the subretinal space and interdigitate with the photoreceptor inner and outer segments, thus allowing the dispersed melanosomes to shield and protect rod outer segments from bleach in bright light. RPE apical projections may be very long (up to 100 μm in some fish species), and they remain extended throughout the phases of melanosome migration.

Apical projections of RPE cells contain both actin filaments and microtubules. Microtubule disruption by intraocular injection of inhibitors *in vivo* blocks motility of melanosomes both in the cell body and in the apical projections, suggesting that melanosome movement is microtubule dependent. However, when inhibitor studies are carried out using dissociated RPE cells in culture, microtubule disruption has no effect on melanosome aggregation or dispersion. Presumably, this discrepancy results from the need for microtubules to provide structural support *in vivo* for the maintenance of the apical projections, or to maintain patent tracks or pathways through which the melanosomes can move. In the isolated cells on the other hand, the attachment of the projections to the substrate likely provides the structural support necessary to keep apical projections intact enough to permit pigment granule translocation. The isolated cell studies therefore demonstrate that microtubules contribute to the structural integrity of RPE apical projections, but are not required for force production for translocation.

In contrast, disruption of the actin cytoskeleton in dissociated RPE cells reversibly blocks both aggregation and dispersion of melanosomes, and prevents maintenance of full aggregation or full dispersion both *in vivo* and in isolated cells. These studies show that actin filaments are necessary and sufficient

for both aggregation and dispersion, while microtubules are not required for force production for either aggregation or dispersion. The actin dependence of melanosome translocation in RPE cells suggests that myosin motor proteins are likely to play a role in force production. Myosin VIIa has been immunolocalized to RPE of human, rodent, and fish RPE. Using *in vitro* motility assays it has been shown that teleost RPE melanosomes do support plus-end directed, actin-dependent motility, and that myosin VIIa is present and enriched on melanosomal membranes.

While the *in vitro* assays demonstrate that teleost melanosomes possess myosin motors capable of moving them along actin filaments, it is not clear whether these motors translocate melanosomes during aggregation, dispersion, or both. Rates of motility observed in assays *in vitro* spanned a wide range, raising the possibility that more than one class of myosin motor is present on melanosomes. Myosin Va, which has been shown to mediate melanosome translocation in melanocytes and amphibian dermal chromatophores, has also been identified in the melanosome fraction from porcine and rodent RPE.

Intracellular Regulation of Retinomotor Movements: The Role of cAMP

Numerous observations suggest that intracellular cyclic adenosine monophosphate (cAMP) plays a critical role in the intracellular regulation of retinomotor movements in both photoreceptors and RPE cells. Experimental studies based on intraocular injections and cultured retinas show that a variety of treatments that elevate cAMP (but not cyclic guanosine monephosphute (cGMP)) produce retinomotor positions characteristic of darkness (night) in teleost rods, cones, and RPE cells and in frog cones. Similar effects were obtained using isolated RPE cells, permeabilized cones, and isolated fragments (inner/outer segments) of rods and cones, suggesting that increased cytoplasmic cAMP levels have a local and direct effect in each cell type. These findings are consistent with other reports suggesting that elevated cAMP levels in the dark are a general feature of cyclic diurnal and circadian signaling in vertebrate photoreceptors. For example, light and circadian control of retinal melatonin release is closely correlated with changes in intracellular cAMP levels. cAMP regulates melatonin synthesis by influencing the activity of the rate-limiting enzyme in melatonin production, which is located in photoreceptors. Retinal melatonin release is elevated at night in both cyclic light and constant dark conditions, consistent with higher dark levels of cAMP in photoreceptors. Together these observations suggest that diurnal and circadian changes in cAMP levels in the inner segment mediate intracellular regulation of retinomotor movements *in vivo*.

Since inhibitors of cAMP-dependent kinase (protein kinase A (PKA)) block dark-adaptive retinomotor movements in both cone and rod isolated inner/outer segments preparations, it seems likely that cAMP mobilizes the photoreceptor cytoskeleton by protein phosphorylation. The observation that cAMP can trigger elongation in detergent-permeabilized cone models further suggests that critical targets of PKA are detergent insoluble, and thus likely to be associated with the cytoskeleton itself. Pharmacological studies of rod inner–outer segment fragment motility suggest that phosphorylation of mediator proteins by PKA is enhanced in darkness and that dephosphorylation is required for light-induced elongation. In rod inner–outer segment fragments, the two primary targets of PKA phosphorylation are phosducin and phosducin-like protein. Phosducin has many roles in the photoreceptor, including binding to $\beta\gamma$ subunits of transducin in its unphosphorylated state. It is not yet clear whether there is any causal relationship between phosducin phosphorylation and retinomotor movements.

Regulation of Photoreceptor Retinomotor Movements by Paracrine Messengers

A role for paracrine signaling in regulation of retinomotor movements is implicated by spectral sensitivity studies of cone retinomotor movements in fish and frog retinas *in vivo*. The action spectrum for triggering light adaptive cone and RPE retinomotor movements most closely fits the absorption curve of the rod photopigment, suggesting that in cones and RPE cells, these movements are not directly triggered by light but instead are activated indirectly via a rod-mediated pathway. The neuromodulator dopamine participates in this rod-mediated pathway as suggested by the ability of intraocularly injected dopamine to block light-induced cone contraction and RPE pigment granule dispersion.

Observations from studies using intraocular injection *in vivo*, isolated retinas in culture, and isolated cone inner–outer segment fragments, further suggest that dopamine plays a central role in paracrine regulation of cone retinomotor movements of fish and frogs. In all these preparations, light and/or dopamine promote cone contraction, whereas darkness or the adenylate cyclase stimulator, forskolin, promotes cone elongation. Pharmacological profiles of this dopamine effect suggest that dopamine is acting through a D4-like or other D2 family dopamine receptor.

This class of dopamine receptors inhibits adenylate cyclase and thus would be expected to lower cone cytoplasmic cAMP levels, consistent with observations that experimentally increasing cAMP produces dark-adaptive movements. In isolated cone fragments, dopamine blocks cone elongation induced by the adenylate cycle stimulator forskolin but not elongation induced by the membrane permeable cAMP analog, dibutyrl cAMP, further confirming that dopamine regulates cone movement by inhibiting adenylate cyclase.

The ability of light and dopamine to regulate retinomotor movement in isolated cone inner–outer segment fragments indicates that these agents can act directly on cones. In teleost retinas, the source of dopamine is the interplexiform cell whose projections extend into the outer plexiform layer. If the D4-like receptors are on the inner (and/or outer) segments as suggested by the cone fragment findings, released dopamine would have to diffuse over tens of microns to reach the inner segments *in vivo*. The very high affinity of D4 receptors (K_d in the nM range) may facilitate this paracrine mode of signaling.

Studies with isolated photoreceptor inner–outer segment fragments indicate that dopamine is much more effective than light in producing myoid contraction in cones, whereas light is much more effective than dopamine in triggering myoid elongation in rods. Furthermore, regulation of fish rod movement by light and circadian signals was unaffected by 6-hydroxydopamine lesion of dopaminergic interplexiform cells. These observations suggest that dopamine does not play a significant role in regulating rod retinomotor movements *in vivo*.

Light-activation of myoid elongation in teleost rod inner out segment fragments *in vitro* requires relatively high light intensities (20% bleach). The photoreceptive mechanism responsible for this activation can apparently count quanta accurately for light pulse durations up to at least 10 min, suggesting that the critical factor in light activation of rod elongation is quantum catch, rather than duration of the light stimulus. Similar high intensity thresholds and photon counting have been reported to mediate entrainment of circadian rhythms in several species. High-intensity threshold and the ability to count quanta over long durations may be common denominators of photoreceptive functions that attune the organism to the daily light-dark cycle rather than mediate vision.

That dopamine also plays a role in circadian regulation of cone retinomotor movement is suggested by results obtained by intraocular injection of dopamine agonists and antagonists in animals maintained in constant darkness (DD). Cone myoid contraction can be induced at midnight by intraocular injection of dopamine or D2 receptor agonists. Partially contracted cones of DD animals at subjective midday can be induced to contract fully by intraocular injection of dopamine or D2 agonists, or to elongate by injection of the D2 antagonist sulpiride. The predawn cone contraction observed in DD animals in response to circadian signals can be completely eliminated by intraocular injection of the D2 antagonist shortly before the expected time of light onset. These observations suggest that circadian regulation of cone myoid length is mediated by endogenous dopamine, acting via D2 family receptors. Dopamine is unlikely, however, to be the sole circadian regulator, since both light induced and circadian cone movements persist (at reduced amplitude) after lesion of interplexiform cells by 6-hydroxydopamine.

The neuromodulator adenosine can also influence cone retinomotor movements in teleosts. In isolated cone inner–outer segment fragments, myoid elongation can be induced by activation of adenosine A2 receptors and inhibited by A2 receptor antagonists. Since A2 receptors are positively coupled to adenylate cyclase, adenosine effects on cone fragments are consistent with previous findings that elevation of cAMP triggers dark-adaptive retinomotor movements. The observation that cone fragments respond to adenosine indicates that A2 receptors must be present on cone inner (and/or outer) segments. Since cones elongate at subjective dusk in fish maintained in constant darkness, and since adenosine stimulates cone elongation, adenosine could provide an endogenous circadian signal for expected dark onset. Alternatively, adenosine effects on cone movements could be a local effect, reflecting photoreceptor metabolic activity. Since an adenosine transporter is present in photoreceptors, increases in adenosine in photoreceptor inner segments might be expected to be accompanied by an increase in adenosine level in the subretinal space. Darkness is associated with increased Na^+/K^+-ATPase activity in photoreceptor inner segments. Increased Na^+/K^+-ATPase activity is likely to be accompanied by an increase in intracellular adenosine levels, and consequently, increased release of adenosine into the subretinal space. The binding of released adenosine to photoreceptor A2 receptors might then enhance dark adaptation of the photoreceptors by stimulating adenylate cyclase, thereby reinforcing the dark signal.

Regulation of Retinomotor Movements in RPE Cells by Paracrine Messengers

Spectral sensitivity studies have shown that RPE pigment migration in the frog has an action spectrum

most closely resembling that of the rod photopigment. These observations suggest that for RPE, as for cones, a rod-mediated pathway triggers light-adaptive retinomotor movement. The observation that pigment position is not affected by light in isolated sheets of teleost RPE further argues that light acts indirectly via a photoreceptor mediated, paracrine pathway.

Pigment migration can be triggered experimentally in isolated sheets of teleost RPE in culture. Dopamine and D2 family agonists induce pigment granule dispersion (the light-adaptive movement) while treatments that elevate cAMP induce pigment granule aggregation (the dark-adaptive movement). In isolated RPE cells aggregated in cAMP, pigment dispersion is induced by microinjection of PKA inhibitors, suggesting that continuous phosphorylation of PKA targets is required to maintain the aggregated state. Since aggregation can also be induced by the phosphatase inhibitor okadaic acid, it seems likely that PKA and phosphatases are simultaneously active in RPE cells, and that their relative activities are altered by light and dark signals from the retina.

Surprisingly, underivatized cAMP is just as effective as membrane-permeant cAMP analogs at activating pigment granule aggregation in isolated RPE sheets. Washout of exogenous cAMP induces dispersion. Thus, cAMP appears either to act on cell surface purinergic receptors or to enter the cell via organic ion transporters. Since ATP and adenosine are ineffective and since organic ion transport inhibitors block cAMP-but not forskolin-induced pigment aggregation, it seems likely that exogenous cAMP can actually enter the cells via organic ion channels to activate pigment aggregation. Thus, in RPE cells, cAMP might be acting not only as a second (intracellular) messenger, but as a first (paracrine) messenger to trigger retinomotor movements associated with dark adaptation. These findings indicate that an increase in cAMP level in the subretinal space in the dark would activate pigment granule aggregation in RPE cells. Cyclic AMP efflux has been shown to be associated with increased intracellular cAMP accumulation in many cell types, including pinealocytes. Thus, diurnal and circadian cycles of cAMP levels in retinal photoreceptors might be expected to produce increased cAMP efflux into the subretinal space at night. This extracellular cAMP in the subretinal space could then serve as a retina to RPE signal for darkness.

Cyclic AMP and intracellular calcium often interact in cellular signaling pathways, either antagonistically or synergistically. Melanosome migration is regulated by calcium in several types of dermal chromatophores. However, increasing extracellular or intracellular calcium has no effect on either pigment granule aggregation or dispersion in dissociated RPE cells. Furthermore, intracellular calcium levels are unaffected when RPE pigment granule motility is triggered by cAMP or cAMP washout. These studies suggest that RPE pigment granule movements are not regulated by calcium but are regulated solely by cAMP, presumably by phosphorylation and dephosphorylation of protein kinase A targets.

Functions and Significance of Retinomotor Movements

Just what role retinomotor movements play in retinal function has been a topic of inquiry and speculation for researchers for more than a century. Direct experimental demonstration of effects of retinomotor movements on vision has been difficult to achieve, primarily because it is extremely difficult to interfere with retinomotor movements without affecting other aspects of retinal function. Nevertheless, several likely functions for retinomotor movements have been suggested. Occurring generally in species that lack pupillary movements, rod and RPE retinomotor movements provide an alternative mechanism for shielding rods in bright light and fully exposing them for dim light vision. Repositioning the photoreceptors likewise provides an ingenious mechanism for optimizing space utilization by positioning the rods first in line to detect light at the focal plane across the entire retinal surface under dim light conditions and then moving cones to this position for bright light vision. These movements permit the entire retinal surface to be used alternately for rod and cone vision. Some researchers have also noted that each photoreceptor type is elongated when it is expected to be silent and have suggested that the cable properties of the elongated myoid might contribute to attenuation of the signal from outer segment to synapse. The great morphological variation in retinomotor movements perhaps reflects the selective optimization of one of these functions in different species.

Summary

Though retinomotor movements are most pronounced in lower vertebrates, their study contributes to our understanding of diurnal and circadian regulation of photoreceptor and RPE physiology in all species. Retinomotor movements provide excellent models for investigating the roles of cytoskeletal elements in cell shape change and intracellular transport. Since photoreceptors are light detectors, their

metabolism and physiology is particularly attuned to the daily cycles of light and darkness. Studies of retinomotor movements have called attention to the importance of cyclic changes in intracellular cAMP levels in the diurnal and circadian regulation of other aspects of photoreceptor physiology and metabolism. The recognition that light induction of cone and RPE movements depends on a rod-mediated paracrine pathway has contributed to recognition that dopamine plays an important role in light and circadian signaling in the retina. Since retinomotor movements exhibit properties of light- and circadian-regulation characteristic of many other aspects of retinal physiology, they provide excellent experimental models for understanding light and circadian-regulatory processes.

Retrograde Neurotrophic Signaling

C Wu and W C Mobley, Neuroscience Institute, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The survival and differentiation of neurotrophin (NT)-responsive neurons are critically regulated by the targets that these neurons innervate. However, the exact mechanism or mechanisms by which the target-derived NT signals produced at the axonal terminals are delivered to the cell body over a significant distance (>1 m in some neurons) remain unclear. These underlying mechanisms have been one of the most intriguing enigmas in modern neurobiology.

The discovery of nerve growth factor (NGF) by Levi-Montalcini and Hamberger provided an important clue to the mechanism: A soluble NGF produced in the target dramatically influenced specific populations of neurons. It is now well established that NGF produced in and released from target tissues activates specific receptors at the distal axons of innervating neurons. The signals thus elicited are subsequently retrogradely transported to the cell bodies to regulate nuclear and cytosolic events that are known to be important for the survival and maintenance of healthy neurons. However, the generation, intracellular sorting, and maintenance of the signal remain the subjects of intensive investigation.

Compartmentalized Nerve Cell Chambers Are Used to Study Retrograde Axonal Traffic

Campenot Chamber

In vitro experimental studies to support the need for retrograde NT signaling have benefited markedly from the use of compartmentalized neuronal cultures pioneered by Campenot and colleagues. In this experimental paradigm, the neuronal cell bodies and proximal axons are separated from distal axons by a Teflon divider sealed with silicone grease onto a collagen-coated surface. Radiolabeled NGF (^{125}I-NGF) can be added to the distal chamber and its retrograde transport from the axonal terminal to the proximal axon or the cell body can be quantitatively measured. Retrogradely transported signaling molecules can also be analyzed by comparing, by means of immunoblotting and immunostaining, the changes in distal axons to those in the proximal axons or cell bodies. The use of this device and its variants has allowed study of the mechanisms for retrograde NGF and NT signaling.

Microfluidic Chambers

A microfluidic device has been developed to serve as a platform for long-term cultures of primary neurons from the central nervous system *in vitro* to study axonal injury and regeneration. Though only recently introduced, it has already proven extremely useful for examining axonal transport. These miniature devices, fabricated with poly(dimethylsiloxane) (PDMS), afford the ability to precisely control, monitor, and manipulate cellular microenvironments. The microfluidic nerve cell chamber has been modified for study of the transport kinetics of retrograde axonal transport of NGF in rat embryonic dorsal root ganglion (DRG) neuronal cultures. The device is depicted in Figure 1. Dissociated DRG neurons are loaded into the left well, and both wells are supplied with standard growth medium (Figures 1(a) and 1(b)). Axons grow across the first microgroove and into the middle chamber in 2–3 days; many then traverse the second microgroove and emerge into the distal axon chamber in an additional 4–5 days.

Among the many advantages of this device is that axons can be confined to the two straight microgrooves whose cross-sectional area (3 μm × 3 μm) and length (in this case, 100 μm) are well defined. An example of rat embryonic DRG culture (7 days *in vitro*, i.e., DIV7) is shown in Figure 1(c). Furthermore, neurons can be loaded at a density at which only a single axon crosses the microgroove. This makes it possible, using microscopy, to more readily track labeled NGF and its signaling molecules. As demonstrated in Figure 2, distal axons from postnatal mouse DRG neurons that were cultured in the device for 7 days (Figure 1) were incubated with biotinylated NGF conjugated to streptavidin-Quantum dot 605, and the retrograde movement of labeled NGF was imaged in the proximal axons (Figure 2). Furthermore, the presence of a middle chamber makes it possible to modify the content of the environment (e.g., to administer various kinase inhibitors) through which the axon transmits neurotrophic signals.

Studying Retrograde NT Signaling *In Vivo*

In vivo studies have most often used ligation to examine transport. In the ligature technique, after anesthesia has been administered, a nerve (in most cases the sciatic nerve) is surgically exposed, and one or

Figure 1 Schematic representation of a modified version of the microfluidic nerve cell chamber showing the top view (a) and side view (b). In (c), Rat E16 DRG neurons were cultured in the device for 7 days, and DRG axons crossed robustly the two microgrooves into the distal chamber. CB, cell body; PA, proximal axon; DA; distal axon; PDMS, poly(dimethylsiloxane).

Figure 2 Postnatal (P0) mouse DRG neurons were cultured in the microfluidic nerve cell chamber for 7 days. Biotinylated NGF that was conjugated to streptavidin-Quantum-dot 605 was added to the distal chamber. Movement of labeled NGF within the proximal axons was imaged in real time by an inverted microscope (100x oil). A series of time-sequenced frames shows the retrograde NGF transport.

more ligatures, separated by a desired distance, are placed. The animals are allowed to recover. Then, after a desired interval, they are sacrificed, and the nerve is taken for immunohistocytochemical, electron microscopic, and biochemical studies. The undamaged contralateral sciatic nerve may serve as control in some experiments. To define the extent of transport of a molecule or organelle, one typically measures the extent to which it accumulates on the most distal ligature (for retrograde transport) or the most proximal ligature (for anterograde transport). The use of a double ligature is useful in controlling for the effect of ligation-mediated injury on the possible local production of the marker of interest. In an alternative procedure, a segment of nerve can be surgically removed and placed on a slab of gelled agarose with both ends placed in a collecting chamber containing a physiological medium. The eluted axoplasm can be analyzed by one or more of the methods specified above.

Another established technique that has been used to study retrograde NT signaling places the molecule of interest in the target area of afferent axons. For example, the hipposeptal cholinergic pathway has been used to examine NGF retrograde transport from the hippocampus to basal forebrain cholinergic neurons. In this experimental paradigm, either radiolabeled or fluorescently labeled NGF is stereotaxically injected into the frontal cortex or hippocampus of anesthetized animals. The animals are allowed to recover for a desired period before sacrifice and analysis. In these experiments, one can determine the extent of transport by measuring the accumulation of the labeled species in the septum using light microscopy for fluorescently tagged molecules or, in the case of radiolabeled molecules, *in situ* autoradiography or gamma counting in the septum.

Retrograde Neurotrophic Signaling: Proposed Mechanisms

Signaling Endosome Hypothesis

This hypothesis posits that the NGF signal is transmitted via endocytosis of complexes containing NGF bound to its activated tyrosine receptor kinase A (TrkA) receptor (i.e., pTrkA), followed by retrograde transport of the 'signaling endosome' thus formed (Figure 3). The hypothesis points to signaling endosomes as an important source of retrogradely transmitted signals. It is consistent with the emerging view that cellular signaling pathways are highly organized and compartmentalized, features that are used to confer specificity and sustainability of signal transduction.

The signaling endosome hypothesis is supported by an increasing body of experimental evidence from a number of laboratories. Studies *in vitro* have shown that (1) NGF at axon terminals must be internalized

Figure 3 NGF–TrkA signaling pathways and retrograde axonal transport of signaling endosomes. (a) NGF activates its high-affinity tyrosine receptor kinase, TrkA, and elicits divergent signaling pathways. The four major pathways are (1) the transient SOS/Ras/C-Raf/MEKK/MEK/Erk pathway; (2) the persistent C3G/Rap1/B-Raf/MEKK/MEK/Erk pathway; (3) the PI3K/Akt pathway; and (4) the PLCγ pathway. Activation of these pathways effects neuronal functions of survival and differentiation. (b) Following endocytosis of NGF and activated TrkA signaling complex, the signaling endosome engages the dynein–dynactin complex to undergo retrograde axonal transport along the microtubule network (MT). NGF, nerve growth factor; TrkA, tyrosine receptor kinase A; FRS2, fibroblast growth factor receptor substrate-2; Shc, SH2-containing protein; SH2-B, SH2-containing protein B; Grb2, growth factor receptor bound protein 2; SOS, son of sevenless; Ras, a small GTPase; C-Raf, Raf kinase C; MEKK, MAPK/Erk kinase kinase; kinase; MEK, MAPK/Erk kinase kinase; Erk (or MAPK), extracellular signal-regulated kinase (or mitogen activated protein kinase); Gab2, Grb2-associated binding protein-2; GIPC, GAIP interacting protein; Shp2, SH2-containing protein phosphatase-2; CrkL, v-crk avian sarcoma virus CT10 oncogene homolog-like; C3G, Crk SH3 binding guanine-nucleotide releasing factor; Rap1, Ras-related protein 1; B-Raf, Raf kinase B; PI3K, phosphatidylinoditiol-3-kinase; Akt, protein kinase B; PLCγ, phospholipase-C-gamma; GAIP, Gα-interacting protein; Rab5, a member of the RAS oncogene family; P, phosphate.

and retrogradely transported to neuron cell bodies for the NGF signal to induce phosphorylation of cyclic adenosine monophosphate response element-binding protein (CREB) and to increase survival of immature neurons; (2) NGF-induced activation of TrkA in axon terminals is also required for survival; (3) NGF induces endocytosis of TrkA and is bound to pTrkA in endosomes; (4) retrograde NGF signals

are decreased by inhibiting endocytosis; (5) NGF–pTrkA complexes are found in clathrin-coated vesicles together with activated components of the Ras/extracellular signal-regulated kinase (Erk)1/2 pathway as well as phosphatidylinoditiol-3-kinase (PI3K) and phospholipase-C-γ; (6) NGF signaling that is present in clathrin-coated vesicles is able in *in vitro* kinase assays to phosphorylate Elk-1, a downstream target of Erk1/2; (7) in what appears to be the next step in the maturation of the signaling endosome within the endosomal pathway, and a step that requires both dynein and intact microtubules, NGF also induces the formation of complexes containing pTrkA and activated components of the Ras-related protein 1 (Rap1)/Erk1/2 pathway in early endosomes; (8) NGF–pTrkA complexes are moved retrogradely in axons to cell bodies, as are the complexes of brain-derived neurotrophic factor (BDNF) and its phosphorylated tyrosine receptor kinase B (pTrkB); (9) retrograde transport of these complexes is blocked by disrupting microtubules; and (10) retrogradely transported pTrk is required for CREB phosphorylation, c-fos induction, protein kinase B (Akt) phosphorylation, and survival of immature neurons. *In vivo* and *ex vivo* observations are consistent in showing that (1) early endosomes containing NGF–pTrkA, together with activated components of the Rap1/Erk1/2 and PI3K pathways, are retrogradely transported in sciatic nerve; (2) increasing NGF levels in the target of innervation increases retrograde transport of these membranes and increases pErk1/2 in DRG neuron cell bodies; conversely; (3) decreasing NGF in the target of innervation by sequestering it with specific antibodies decreases the retrograde transport of endosomes containing pTrk and pErk1/2; and (4) it has been demonstrated recently *in vivo* that NGF was localized within early endosomes in cholinergic terminals, and after hippocampal injection, ^{125}I-NGF was coimmunoprecipitated with antibodies against TrkA.

NGF-Independent Retrograde Signaling

There is evidence that NGF retrograde signaling may not always be coupled to retrograde transport of NGF. Senger and Campenot found that while it took at least 30 min for ^{125}I-NGF to arrive at the cell body/proximal chamber at a detectable level following addition of ^{125}I-NGF to the distal chamber in the compartmentalized culture of sympathetic neurons, TrkA and other signaling molecules were more rapidly activated in the cell body/proximal axons. Utilizing NGF that was covalently cross-linked to beads, thus rendering it incapable of internalization, Campenot's group further demonstrated that this source of NGF was able to trigger activation and axonal transport of TrkA and PI3K/Akt signaling proteins at levels adequate to support survival of sympathetic neurons for up to 30 h. Taken together, the findings suggest that signaling events initiated by NGF at the axonal terminals can be transported retrogradely without NGF. More recently, Mok and Campenot used Go6976 a very potent drug in inhibiting TrkA phosphorylation, to block TrkA phosphorylation in the cell body/proximal axons in compartmentalized sympathetic neurons. Go6976 itself exerts no survival effects on sympathetic neurons deprived of NGF. After applying Go6976 to locally block TrkA phosphorylation in the cell body/proximal axons, NGF added to distal axons still resulted in activation of survival signaling pathways (e.g., pAkt, pCREB) in the cell body/proximal axons. These investigators concluded that retrograde transport of signaling molecules downstream of phosphorylated TrkA, but not phosphorylated TrkA itself, is necessary to support neuronal survival.

Other Hypotheses

Other possible mechanisms for retrograde signaling can be envisioned. In a general sense, they conform either to the 'wave model' or to the 'signaling effector model.' The former suggests that NGF binds to and activates TrkA at the distal axonal terminals. Activated TrkA and/or signaling molecules downstream of activated TrkA are subsequently propagated and transported back to the cell body. The latter model postulates that second messengers such as ionic fluxes (e.g., cytosolic Ca^{2+}), instead of NGF–pTrkA, are retrogradely transported. There is little experimental data to support these alternatives, but given the paucity of knowledge for retrograde signaling mechanisms, continued attempts should be made to discover and characterize alternative models.

The Nature of Intracellular Vesicles That Carry Retrograde NGF Signaling

There is no consensus about the type of endocytic vesicle or vesicles that transport retrograde NT signaling in axons. An early study suggested that lysomes/multivesicular bodies (MVBs) contained the majority of ^{125}I-NGF that was retrogradely transported in cultured sympathetic neurons. Studies from Hendry laboratory showed that ^{125}I-NGF transported from the eye to the sympathetic and sensory ganglia was concentrated in MVBs. These findings led to the proposal that MVBs are the major vesiclar carriers within axons for retrograde NT signaling. Depending on the experimental conditions, investigators from a numbers of laboratories discovered that

NGF or its signaling components such as pTrk resided in pincher-positive complex structures, in 'uncoated' vesicles, in the *trans*-Golgi network, in late endosomes that are marked by Rab7, or in Rab5-positive early endosomes. It is possible that many different endocytic vesicle types are engaged in transporting NGF signals and that different neurons use a different complement of such organelles. Resolving this issue is an important next step in clarifying retrograde signaling pathways.

Role of MT/Dynein in Mediating Retrograde Transport of NT Signaling

It is not surprising that retrograde transport of NT signaling endosomes in axons, like many other subcellular organelles (mitochondria, RNA particles, etc.), requires the microtubule network (MT) for movement. In support of this, infusion of nocodazole, a drug that causes the collapse of MT, into isolated sciatic nerves blocked retrograde NGF transport. Similarly, another MT collapse-causing drug, colchicine, suppressed Trk phosphorylation of cell bodies in response to neurite stimulation in DRG neurons. Colchicine pretreatment also blocked CREB phosphorylation in response to stimulation of the cell bodies, as well as the neurites.

The dynein motor protein complex is primarily responsible for powering retrograde movement within a cell. It comprises many different subunits (the heavy chains, the intermediate chains, and the light chains). Evidence from Chao laboratory suggests that Trk associates with both the 14 kDa light and the 74 kDa intermediate chain of dynein. Furthermore, Segal and colleagues found that pTrk was found to co-localize with dynein, but not with the anterograde motor kinesin, in rat sciatic nerve axons. In addition, the 74 kDa subunit of dynein was found in retrograde transport vesicles that contain NGF–pTrkA isolated from rat sciatic nerve axons. More recently, disruption of the dynein function by introduction of the 50 kDa subunit (dynamitin) of dynactin, an established method to dissociate the dynein–dynactin complex, blocked retrograde transport of NGF and BDNF and led to atrophy and cell death in neurons. These results demonstrate that retrograde transport of NT signaling is driven by the dynein–dynactin complex.

Disrupted Retrograde Transport NT Signaling in Neurodegenerative Diseases

Given the role that active retrograde NT signaling plays in the development of the nervous system, and evidence that continued production in targets of innervation are needed to maintain mature neurons, it is noteworthy that an increasing body of data points to a link between defects in retrograde NT signaling and dysfunction and degeneration of neurons in neurodegenerative diseases. Salehi et al. recently demonstrated that in a mouse model of Down syndrome (Ts65Dn), the presence of one extra copy of the amyloid precursor protein selectively disrupted retrograde NGF transport and resulted in degeneration of basal forebrain cholinergic neurons (BFCNs), a pathological hallmark in Alzheimer's disease. In an earlier study, Cooper et al. showed that NGF was retrogradely transported via the hipposeptal pathway. The age-related degeneration of BFCNs (decrease in cell numbers and profile area of cell bodies) in Ts65Dn mice could be reversed by direct intracerebroventricular NGF infusion. Similarly, a severe defect in retrograde NGF transport has also been reported by Yang and colleagues in cultured postnatal DRG neurons of a mouse model of giant axon neuropathy, a disorder that affects a number of neuronal populations in the peripheral and central nervous system.

Defective retrograde NT transport has also been implicated in Huntington's disease (HD), a condition that results from an expansion of polyglutamine tract (>37 glutamines) in huntingtin (htt). In a recent study, Rong et al. observed that htt-associated protein-1, a contributing factor to HD pathology, interacts with the dynein motor in sympathetic neurons. Mutant htt appears to influence this interaction and in so doing reduces the stability of intracellular TrkA. As a result, retrograde NGF signaling may well be compromised in the diseased neurons.

Given that retrograde neurotrophic signaling may share mechanisms and protein machinery with other retrograde processes, it is conceivable that disruption or alteration in any components of the machinery will also inevitably affect retrograde NT signaling. Disruption of retrograde axonal transport has been suggested to contribute to the pathogenesis of a number of progressive disorders of motor neurons. In one study, transgenic overexpression of p50 was shown to result in inhibition of axonal transport and cause late-onset progressive degeneration in motor neurons. In addition, a family with chronic motor neuron disease has been shown to harbor a mutation in p150 glued, a protein that plays a critical role in the function of the dynein complex.

Genetic mutations that affect the stability of the microtubules have been suggested to cause progressive motor neuronopathy in mice. A Trp524Gly substitution at the last residue of the tubulin-specific chaperone e protein (gene locus: chromosome 13) leads to a reduced number of microtubules in the sciatic and phrenic nerves. The affected mice develop progressive caudocranial degeneration of their motor

axons from the age of 2 weeks and die 4–6 weeks after birth. Axonal degeneration apparently starts at the endplates and is prominent in the sciatic nerve and its branches and the phrenic nerve. Since intact microtubules are required for retrograde NGF transport, it is conceivable that retrograde NGF–pTrkA signaling is compromised in these mice as well, which may well in turn contribute to the disease.

In another example, alsin, a putative guanine nucleotide exchange factor for Rab5, plays a critical role in regulating early endosomal fusion. Loss of alsin-2 function is believed to be the cause for a subset of amyotrophic lateral sclerosis (ALS) in humans, juvenile-onset primary lateral sclerosis. In Als2(−/−) mice, endosomal transport of insulin-like growth factor 1 and BDNF receptors was selectively disturbed. In another mouse model of ALS, a missense mutation L967Q in Vps54 has been identified in the spontaneous autosomal recessive wobbler mutation. Axonal transport is impaired in wobbler mice, and Vps54 might be critical for retrograde vesicular transport and in particular for axonal transport in motor neurons. Since internalized NGF was found to localize in early endosomes in cholinergic neurons, retrograde NGF signaling is likely affected in these neurons as well.

Recent studies have revealed that late endosomes that are marked by Rab7 may also play a role in modulating retrograde NGF–pTrkA signaling. In genetic studies, the locus for Rab7 has been implicated as the disease gene for Charcot-Marie-Tooth disease type 2B (CMT2B). CMT2B is a rare autosomal dominant genetic disorder that leads to peripheral sensory neuropathy with prominent axonal degeneration. Missense mutations in the highly conserved C-terminus of Rab7 (Leu129Phe, Val162Met, Lys157Asn) have been identified in CMT2B patients. It will be of great interest to examine whether retrograde NT trafficking or signaling is affected in neurons that harbor Rab7 mutations.

Summary

Retrograde NT signaling plays a critical role in regulating survival and differentiation of specific populations of neurons in both the central nervous system and the peripheral nervous system. There is increasing evidence that NGF and other NTs bind to and activate their receptors at the axonal terminus to elicit the recruitment of an array of signaling molecules. Endocytosis of the NT–pTrk signaling complex is then sorted into a subpopulation of early endosomes or other cellular organelles to give rise to signaling endosomes. The signaling endosome driven by the dynein motor complex is retrogradely transported via the MT to the cell body to effect gene expression and other somal events. Retrograde NT signaling thus appears to be a very complex process that involves numerous cellular components and events. Disruption of retrograde NGF and NT signaling may contribute or lead to many types of neurodegenerative diseases.

Retrograde Transsynaptic Influences

G W Davis, University of California at San Francisco, San Francisco, CA, USA

Introduction

More than 50 years ago, work by Victor Hamburger and his contemporaries identified target-derived factors that influence neuronal growth. Since that time it has been demonstrated that target-derived molecules are essential for many aspects of neural development, including dendrite growth, synaptic growth, synaptic stabilization, and the choice of neurotransmitter. In general, these studies have highlighted the action of growth factors, neurotrophins, and morphogen signaling proteins. These signaling proteins and their receptors are potent intercellular signaling molecules utilized repeatedly throughout development. Although studied extensively, new functions for these signaling systems continue to be identified in the context of axon guidance, stem cell maturation in the brain, and neurodegenerative disease.

Other retrograde, transsynaptic signaling systems also exist that are essential for the proper development and function of neural circuitry. In many cases, the molecular bases of these retrograde influences are not known. This article covers three fundamental phenomena that seem to require retrograde, transsynaptic signaling. First, retrograde signaling during synapse formation is considered. Retrograde signaling is well established in this context and several molecular players are known, yet the full repertoire of retrograde signaling molecules remains to be defined. This is followed by a discussion of two phenomena that require retrograde signaling of unknown identity. These include the specification of presynaptic release probability during synapse development, and the homeostatic modulation of presynaptic release probability.

Retrograde Signaling during Synapse Formation

Synapse formation involves the transformation of a motile growth cone into a stable synapse capable of mediating high-fidelity neurotransmission. This process requires the assembly and precise apposition of pre- and postsynaptic protein assemblies. These protein assemblies are known as the pre- and postsynaptic densities due to their electron-dense appearance when examined using transmission electron microscopy. The presynaptic density includes proteins that are necessary for the calcium-dependent release and recycling of synaptic vesicles. The postsynaptic density includes neurotransmitter receptors, signaling molecules, and scaffolding proteins that control the detection of neurotransmitter. Bidirectional communication between the pre- and postsynaptic cells occurs during synapse formation in order to precisely assemble the pre- and postsynaptic element. Insight into the nature of this bidirectional signaling has been achieved at both the neuromuscular junction (NMJ) and at synapses in the central nervous system.

Synaptogenesis at the Neuromuscular Junction

At the vertebrate neuromuscular junction, prior to the arrival of the growth cone, cellular specializations exist both pre- and postsynaptically; these set the stage for ensuing synapse formation. Presynaptically, the growth cone is able to release neurotransmitter and other signaling molecules that are required for synapse formation. Postsynaptically, neurotransmitter receptors (acetylcholine receptors; AChRs) are prepatterned into AChR clusters in a loose array that prefigures the site of eventual synapse formation. It remains unknown how many signaling molecules in addition to AChRs are also prepatterned to the site of eventual synapse formation.

Upon arrival at a muscle target, the presynaptic growth cone releases agrin, a heparan sulfate proteoglycan, which is deposited into the synaptic basal lamina. Agrin represents an anterograde signal that is necessary for the induction of the postsynaptic density (Figure 1). Agrin signals to the muscle via two highly conserved muscle proteins, muscle-specific kinase (MuSK) and an associated adaptor protein named rapsyn. Genetic knockout experiments demonstrate that each of these proteins is necessary for synapse formation to proceed, identifying agrin–MuSK–rapsyn signaling as an essential anterograde signaling cascade that is required for synaptogenesis. The release of the neurotransmitter acetylcholine (ACh) also participates in the early process of synapse formation. Genetic experiments in mice combining mutations in the ACh synthetic enzyme choline acetyltransferase (ChAT) with mutations in MuSK and agrin support a model in which ACh released onto the muscle actively disperses prepatterned AChRs (mechanism unknown), while agrin stabilizes those receptors that reside directly at the site of synapse formation.

The next stage of synapse formation requires a retrograde signal from muscle to nerve that directs the maturation of the presynaptic nerve terminal

Figure 1 Reciprocal signaling during synapse formation at the neuromuscular junction. At left, the motile growth cone releases both agrin and acetylcholine (ACh). ACh disperses prepatterned ACh receptor (AChR) clusters (orange box) that reside at the site of innervation. Agrin, deposited in the basal lamina, counteracts the effects of ACh and stabilizes AChRs by signaling through muscle-specific kinase (MuSK) and rapsyn in muscle. This results in AChR clustering and stabilization at the neuromuscular junction (middle diagram). Following the formation of the postsynaptic density, a retrograde signal specifies presynaptic maturation, including the formation of presynaptic dense bodies and clustered presynaptic calcium channels (blue oval) directly opposite the postsynaptic receptors. Molecules implicated in this retrograde signal include laminins and integrins.

(Figure 1). The release of this retrograde signal follows the induction of the postsynaptic specialization. In support of this conclusion, the transformation of a motile growth cone into a fully differentiated presynaptic terminal will not proceed in animals that lack MuSK or rapsyn. Indeed, muscle transplant experiments provide evidence that presynaptic maturation may never occur in the absence of postsynaptic differentiation. Thus, it appears that the agrin-dependent induction of the postsynaptic specialization leads to the production of a retrograde signal that is subsequently required to transform a motile motoneuron growth cone into a stable presynaptic terminal (Figure 1).

The retrograde signal that induces the maturation of the presynaptic terminal remains unknown, though several candidates are strongly implicated. Laminins present in the synaptic basal lamina have a well-established function in presynaptic maturation. Genetic deletion of laminin-β2 leads to a poorly differentiated presynaptic nerve terminal and impairs the association of the Schwann cell with the presynaptic terminal. Knockout of laminin-α4 leads to misalignment of the presynaptic active zone with postsynaptic specializations, though presynaptic maturation proceeds. Although a role for laminin in presynaptic induction seems clear, the means by which the laminins induce the transformation of a growth cone into a presynaptic nerve terminal are less obvious. One interesting possibility is that laminins interact directly with key presynaptic proteins. Laminin-α4 has been suggested to be a 'ligand' for presynaptic calcium channel 'receptors.' Presynaptic calcium channels may well constitute an organizing center for the construction of a presynaptic nerve terminal. Other retrograde influences also exist. Recently, integrin-mediated signaling has also been implicated in presynaptic induction. Deletion of integrin-β1 in muscle results in failure of the presynaptic nerve terminal to fully differentiate, a phenotype resembling the MuSK knockout.

Systems amenable to forward genetic analysis of synapse formation hold promise for identification of new genes that participate in the bidirectional signaling necessary for synapse formation. Genes that influence the specificity and speed of synapse formation have been found by forward genetic approaches, several of which are highlighted here. At the *Drosophila* NMJ, a four-transmembrane-spanning protein (tetraspanin) encoded by a gene termed *late bloomer* (*lbl*) is required presynaptically, for the efficient transformation of a motile growth cone into a stable presynaptic nerve terminal. However, as is the case for many synaptogenic proteins (see later), synapse formation ultimately proceeds in the absence of the *lbl*-encoded protein.

In the nematode *Caenorhabditis elegans*, forward genetic approaches have identified an intercellular signaling system that is necessary for proper synapse formation. These studies demonstrate that two presynaptic scaffolding molecules, SYD-1 and SYD-2, are necessary for the assembly of the presynaptic active zone. In mutants that lack the genes for these proteins, synaptic vesicles and other presynaptic proteins fail to accumulate at the developing active zone. These scaffolding proteins function, genetically, downstream of the intercellular signaling proteins SYG-1 and SYG-2, which are required for the proper placement of motoneuron synapses (synapse specificity). The SYG-1 protein is an immunoglobulin (Ig) domain-containing protein with similarity to vertebrate NEPH1. SYG-2 is present on an epithelial guidepost cell that prefigures synapse placement. SYG-2 binds to SYG-1, which is expressed by the motoneuron. Together, these studies suggest a model in which intercellular signaling mediated by SYG-2 and SYG-1 organizes presynaptic SYD-1 and SYD-2, which, in turn, direct the assembly of the presynaptic active

zone. Although synapse formation proceeds at inappropriate sites in a *syg-1* mutant, this transsynaptic signaling system represents a potent intercellular signaling system capable of directing appropriate synapse formation.

Synaptogenesis in the Central Nervous System

In the vertebrate central nervous system, the Wnt family of morphogen signaling molecules are involved in both axon guidance and synapse formation. Data support a model in which Wnt, released from the target cells, causes growth cone stalling and characteristic cytoskeletal rearrangements that are observed during normal synaptogenesis Although synapse formation proceeds *in vivo* in a Wnt receptor knockout, the process is delayed, suggesting that Wnts can function to promote synapse formation. A similar function has also been attributed to target-derived fibroblast growth factor 22 (FGF-22) during synapse formation in the vertebrate central nervous system.

Other proteins have been identified that are sufficient to induce the transformation of a motile growth cone into a presynaptic nerve terminal *in vitro*. These signaling proteins include neuroligin and the Ig domain-containing protein SynCam. In both cases, expression of these proteins on the surface of a heterologous cell is sufficient to transform a growth cone into a structure that resembles a presynaptic terminal. The presynaptic terminals that form on these heterologous cells share ultrastructural and molecular hallmarks of presynaptic nerve terminals and are capable of vesicular neurotransmitter release. Neuroligin can signal to the presynaptic nerve terminal by binding presynaptic neurexin, which, in turn, can be linked biochemically to an extensive array of presynaptic proteins including presynaptic calcium channels. Thus, a model has emerged that is similar to that proposed in the nematode. Transsynaptic signaling via a receptor–ligand pair induces the formation of pre- and postsynaptic protein scaffolds that serve as a template for the eventual assembly of pre- and postsynaptic densities.

Target-Dependent Control of Presynaptic Release Probability

There is now widespread agreement that target-derived retrograde signals participate in the activity-dependent modulation of presynaptic function. Retrograde signals include the endocannabinoids, neurotrophins, and growth factor signaling molecules. Throughout the nervous systems of both vertebrates and invertebrates, evidence has also accumulated demonstrating that target cells specify the steady-state release properties of impinging presynaptic nerve terminals. The basis for this phenomenon is the demonstration that a single presynaptic neuron can establish synaptic connections with very different release properties, simultaneously, on different target cells (Figure 2(a)). A common finding is that a presynaptic neuron can simultaneously form low-release probability, facilitating synapses with one target, and high-release probability, depression-prone synapses with a second target (Figure 2). In each example, it is clearly established that differences in release probabilities and short-term dynamics are a consequence of presynaptic differences, rather than reflecting differences in the detection of neurotransmitter by the postsynaptic targets. As a result, it seems likely that the target cell, or a target-associated glial cell, determines the steady-state release properties of impinging presynaptic nerve terminals. If so, this type of retrograde influence may be a general feature of synapse development, even in circumstances wherein presynaptic terminals are formed at only a single target type.

The ability of a single presynaptic neuron to form synaptic connections expressing a different release probability at separate targets has profound importance

Figure 2 Retrograde specification of presynaptic release probability. (a) A single neuron is able to make synapses of different types, simultaneously, at two different target neurons. Synaptic terminals at target A have a low probability of release and facilitate during a train of action potentials. Synaptic terminals at target B have a high probability of release and depress during a train of action potentials. (b) In the rat cortex, layer 2/3 pyramidal cells are able to make synaptic connections simultaneously with bitufted and multipolar interneurons. Synapses contacting bitufted interneurons have a small presynaptic calcium transient and low-release probability and express facilitation. Synapses with multipolar interneurons have a large presynaptic calcium transient and high-release probability and express short-term depression.

for neural circuit function and animal behavior. For example, in the leech nervous system, a single sensory neuron makes low-probability, facilitatory synapses with one motoneuron (MN1) and high-probability, depression-prone synapses with a second motoneuron (MN2). In response to noxious stimulation, the sensory neuron first recruits MN2, leading to a contraction of the skin. After a short delay, synaptic facilitation brings MN1 to threshold, leading to a body bend away from the noxious stimulus. In this manner, the sequential emergence of two distinct behaviors is achieved by a single sensory neuron. As another example, in the arthropod, distinct classes of external sensory organs encode information about wind velocity versus acceleration. Acceleration detectors contact one postsynaptic target with low-probability, facilitatory synapses while velocity sensors contact a second target with high-probability, depression-prone synapses. A small number of sensory organs encode both velocity and acceleration and contact both postsynaptic targets, simultaneously making synapses appropriate for each target cell type. Again, it appears that the target cell specifies the release properties of impinging presynaptic nerve terminals, and this is directly relevant to the function of the surrounding neural circuit and animal behavior.

Nearly identical phenomena have been observed in the mammalian central nervous system (CNS). For example, layer 2/3 pyramidal neurons in the cortex contact bitufted interneurons with low-probability, facilitating synapses, and simultaneously contact multipolar interneurons with a higher probability, depression-prone synapse. Similar phenomena have been observed in other regions of the mammalian CNS. In each example, target-dependent specification of presynaptic release properties is predicted. Interestingly, in the cortex, target specification of presynaptic release probability changes over the course of development. It is interesting to speculate that stable, steady-state release properties of the presynaptic terminal could be modulated by retrograde signaling systems over time. Ultimately, the retrograde signal that is responsible for specifying presynaptic release probability and associated short-term plasticity is unknown.

Retrograde Signaling and the Homeostatic Modulation of Presynaptic Function

Homeostasis refers to the ability of a cell or a system of cells to respond to a perturbation and maintain a constant physiology. Experimental evidence now supports the existence throughout the nervous system of homeostatic signaling systems that control the firing properties of individual cells. Based upon these data, it is hypothesized that homeostatic signaling systems interface with the mechanisms of neural plasticity in order to maintain stable neural function over time.

Experimental support for homeostatic control of neural function has been documented throughout the central and peripheral nervous systems. In each case, (1) homeostatic regulation was observed following an experimental perturbation that altered the steady-state electrical properties of nerve or muscle cells, (2) the cells responded to the experimental perturbation by altering ion channel density, neurotransmitter receptor density, or the probability of neurotransmitter release at impinging presynaptic nerve terminals, and (3) the modulation of these parameters restored cellular activity to baseline levels observed prior to the experimental perturbation. This precise restoration of baseline (set-point) cellular activity is a fundamental property of homeostatic signaling.

There are several examples wherein homeostatic regulation of nerve or muscle activity is achieved by a retrograde signal that modulates synaptic transmission. For example, central neurons, both *in vitro* and *in vivo*, that experience chronic activity blockade undergo a wide range of compensatory, homeostatic changes (**Figure 3**). Chronic activity blockade leads to altered ion channel density at the cell surface as well as altered surface expression of both excitatory and inhibitory neurotransmitter receptors. In several cases, the impinging presynaptic nerve terminals are also modified in a homeostatic manner. Presynaptic changes include altered neurotransmitter release, altered active zone size, and altered synaptic vesicle pool size. Some of these effects may be a direct consequence of altered postsynaptic neurotransmitter receptor abundance. However, other changes, such as presynaptic release probability, may require active, homeostatic signaling from the postsynaptic cell to the presynaptic element. The molecular basis of such a transsynaptic, homeostatic signaling system is unknown. Interestingly, a glial-derived intercellular signal mediated by tumor necrosis factor-α (TNF-α) is both necessary and sufficient for the homeostatic modulation of glutamate receptor abundance in the CNS. Whether this signal could mediate altered presynaptic release remains to be determined.

The neuromuscular junction of organisms ranging from *Drosophila* to rodents and humans shows clear evidence of a homeostatic signaling system that requires a retrograde signal from muscle to nerve. For example, at the *Drosophila* NMJ, chronic impairment of postsynaptic neurotransmitter receptor sensitivity leads to a compensatory increase in presynaptic transmitter release that precisely counteracts the change

Figure 3 Homeostatic control of neural function. Top: The activity of a neuron is determined by a balance of synaptic excitation (synapses with red vesicles and red receptors), synaptic inhibition (blue vesicles and blue receptors), and the abundance of ion channels that depolarize the cell (red ovals) or hyperpolarize the cell (blue ovals) in the central nervous system (CNS). In response to pharmacological activity blockade (black arrow), central neurons can change the abundance of ion channels to reestablish baseline neural activity. Chronic activity blockade can also cause homeostatic changes in the surface expression of neurotransmitter receptors, including excitatory (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid)-, inhibitory (γ-aminobutyric acid)-, and *N*-methyl-D-aspartate-type postsynaptic neurotransmitter receptors. Bottom: At the neuromuscular junction (NMJ), impairment of postsynaptic neurotransmitter receptor sensitivity leads to a compensatory increase in presynaptic neurotransmitter release that precisely offsets the change in receptor function, to achieve normal synaptic depolarization of the muscle. Adapted from Marder E and Prinz AA (2002) Modelling stability in neuron and network function: The role of activity in homeostasis. *Bioessays* 24: 1145–1154; and Davis GW (2006) Homeostatic control of neural activity: From phenomenology to molecular design. *Annual Review of Neuroscience* 29: 307–323.

in receptor function to achieve normal muscle depolarization (Figure 3). Several variations on this experiment have been performed. For example, impairing postsynaptic membrane excitability directly, through overexpression of an inward rectifying potassium channel (Kir2.1), initiates a similar retrograde, homeostatic increase in presynaptic transmitter release. Conversely, increasing muscle excitation by superinnervating the muscle leads to a compensatory decrease in presynaptic release probability. Nearly identical experimental results have been obtained at the rodent and human NMJ, demonstrating the existence of a highly conserved, homeostatic, retrograde signaling system.

Although the nature of the retrograde signaling systems capable of increasing and decreasing presynaptic release remains unknown, a recent series of experiments has defined several parameters that specify how this retrograde transsynaptic signaling system may work. First, it was demonstrated that a homeostatic increase in presynaptic release could be achieved in 10 min following application of sub-blocking concentrations of a postsynaptic glutamate receptor antagonist (philanthotoxin). In these experiments, evidence of altered presynaptic release could be observed in as little as 2 min, suggesting that the homeostatic signaling system was able to detect altered receptor function and initiate a change in presynaptic release in a time frame of seconds to minutes, far more rapidly than previously thought. This study also demonstrated that the induction of homeostatic signaling is independent of new protein synthesis and is independent of neural activity. The experimenters suggested that the spontaneous release of neurotransmitter that persists in the absence of activity-dependent neurotransmitter release is sufficient to induce the retrograde, homeostatic modulation of presynaptic release following postsynaptic receptor inhibition.

Another interesting feature of retrograde, homeostatic signaling is that presynaptic transmitter release is precisely (quantitatively) tuned by the retrograde signaling system to correctly offset the magnitude of postsynaptic receptor perturbation. For each synapse analyzed, the decrease in postsynaptic receptor sensitivity, estimated by average spontaneous miniature excitatory postsynaptic potential (mEPSP) amplitude, is precisely offset by a compensatory increase in presynaptic vesicle release such that muscle depolarization (EPSP amplitude) is constant. Thus, the retrograde homeostatic signaling system is not only rapid, but is also sensitive enough to detect small changes in postsynaptic receptor sensitivity. Furthermore, the retrograde signal is able to convert the magnitude of the postsynaptic perturbation into a precise change in presynaptic release. Such a precise modulation of presynaptic release is quite remarkable when compared to other forms of synaptic plasticity.

The molecular mechanisms of rapid, precise, homeostatic modulation at the *Drosophila* NMJ have yet to be clearly defined. However, forward genetic screens are beginning to identify some of the molecular players. It was recently shown that mutations that perturb the functionality of a presynaptic $Ca_V2.1$ calcium channel homolog abolish the rapid induction and sustained expression of synaptic homeostasis at the *Drosophila* NMJ. The involvement of a presynaptic calcium channel fits with the rapid, precise modulation of presynaptic release in this system. The requirement of a presynaptic calcium channel for synaptic homeostasis induced by postsynaptic receptor inhibition also supports the existence of a retrograde, transsynaptic signaling system.

The nature of the retrograde signal at this synapse remains to be identified. Recent experiments have demonstrated that bone morphogenetic protein (BMP) signaling strongly influences the growth and stability of the *Drosophila* NMJ. These experiments provided evidence that the BMP ligand, named glass-bottom-boat, can be released from muscle and can signal to BMP receptors on the presynaptic motoneuron. The presynaptic receptors and the downstream canonical signaling pathway to the motoneuron nucleus are necessary for normal synaptic growth. Recent experiments demonstrate that the BMPs are necessary for the homeostatic modulation of presynaptic release in response to postsynaptic glutamate receptor blockade. However, because the BMPs are also necessary for both synaptic growth and synapse stability, it remains unclear whether the BMPs represent a homeostatic signal, or whether the NMJ is simply crippled following the loss of BMP signaling. Thus, the precise nature of the retrograde signal at the NMJ remains to be clearly defined.

Conclusions

Retrograde signaling during synapse formation and modulation is a common process. Retrograde signals are diverse and include direct transsynaptic linkages, growth factors, morphogens, and endocannabinoids. Despite remarkable advances, many phenomena exist that seem to require retrograde signaling systems of unknown identity. Forward genetic and proteomic approaches to neural development may hold the key to identification of these elusive transsynaptic signaling systems.

Retronasal Olfaction

Introduction

Definitions of Retronasal Smelling and Retronasal Olfaction

Preliminary definition A literal meaning of retronasal is behind the nose. Olfaction can mean smelling. Consequently, retronasal olfaction can mean smelling from behind the nose. That definition immediately raises two questions: Where is behind the nose, and what is there to be smelled? In this context, nose denotes not only the protruding part of the face that is equipped with the nostrils but also the space (nasal cavity) and nasal structures that immediately follow each nostril (Figure 1). During respiration with the lips closed, air moves through the nasal cavities and across their structures, as well as through the pharynx. When exhalation occurs with the lips closed, air from the respiratory system travels through the pharynx, then through the nasal cavity, and exits from the nostrils.

Final definitions The region of the pharynx closest to the nasal cavity is called the nasopharynx. Farther away from the nose, the pharynx forms the back of the mouth (also called the oral cavity). For a typical mammal that moves around on four legs, the region behind the nose includes the oral cavity. In humans and other bipedal mammals, the upright posture changes behind to below for the oral cavity. Nonetheless, the oral cavity is after, or back from, the nose, if one thinks of inhaling air through the nose and then follows the inward airflow path. This inward airflow pathway, beginning at or near the nostrils and passing through the nasal cavities into the pharynx, is called the orthonasal pathway (Figure 1).

The exhalation airflow pathway, along which air flows in a direction opposite to orthonasal movement, is known as the retronasal airflow path (Figure 1). During an exhalation, air will always move through the pharynx. Because the pharynx is the back of the oral cavity, a respiratory exhalation will include some air from the oral cavity. From this oropharyngeal region, expired air may primarily exit from the mouth if the lips are parted, or retronasal airflow may move through the nasal cavities if the lips are closed (airflow from the oropharyngeal region can be excluded from the nasal cavities by elevation of the velum (Figure 1) or by closure of the nostrils). If there are substances in the oral cavity air that could be smelled (all such substances are known as odorants), and if those odorants, at a sufficient concentration, reach appropriate sensory receptors, then retronasal smelling will occur. Therefore, retronasal smelling denotes smelling odorants that originate from the oral cavity (and odorants coming from the oral cavity are called retronasal odorants). When retronasal smelling occurs with air exiting entirely from the mouth, with none reaching the nasal cavities, the relevant sensory receptors must be in the oropharyngeal region (Figure 1).

Retronasal smelling becomes retronasal olfaction if the smelling of odorants that originate from the oral cavity occurs only after the odorants reach the nasal cavity, and stimulates there only the olfactory receptors (see the section titled 'Nasal cavity receptors'). Stated differently, all smelling of odorants from the oral cavity can be called retronasal smelling. Smelling from the oral cavity is probably retronasal olfaction if the odorants must reach a nasal cavity to be smelled, and is unequivocally retronasal olfaction if the odorants require an intact olfactory system to be smelled (see the section titled 'Nasal cavity sensory systems').

Odorants from the Oral Cavity

What may be smelled from the oral cavity largely depends on what one chooses to put there. Under normal circumstances, all food or drink enters through the oral cavity. Once in the mouth, ingested foods change as they mix with saliva and are chewed and manipulated. This modifies both the concentrations and the characteristics of the food-derived odorants available for retronasal smelling. Physical measurements verify that odorants released from foods in the oral cavity (i.e., retronasal odorants) can reach a nasal cavity and exit via a nostril (Figure 2). In addition, separate from eating or drinking, pathological conditions of gums, tongue, or other oral cavity tissues can result in oral cavity odorants.

Sensory Systems for Retronasal Smelling and Retronasal Olfaction

Oral cavity receptors There are a number of sensory receptors in the oral cavity that respond to chemical, thermal, or mechanical properties of substances in the mouth. Some of these receptors can be stimulated by certain odorants. Those oral cavity sensory receptors that respond to vapor phase (dissolved or suspended in air) odorants are part of the trigeminal sensory system (Figure 1). The odorants that can stimulate the receptors of the trigeminal sensory system,

Figure 1 Model of the human left nasal cavity. The nasal valve (not shown) is a region of deformable, elastic cartilage not very far (1–2 cm) from the nostril. Much of the nasal cavity is innervated by branches of the trigeminal nerve (see **Figure 3**); the ethmoid and palatine branches are shown. Within the nasal cavity, the olfactory epithelium, where the olfactory receptor neurons (ORNs) are located, is depicted on the upper part of the middle turbinate and on the superior turbinate. The area labeled 'Olfactory epithelium' also represents the narrow cavity called the olfactory cleft. The axons of the ORNs, depicted as fascicles (nerve bundles) of the olfactory nerve, are shown originating in the olfactory epithelium, passing through the skull, and terminating in the olfactory bulb of the central nervous system. The orthonasal smelling pathway, with odorant entering through a nostril, is shown to the right of the figure. On the left, the retronasal smelling pathway, with odorant entering from the nasopharynx, is depicted. When the velum (far left portion of the soft palate) is down, as shown, a connection between the oral and nasal cavities is available. Below the nasopharynx, the pharynx continues, forming the back of the oral cavity (not shown). The palate is the roof of the oral cavity.

Figure 2 Mass spectrometer (MS-Nose) analyses of ions in the breath of a human while eating an imitation cheese. Input to the MS-Nose was from a nostril via an open tube and a perpendicular capillary. The cheese was in bite-size pieces and was eaten naturally, without constraints. Molecular ion 145 was ethyl hexanoate; 131 was isoamyl acetate; and 107, benzaldehyde. All three molecules had been incorporated into the imitation cheese. The known molecular ions appeared with each exhalation and disappeared after one or two swallows. Modified from Deibler KD (2001) *Measuring The Effect of Food Composition on Flavor Release Using the Retronasal Aroma Simulator and Solid Phase Microextraction*. PhD Thesis, Cornell University, with permission.

whether in the oral cavity or elsewhere (e.g., the nasal cavities), are called trigeminal odorants.

Each time a terrestrial mammal exhales, some of the air in the oral cavity, and the odorants in it, moves as part of the exhaled air. As already noted, with the lips closed, airflow during exhalation will reach and pass through the nasal cavities. Nonetheless, during an early phase of such retronasal airflow, if trigeminal odorants are present, stimulation by trigeminal odorants of trigeminal receptors in the oropharyngeal region may occur before these retronasal odorants reach the nasal cavities.

Nasal cavity receptors If one exhales with the lips closed, the air sampled from the oral cavity travels through the nasal cavities. If there are vapor phase chemicals in the oral cavity, they will reach the nasal cavities and outflow through the nostrils (**Figure 2**). As is the case for the oral cavity, there are many sensory receptors in the nasal cavities that can respond to chemical, thermal, and mechanical events. Among these nasal cavity sensory receptors are trigeminal receptors that respond to trigeminal odorants (see **Figures 1 and 3**). These nasal cavity trigeminal receptors may be stimulated not only during retronasal airflow (exhalation) but also during orthonasal airflow (inhalation).

In vertebrates the receptors of another sensory system that responds to odorants occur only in the nasal cavities. They are the receptors of the olfactory system, that is, olfactory receptor neurons (ORNs; see the section titled 'Nasal cavity sensory systems'). As a group, ORNs are responsive to very low concentrations of many different odorants, with each ORN responsive to only some odorants. ORNs can be stimulated during exhalations (retronasal airflow) or inhalations (orthonasal airflow).

There is a nonsymmetrical relationship between ORN responses to odorants and trigeminal receptor

Figure 3 Schematic representation of the sensory innervation of the nasal cavity. An olfactory receptor neuron (ORN) of the olfactory epithelium is depicted surrounded by supporting cells, with the most distal part of its dendrite, and many of its cilia, extending beyond the cellular olfactory epithelium into the noncellular, continuously secreted mucus layer that overlies the epithelium. The axon of the ORN extends toward the olfactory bulb (not shown). The trigeminal nerve endings (lower portion of figure; also called trigeminal receptors) are depicted within the epithelia, both in the olfactory epithelium (left portion of figure) and in the nonolfactory respiratory epithelium (right portion of figure). In the mucus layer, odorants which had partitioned from respiratory air are shown. Once in the mucus layer, odorants can reach and stimulate the cilia of the ORN that are within it (indicated by short, solid arrow), but odorants must travel a longer distance, penetrating into the cellular epithelia (long, dotted arrows), before trigeminal stimulation is possible. Modified from a schematic drawing provided by Charles J Wysocki, Monell Chemical Senses Center, Philadelphia, PA.

responses: because of the high sensitivity and broad responsiveness of the population of ORNs, some of the ORNs will probably respond to any trigeminal odorant, but trigeminal receptors will not respond to some olfactory odorants and can respond to certain others only at high concentrations. The odorants that appear to stimulate only ORNs are known as purely olfactory odorants. In human they include vanillin, phenylethyl alcohol, and octanoic acid. Conversely, very effective human trigeminal odorants (which will also, of course, stimulate ORNs) include heptyl alcohol, DL-menthol, and valeric acid.

Air and Odorant Movement and Access to Sensory Receptors

Fluid flow Air is a fluid. It is less dense than liquid fluids such as liquid water, but nonetheless, movement of air has many similarities to movement of water. Because we usually cannot see the movement of air, it can be difficult to think about what happens when moving air abuts surfaces. With reference to the nasal and perhaps oral cavities, the effects on the flow of air of interactions between air and the surfaces or objects that air contacts as it moves can be important.

Considering liquid water instead, imagine a relatively small stream. Now imagine a rock or similar object near one bank of the stream, not blocking the stream but protruding into it. Far from the rock, both before it and after it, the water may move smoothly, with no obvious effects of interactions between the rock in the moving fluid and the fluid. However, in the immediate vicinity of the rock, turbulence develops, eddies form in some places, still water in others. The result is that contact between the water (and whatever is dissolved in the water) and the bank and bed of the stream is changed in the immediate vicinity of the object that protrudes into the flowing fluid.

Suppose that at one point the stream widens, so that one side continues at the usual depth but the other side is shallower. Most of the water will continue to flow in the deeper region, but a small proportion will reach the wider area. The small volume of water flowing through the wider region may move more slowly and is likely to contain fewer of the particles that are suspended in the rapidly flowing water. Because of this, the banks and bed of the shallower area are protected from mechanical damage that may occur in the rest of the stream. The concentrations of substances dissolved in the water are probably equal in the large flow volume and the small flow volume regions, but the total amount of the substances present in the small flow volume region must be less.

Nasal cavities The hypothetical effects of a rock in a stream of water have similarities to moving respiratory air and the odorants dissolved in it. As the air passes through the nasal cavities, small protuberances in the narrow and complex spaces of a nasal cavity can have substantial local effects on the pattern of air movement. The consequence is that odorants can more easily reach some parts of the nasal cavities than others. Because of this, some of the sensory receptors of the nasal cavities can receive greater amounts of odorant stimulation than other nearby

regions that are separated by a small bump or a sharp turn. In addition, the characteristics of some nasal cavity structures result in differences between the flow patterns of inhaled versus exhaled air. These differences mean that odorant access during retronasal airflow can be different from that during orthonasal airflow (see the section titled 'Functional anatomy of retronasal olfaction and retronasal smelling').

A similarity also exists between airflow in the nasal cavities and the hypothetical widened region of the stream, described above, that received only a small proportion of the total fluid flow. In the nasal cavities, most of the respiratory air flows across structures that have only trigeminal sensory receptors (Figure 1). Only a small proportion of the flowing air arrives at the ORNs of the olfactory epithelium, which is located on nasal cavity structures (turbinates) away from the main airflow pathway. Because of this, the amounts of odorants that can have access to the ORNs are much less than the total amount in respiratory air.

Oral cavity It is possible that airflow in the oral cavity may be complex in some locations. Unfortunately, adequate data are not available.

Functional Anatomy of Retronasal Olfaction and Retronasal Smelling

Nasal Cavity Structure

A region of high resistance to airflow near each nostril of the nasal cavities can modulate movement of respiratory air. This region, the nasal valve (there may be more than one in humans; Figure 1), functions differently during exhalation and during inhalation. One result is that the pattern of retronasal odorant movement in the nasal cavities differs from that of orthonasal odorants (orthonasal odorants are odorants originating at or near the nostrils). After the valve(s), narrow, twisting spaces through which respiratory air must flow can be created by epithelium-covered curved bones (the turbinates). The size, shape, and number of turbinates vary considerably among mammals. As the air flows, some of the odorants it carries adhere to the mucus that covers the turbinates, with the physical and chemical properties of the odorants allowing differential partitioning into the mucus (Figure 3). This permits odorants to reach the sensory receptors that protrude into (cilia of ORNs) or lie beneath (trigeminal receptors) the mucus. In addition, transfer of odorants into the mucus reduces the concentrations of odorants available for subsequent receptors. Therefore, because overall respiratory flow within the nasal cavities is in different directions for exhalation and inhalation, the locations of maximum and minimum odorant concentrations may be quite different during retronasal and orthonasal airflow. The general concept of selective transfer of odorants from the respiratory air onto and into the mucus that overlies the epithelium-covered turbinates has been termed the gas chromatographic model of olfaction.

Nasal Cavity Sensory Systems

Two different sensory systems supply receptors in a nasal cavity (Figures 1 and 3). Trigeminal receptors occur on all its surfaces, but ORNs are located only in an area away from the main path of respiratory air. In humans, the olfactory epithelium occurs on the superior turbinate and the upper part of the middle turbinate (Figure 1). This area, the olfactory cleft, receives air that is at body temperature, is humidified, and is free of large suspended particles because of the twisted airflow paths produced by the turbinates. A consequence is that only the chemicals in respiratory air are available to stimulate the ORNs. In some mammals, perhaps including humans, ORNs that respond well to one type of odorant are grouped together, somewhat separate from ORNs that respond well to another type of odorant. Because of this local grouping of ORNs, the opposite flow directions of retronasal and orthonasal olfaction may produce opposite patterns of ORNs responses.

Olfactory receptors are not permanent Individual ORNs are not permanent structures. In vertebrates, including humans, each is replaced in normal adults on a timescale of several months. Every new ORN must extend to and make appropriate connections in the central nervous system (CNS; see the section titled 'CNS connections') in order to maintain a functional olfactory system.

Trigeminal receptors are not replaced In contrast, trigeminal sensory neurons, in common with all other nonolfactory peripheral sensory neurons, are not replaced in mammals. Recovery is possible if the receptor end is damaged, but loss of an entire trigeminal neuron is permanent.

CNS Connections

Olfactory bulb Each ORN has an axon that can carry into the CNS action potentials generated at the receptor end (Figure 3). All these axons end in a CNS structure, the olfactory bulb (Figure 1), where thousands synapse with one of the principal neurons of the olfactory bulb (called mitral and tufted cells). These synaptic regions are known as glomeruli.

In some mammals, and perhaps in humans, the axons of ORNs that respond better to one type of odorant than to other types of odorants (related to the molecular features of the odorants) converge into a few glomeruli. Such odorant-dependent (molecular feature-related) convergence can produce glomerular regions that are functionally distinct from other regions. This may yield, in the olfactory bulb, clusters of neural activity that are related to the odorants present at that time at the cilia of the various ORNs. For some fixed sets of odorants, retronasal olfaction may give bulbar neural activity patterns that are different from those for orthonasal olfaction. This can occur because odorants in retronasal airflow may reach, and stimulate, some ORN regions earlier than would odorants in orthonasal airflow. In addition, the opposite concentration profiles resulting from opposite flow directions across the mucus will contribute to different active olfactory bulb regions across time.

The olfactory bulb is a complex CNS structure. Its mitral and tufted cells have connections to each other through small neurons within the olfactory bulb (interneurons) which transform the input from the ORNs. The mitral and tufted cells themselves have axons which leave the olfactory bulb and reach other parts of the CNS. In addition, axons from other CNS areas enter the olfactory bulb and affect its neural activity.

Trigeminal CNS nuclei The trigeminal sensory receptors, which are the sensory ends of neurons, have axons which enter the CNS quite separately from the axons of ORNs and synapse in very different locations. The trigeminal axons from the oral and nasal cavities go to one or more hindbrain nuclei, including the principal (i.e., sensory) nucleus and the spinal nucleus of the trigeminal nerve. The synaptic positions in these nuclei reflect the locations of trigeminal receptors in epithelia of the nasal or oral cavities, that is, a somatotopic mapping. Because of this spatial correspondence between trigeminally innervated regions in the nose or mouth and areas of termination in the brain, the patterns of activity in these CNS nuclei may reflect the movement of trigeminal odorants through the oral or nasal cavities. Consequently, the pattern of activity in trigeminal regions of the CNS in response to retronasal smelling may differ from that in response to orthonasal smelling.

Human Retronasal Responses

Psychophysical Judgments

Airflow patterns and odorant distributions in the nose and mouth during inhalation and exhalation are known to differ. These distinctions between orthonasal and retronasal airflow are related to the structural characteristics of the oral and nasal cavities. The olfactory or trigeminal sensory systems innervate these cavities. Their molecular-feature or topographic-related terminations in the CNS may have functional importance for retronasal smelling. However, interest in these anatomical, chemotopic, and fluid-dynamical data must be motivated by observations that psychophysical measures of retronasal and orthonasal smelling show noteworthy differences or important interactions. In addition, reports that retronasal smelling can show dysfunction in humans would also be important. Both the psychophysical differences and selective retronasal pathology are described in the next section and the section titled 'Clinical relevance.'

Thresholds For humans to detect them, odorants from a retronasal location, that is, normally originating from the oral cavity, must be at a higher concentration than the same odorants from an orthonasal location (at or near the nostrils). Stated more succinctly, detection thresholds are higher for odorants from a retronasal location than from an orthonasal location. This difference could be the result of disparate airflow and odorant delivery from the two loci, or it might reflect higher sensitivity of the sensory systems if odorants enter the nasal cavity from the nostrils. The latter possibility, greater sensitivity for odorants from a orthonasal location, was confirmed by delivering odorants at constant flow rates through tubes that were placed just after the nasal valve for a orthonasal locus or just beyond the nasal cavity (in the nasopharynx) for a retronasal location (see Figure 1). A physical measurement, based on odorants arriving in the olfactory cleft, demonstrated equal concentrations at the olfactory epithelium.

Identification Identifications of odorants from a retronasal location are less accurate than identifications when the odorants arrive from a orthonasal location if relatively low concentrations are used or if only quiet normal breathing is permitted. However, differences between orthonasal and retronasal identification accuracy diminish or disappear if higher concentrations are employed, if deep breathing is encouraged, or if the concentration are selected to provide equal retronasal and orthonasal intensity (i.e., isointense concentrations). Thus, rather than a difference in identification ability, a retronasal sensitivity that is less than orthonasal may be the cause. Nonetheless, a need for higher concentrations may not be the only factor, because odorants, when in a retronasal location, may be described differently than

when in an orthonasal location. This implies that, in addition to diminished sensitivity, qualitative processing of retronasal stimulation may differ from orthonasal processing.

Intensity There is a lack of consistency with regard to effects of odorant location on intensity. For the odorants lavender, butanol, farnesol, and hydrogen sulfide (possibly a trigeminal odorant), delivered either near a nostril (orthonasal location) or in the nasopharynx (retronasal location), retronasal intensity is less than orthonasal. However, applying the same procedure using phenylethyl alcohol (purely olfactory odorant) and chocolate, no difference occurs between retronasal and orthonasal intensity. It is not obvious why there are intensity differences for some odorants but not for others. With a more conventional odorant delivery procedure, odorants that had first been selected to be isointense retronasally and orthonasally are less intense retronasally when judged over time (time–intensity tracking). In this instance the psychophysical procedures may explain the difference.

Adaptation In most sensory systems, prolonged exposure to an unchanging stimulus results in a reduced response magnitude. This phenomenon is known as adaptation. The rate of response decline, the presence or absence of a brief, initial high magnitude response (phasic or dynamic component), and the existence of a sustained response to continuing stimulation (tonic or static component) all differ between sensory systems and sometimes between types of receptor within a sensory system (e.g., slowly versus rapidly adapting cutaneous mechanoreceptors). Olfactory adaptation to orthonasal odorants has been extensively described in the literature, but few data are available for retronasal adaptation. Direct comparisons using anise, orange, coffee, peppermint, and strawberry odorants found a general similarity between retronasal and orthonasal adaptation over 60 s. However, for odorants in the orthonasal location, but not in the retronasal, intensity rose before declining. This result (a phasic component only to odorants from an orthonasal location) suggests that there is a CNS processing distinction between retronasal and orthonasal smelling. Replication and further exploration of these observations will be informative.

Interactions Under typical eating conditions for humans and other terrestrial mammals, food-derived odorants originating from the oral cavity and via the nostrils may occur successively. Once in the mouth, ingested foods change as they mix with saliva and are chewed and manipulated. This modifies both the concentrations and the characteristics of the food-derived odorants available for retronasal smelling, compared with the unmodified odorants delivered via the orthonasal route. With natural breathing, a brief interval (1–2 s in humans) would separate stimulation via the oral cavity from orthonasal input during eating because there is typically a pause between inhalation and exhalation. This temporal separation might prevent sensory interactions between retronasal and orthonasal smelling or might limit interactions to an overall reduction in identifications. Surprisingly, the accuracy of identifications of odorants smelled by humans in this cyclical manner (without sniffing) was lower only for orthonasal odorants. This outcome could reflect processing effects or attention differences that favor retronasal smelling under these circumstances. However, the measurements were made after the odorants were removed. It follows that odorant memory was an important factor, perhaps with unequal consequences for orthonasal and retronasal odorants. In addition, the odorant smelled second (i.e., last) was generally reported as having been smelled first, irrespective of its oral (retronasal) or nasal (orthonasal) origin. This recency effect is commensurate with prior observations that odorant-based judgments of serial order are often unreliable. Overall, these data reveal interesting and potentially important differences between retronasal and orthonasal smelling. However, their relevance to normal eating is unclear because under natural conditions, memory would be a less significant factor.

CNS Responses in Humans

Odorant-evoked potentials Electroencephalogram-type recording made in synchrony with a brief sensory event may yield a CNS event-related potential (ERP). Generally, stimuli must be repeated many times and averaged to obtain a measurable ERP. ERP is a direct measure of CNS bioelectric activity, albeit of relatively large populations of neurons. ERP studies with auditory or visual stimuli can use large numbers of very brief stimuli, with short time intervals between the presentations. This is the case because the stimuli are rapidly transduced (converted from environmental energy to cellular biological activity), with the mechanical or electromagnetic energy fully dissipated. When the stimuli are odorants, both access to vertebrate receptors and transduction are slower. Perhaps more important, the odorant chemicals remain within the mucus and the epithelium, in the immediate vicinity of the receptors,

for an extended time. Because of these factors, studies of olfactory ERPs (OERPs) generally must employ stimulus durations of hundreds of milliseconds and must allow long intervals between presentations. A result is that about 30 min may be required for a sufficient number of odorant presentations, compared with 1–2 min for auditory or visual stimuli. An additional complexity is that odorant stimulation of terrestrial vertebrates normally requires the movement of air, thus adding a potential mechanical stimulation to the chemical event of interest. The possibility of responses to air movement itself may not be troublesome when investigators are recording directly from olfactory receptors or their axons, but it must always be controlled for in OERP studies.

Human retronasal and orthonasal OERPs were compared by means of a presentation of 200 ms of phenylethyl alcohol or H_2S, separated by 40 s and delivered 40 times each. Presentations were either orthonasal, delivered just beyond the nasal valve, or retronasal, delivered to the nasopharynx (see Figure 1). All OERP components of interest had mean latencies greater than 400 ms and would be considered long-latency cerebral cortical components, perhaps with substantial cognitive aspects. The amplitude of N1 (first negative-going component) did not differ as a function of odorants originating from retronasal or orthonasal loci, although N1 retronasal latency was longer for phenylethyl alcohol. However, retronasal P2 (second positive-going component) amplitudes to phenylethyl alcohol were significantly smaller. For both odorants, retronasal P2 latencies were longer. The longer retronasal latency and lower amplitude to retronasal odorant delivery suggest smaller CNS response magnitudes. Paradoxically, psychophysical measures found reduced retronasal intensity for H_2S but not for phenylethyl alcohol (see the earlier section titled 'Intensity'). Thus, differences between orthonasal and retronasal OERPs can be observed, but the interpretation is unclear.

Functional magnetic resonance imaging Within the CNS, the more active neural regions will have a higher metabolic rate and will use more oxygen. Therefore, an indirect indication of increased regional neural activity is a local alteration in the oxygen level of the blood, specifically in the hemoglobin of the oxygen-carrying cells, the erythrocytes. The resultant status of vascular hemoglobin is called blood oxygen level demand (BOLD). For the intact human brain, BOLD can be measured by magnetic resonance imaging (MRI). MRI uses imposed electromagnetic fields to determine the state of the hydrogen atoms in hemoglobin, thereby indicating the extent to which oxygenated hemoglobin has changed in regions of the brain. Computer-based comparisons of MRI signals in several areas of the brain is called functional MRI (fMRI). If responses to odorants are studied with fMRI, odorless airflow control conditions must be used, as is required for OERPs. Another similarity to OERP stimulus protocols is that to yield useful fMRI data, odorant presentations must be repeated many times.

In one study, odorants were delivered in 1 s odorant pulses every 3 s for 30 s in constantly flowing air to the nasopharynx (retronasal location) or just beyond the nasal valve (orthonasal location), with the velum elevated to isolate the nasal cavities from the oral cavity. Isolation of the nasal cavities using this velopharyngeal closure technique permits delivery of odorants to be independent of respiration and precludes possible oral cavity sensory stimulation. Differential cortical activation was observed, with larger responses to odorants (especially lavender) delivered to the retronasal locus found at the base of the left central sulcus and in the ventral insula. The left central sulcus region corresponds to the area previously found for somatosensory stimulation of the oral cavity. This cortical location for responses to retronasal smelling suggests a convergence of oral cavity-related sensory inputs. Unfortunately, the basis for the differential activation is unclear, because the participants judged the lavender odorant to be more intense orthonasally. However, another odorant, chocolate, which was judged to be isointense, also produced differential activation. Chocolate, delivered to the retronasal location, gave greater responses in the medial orbitofrontal cortex as well as in subcortical regions including the hippocampus and thalamus than when it was delivered orthonasally. Differences between areas of cortical activation for odorants delivered from retronasal versus orthonasal loci support the idea that retronasal and orthonasal smelling are processed differently.

Use of an elevated velum together with odorant delivery through intranasal tubes permits control of where and when odorants are delivered. This is a desirable outcome. To secure this control, the temporal pattern of odorant presentations is intentionally separated from the breathing rhythm and from sniffing, and the possibility of oral cavity stimulation by odorants is intentionally prevented. However, there may be accompanying drawbacks. First, smelling is decoupled from its normal sensorimotor context. This could be problematic because of suggestions that a lack of sniffing, or of breathing-patterned smelling, degrades olfaction. Second, preventing a potential sequence of oral cavity retronasal odorant stimulation followed by

nasal cavity stimulation might yield CNS responses to odorants from retronasal loci that differ from those to an unimpeded sequence.

Clinical Relevance

Because retronasal smelling is important in responses to food and beverages, quality of life may be reduced if retronasal smelling is impaired. Changes in nasal cavity architecture between the olfactory cleft and the nasopharynx (**Figure 1**) may alter retronasal smelling while having little effect on orthonasal smelling. A consequence of this nasal cavity pathology could be individuals who appear to have no olfactory deficit (i.e., they are normosmic) when tested orthonasally but who nonetheless complain of changes in appreciation of food. Retronasal dysfunctions of this sort have been verified: patients have been found with reduced ability to smell odorants from a retronasal location (i.e., retronasal hyposmia) but with orthonasal normosmia. This observation suggests that if complaints about food are accompanied by orthonasal normosmia, retronasal testing should be considered.

The opposite circumstance, retronasal normosmia but orthonasal hyposmia, has been found in patients exhibiting chronic swelling of nasal and sinus membranes (chronic rhinosinusitis) and numerous swollen tissue masses that arise from the epithelium of the nasal cavities or sinuses (multiple polyposis). In this case, the dysfunction of orthonasal olfaction might be due to mechanical obstructions in the anterior portion of the olfactory cleft. However, for this symptom and the previously noted retronasal hyposmia, more-complex functional factors may be involved. This is suggested because severe deficits in the ability to smell orthonasal odorants, together with retronasal normosmia, but unaccompanied by macroscopic pathology of the nasal cavities, has been reported. Specifically, abnormal smelling of odorants from an orthonasal location (orthonasal dysosmia) or even a total absence of ability to smell orthonasal odorants (orthonasal anosmia), together with absent OERPs to orthonasal odorants, but retronasal normosmia, has been observed in patients who showed no clinical abnormalities with computed tomographic scans and nasal endoscopic examinations.

Gene Expression

Genomic DNA contains the core genetic information of the cell; this information is contained in the sequence of the four DNA bases: adenine (A), cytosine (C), guanine (G), and thymine (T). During development, somatic cells display distinct patterns of gene expression that are stably inherited through cell division. Thus, in addition to the need for each somatic cell to contain the same primary DNA sequence as contained in every other somatic cell, there must be an additional layer of information that specifies which genes are to be used at which stage of development. The term 'epigenetics' was coined to describe variations in gene expression that are not due to changes in the DNA sequence.

Imprinting

Genomic imprinting is an epigenetic mechanism that regulates gene expression during mammalian development. Imprinting is a normal process by which certain genes are marked as coming from either the mother or the father. Based on the imprint, a subset of genes will be expressed or repressed, depending on parental origin, during development. It is thought that the differential modification of the maternal and paternal alleles is likely to affect the overall conformation of the chromatin, containing each allele, thus influencing interactions between the transcription machinery and the genomic template.

Some imprinted genes are expressed from a maternally inherited chromosome and are silenced on the paternal chromosome; while other imprinted genes are only expressed from a paternally inherited chromosome. Thus, imprints can act as a silencer or an activator for imprinted genes. Genomic imprinting plays a role in embryogenesis. Large numbers of imprinted genes identified in humans are involved in pre- and postnatal development. Multiple lines of evidence suggest that imprinted mammalian genes influence complex neuropsychological behavior and neuropathological disorders.

DNA methylation plays a critical role in imprinting. Differential methylation of specific DNA sequences, based on whether they are maternal or paternal in origin, is one method by which genes are identified and their expression is regulated. DNA methylation occurs in almost all living organisms. DNA methylation occurs primarily at the fifth position of cytosine (5mC) in the dinucleotide CpG (in which the 'p' represents a phosphate diester). CpG methylation can affect gene expression either directly or indirectly. By the direct route, CpG methylation alters the DNA sequence so that it is no longer recognized by transcription factors. By the indirect route, CpG methylation produces a ligand for chromatin-binding proteins such as MeCP2. These proteins bind to methylated CpG sequences and then target repressor complexes that contain histone deacetylases (HDACs), leading to the formation of a deacetylated and repressed chromatin structure that is refractory to the transcription machinery. Overall, DNA methylation results in gene silencing via the repression of transcription, by both direct and indirect routes.

The list of human diseases caused by or involving DNA methylation abnormalities has become quite long. Rett syndrome is an example of a disorder due to abnormalities in DNA methylation.

Rett Syndrome

Rett syndrome is a progressive disorder of brain development that is characterized by the loss of acquired motor and language skills, stereotypic movements, autistic features, and both sleep and respiratory abnormalities. Rett syndrome is caused by mutations in the X-linked gene (*MECP2*) encoding the methyl-CpG-binding protein 2 (MeCP2). The spectrum of *MECP2* mutations that cause Rett syndrome includes nonsense, missense, and frameshift mutations as well as intragenic deletions. Different mutations are associated with distinct clinical phenotypes. Rett syndrome is an autosomal dominant disorder with a penetrance of almost 100%.

Clinical Features

Females Classic Rett syndrome is seen in girls who are normal at birth and achieve expected developmental milestones until reaching 6–18 months of age. These affected females then develop deceleration of head growth, leading to microcephaly, with a loss of acquired language, cognitive, social, and motor skills. A distinctive feature is repetitive hand wringing that replaces purposeful hand movement. Additional stereotypies include clapping and mouthing.

In addition, there is development of an array of motor abnormalities, including gait apraxia, ataxia, spasticity, tremor, and dystonia. A temporary 'autistic-like' phase often occurs at the onset of the disorder,

Table 1 Phenotypes of Rett syndrome

Characteristic	*Classic Rett*	*Severe Rett*	*Atypical Rett*
Karyotype	46,XX 47,XXY 46,XY; somatic mosaic	46,XY	46,XY
Clinical features	Normal until 6–18 months Loss of milestones Microcephaly, hand wringing	Severe encephalopathy Death during infancy	Mild-to-moderate mental retardation

and older children are known for their social engagement through intense eye gaze. In addition, seizures and breathing irregularities, such as hyperventilation and apnea, develop. After an initial regression of attained milestones, the condition stabilizes and children typically survive until reaching an age between 15 and 20 years. The incidence of Rett syndrome is between 1/10 000 and 1/15 000 live births in females.

Males Prior to the identification of the *MECP2* gene and its mutations, it was thought that Rett syndrome in a male was lethal at the embryonic stage. However, it is now known that males are born with *MECP2* mutations and fall into one of three main phenotypic categories: (1) males with classic Rett syndrome, (2) males with severe encephalopathy and infantile death, and (3) males with less severe neurologic and/or psychiatric manifestations that include mental retardation.

Males with classic Rett syndrome have either a 47, XXY karyotype or are somatic mosaics with a 46,XY karyotype. Individuals who are somatic mosaics display varying levels of expression of a specific gene in different cells and tissues within the body. Thus, males who are somatic mosaics for a *MECP2* mutation may express the mutant MeCP2 protein in only specific regions of the brain, rather than throughout the brain. In other regions of the brain, and in other regions of the body, the mutant MeCP2 may be expressed at low levels, if at all. In theory, this could result in the phenotype of classic Rett syndrome, rather than a more severe phenotype. Males who fall into the phenotype of having classic Rett syndrome express the same phenotype as found in girls with classic Rett syndrome.

Males with severe Rett syndrome exhibit severe encephalopathy, die during infancy, and have a 46, XY karyotype. Males with either classic or severe Rett syndrome have the same MeCP2 mutations that cause classic Rett syndrome in girls. Those boys who have been identified with less severe neurological and/or psychiatric manifestations carry mutations in the *MECP2* gene that are not found in girls with any identifiable phenotypic abnormality of the central nervous system. Presumably, this is because any girl carrying such a mutation is a heterozygote (i.e., also carries a normal *MECP2* gene) and therefore the effect, if any, on phenotype is mild (see Table 1).

Neuropathology

Pathologic studies of the Rett syndrome brain were first described in 1986. The Rett patient brain is small for the age of the patient. There is no evidence of atrophy, degeneration, or demyelination or an inflammatory response. There is a significant poverty of dendrites in the frontal, motor, and inferior temporal lobes, with a simplified branching pattern in the dendrites that do exist. This finding is of significance because there is a temporal correlation between the age at which clinical regression is seen in classic Rett syndrome (6–18 months) and the time during which the projection and circuits of cortical layers III and V are organized (12–36 months). Taken together, these data support the hypothesis that Rett syndrome is a disorder of brain development.

Treatment

To date, there is no treatment for Rett syndrome. Prior to the discovery of the genetic defect that causes Rett syndrome and the development of animal models, only two compounds were subjected to well-designed clinical trials. Based on two reports indicating that L-carnitine may be helpful in Rett syndrome, a randomized, placebo-controlled, double-blind study was performed. Study participants were evaluated using a standardized scale that assessed both motor and behavioral skills. The trial revealed that there was no significant benefit to treatment with L-carnitine.

Naltrexone was also used in a clinical trial. The rationale for this study was that several studies reported increases in β-endorphin levels in the cerebrospinal fluid of girls with Rett syndrome. Thus, it was hypothesized that treatment with the opiate antagonist naltrexone may be beneficial. However, a controlled, randomized, double-blind clinical trial did not find any significant improvement in motor or behavioral skills with naltrexone therapy. It is

hoped that, with the availability of animal models of Rett syndrome, the evaluation of potential treatments for Rett syndrome will be enhanced and occur at a more rapid pace.

Methyl-CpG-Binding Protein 2

Mutations in the MeCP2 result in the neurodevelopmental disorder known as Rett syndrome. MeCP2 is a chromosome-binding protein that selectively binds 5-methylcytosine residues in symmetrically positioned CpG dinucleotides. These residues are preferentially located in the promoter regions of genes that are subject to transcriptional silencing after DNA methylation. MeCP2 contains two functional domains, an 85-amino-acid methyl-CpG-binding domain (MBD), essential for binding to 5-methylcytosine and a 104-amino-acid transcriptional repressor domain (TRD) that interacts with a variety of corepressor complexes, including histone deacetylase and the transcriptional corepressor Sin3A. Thus, a functional MeCP2 recognizes and binds to 5-methylcytosine residues in CpG islands. In turn, MeCP2 interacts with HDAC and Sin3A, resulting in a DNA–protein complex that renders the promoter region of the target gene inaccessible for the initiation of transcription. In this manner, MeCP2 is thought to play a critical role in gene repression.

Mutations in MeCP2 may result in the dysregulation of expression of hundreds or thousands of target genes. It is possible that mutations resulting in the loss of function of MeCP2 could result in overexpression of genes that may be detrimental to the development of the nervous system. One hypothesis regarding the pathophysiology of Rett syndrome is that the stability of brain function, or altered brain development, is due to the misregulation of genes in the absence of functional MeCP2 protein. However, the fact that Rett patients do not suffer severe abnormalities during fetal and early postnatal development implies that no specific programs of developmental gene expression are disrupted. It is conceivable that loss of function of this protein in some cells, especially differentiated and postmitotic neurons, would lead to the overexpression of some genes that may be detrimental during nervous system maturation.

Animal Models of Rett Syndrome

In order to understand the mechanism by which MeCP2 mutations result in Rett syndrome, three distinct mouse models have been generated. One model did not express MeCP2 in any tissue of the body. Another model did not express MeCP2 in neuronal tissue. In both models, developed in differential laboratories, the resultant mice exhibited a phenotype similar to that seen in children with classic Rett syndrome. The mice displayed normal development until approximately 6 weeks of age, followed by progressive neurological dysfunction and death by 10 weeks of age. A third mouse model, in which a truncated version of the MeCP2 protein was expressed, displayed a milder phenotype, with forepaw stereotypies, motor dysfunction, behavioral impairments, and learning deficits. These mouse models recapitulate relevant features of the human disease and will serve as useful tools in the study of the pathophysiology of Rett syndrome. Specifically, by studying the relationships between the MeCP2 protein and the genes affected by it, investigators hope to develop treatments specific for the abnormalities in gene expression that are responsible for Rett syndrome.

Reward and Learning

T A Stalnaker, Y Takahashi, and G Schoenbaum, University of Maryland School of Medicine, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

A reward can be defined most broadly as any condition or object that an organism seeks to attain or obtain access to. Thus, rewards for humans can be of tremendous variety, including food, water, money, and social approval. Rather than being identified by their sensory characteristics, rewards can only be inferred through the behavior that they elicit, and then only relative to the current motivational state of the organism. For example, water is considered a reward because it will elicit approach and consumption in an animal that has been deprived of water, but it will fail to do so for an animal that is not thirsty. Often, a distinction is drawn between primary rewards, such as water, naturally occurring rewards to which responses are assumed to be hard-wired, and secondary rewards, such as money, to which responses are learned through experience.

When an animal detects a reward in its environment, seeking and consummatory behaviors are by definition elicited. However, rewards also trigger learning. Broadly speaking, reward-associated learning seeks to identify the conditions in which rewards are likely to be experienced in order to promote the more accurate prediction and discovery of reward in the environment in the future. Behavioral studies have dissociated a number of different aspects of reward learning, supported by different brain circuits, that occur separately or in concert when an organism experiences a reward. The sections that follow briefly describe some of these different forms of reward-associated learning.

Reward and Pavlovian Learning

One of the simplest forms of learning about rewards is assessed in a procedure called Pavlovian conditioning, in which a neutral cue, or stimulus, is repeatedly presented with a primary reward. Learning is inferred from changes in the response of an animal to the presentation of the previously neutral stimulus, called the conditioned stimulus (CS). The resultant learned, or conditioned responses (CRs) include the following: (1) conditioned approach, in which the animal approaches the area where the reward has been delivered; (2) autoshaping, in which the animal approaches the location of the CS itself; (3) conditioned orienting, in which the animal orients to the CS; and (4) many conditioned autonomic changes, such as a slowing of heart rate. In each of these cases, the neutral CS gains control over a CR by virtue of its relationship to the reward.

The striatum, a part of the basal ganglia, is thought to be particularly critical to associative learning that directly links CSs with motor responses, including CRs such as conditioned approach. Such stimulus–response, or S–R, associations, are also critical to operant responding (see the section titled 'Reward and operant learning) The central nucleus of the amygdala (CeA) is required for the acquisition and/or expression of many of the other CRs previously described. In addition, the CeA is necessary for a CS to activate nonspecific motivational representations that were originally linked to the primary reward. These motivational representations can then elicit and/or enhance certain categories of relevant behavior. The effect of associations between the CS and these motivational representations may be demonstrated by training an animal to associate a CS with a reward and then training it to make an operant response to receive the same reward, or in some cases to receive a different reward. Subsequently, if the animal is allowed to perform the operant response in the presence of the reward-predictive CS, it increases its rate of operant responding. This phenomenon is called Pavlovian-instrumental transfer (PIT), and is thought to reflect a learned association between the stimulus and affect or feeling that accompanies receipt of the reward. Damage to the CeA disrupts PIT, and further experiments have supported the hypothesis that a circuit from the CeA to midbrain dopamine neurons and onward to the nucleus accumbens is essential to the expression of PIT.

Unlike the CeA, the neighboring basolateral nucleus of the amygdala (ABL) is not directly critical for the acquisition or expression of many appetitive CRs. However, the ABL is necessary for CSs to become associated with certain intermediary representations of the primary reward. These representations become critical in situations in which expression of a previously learned CR must be modified, for example, when the incentive value of a reward changes. In so-called devaluation paradigms, the value of a reward that has been previously associated with a CS is modified by pairing the food with illness or by satiating the animal with that particular food. Either of these manipulations will cause a normal animal to reduce its conditioned approach behavior to the CS that predicts the devalued reward. This reduced response indicates that the CS is able to evoke a representation of the current value of the food. This representation differs from the one that supports PIT, because it

contains information about the specific reward that triggered the original learning. Furthermore, it depends on different neural circuits than does PIT; animals with damage to the CeA retain the ability to form these associations, while animals with damage to the ABL fail to do so. Another region that is closely connected with the ABL, the orbitofrontal cortex (OFC), is also necessary for the control of CRs by the expected value of a CS. Thus, lesions of the OFC done either before or after acquisition of the CS–food association result in rats that do not reduce their responding to a CS associated with devalued food. These and other experiments have led to the conception of the OFC and ABL as forming a circuit that encodes an 'expectancy' that reflects a predicted value under given environmental conditions and goals of the animal. In the case of the devaluation paradigm, the expectancy encoded by the OFC allows the animal to use the CS to predict the devalued food, and hence to reduce responding to that particular CS.

Reward and Operant Learning

Learning to predict and prepare for rewards based on environmental cues takes an animal only so far toward actually receiving rewards. In a natural environment, an animal must often learn to make an action or series of actions in order to obtain a reward. This kind of learning is measured through an operant-learning paradigm, in which rewards are delivered contingent on the performance of a specific arbitrary action or series of actions. After repeated experience, animals will perform the trained actions even in the absence of reward delivery, demonstrating that learning has occurred. As in Pavlovian conditioning, several different kinds of learning can support operant behavior. In some cases, operant behavior may consist of goal-directed behavior, which is defined as that which depends on (1) knowledge of action–outcome contingencies, and (2) a representation of the outcome itself. Thus goal-directed behavior depends on learned associations between representations of actions and rewards. Animals typically exhibit goal-directed operant responding after limited, but not extended, training. Conversely, after overtraining, operant responding becomes less goal directed, and is often described as being habitual. Habitual responding is thought to depend on associations between antecedent stimuli and operant responses (S–R associations); receipt of the reward encourages formation of these associations, but reward is not explicitly represented in the associations themselves. Consequently, any changes to the incentive value of the outcome or in response–outcome contingencies have little effect, at least in the short term, on established habitual responding. Various aspects of operant responding are thought to depend on different parts of the basal ganglia. Recent studies have suggested that there may be two distinct functional systems within the adjacent regions in the dorsal striatum. The dorsolateral striatum may be critical for the learning of S–R associations, whereas the dorsomedial striatum may involve in the learning of action–outcome associations. For example, in interval schedules of instrumental conditioning, lesions of the dorsolateral striatum in rats became insensitive to the posttraining devaluation of the outcome. However, both pre- and posttraining lesions of the posterior dorsomedial striatum as well as local inactivation of this area reduced the sensitivity of rats' instrumental performance both to changes in the action–outcome contingency and to posttraining outcome devaluation.

The idea that learned operant behavior can be supported either by a goal-directed system or by a habitual system begs the question of how control is apportioned between these two systems during learning. In other words, what mechanism causes an extensively practiced action to become a stronger habit and to lose the characteristic of being goal directed? Although the answer to this question is not known in detail, one hypothesis supposes that parts of the medial prefrontal cortex (mPFC) control the balance between these processes. In support of this hypothesis, lesions of the infralimbic region of the mPFC prevent an action from losing its goal-directed nature, even when it has been extensively trained. Conversely, lesions of prelimbic region of the mPFC cause even an extensively trained action to remain goal directed. These results are in accord with general theories of PFC cognitive control that suggest that the PFC controls mappings between inputs and actions.

Dopamine and Reward Signaling

As previously described, it is clear that in both Pavlovian and operant paradigms a variety of associations among stimuli, rewards, and responses underlie learned changes in behavior after exposure to reward. While one of the contributions of neuroscience has been to tease apart brain circuits that may be specialized for encoding and/or using particular aspects of these reward-related associations, it is also important to realize that many of the processes described occur in parallel as organisms learn and respond to rewards in their environment. One of the

unifying factors, thus far not discussed, that may contribute to much reward-related learning across the circuits discussed is the effects of the neurotransmitter dopamine. Dopamine receptor stimulation has been shown to effect cellular processes that may contribute to learning, and dopaminergic neurons, which project to all brain regions associated with reward learning, fire during learning in patterns consistent with a role in reinforcement learning. Specifically, dopamine neuronal firing is proposed to signal when reward or reward-predictive situations differ from expectations, based on prior associative learning. Such a signal is often called a 'teaching' signal and could facilitate new learning across multiple brain regions about stimuli and actions that predict reward.

Introduction

A Northwestern crow (*Corvus caurinus*) swoops down to a beach from its perch atop a nearby cliff. Gliding a few feet above the intertidal zone, it scans attentively before alighting. The crow's beak probes the sand repeatedly and emerges holding a small whelk. After a brief pause, the bird drops the whelk and searches for another, eventually finding a larger one that meets its fancy. The crow then flies along the beach to a rocky area, ascends almost vertically, drops the mollusk, and dives to inspect the result. The spire has broken off, and the crow easily extracts the body, which it swallows in a single gulp. Returning to the water's edge, the crow again searches the sand, rejecting small whelks and eventually flying off with a large one. This time, the shell remains intact after the first drop and several subsequent ones. Rather than abandoning the obstinate prey, the crow persists until the shell has broken and then harvests its reward.

At multiple steps in this vignette, the crow is faced with consequential choices. Rather than setting off to search for new prey on its own, the bird may have the option of scrounging food from another crow that has procured a prey item too large to consume quickly, such as a fish. While gliding over the intertidal zone, the crow selects a propitious landing spot among multiple candidates. It seems particularly choosy in accepting or rejecting whelks it has dug out of the sand and very persistent in continuing to drop a whelk that has not yet broken open.

Experiments have revealed the adaptive quality of such choices. For example, the smaller whelks do not offer a net average energy gain; they have a low probability of breaking when dropped, and their energy content fails to offset the high cost of multiple ascents to the drop point. In contrast, the larger whelks are profitable because they break more readily and contain more food energy. The probability of breaking a whelk shell seems independent of the number of times it has already been dropped; if so, abandoning a whelk that has failed to open is inefficient, because after having paid the cost of procuring another, the crow, on average, would be no closer to mealtime.

The foraging behavior of the Northwestern crow highlights several variables critical to decisions about reward seeking: reward magnitude (as indexed by the size of the whelk), procurement and handling costs, and risk (a function of the probability that the whelk shell will survive a drop) all contribute to the choices made by the crow. Experimental paradigms have been developed to manipulate such variables under simplified, highly controlled, laboratory conditions. These paradigms have been used in conjunction with neurobiological methods, such as electrophysiological recording, neurochemical measurements, pharmacological treatments, brain stimulation, and lesions, to study the neural circuitry involved in adaptive decision making.

Many experiments that apply neurobiological methods to study decision making under laboratory conditions have been carried out using rodents working at operant tasks to obtain rewards. Responses, such as pressing a lever, serve as simplified analogs to procurement behaviors seen in the wild. Rewards such as food pellets are harvested after the operant requirement has been satisfied. Cost is manipulated by varying the amount of work (e.g., the number of lever presses) required to deliver a reward, the effort required to execute each response, or the time that must be invested. The work or time requirement for earning each reward may be either fixed or variable. Additional dimensions of reward that are commonly manipulated include amount (e.g., size of a food pellet or volume of liquid), intensity (e.g., concentration of sucrose), delay (time between meeting the work or time requirement and delivery of the reward), and kind (e.g., food vs. water).

Intensity, Rate, and Cost

Brain Stimulation Reward

An experimental model that has seen particularly heavy use in studies of the neural basis of decision making in laboratory rodents entails delivery of electrical stimulation via chronically implanted electrodes. Rats will work vigorously and insatiably for such stimulation when the electrode is appropriately positioned within the brain. The behavior performed to trigger the stimulation is called self-stimulation, and the effect that draws the rat back to the lever is called brain stimulation reward (BSR). Electrical stimulation of the medial forebrain bundle can compete with, summate with, or substitute for goal objects such as sucrose solutions, water, or food pellets. It has been proposed that a neural signal arising from the stimulation mimics those that encode the intensity of a natural reward.

Computing the Payoff from BSR

Gallistel and co-workers have carried out experiments employing rewarding brain stimulation to model the decision-making processes of foragers. They reasoned that to allocate its behavior adaptively, a successful forager must multiplicatively combine information about the intensity of the reward and the rate at which it is encountered. Imagine a bird foraging for berries that vary in sugar concentration and abundance. One bush offers sweet, ripe berries at a low density; while foraging there, the bird will encounter intense rewards at a relatively low rate. Another bush offers a higher density of less ripe berries. Under such circumstances, the product of intensity and rate should provide a reasonable estimate of the energy return from each bush. In the brain-stimulation experiments, reward intensity was controlled by varying the number of pulses in each stimulation train (and thereby the induced impulse flow in the stimulated neurons), and reward rate was controlled by varying the average delay to rearming of the lever after a reward had been harvested. The experimenters measured the preferences of the rats for stimulation trains that varied in intensity and rate. The rats behaved as if they had computed the payoff from the trains of stimulation pulses by multiplying the intensity and rate of reward.

Conover and Shizgal trained rats on a task that provides control over the opportunity cost of rewarding brain stimulation. In order to earn a reward, the rats had to be holding down a lever at the time that an unpredictable, unsignaled interval timed out; cost was controlled by varying the average duration of the interval. The longer the rat held down the lever, the less it could engage in alternate activities such as grooming, exploring, or resting. Thus, cost in this paradigm is roughly analogous to the average time required for the crow to harvest a whelk; during this time, the bird must forgo the benefits of alternate activities, such as nest building. The behavior of the self-stimulating rats is well described by a model that equates the payoff from the stimulation to the ratio of reward intensity and cost. This result is consistent with the finding of Gallistel's group in that opportunity cost is the inverse of the reward rate that a subject in the Gallistel experiments would achieve if it spent all of its time working at a particular lever.

The Role of Dopamine in BSR

In models of operant performance, such as the matching law, behavioral allocation is tied to the net payoffs from the competing options; the multiple components of payoff (such as the intensity and cost of reward) act in concert in determining choice (e.g., by scalar combination, as illustrated above). This makes functional sense, but it poses a challenge for experiments on the neurobiological underpinnings of decision making: if a given manipulation shifts the allocation of behavior to reward seeking, through which component(s) of payoff did the manipulation act? This problem is illustrated by the controversy over the role of dopaminergic neurotransmission in the evaluation, selection, and procurement of rewards.

The first experiments linking dopaminergic neurons to reward were carried out on self-stimulating rats, and it has been shown repeatedly that manipulation of dopaminergic neurotransmission profoundly alters the effectiveness of BSR. Reward effectiveness can be estimated from the strength of the stimulation required to sustain a given level of performance; if low-stimulation currents or frequencies suffice, then the reward produced per unit of stimulation must be high, and thus the stimulation is deemed very effective at inducing reward. The effectiveness of BSR is increased by drugs that boost dopaminergic signaling, such as those that block the dopamine transporter, and decreased by drugs that attenuate dopaminergic signaling, such as those that block postsynaptic receptors.

Either explicitly or implicitly, most of the reports detailing the modulation of BSR following perturbations in dopaminergic neurotransmission attribute the observed change in performance to alteration of the intensity of the induced reward signal. However, an alternative account is suggested by work conducted by John Salamone's group on the effects of dopamine-specific lesions on performance for natural rewards. They show that there is little change in performance when work requirements are low and a substantial change when requirements are large. The nature of the reward costs determines the effect of the dopaminergic modulation. Performance on tasks requiring intense physical effort, such as scaling a barrier or repeatedly pressing a lever at a high rate, is very sensitive to decreases in dopaminergic neurotransmission, whereas performance appears to be little affected on low-intensity tasks that entail few responses or merely waiting for a reward. Such results could be due to dopaminergic influence on the proclivity of the subject to invest effort in the pursuit of reward. Conversely, changes in reward effectiveness could have differential effects on performance for low- and high-cost rewards due to the nonlinear relationship between performance and reward strength. The degree to which changes in reward intensity and proclivity to pay high effort costs contribute to the effects of dopaminergic manipulations on performance for either rewarding brain stimulation or natural rewards has yet to be worked out definitively.

Different Roles for Phasic and Tonic Signaling by Dopaminergic Neurons?

Should dopaminergic neurotransmission prove to influence reward intensity, questions remain concerning the underlying mechanism. Two intertwined issues must be resolved: (1) Do dopaminergic neurons lie in series with the neural signals representing reward intensity, or do they modulate transmission in the reward-signaling pathway? (2) What are the relative roles of the phasic and tonic components of dopaminergic signaling? The neural signal that gives rise to BSR is short-lived: it builds up quickly, particularly when the stimulation is strong, and it decays quickly as well. One mode of dopaminergic signaling consists of brief bursts of action potentials lasting a few hundred milliseconds. Could this phasic activity underlie the phasic signal that gives rise to BSR? This seems unlikely. The phasic release of dopamine can be monitored *in vivo* by electrochemical means. In rats trained to self-administer brief trains of pulses via electrodes positioned near the cell bodies of midbrain dopamine neurons, phasic dopamine release in the ventral or dorsal striatum was rarely seen during self-stimulation; in the few cases in which it was observed at the start of a test session, the phasic dopamine signal declined quickly and was no longer detectable after a minute or so; in contrast, the rats continued to work vigorously for the stimulation. These results are difficult indeed to reconcile with the notion that the reward signal is encoded in the phasic release of striatal dopamine.

A second mode of dopaminergic signaling entails the steady release of the neurotransmitter over longer timescales. The existing data on the influence of dopaminergic manipulations on BSR are consistent with the notion that such sustained release gates transmission of the reward signal. In this view, the dopamine neurons do not compose part of the direct pathway that translates the neural activity induced by the electrode into the rewarding effect. Instead, these neurons regulate the strength of the reward signal by modulating transmission of the phasic signal induced by the electrode. In turn, dopamine tone is increased by the rewarding stimulation. Due to positive feedback between the rewarding effect and dopamine tone, performance is remarkably persistent when stimulation strength is high.

A distinction between a phasic reward signal and the phasic firing of dopaminergic neurons has also emerged from extensive research on dopaminergic responses to conditioned stimuli and natural goal objects. Schultz's group has shown that the firing of dopaminergic neurons resembles the reward-prediction error in reinforcement-learning models. The reward is a drop of juice, and the simian subjects are thirsty during testing. Delivery of the reward is preceded by an initially neutral stimulus. The initial presentation of the juice reward elicits a vigorous burst of firing from the dopamine neurons. However, as learning proceeds and the onset of the conditioned stimulus comes to predict the drop of juice that follows, these neurons no longer respond to delivery of the reward; if the now-expected reward is omitted, firing is suppressed below its baseline rate. Thus, the phasic activity of the dopamine neurons appears to encode the difference between the reward the monkey was expecting and the reward it receives. In this view, a nondopaminergic 'primary' reward signal is relayed to the dopamine cells and compared with a reward prediction to generate an error signal, which is encoded in the phasic firing of the dopamine neurons. This error signal serves to train the neural network that generates the reward prediction and to adjust action patterns to maximize the harvest of rewards. Perhaps the neural signal that gives rise to BSR corresponds to the primary reward signal in this model. The identity of the neurons that produce this signal has yet to be established, but there is accumulating evidence implicating the extended-amygdala network.

Risk

The introductory vignette illustrates a form of risk sensitivity in foraging behavior. Every time the crow makes the arduous ascent to the drop point, it runs a risk that its efforts will be for naught. Prey selection appears to take this risk into account, in the form of a preference for larger whelks that are more likely to break when dropped.

In laboratory rats, there is evidence that circuitry in a particular brain region plays a role in determining risk sensitivity. Lesions of the core region of the nucleus accumbens, a dopaminergic terminal field, shifted choices toward small certain rewards and away from larger probabilistic ones. The lesioned rats behaved disadvantageously, choosing rewards with lower expected values (e.g., 1 food pellet delivered with $p = 1$) in preference to those with higher expected values (e.g., 4 food pellets delivered with $p = 0.32$ or 0.7). Thus, the circuitry disrupted by the lesion, which is modulated by dopaminergic input, appears to contribute to the rats' ability to assign adaptive weights to low-probability rewards. In this light, is it interesting to note case studies in which pharmacological treatments that increase dopamine tone appear to boost the incidence of pathological gambling. These findings have been interpreted to suggest that sustained activity of dopaminergic

neurons influences risk appetite in humans. Patients with lesions of the ventromedial region of the prefrontal cortex, another dopaminergic terminal field, show increased risk tolerance.

Delay

The effectiveness of rewards depends not only on their probability but also on their imminence. Imagine a cheetah lurking in the tall grass. Scanning the savanna, it spies two similar gazelles trotting towards its hiding place from different locations. Clearly, the gazelle that will first enter the cheetah's striking range is the better prospect. Thus, the values of the two gazelles can be said to be discounted according to their projected arrival times, and the value of the nearer one is less diminished due to the smaller delay. However, if the more distant gazelle is larger than the nearer one, the cheetah is faced with a dilemma: pursue the smaller, sooner reward or wait for the larger, later one? If there is a constant probability over time that either gazelle will change direction or will be pursued by another cheetah before it comes into range, then the present value of each gazelle should decline exponentially as a function of its predicted time of arrival. The cheetah will forgo the small gazelle and wait for the larger one if the size difference outweighs the difference in the temporal discounts, regardless of whether the expected arrival is imminent or far off.

Experiments carried out on many different animals paint a more complex and intriguing picture of the discounting problem. The discount function deviates from a simple exponential and is approximated by a rectangular hyperbola. This widespread finding implies that imminent rewards are attributed even greater relative weight than a simple exponential discounting model predicts. Moreover, the preference of a decision maker who discounts hyperbolically can reverse as a function of its temporal vantage point. A cheetah behaving in this way would fix its sights on the larger, later reward if both predicted arrival times are relatively far off in the future; as the gazelles approached, its preference would shift to the smaller, sooner reward. The latter behavior is said to be 'impulsive.' The steeper the discount curve, the more dramatic the preference reversal, and the more shortsighted the behavior of the cheetah will appear. Thus, it is not surprising that neural mechanisms involved in temporal discounting have been implicated in impulse-control disorders, which are believed to entail excessive discounting of negative long-term consequences in the pursuit of modest short-term gains.

Cardinal and colleagues have shown that lesions of the core region of the nucleus accumbens not only steepen probability discounting but also steepen temporal discounting, shifting the preference of laboratory rats toward smaller, sooner rewards. In the inferotemporal cortex, another dopaminergic terminal field implicated in decision making, dopamine release increases during performance of a temporal discounting task but release of serotonin does not; in contrast, serotonin release is boosted in the medial prefrontal cortex during the discounting task whereas dopamine release is decreased. It has been argued that there is a division of labor between cortical territories, with the temporal and reward-magnitude dimensions of the task processed preferentially in the medial prefrontal cortex and the orbitofrontal cortex, respectively; neurochemically distinct diffuse projection systems originating in the brain stem appear to differentially modulate the operation of the distributed cortical circuitry.

Kind

Animals must procure diverse resources in order to ensure survival and successful reproduction. These resources are sorted into differentially fungible categories (kinds) by physical, chemical, physiological, and ecological realities. An excess of stored food cannot offset a deficit in hydration or compensate for a lack of nest-building materials. In contrast, pathways of metabolism provide for partial convertibility of nutrients; although all macronutrients can be used as sources of cellular energy, carbohydrates provide a superior means of meeting short-term needs whereas fats provide a superior input to long-term stores. Thus, animals face what economists call a substitution problem. Their task is not merely to procure the most valuable single resource from a set of possible options but rather to assemble, at the lowest cost and risk, the basket of goods that best meets a diverse set of needs. Due to the variable degree to which items can be substituted for each other to meet particular needs, the contribution of each item to the value of the basket cannot be computed merely by adding the individual values. The computational task is rendered even more challenging by the fact that a given goal object may contain resources of many different kinds. For example, a prey item typically contains macronutrients from all three classes, water, minerals, and vitamins.

How does the nervous system go about solving the substitution problem? It has been suggested that functional subdivision of brain reward circuitry may contribute to this important task. Perhaps dedicated circuitry processes the reward value of resources of a given kind. Combining the outputs of such specialized circuits on the basis of the substitutability of the rewards they evaluate could then help distribute

the choices of the decision maker so as to achieve an appropriate basket of goods. Evidence for functional specialization of brain reward circuitry is provided by studies of the effects of energy balance on BSR. When the tip of the stimulating electrode lies in a particular region of the lateral hypothalamus, dorsolateral to the fornix, depletion of the long-term energy stores boosts the rewarding effect; leptin, a hormone produced by adipocytes in proportion to their fat content, attenuates the rewarding effect of stimulation delivered to this region. In contrast, when nearby portions of the medial forebrain bundle are stimulated, the rewarding effects are unaltered by depletion of the fat stores and either unchanged or increased by administration of leptin. Such evidence suggests that physiological feedback signals differentially modulate the rewarding effects produced by stimulation of different brain sites.

The Origin of Reward Signals

The neural signals representing the intensity, amount, and kind of rewards interact with signals representing general information about rate, cost, risk, and delay. In addition to the evaluation of rewards, many fundamental psychological processes, such as interval timing and memory, are essential to such computations. Thus, it is not surprising that a wide array of brain structures has been implicated in reward-related decision making, including multiple territories in the prefrontal cortex, the striatum and ventral pallidum, the amygdaloid complex and extended amygdala, the hippocampal formation, the medial forebrain bundle, and the midbrain nuclei that give rise to ascending dopaminergic, noradrenergic, serotonergic, and cholinergic projections. Using the gustatory system as an example, the following section addresses the origin of reward signals and their processing prior to combination with other information required for decision making.

Taste plays a crucial and obvious role in determining the rewarding properties of food items, and a considerable body of research has been devoted to the origin of gustatory reward signals. A bifurcation of information flow is implicit in any sensory pathway that gives rise to reward signals. One function of sensation is to determine the identity and quality of a stimulus; another is to indicate what that stimulus is worth at the present moment. In contrast to the circuitry dedicated to determining what the stimulus is, the circuitry charged with computing stimulus value functions in an inherently subjective manner. No taste stimulus is inherently good: a food that seems irresistible when we are hungry may become disgusting after we have overindulged. Thus, the computation of gustatory reward by the evaluative channel implies a weighting of sensory information by internal signals reflecting the current physiological state, a process that Cabanac has labeled 'alliesthesia.' Further modulation of stimulus value occurs as a result of learning, short-term exposure, and modulation by hormonal, circadian, and photoperiodic factors.

In rodents, there is a bifurcation in the gustatory projection. Gustatory information from the nucleus of the solitary tract is relayed to the parabrachial region, which, in turn, projects in parallel to the gustatory thalamus and to basal forebrain targets in the lateral hypothalamus and extended amygdala. Norgren and Grill proposed that the informational function is subserved by the thalamocortical branch, whereas the evaluative function depends on the basal-forebrain branch. Consistent with this view is the finding that sucrose, a rewarding gustatory stimulus, fails to increase dopamine release in the nucleus accumbens following interruption of the basal-forebrain projection but continues to do so following interruption of the thalamocortical branch.

The parabrachial relay for corticopetal gustatory information appears to be absent in the primate, and there is abundant evidence for the processing of gustatory rewards by cortical circuitry. At early stages of processing in the primate gustatory system, up to and including the primary gustatory cortex, food deprivation does not appear to modulate the responses of taste-sensitive neurons. However, such modulation is seen in the secondary gustatory cortex, within the orbitofrontal region as well as in the lateral hypothalamus. Rolls has proposed that neurons in the latter regions are involved in evaluative processing, whereas the early stages of the pathway and the primary gustatory cortex are involved in informational processing. Within the orbitofrontal cortex, his group has demonstrated separate representations of multiple sensory characteristics of foods, such as sweetness, viscosity, and graininess, as well as neurons tuned to combinations of several different sensory qualities. Also represented there are rewards processed in different sensory modalities, such as somesthesis. The elaborate representations within the orbitofrontal cortex seem well suited to tackle the substitution problem by means of a weighted combination of signals representing the values of different goal objects and their components.

Conclusion

Animals searching for sustenance, shelter, or mates, must solve multidimensional decision problems on an ongoing basis, trading off the benefits and costs of rewards against those of territorial defense and predator avoidance. Neuroscientific research into the mechanisms underlying such decisions is at an

early stage. Nonetheless, components of the computational processes underlying reward-related decisions have been brought under experimental control and linked to neurochemically and anatomically characterized circuitry in the brain.

Reward Neurophysiology and Orbitofrontal Cortex

Introduction

The (primate and human) orbitofrontal cortex receives taste, olfactory, visual, somatosensory, and auditory inputs from cortical regions which are toward the end of the unimodal cortical processing streams that build representations of what stimulus is present in each of these sensory modalities (see Figure 1). Neurophysiological studies in primates show that it is the reward value of taste, olfactory, oral texture, and visual stimuli that is represented, as shown, for example, by the reduction to zero of the neuronal responses after feeding to satiety on a particular food. The reward is partly specific to a particular food, as shown by sensory-specific satiety-related neuronal responses. Visual and olfactory stimuli become rewarding by learned association with a primary (unlearned) reinforcer such as the taste of food. This learning can be reversed (in as little as one trial for visual stimuli) and may be facilitated by error neurons that respond when an expected reward is not obtained. Complementary neuroimaging studies in humans show that abstract reinforcers such as monetary reward are also represented in the orbitofrontal cortex, and that the expected value of a reward may be represented in the orbitofrontal cortex.

Taste Reward Neurons

Many neurons in the orbitofrontal cortex respond to gustatory stimuli. Each neuron responds typically with distributed encoding to a combination of sweet, salt, bitter, sour, and umami tastants. It is the reward value that is represented, for feeding the macaque to satiety decreases the responses of the neuron to zero to the food fed to satiety. The decrease is specific to the taste that has been fed, indicating that sensory-specific satiety is being represented (see Figure 2). These effects of satiety are not found one synapse earlier, in the primary taste cortex, so that the representation of taste reward is implemented in, and is an important function of, the orbitofrontal cortex. Given that in primates the brain stem taste relay, the nucleus of the solitary tract, projects to the taste thalamus and then to the primary taste cortex without direct subcortical connections, the orbitofrontal cortex is in an important position in connection with the computation of taste reward.

Taste neurons are found in many parts of the primate orbitofrontal cortex, from laterally almost in the inferior convexity, to within a few millimeters of the midline. All five prototypical tastes are represented, so taste as a punisher, as well as taste as a reward, is represented.

Olfactory Reward Neurons

Many orbitofrontal cortex neurons respond to odors, and distributed representations are typical. For approximately 40% of the olfactory neurons, the olfactory stimuli to which the neurons respond are determined by the taste with which the odor is associated. These neurons can reverse the association, with relatively slow learning (e.g., 40 trials) compared with visual to taste association learning. The learned representation of a flavor, a taste–olfactory combination, is thus relatively stable. Some of these neurons respond to odors associated with the taste and texture of food and thus learn to represent the reward value of the odor. Other orbitofrontal cortex neurons respond to odors associated with aversive tastes such as salt (NaCl) and thus learn to represent the punishment value of the odor.

The olfactory neurons with food-related responses decrease their responses to zero when the macaque is fed to satiety with a food, and this is asensory-specific effect. Thus olfactory reward and sensory-specific satiety are represented in the orbitofrontal cortex. They are probably computed there, for a functional imaging study has shown that the subjective pleasantness of odors is represented in the human orbitofrontal cortex but not in the primary olfactory cortex. The representation of odor in the orbitofrontal cortex is distributed, that is, each neuron responds to a subset of the odors being used, and this is a useful part of the mechanism of the sensory-specific reduction in the pleasantness and reward value of a particular food eaten to satiety, for this reduction can be computed by making the synaptic connections from the neurons that convey the olfactory inputs related to the food being eaten adapt over the time course of the meal.

Experiments with sensory-specific satiety have shown that the reward value or pleasantness can be decreased in part by exposure to the odor for the same time as a food would be eaten in a meal. However, for the reward value to decrease to zero, the food must be swallowed, and a crucial signal is gastric distension. This is shown by experiments in which feeding resumes almost immediately after the stomach is drained. This evidence shows that part of the computation of reward

Figure 1 Schematic diagram of the connections of the orbitofrontal cortex in primates, showing how taste, olfactory, somatosensory, and visual pathways converge in the orbitofrontal cortex. The gate functions shown refer to the finding that the responses of taste, olfactory, visual, and oral somatosensory neurons in the orbitofrontal cortex and the lateral hypothalamus are modulated by hunger and thus represent reward value. VPL, ventral posterolateral; VPMpc, ventral posteromedial thalamic nucleus; V1, V2, V4, visual cortical areas.

value in the primate orbitofrontal cortex must involve feedback satiety signals from the gastrointestinal tract (and other satiety signals too), and these must reach the orbitofrontal cortex to produce this effect.

Other neurons in the orbitofrontal cortex respond to odors, but their response does not depend on the taste association of the odor. These other neurons may represent the reward and punishment value of nonfood-related olfactory stimuli, and consistent with this, the subjective pleasantness of olfactory stimuli is correlated with activations in the human medial orbitofrontal cortex, and the subjective unpleasantness of odors is correlated with activations in more-lateral parts of the human orbitofrontal cortex.

Visual Reward Neurons

Some neurons in the primate orbitofrontal cortex respond to visual stimuli, and in a visual discrimination task, some of these learn in as little as one trial to respond to the reward or punishment value of the taste associated with the visual stimuli. Some of these neurons even reverse by a rule-based rather than purely associative mechanism, in that in a well-learned go, no-go visual discrimination task, after the previously rewarded stimulus becomes associated with an aversive taste, the neuron may respond to the other stimulus as rewarding, even though it has not recently been paired with reward. A mechanism

Figure 2 The effect of feeding to satiety with glucose solution on the responses of a neuron in the secondary taste cortex to the taste of glucose and of blackcurrant juice (BJ). The spontaneous firing rate is also indicated (SA). Below the neuronal response data for each experiment, the behavioral measure of the acceptance or rejection of the solution on a scale from +2 to −2 (see text) is shown. The solution used to feed to satiety was 20% glucose. The monkey was fed 50 ml of the solution at each stage of the experiment, as indicated along the abscissa, until he was satiated, as shown by whether he accepted or rejected the solution. OFC, orbitofrontal cortex; Pre, the firing rate of the neuron before the satiety experiment started. The values shown are the mean firing rate and its standard error. Adapted from Rolls ET, Sienkiewicz ZJ, and Yaxley S (1989) Hunger modulates the responses to gustatory stimuli of single neurons in the caudolateral orbitofrontal cortex of the macaque monkey. *European Journal of Neuroscience* 1: 53–60.

by which this is implemented involving quenching of a rule-based attractor network by nonreward, and the use of this network to bias the competition between neurons that respond to particular combinations of visual stimuli and whether or not they are currently associated with reward, has been proposed (see Figure 3). The quenching process on the rule attractor neurons is produced by the extra input to the orbitofrontal cortex from error neurons acting via inhibitory feedback neurons to decrease the activity in the rule attractor module. Because of some synaptic or neuronal adaptation in the rule attractor neurons, when the neuronal firing activity emerges out of the spontaneous firing rate, the neurons in the attractor that has not recently been active are those that win, and the result is that the opposite attractor state, representing the alternative rule, is expressed.

These visual neurons reflect the reward value of the stimuli, in that their responses decrease to zero to a food with which satiation has been produced. In this sense, the relative reward value of visual stimuli is represented.

Some primate orbitofrontal cortex neurons respond to face expression and to vocalization, and these are potentially reinforcers. Consistent with this, orbitofrontal cortex damage in humans can result in face and/or voice expression deficits in the absence of deficits in face or sound identification. Further, activation of the human orbitofrontal cortex can be influenced by the attractiveness of a face.

Somatosensory Reward Neurons

Some orbitofrontal cortex neurons are activated by oral texture (e.g., with viscosity tuning, or with fat responsiveness), temperature, and/or capsaicin. At least some of these neurons respond to the reward value of texture, in that the responses to fat can decrease to zero when a fatty food is eaten to satiety. Consistent with a somatosensory representation in the orbitofrontal cortex that reflects the reward value or aversiveness of somatosensory stimuli, activation of the orbitofrontal cortex in humans can be produced by pleasant touch to the hand or by pain (relative to neutral stimuli).

Auditory Reward Neurons

Some primate orbitofrontal cortex neurons respond to vocalization, different types of which are potentially

Figure 3 Cortical architecture of a reward reversal model for implementing rapid reversal of visual–taste associations. There is a rule module (top) and a sensory–intermediate neuron–reward module (below). Neurons within each module are fully connected and form attractor states. The sensory–intermediate neuron–reward module consists of three hierarchically organized levels of attractor network, with stronger synaptic connections in the forward than in the back projection direction. The intermediate level of the sensory–intermediate neuron–reward module contains neurons that respond to combinations of an object and its association with reward or punishment, such as object 1–reward (O1R, in the direct-association set of pools), and object 1–punishment (O1P in the reversed association set of pools). The rule module acts as a biasing input to bias the competition between the object–reward combination neurons at the intermediate level of the sensory–intermediate neuron–reward module. The synaptic current flows into the cells are mediated by four different families of receptors. The recurrent excitatory postsynaptic currents are given by two different types of excitatory postsynaptic potentials, respectively mediated by α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and *N*-methyl-D-aspartate receptors. These two glutamatergic excitatory synapses are on the pyramidal cells and interneurons. The external background is mediated by AMPA synapses on pyramidal cells and interneurons. Each neuron receives excitatory AMPA synaptic connections from outside the network. The visual input is also introduced by AMPA synapses on specific pyramidal cells. Inhibitory γ-aminobutyricacidergic synapses on pyramidal cells and interneurons yield corresponding inhibitory postsynaptic potentials. OFC, orbitofrontal cortex. Adapted from Deco G and Rolls ET (2005) Synaptic and spiking dynamics underlying reward reversal in the orbitofrontal cortex. *Cerebral Cortex* 15: 15–30.

reinforcers. Consistent with this, in humans, activation of the orbitofrontal cortex can be influenced by consonant versus dissonant auditory stimuli.

Multimodal Reward Neurons

As indicated above, many neurons in the orbitofrontal cortex respond to combinations of the outputs of the unimodal cortical processing streams that generate representations of 'what' stimulus is present. For example, some orbitofrontal cortex neurons respond to the taste, odor, sight, and texture of food. These neurons reflect the reward value of the food in all these modalities, for feeding to satiety reduces the response of these neurons to each of their multimodal inputs.

Nonreward (Error) Neurons

Researchers have shown that a small proportion of neurons in the primate orbitofrontal cortex respond for many seconds when an expected reward is

not obtained. Different neurons respond to different types of nonreward, such as in extinction (when an expected reward is not obtained) or in visual discrimination reversal. These error neurons may be involved in the process by which neurons are reset to reflect new reward contingencies and, more generally, in correcting behavior. Consistent with this, activation of the human orbitofrontal cortex is produced when a face expression (e.g., anger) indicates that behavior should change in a simple model of social behavior.

Abstract Reward

More-abstract rewards are also represented in the orbitofrontal cortex. For example, it has been shown that in a probabilistic monetary reward task, the activation in the medial orbitofrontal cortex is linearly related to how much money is won on an individual trial and, in the lateral orbitofrontal cortex, to how much money is lost on each trial. Moreover, performance of the same task is impaired in humans with surgical lesions of the orbitofrontal cortex, particularly when the contingencies reverse.

However, the question arises of how the value of a stimulus is represented if the reward magnitude is high but the probability of obtaining the reward is small. Approaches used in reinforcement learning can be adopted, and we can use the terms 'reward value' (RV) for the magnitude of the reward obtained on a trial, that is, the reward outcome, and the 'expected value' (EV) as the probability of obtaining the reward multiplied by the RV. In an approach related to microeconomics, expected utility theory has provided a useful estimate of the desirability of actions and indicates that, except for very high and very low probabilities and for decisions with framing issues, expected utility, indicated by choices, approximately tracks EV. A recent investigation found that in the medial orbitofrontal cortex, the activation related to the EV period paralleled the activation to the RV. An implication is that the orbitofrontal cortex activations tracked the best estimate of RV throughout each trial. This makes the medial orbitofrontal cortex a candidate brain region where the neurons that represent RV have their firing modulated by the probability that the RV will be obtained to represent EV.

Cognitive Effects on Orbitofrontal Cortex Reward Activations

Cognition can reach down into the orbitofrontal cortex to influence affect, as shown by the effects that word descriptors (such as 'cheese' vs. 'body odor') have on the activations produced by olfactory stimuli in the medial orbitofrontal cortex. These cognitive modulations are of the pleasantness or RV of the olfactory stimuli. This modulation is suggested to be implemented by a top-down-biased competition mechanism of the type believed to be involved in attention.

Functions of the Reward Representations in the Orbitofrontal Cortex

Emotions can be defined as states elicited by rewards and punishers or, in other words, by instrumental reinforcers. Part of the importance of the orbitofrontal cortex in emotion is that it decodes and represents primary reinforcers. In other words, the orbitofrontal cortex in primates including humans is the first stage in processing of very many stimuli in which the reward or punishment value is made explicit in the representation, that is, in which the neuronal firing rate indicates the reward or punishment value of stimuli. The RV does not appear to be represented in areas that project to the orbitofrontal cortex in primates, including the primary taste cortex, the primary olfactory cortex, and the inferior temporal visual cortex.

Another part of the importance of the orbitofrontal cortex is that it learns associations between previously neutral visual stimuli, for example, visual and many olfactory stimuli, and primary reinforcers such as taste. This learning can be very fast, may be rule-based, and may be faster than that of the amygdala.

The representation in the orbitofrontal cortex of rewards and punishers is of the value of stimuli, and neuronal activity in it does not code for the behavioral responses being made. Consistent with this, it has little response-related activity. The orbitofrontal cortex is thus involved in representing the RV of stimuli and in stimulus–reinforcer association learning, in which the reinforcer is a stimulus (such as taste or touch), and the learning is thus of stimulus–stimulus associations.

Outputs of the orbitofrontal cortex reach the ventral striatum, ventral part of the head of the caudate nucleus, and the hypothalamus. It is via routes such as these that the orbitofrontal cortex may be able to influence the activity of dopamine neurons, as indicated in Figure 1.

Consistent with these concepts, orbitofrontal cortex lesions in humans have major effects on emotional behavior.

The neurophysiology of rewards and punishers in the orbitofrontal cortex described here thus gives an account of how the precise details of many different

types of reward and punisher can be represented in the primate orbitofrontal cortex and thus how the orbitofrontal cortex contributes to emotion.

Reward Neurophysiology and Primate Cerebral Cortex

Introduction

The primate cerebral cortex is functionally and anatomically organized such that each cortical domain processes specific information; sensory information is processed in the sensory areas that receive specific sensory input and motor information is processed in the motor areas that give output to the skeletal muscle system.

The reward system, which represents appetitive value such as pleasure and happiness, has no dedicated receptor. Reward signals have to be generated inside the brain based on sensory information and associated memories. In the example of Pavlovian conditioning, an initially neutral bell sound acquires appetitive value because it is consistently followed by food, which makes a dog salivate in response to the sound. To attach reward value to the bell sound, the neural system has to make the stimulus–reward association.

The reward system has no specific effector organ. The effects of reward may become observable as an autonomic response, such as salivation, or as voluntary actions. For instance, if animals can obtain food by pressing a lever, the neural system has to learn the action–reward association.

Reward value is not always simple to determine because many factors may influence the value. For instance, two apples are more valuable than one (magnitude), one apple for sure might be more valuable than two uncertain apples (risk), and one apple for free might be more valuable than two that require some effort (cost–benefit analysis). To make these economical considerations, the reward system might need help from some cognitive brain areas.

Mesencephalic dopamine neurons play a central role in the reward system. Reward signals carried by dopamine neurons are thought to be generated through the cortico-basal ganglia network. The generated reward signals might also influence activities in the cortex and basal ganglia via diffuse dopaminergic projections to these structures. The integrated nature of the reward system might correspond to the fact that reward-related activity is observed in surprisingly many areas of the brain. When looked at in detail, however, different brain areas process different types of reward information. This article summarizes recent findings on reward processes in the primate cerebral cortex obtained by using single-neuron recording methods with behaving monkeys.

Orbitofrontal Cortex

The orbitofrontal cortex (OFC) is a structure in which multiple sensory information and reward information converge. Anatomically, both the primary olfactory (pyriform) cortex and primary gustatory cortex send direct projections to the OFC. The OFC also receives visual, somatosensory, and auditory inputs through the uncinate fascicles and/or through the subcortical structures. The OFC is also densely connected with limbic/paralimbic structures. Dopamine neurons directly project to the OFC mostly from the ventral tegmental area and the retrorubral area. This anatomical background makes the OFC an ideal place for stimulus–reward association, which enables animals to predict reward outcome based on knowledge of the potential resources of the environment.

Monkey lesion studies provide evidence that the OFC is involved in processing stimulus–reward association. Monkeys with lesions in the OFC show deficits in object-reversal tasks, such that monkeys respond to the object which was formerly, but no longer, associated with reward. After bilateral OFC ablations, monkeys show abnormal food preference, such as eating meat, which normal monkeys rarely do.

Neurophysiological studies provide evidence that the OFC is involved in the representation of reward value. For instance, neurons in the caudolateral part of the OFC show activations to gustatory stimuli, and they are attenuated when monkeys are satiated by feeding. This suggests that the OFC reflects the value, not the identity, of the food.

The value of reward may also change by the amount of offered reward and by subjective preference for the reward. When monkeys choose between different kinds of juice of different amounts, neuronal activity in the OFC often correlates with total reward value including both magnitude and subjective preference (Figure 1). Some OFC neurons reflect the reward value of the juice that the monkey chooses to consume independently of which juice it is. Others reflect the reward value of a specific juice offered.

Unlike neurons in many other cortical areas, OFC neurons generally do not change activity by the direction of the motor response that the animal needs to make to obtain reward. Little correlation between OFC activity and motor response has also been

Figure 1 Orbitofrontal neurons reflect value of offered juice: (a) trial structure; (b–f) activity of six orbitofrontal neurons. As shown in (a), each trial begins with the monkey fixating the center of a computer monitor. After 1.5 s, two sets of squares appear on opposite sides of the fixation point (offer). The color of the squares indicates the juice type and the number of squares indicates the juice amount; for example, a monkey offered three blue squares versus one yellow square chooses between three drops of peppermint tea and one drop of grape juice. After a randomly variable delay (1–2 s), two saccade targets appear near the offers (go). The monkey indicates its choice with an eye movement. In (b–f), the top panels show the choice pattern for each cell. The percentage of trials in which the monkeys chose juice B (*y* axis) for various offer types ([amount of juice B] : [amount of juice A]; *x* axis) are plotted. The bottom panels show the activity for each cell. In (b–d), responses encode the chosen value; the response in (d) is negatively correlated with the chosen value (high activity for low value). In (e–f), responses encode the value of juice A offered (e) and the value of juice B offered (f). Responses were recorded in the postoffer ((b, e, f), blue), prejuice ((c), cyan), and postjuice ((d), black) time windows. For each cell, the curves in light gray show the activity in the preoffer time window. Error bars represent s.e.m. Adapted from Padoa-Schioppa C and Assad JA (2006) Neurons in the orbitofrontal cortex encode economic value. *Nature* 441: 223–226.

demonstrated by using nonspatial types of motor response, such as go/no-go responses. When monkeys perform a go/no-go task, in which pictures instruct the behavioral reaction to be performed (movement versus nonmovement) and the reinforcer to be obtained (liquid versus sound), much of the instruction-cue-evoked activity in the OFC neurons differentiates between the associated reward outcomes. Few neurons change activity depending on the instructed behavioral reaction, irrespective of the type of reinforcer. These results indicate a greater involvement of the OFC in the stimulus–reward association than in the stimulus–response association.

Some OFC neurons reflect the learning process of stimulus–reward associations. When monkeys are presented with a new set of cue pictures that predict different reward outcomes, some OFC neurons respond exclusively during learning or, conversely, become entirely unresponsive. Such changes begin during the initial learning phase and extend into the subsequent consolidation phase.

OFC neurons appear to be sensitive to the magnitude of both reward and penalty. When monkeys perform a choice task in which they are rewarded by a large or small reward or penalized by a long or short time-out penalty, the OFC neurons generally show higher activity when the promised reward is larger and less activity when the threatened penalty is larger.

Anterior Cingulate Cortex

The anterior cingulate cortex (ACC) is a structure located in the medial wall of the frontal lobe. The ACC has reciprocal cortico-cortical connections with the dorsolateral prefrontal cortex and it sends dense projections to the motor cortex and spinal cord. The ACC is the main target area of the mesocortical dopamine system, which originates in the ventral tegmental area. This anatomical background enables the ACC to act as an interface for cognition, motivation, and action.

Neuropsychological and functional imaging studies suggest that the ACC plays a role in detecting the presence of conflicts in behavioral responses and monitoring self-performance by detecting error. Studies on event-related potentials also report a large negative polarity peak, which is thought to be generated in the ACC, occurring between 50 and 100 ms after subjects make errors in reaction-time tasks. Error-related processing in the ACC indicates its sensitivity to negative outcomes. However, evidence is accumulating that the ACC also guides actions for positive outcomes. For example, lesions or inactivation of the monkey ACC significantly impairs the ability to select actions on the basis of rewards (e.g., pull joystick upward after receipt of a pellet to obtain a second pellet and turn joystick to the side after receipt of a peanut to receive a second peanut).

Primate physiology research also provides evidence that the ACC is involved in the process of reward-based action selection. When monkeys perform a visual discrimination go/no-go task, in which different cue pictures instruct different motor responses (go/no-go) and different reward outcomes (presence or absence of liquid reward), many ACC neurons show a large response only to particular response–reward combinations (11–18% of neurons). Very few ACC neurons show activity that correlates with stimulus–reward associations.

ACC neurons are very sensitive to the proximity of the reward. When monkeys perform a task in which visual cues indicate the number of trials (one, two, or three) to be performed before receiving a reward, approximately one-third of ACC neurons increase their activity progressively in every trial as the rewarded trial approaches.

When monkeys have to choose an optimal target out of two paired stimuli associated with rewards of different magnitudes and probabilities, approximately 30% of ACC neurons change activity with the value of the game (theoretical average of reward value associated with the stimulus) independently of whether the game is probabilistic or certain. When monkeys make errors, approximately 12% of task-related ACC neurons show error-related activation, which often covaries with the amount of expected reward – the larger the missed reward, the larger the error-related activity. These findings suggest that the ACC guides behavior by encoding outcome value and deviation from a predicted goal.

Dorsolateral Prefrontal Cortex

The primate dorsolateral prefrontal cortex (DLPFC) has long been implicated in higher cognitive functions, such as switching attention, working memory, maintaining abstract rules, and inhibiting inappropriate responses. For instance, in studies of working memory, animals are typically required to remember a position of a visual cue for a brief period to make a response to the remembered position afterward. DLPFC neurons typically show sustained activity during the memory period. Also, neurons in the DLPFC often have a preferred position in the visual space, so memory-period activity is particularly high when a target is in the preferred position of the neurons (memory field). The spatially tuned activity bridging the gap between sensory and motor events has been regarded as a neural correlate of spatial working memory.

Recent research highlights the influences of reward on activity in the DLPFC. When working memory

Figure 2 Modulation of spatial working memory by reward expectation in dorsolateral prefrontal neurons: (a) population activity of dorsolateral prefrontal neurons when the target was inside the memory field; (b) population activity of dorsolateral prefrontal neurons when the target was outside the memory field; (c) spatial information (*Is*) of the cue encoded in the spiking activity of dorsolateral prefrontal neurons. Monkeys performed a memory-guided saccade task in which a target appeared either inside or outside the memory field of neurons and the monkeys had to remember the location to make a saccade afterward. The color of the target indicated whether the monkeys could get reward or not after correct performance. Activity is shown in reward-present (black lines) and reward-absent (gray lines) conditions. In (a) and (b), reward expectation enhanced the memory-period activity only when the target was inside the memory field. Error bars indicate s.e.m. Adapted from Kobayashi S, Lauwereyns J, Koizumi M, Sakagami M, and Hikosaka O (2002) Influence of reward expectation on visuospatial processing in macaque lateral prefrontal cortex. *Journal of Neurophysiology* 87: 1488–1498.

tasks are modified such that animals remember cued information briefly to obtain different reward outcomes, DLPFC neurons show sensitivity not only to what animals need to remember but also to what animals will obtain as a result of performing the task (Figures 2 and 3). The effects of reward are often temporally confined such that activity is enhanced during the memory period. The effects of reward are also spatially confined such that the activity is enhanced when monkeys remember the cue location that is inside the neurons' memory field. The combined representation of memory contents and reward outcome indicates that reward expectation has modulatory effects on working memory processing in the DLPFC.

DLPFC neurons are sensitive to various aspects of reward, including quantity (e.g., large versus small), quality (e.g., raisin versus cabbage), availability (present versus absent), and delay (short delay versus long delay) of rewards. The example of lateral prefrontal activity illustrated in Figure 3 shows different levels of delay-period activity to different kinds of reward expected after performing a delayed-response task.

DLPFC neurons appear to be more sensitive to appetitive than aversive processes. When monkeys perform a working memory task to obtain a reward, to avoid air-puff punishment, or to obtain only sound feedback, neurons respond preferentially to reward-predicting cues (24% of task-related neurons) than to aversively associated cues (6% of task-related neurons).

Reward information instructed by a visual cue reaches the OFC earlier than the DLPFC. This suggests that reward information in the DLPFC might come from the OFC through cortico-cortical connections. Another possible source of reward information in the DLPFC is the mesencephalic dopamine neurons. Various studies have confirmed the effects of dopamine on the functions of the DLPFC: (1) depletion of dopamine impairs the performance of working memory tasks in monkeys, (2) spatial tuning of DLPFC neurons is modulated by the stimulation of dopamine D1 receptors, and (3) extracellular dopamine concentration in the DLPFC increases while monkeys perform a working memory task.

Motor Areas

In the cerebral cortex, movements are represented in anatomically and physiologically distinguishable areas, including the primary motor cortex, premotor area (PM), supplementary motor area (SMA), and

Figure 3 Effects of various food and liquid rewards on the activity of the dorsolateral prefrontal neurons: (a) sequences of events in the three different types of delayed-response tasks; (b–d) examples of a reward-dependent prefrontal delay neurons displaying spatial specificity in the three task types. In (a), the animal first depressed the lever for 6–8 s, and a cue appeared for 1 s, either (1) a visible food reward presented on the right or left window behind the transparent screen or a red light presented on the right or left key as (2) a stimulus associated with food or (3) a stimulus associated with liquid). There was then a delay period of 5 s, which was followed by a go signal of white lights on both keys, and the animal was required to respond to the cued side. Correct responses were rewarded with the food or liquid which had been presented during the cue period (1) or which had been prepared (2 and 3). As shown in (b–d), this neuron showed differential anticipatory activity changes with the different rewards in the left-side trials. Adapted from Watanabe M (1996) Reward expectancy in primate prefrontal neurons. *Nature* 382: 629–632.

cingulate motor area (CMA). There are motor areas devoted to ocular movements, including the frontal eye field and supplementary eye field (SEF). Intracortical electric stimulation in these areas evokes specific movements at low threshold.

Behavioral responses are facilitated by reward expectation in many kinds of behavioral tasks for monkeys. For example, in a saccade task, monkeys make a faster and more accurate eye movement when a higher-value reward is expected. This implies that

motivational states modulate the motor signals represented in the motor areas.

The impact of reward on neuronal activity varies across different motor areas. Neuronal activity prior to movement tends to increase when a large reward is expected, particularly in the PM and SMA. Such enhancement of movement-related activity is presumed to be attributable to motor readiness that changes with the expected reward.

Motor areas also show reward-related activity not directly linked to movements. Two types of reward-related activity were identified in SEF: one predicts the imminence of reward with activity starting before eye movement onset and culminating at the onset of reward; the other signals reward occurrence with activity silent before reward onset and bursting on reward delivery. In the CMA, one of the higher-order motor areas, neurons show more cognitive types of

Figure 4 Activity of rostral cingulate motor area (CMAr) neurons related to voluntary movement selection based on reward: (a) activity of four types of CMAr cells (1)–(4) showing increased discharges after the reward was reduced and before initiation of a newly selected movement; (b) the four cells showing less activity under the constant reward condition, when subjects could not select an alternative movement; (c) discharges of CMAr cell (1) when the reward was reduced but the monkey did not select the alternate movement. In (a), each raster corresponds to a single trial when the animal switched from Turn to Push (1)–(2) or Push to Turn (3)–(4), with 5–12 trials in between: (1) short-lasting activity after the reward; (2) long-lasting but decaying activity; (3) continuous activity; (4) activity that increases progressively before the next movement. In (b), dots in the raster displays represent individual discharges of a single cell and small crosses denote the onset of movement. In the histograms, discharges over 11 trials are aligned at the onset of the reward and summed, except for (4), which is aligned at onset of next movement. A step in the ordinate denotes 10 spikes s^{-1}. A horizontal bar in the top right of a raster display indicates the time range of occurrences of the next movement. Adapted from Shima K and Tanji J (1998) Role for cingulate motor area cells in voluntary movement selection based on reward. *Science* 282: 1335–1338.

activity related to both reward outcome and choice of movement. In one study, monkeys selected one of two different arm movements (either pushing or turning a handle). During a series of constant-reward trials, monkeys kept selecting a particular movement. If the reward was reduced, they chose to perform the alternative movement. One-third of task-related neurons in the rostral CMA changed activity during the interval between the occurrence of the reduced reward and the initiation of a new selected movement, suggesting that the CMA plays a role in reward-based motor selection (Figure 4).

Posterior Parietal Cortex

The posterior parietal cortex plays a key role in spatial representation of objects for action planning and control. Primate neurophysiology studies suggest that the posterior parietal cortex receives multimodal sensory inputs and transforms the information from sensory-based coordinates to effector-based coordinates.

Recent studies revealed that the posterior parietal cortex not only serves for hard-wired sensory-motor conversion but also reflects endogenous factors, such as attention and reward expectation. For instance, neurons in the lateral intraparietal area (LIP) of the posterior parietal cortex change activity according to the magnitude or probability of the expected reward after making an eye-movement response.

Neurons in the LIP discharge action potentials in response to visual stimuli that lie in restricted regions of visual space (the neuron's receptive field (RF)). The activity of LIP neurons increases if a target in the RF predicts a higher reward outcome and decreases if a target outside the RF predicts a higher reward outcome (Figure 5).

Reward representation becomes critically important when animals are required to choose responses based on reward. For instance, when animals are free to choose one of the two targets and the reward outcome after each choice varies deliberately in every trial, they cannot plan actions simply by sensory-motor conversion; instead the optimal choice fluctuates in every trial based on expected reward outcome.

The LIP might contribute to guiding choice behavior by its reward-sensitive activity. According to the conventional sensory-motor conversion theory, the simultaneous presentation of two targets activates two concurrent saccade processes. One way to explain how one out of the two saccades is chosen is to assume a covert competition between the two saccade processes that are weighted by the associated reward outcomes. The saccade process associated with higher reward outcome wins the competition and guides a response to the target. The physiological properties of LIP neurons already described support this model.

Temporal Cortex

The inferior temporal (IT) cortex plays a critically important role for the visual recognition of objects. The visual recognition system in the IT cortex is distributed in multiple areas, including area TE and the rhinal cortex. Area TE is a unimodal visual-association area located at the final stage of the ventral visual pathway. The rhinal cortex, which consists of the perirhinal and entorhinal cortices, is a limbic polymodal association area located in the medial temporal lobe. Primate research has revealed that (1) lesions in these areas produce deficits in visual recognition memory, (2) TE neurons selectively respond to various complex features of objects, and (3) the perirhinal cortex is involved in the retrieval of visual long-term memory.

In addition to the functions of visual recognition and memory, IT cortex plays an important role in associating visual stimuli with reward outcome. Anatomically, area TE and the rhinal cortex are mutually interconnected. The perirhinal cortex has strong connections with reward-related sites, including the amygdala, OFC, ventral striatum, and midbrain dopamine neurons.

Lesions in the IT cortex cause behavioral changes that depend on reward schedule. In one study, monkeys learned a task in which visual cues indicated the number of successful trials (one, two, or three) required to receive a reward. Monkeys performed each trial differently depending on the reward schedule, but lesioning or suppressing the expression of dopamine D2 receptors in the perirhinal cortex abolished the reward-schedule-dependent behavior.

Neurons in the IT cortex show activity related to reward. When monkeys perform a go/no-go task in which each visual cue indicates a required action (release or keep pressing a lever) as well as reward availability, approximately one-third of perirhinal neurons and one-fifth of TE neurons show sensitivity to reward availability. In both areas, initial activity shows selectivity to visual stimuli (105 and 123 ms after stimulus onset in the TE and perirhinal cortex, respectively), followed by a reward-sensitive component (198 and 222 ms after stimulus onset in the TE and perirhinal cortex, respectively). The required actions have much less influence on neurons in both areas.

Although it is still unclear, the conversion from visual to reward information might involve the circuitries in the TE and perirhinal cortex, or the conversion might take place in further downstream areas such as the OFC and amygdala, which might in turn project the reward information back to the IT cortex.

Figure 5 Representations of value in the parietal cortex: (a) the sequence of an oculomotor matching task; (b) dynamic matching behavior; (c) slope space using the same data as in (b), plotted to allow visualization of the ongoing covariation in local ratios of income and choice; (d) activity of LIP neurons dependent on reward probability. In (a), the sequence is fixate (to begin a run of trials, the animal must fixate the central cross); delay (saccade targets appear, randomized spatially by color, in opposite hemifields while the animal maintains fixation); go (dimming of the fixation cross cues a saccadic response and hold); and return (brightening of the fixation cross cues return; the target colors are then rerandomized, and the delay period of the next trial begins). The overall maximum reward rate is set at 0.15 rewards s^{-1}. Relative reward rates change in blocks (~100–200 trials) without warning; the ratios of reward rates were chosen unpredictably from the set {8 : 1, 6 : 1, 3 : 1, 1 : 1}. In (b), the representative dynamic matching behavior of a monkey during a single session is shown. The continuous blue curve shows cumulative choices of the red and green targets. Black lines show the average ratio of incomes (red : green) within each lock (here, 1 : 1, 1 : 3, 3 : 1, 1 : 1, 1 : 6, and 6 : 1). Matching predicts that the blue and black curves are parallel. In (d),the response histograms show average peak-normalized firing rates for 43 cells with activity that regresses significantly on fractional income (the income from that option divided by the total income from all available options). Before normalization and averaging, raw spike trains were smoothed with a Gaussian kernel (SD = 20 ms). Activity is aligned on both the appearance of the visual target (left) and the time of the saccade (right) and is shown separately for choices into (blue) and out of (green) the cell's RF. Trials are further subdivided into four groups according to the local fractional income of the chosen target: solid thick lines, 0.75–1.0; solid medium lines, 0.5–0.75; solid thin lines, 0.25–0.5; dotted thin lines, 0–0.25. LIP, lateral intraparietal area; RF, receptive field; SD, standard deviation. Reward Processing: Human Imaging

Introduction

A reward is anything an animal or human will work to attain. Some rewards are primary reinforcers in that they have innate (or unlearned) value to the organism, whereas other rewarding stimuli can be considered secondary reinforcers in that they have acquired value through being associated with primary reinforcers. Seeking out rewards (or avoiding punishers) forms the basis of most goal-directed behaviors. Therefore, understanding how rewards are processed in the brain is central to understanding the neural basis of behavior. In the last 15 years, modern neuroimaging techniques in humans such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) have complemented single-unit neurophysiology and lesion study approaches in nonhuman animals as a means of providing insight into the neural mechanisms underlying reward processing in the human brain. In this article, the contribution of human neuroimaging studies to our current understanding of neural processes underlying reward is reviewed.

Key Brain Regions Involved in Reward Processing

Although reward-related modulation of neural activity has been found to be widespread in the brain, having been reported in the parietal cortex, dorsal prefrontal cortex, and premotor and posterior cingulate cortices, among other areas, in this article we focus on the functions of a core network of brain areas that play a key role in reward processing. These areas are the amygdala in the medial temporal lobes, the orbitofrontal cortex on the ventral surface of the frontal lobes, the adjacent medial prefrontal cortex, the ventral and dorsal striatum, and the dopaminergic neuron-containing nuclei in the midbrain.

Technical Challenges Facing Human Imaging Studies of Reward

Studying reward presents a relatively unique set of challenges to the imaging neuroscientist. This arises due to an interaction between the physiological properties of the reward system and the properties of the imaging techniques themselves. First, the vast majority of functional neuroimaging studies at present make use of the blood oxygenation level-dependent contrast (BOLD) in magnetic resonance imaging (MRI). This measure depends on detecting subtle differences in local magnetic susceptibility effects caused by neural activity-induced changes in the concentration of deoxy-hemoglobin, as opposed to oxy-hemoglobin. Yet many of the brain areas that are the natural focus of reward studies – namely the orbitofrontal cortex, amygdala, and ventral striatum – happen to be at the border of areas with large susceptibility differences between brain tissue and air in the sinuses. The presence of these large extrinsic susceptibility differences can produce dropout or loss of signal as well as spatial distortion in the BOLD contrast images. A number of techniques have been developed to deal with this problem which can recover much, although not all, of the signal loss in these areas; these include tilted acquisition (typically at 30° to the anterior commissure–posterior commissure (AC–PC) line), application of a compensation gradient prepulse, and the use of a short echo time. An alternative approach is to use PET, which does not suffer from dropout, but the poor temporal and spatial resolution of that technique substantially limits its usefulness. Other MRI techniques such as perfusion MRI may also be less affected by dropout, although at the expense of sensitivity. A second challenge for the imaging of reward systems is that many aspects of reward processing may relate to the functions of specific neurotransmitter systems, including the dopamine system and opioid system, the specific effects of which cannot be isolated with standard hemodynamic imaging approaches. To study this in humans requires administration of specific targeted radioligand molecules which bind with the relevant receptors and that can then be recorded using PET, for example, using the radioligand raclopride to image the dopamine system. Alternatively, the effects of pharmacological modulation of these neurotransmitter systems (by the systemic administration of an agonist or antagonist) on neural activity can be assayed with standard hemodynamic imaging techniques.

Distinct Components of Reward Processing

Reward processing can usefully be fractionated into four distinct components: (1) neural responses pertaining to receipt of a rewarding outcome, (2) neural responses related to expectation or anticipation of a rewarding outcome, (3) neural signals underlying

learning of reward expectancies, and (4) neural responses related to action choice for reward. Here we discuss the role of the different brain regions in the reward network in mediating these distinct components.

Receipt of a Rewarding Outcome

In order to survive, an animal needs to be able to quickly evaluate the affective significance of stimuli in its environment to determine whether such stimuli are beneficial (rewarding) or harmful (punishing) so that appropriate approach or avoidance behavior can be initiated. This raises perhaps the most fundamental question about how rewards might be processed in the brain: Where in the sensory processing pathway is the reward (or punishment) value of a stimulus encoded? Rewarding or punishing stimuli can be present in each of the five sensory modalities, each of which have dedicated sensory-processing pathways. One possibility is that reward value is encoded within the sensory pathway of each modality separately, such that there are separate neural apparatuses for decoding reward value in each sensory pathway. Alternatively, the decoding of reward value may occur in multimodal brain area(s) such that a single dedicated apparatus accomplishes this for each sensory modality. Substantial evidence has now accrued from single-unit neurophysiology studies to support the latter hypothesis, which is that one or two brain areas appear to be involved in encoding the reward value of stimuli from each sensory modality. These areas are the orbitofrontal cortex and the amygdala. Both of these areas receive direct inputs from each of the sensory pathways and are therefore highly multimodal brain regions.

Role of orbitofrontal cortex in encoding stimulus reward value Single-unit neurophysiology studies have reported evidence that neural responses in the orbitofrontal cortex to a stimulus input can be modulated as a function of changes in the value of that stimulus to the animal. Brain-imaging studies in humans also support the conclusion that there is a key role for this area in encoding stimulus reward value for a variety of rewards in different modalities. In a typical study, subjects are scanned while being presented with a range of different stimuli in a specific modality that are either pleasant, affectively neutral, or aversive to the subject. For instance, to study areas encoding stimulus reward value in the olfactory modality, subjects might be presented with a range of odors, some of which are perceived to be pleasant by the subject, some of which are neutral, and some of which are considered aversive. Direct comparisons can then be computed among areas activated in response to the pleasant, aversive, and neutral odors, such that areas involved in encoding positive reward value for an odor could be revealed by testing for areas showing increased activity to the pleasant compared to the neutral or aversive odors. Such studies have revealed increased activity in parts of the orbitofrontal cortex to the receipt of pleasant as opposed to neutral or aversive odors. Other regions of the orbitofrontal cortex have been identified as showing increased responses to aversive odors. A similar methodology has been used in studies exploring the neural encoding of value in other modalities, such as touch, taste, audition, and vision. An example of rewarding stimuli in the visual modality is attractive faces, which human subjects are prepared to work for in order to view, particularly those of the opposite sex. As in the olfactory domain, attractive faces produce significant activity in the orbitofrontal cortex (**Figure 1(a)**). This is also the case for rewards in each of the other sensory modalities that have been tested. An alternative approach to comparing neural responses to stimulus categories is to correlate individual subjective ratings of pleasantness for a given stimulus with neural activity in response to that stimulus to determine the regions that correlate positively with perceived pleasantness. In the case of the attractive face example, this approach again reveals strong activity in the orbitofrontal cortex that correlates positively with subjective ratings of pleasantness for a stimulus.

Yet another approach is to make use of the phenomenon of selective satiation or sensory-specific satiety. This is the phenomenon whereby if a particular food is eaten to satiety, the pleasantness of that food can selectively decrease while the pleasantness of other foods not eaten can remain pleasant. An example of this is a person eating a main course of spaghetti in a restaurant until satiated but still having room for an additional dessert course of, say, tiramisu. The spaghetti has gone from being initially pleasant to having little or no reward value (and may even be aversive if too much is consumed), whereas the tiramisu still has high reward value until it too is consumed to satiety. Neural encoding of reward value can be studied in this way by presenting subjects with two or more food stimuli considered pleasant by a hungry subject, measuring neural activity elicited by these stimuli, and then feeding the subject to satiety on only one of the foods. If, following this feeding procedure, the subject is again scanned while being presented with the two foods, the food eaten to satiety will no longer be pleasant, whereas the food not eaten will remain pleasant. By testing for brain regions responding to the food stimuli that decrease selectively to the food eaten postsatiety, it is possible to identify regions encoding reward value. Once again, these studies reveal

Figure 1 Representation of stimulus–reward value in human orbitofrontal cortex. (a) fMRI study in which subjects were presented with faces that were high and low in attractiveness; (b) fMRI study in which subjects made choices in order to win arbitrary points which they were informed would be converted into money after the experiment. In (a), attractive faces are a class of rewarding visual stimuli that activate the orbitofrontal cortex (example faces from the high-attractive category are shown on the left). A region of medial orbitofrontal cortex showed increased activity during presentation of high-compared to low-attractive faces (right and middle). In (b), the orbitofrontal cortex also activates in response to abstract rewards such as money or arbitrary points. The medial orbitofrontal cortex was found to respond at the time of reward receipt (left and middle). Moreover, the magnitude of activity in this region scaled according to the magnitude of the points received (right). fMRI, functional magnetic resonance imaging. activity in the orbitofrontal cortex tracking changes in the perceived reward value of stimuli (for both olfactory food rewards and for whole-food stimuli).

Some rewards are not clearly tied to specific modalities, but are more abstract in nature. A paradigmatic example of this is monetary reward, the receipt of which can be conveyed in multiple modalities. Consistent with other types of rewarding stimuli, monetary rewards also activate the orbitofrontal cortex (Figure 1(b)). Furthermore, the magnitude of activation in this area scales with the magnitude of the monetary reward received. Moreover, neural responses to abstract rewards are significantly enhanced if they are obtained in a social context, such as when delivered by a human opponent during the performance of an economic game, compared with delivery in a nonsocial context, typically induced experimentally by informing subjects that they are playing against a computer instead of an individual.

Amygdala and reward In the early neuroimaging literature, the amgydala was often implicated in aversive learning such as fear conditioning, in the perception of fearful or angry faces, or in responding to aversive tastes or odors. This led to an initial emphasis on the role of the human amygdala in negative affect. However, more recently the amgdyala has also been implicated in responding to rewarding stimuli in different modalities, including pleasant tastes, odors, and monetary gain, suggesting that, consistent with the results of single-unit neurophysiology and lesion studies in animals, the amygdala is involved in appetitive as well as aversive processing.

However, the role of the amygdala in encoding either positive or negative valence, has recently been challenged. In two separate studies, one involving gustatory reward and the other olfactory, the intensity and valence of a stimulus were varied separately such that some stimuli were rated by subjects as intense but not pleasant, whereas other stimuli were rated as pleasant but not intense. These studies found that the amygdala responded to the intensity but not the pleasantness of the stimuli. However, a further investigation showed that the amygdala cares not only about intensity but also about the interaction between intensity and valence, such that it responds

more to a highly intense but highly pleasant stimulus than it does to a less intense but still highly pleasant stimulus. This suggests that the amygdala is involved in encoding stimulus reward value, which is the combination of intensity (or magnitude) and valence rather than either valence or intensity alone.

Expectation of Reward

The ability to predict when and where rewarding or punishing stimuli will arrive confers considerable advantage to an animal because it enables appropriate behavior to be organized prospectively. For this reason, humans and other animals have developed sophisticated neural mechanisms to exploit statistical structure in the environment to learn to predict the arrival of such stimuli. Classical or Pavlovian conditioning is the simplest paradigm for studying reward prediction in the laboratory. In Pavlovian conditioning, an arbitrary neutral stimulus takes on predictive value through being repeatedly paired with the subsequent delivery of a behaviorally significant stimulus. Human imaging studies have used Pavlovian conditioning procedures to assay brain regions involved in encoding predictions of future reward. In a typical study, subjects are scanned while being presented with different visual cues (such as fractal images). One of these cues (designated the CS+) is paired repeatedly with subsequent delivery of reward (such as a pleasant odor or a pleasant taste or juice stimulus), whereas another cue (the CS−) is either paired with nothing or with an affectively neutral stimulus. Neural responses related to reward prediction can then be isolated by comparing activity to the onset of the CS+ compared to the CS−. Such studies have revealed significant responses related to reward prediction in both the orbitofrontal cortex and amygdala (Figure 2), suggesting that these regions are involved not only in responding to the receipt of a reward itself but also in anticipating the subsequent delivery of reward. Another region found to show strong expected reward responses is the ventral striatum, composed of the nucleus accumbens and adjacent ventral putamen. Expected reward signals have been found in each of these areas during anticipation of olfactory, taste, flavor, and monetary rewards.

Neuroeconomic variables and expected reward As already demonstrated, the application of paradigms borrowed from the field of behavioral psychology, such as Pavlovian conditioning, has proved useful in neuroscientific investigations of reward processing. Another fruitful avenue has been to bring to bear well-defined concepts from the field of economics as part of the emerging interdisciplinary research agenda known as neuroeconomics. Relevant concepts from economics include expected value, which formally is the product of the probability of obtaining a reward times the magnitude of the reward, and utility, which captures an individual's revealed preferences as a function of the magnitude (quantity) or type of reward. Utility can be expressed as a function of reward magnitude and can be a nonlinear function thereof. For example, the marginal (or relative difference in) utility for an individual of obtaining $102 as opposed to $100 may be much less than the marginal utility of obtaining $4 as opposed to $2, even though the difference in objective reward magnitude is the same. When the preferences for that individual are plotted as a function of magnitude, a concave utility curve is obtained showing that there is a much shallower increase in utility at the $100–102 end of the scale than at the $2–4 end. Expected utility is simply the probability of reward times its utility. This concept can be used to explain differences in preference between risky and nonrisky gambles even if the expected values for the gambles are identical. Variations of utility and expected utility theory have been proposed to account for various anomalies in human preference behavior, such as prospect theory, which accounts for asymmetries in subjects' propensity for risky decision making for gambles involving losses compared to gains.

These concepts have been applied in human neuroimaging studies to investigate neural responses related to expected value, expected magnitude, and expected probability. A number of studies have manipulated these variables by presenting visual cues that independently signal differing probabilities and magnitudes of subsequent reward. Correlations can then be computed between neural activity in response to the different cues and these variables to reveal areas responding separately to probability, magnitude, or the product of the two. Such studies revealed responses to expected magnitude, probability, and expected value in the ventral striatum and medial prefrontal cortex (Figure 3). As yet, no clear evidence has emerged of expected utility signals in the human brain, possibly because neural representations of expected utility may be difficult to dissociate experimentally from expected value because the signals may under many circumstances differ only subtly.

Risk Another variable relevant to anticipated reward is the variance in the distribution of expected reward, referred to as risk or uncertainty. Risk is a quadratic function of the probability of reward, such that risk is maximal at probability 0.5, when the delivery of reward is maximally uncertain, and minimal at 1.0 or 0 probability, when the reward is

Figure 2 Neural responses during anticipation of reward: (a) neural responses during anticipation of a pleasant taste reward; (b) areas of the orbitofrontal cortex and amygdala showing anticipatory responses that track changes in the value of an associated olfactory reward induced by selective satiation. In (a), human subjects were presented with a visual cue that indicated subsequent delivery of either a pleasant sweet taste, a mildly unpleasant taste, or an affectively neutral control solution. Shown are the areas responding more to anticipation of the pleasant (left) compared to the mildly unpleasant taste (right). In (b), hungry subjects were conditioned to two cues which signaled the subsequent delivery of two food-related odors rewards (vanilla and peanut butter). Subjects were then fed to satiety on one of the foods, selectively devaluing one of the food-related odors. Subjects were then scanned again while being presented with the same two conditioned stimuli. Shown are the amygdala (top left) and orbitofrontal cortex (bottom left) responses to the cues that track changes in the value of the associated odors, indicating that these areas encode anticipatory reward value. The right plots show the difference in activity between pre- and postsatiety to conditioned cues associated with the odor of the food fed to satiety (Tgt CS + u) compared to response to cues associated with odor of food not fed to satiety (nTgt CS + u). (a) Adapted from O'Doherty J, Deichmann R, Critchley HD, and Dolan RJ (2002) Neural responses during anticipation of a primary taste reward. *Neuron* 33(5): 815–826. (b) Adapted from Gottfried JA, O'Doherty JP, and Dolan RJ (2003) Encoding predictive reward value in human amygdala and orbitofrontal cortex. *Science* 301(5636): 1104–1107.

either certain to occur or certain not to occur. Humans are known to vary in their sensitivity to risk; some individuals are risk averse, preferring a nonrisky gamble to a risky gamble if the gambles are equal in expected value, whereas other individuals are risk prone, favoring a risky over a nonrisky gamble with equal expected values. Other individuals are risk neutral in that they show no preference either way. Several fMRI studies have revealed increased activity in the anterior insula or lateral orbitofrontal cortex when subjects are presented with risky as opposed to nonrisky gambles. Given that these areas are often implicated in aversive processing, such as responding to pain or its anticipation, and to receipt of monetary loss, responses to risk in these areas could reflect the negative affective component of risk, at least in those subjects who are risk averse. Risk signals have also been found to be present in the tonic ramping activity of dopamine neurons in singleunit neurophysiology studies in nonhuman primates. Similar signals have been found in fMRI studies in target areas of dopamine neurons such as the ventral striatum; tonic ramping anticipatory activity in this area has been found to correlate

Figure 3 Neural coding of expected reward probability, expected reward magnitude, and expected value in humans: (a) outline of experimental design by Tobler and colleagues; (b) regions of the ventral striatum responding to either magnitude (green), probability (red), or expected value (blue). In (a), subjects were presented with different cues which vary in both color and shape (number of circles). The different colors signaled the probability that reward would subsequently be delivered and the number of circles of indicated the magnitude of reward that would be delivered (in arbitrary points). The blue numbers indicated the expected value (probability × magnitude) for each cue. On each trial, subjects were presented with one of these cue configurations, which signals the probability and magnitude of subsequent reward. Adapted from Tobler PN, O'Doherty JP, Dolan RJ, and Schultz W (2006) Human neural learning depends on reward prediction errors. *Journal of Neurophysiology* 95: 301–310.

Figure 4 Anticipatory risk signals in the human brain: (a) tonic anticipatory signals in the ventral striatum related to the risk or variance in anticipated reward from an fMRI study by Preuschoff and colleagues; (b) plot of fMRI responses in this region as a function of reward probability, demonstrating a maximal response on trials when reward delivery is most unpredictable (i.e., with a probability $p = 0.5$) and a minimal response when the reward delivery is least unpredictable and is either certain to occur or not to occur ($p = 0$ and $p = 1$, respectively). fMRI, functional magnetic resonance imaging; L vst, left ventral striatum; R vst, right ventral striatum. with risk or uncertainty (Figure 4). The presence of risk signals in addition to expected value could be important for behavioral decision making because, as discussed earlier, most individuals are sensitive not only to the expected value of a given choice but also to the variance of the expected reward outcome when making decisions.

Learning Expected Reward Signals

The finding of expected value signals in the brain raises the question of how such signals are learned in the first place. An influential theory from behavioral psychology put forward by Rescorla and Wagner suggests that learning of reward expectancy is mediated by the degree of surprise engendered when an outcome is presented or, more precisely, the difference between what is expected and what is received. Formally this is called a prediction error, which in the Rescorla–Wagner formulation can take on either positive or negative sign depending on whether an outcome is greater than expected (a positive prediction error signal) or less than expected (a negative prediction error signal). This prediction error is then used to update the expected reward associated with a particular stimulus or cue in the environment, so that, if this cue always precedes

reward (and hence is fully predictive of reward), eventually the expected value of the cue will converge to the value of the reward, at which point the prediction error is zero and no further learning will take place. The role of prediction error signals in reward learning in the brain was first uncovered through observation of the phasic activity of dopamine neurons in nonhuman primates during the performance of simple conditioning tasks. These neurons were found to demonstrate a response profile approximately captured by real-time extensions of the Rescorla–Wagner model such as temporal difference learning. fMRI studies in humans have found evidence for prediction error signals in target regions of dopamine neurons such as the ventral striatum and orbitofrontal cortex during reward learning (Figure 5). A recent study attempted to directly link prediction error signals observed in fMRI to dopamine release by administering systemic dopamine agonists and antagonists to human subjects while they performed a simple reward-learning task. Prediction error signals in the striatum were found to be significantly affected by the pharmacological manipulation, suggesting that the generation of such signals in humans may be directly related to the activity of dopamine neurons.

Action Selection for Reward

Once predictions of future reward are established, the next step is to use these predictions to guide behavior. More specifically, humans and other animals need to be able to bias their action selection so that they choose those actions which in a given context lead to the greatest probability of obtaining future reward or avoiding punishers. This phenomenon is often referred to as instrumental conditioning and involves learning of stimulus–response and/or stimulus–response–outcome associations. Human neuroimaging studies of reward-based action selection have implicated the dorsal part of the striatum, which is activated when a contingency is established between responses and reward or even when such a contingency is merely perceived. Other regions that may play a role in reward-based action selection include the anterior cingulate cortex, premotor cortex, and lateral prefrontal cortex.

A major focus of current research is to gain an understanding of how the brain can make choices or decisions between different available actions. Human imaging studies have begun to probe the brain regions involved in implementing behavioral decisions using simple choice paradigms. Perhaps the simplest paradigm for this is the *n*-armed bandit task, in which a subject is presented with a number of different options, or bandits, each of which pays out reward with differing probabilities or magnitudes. One of the bandits is generally better than the others in that the consistent selection of that bandit will lead to more cumulative reward than is available from the others. The subjects' objective is to establish which bandit

Figure 5 Prediction error (PE) signals in the human striatum (ventral putamen) and orbitofrontal cortex: (a) schematic of putative temporal difference PE signals during the experiment; (b) parts of the human ventral striatum (top) and orbitofrontal cortex (bottom) that showed a significant correlation with the temporal difference PE signal. The study was a classical conditioning paradigm in which in one trial type (CS+) an arbitrary visual cue was associated 3 s later with delivery of a taste reward (1M glucose) and in another trial type (CS–) a different cue was followed by no taste. In addition, occasional surprise trials occurred in which the CS+ was presented but the reward was omitted (CS+ omit) and in which the CS− was presented but a reward was unexpectedly delivered (CS− unexpreward). In (a) schematics of putative temporal difference PE signals during the experiment are shown. During early CS+ trials (before learning was established), the PE signal should occur at the time of delivery of the reward, whereas by the late CS+ trials (postlearning) the signal should switch to the time of presentation of the CS. During CS+ omit trials, a positive PE signal should occur at the time of presentation of the CS+, but a negative PE signal should occur at the time the reward was expected. CS− unexpreward trials should be associated with a positive signal at the time the reward was presented. CS, conditioned response; UCS, unconditioned response. Adapted from O'Doherty JP, Dayan P, Friston K, Critchley H, and Dolan RJ (2003) Temporal difference models and reward-related learning in the human brain. *Neuron* 38(2): 329–337, with permission from Elsevier.

pays the most and choose that consistently in order to maximize reward. However, the subject is not informed at the beginning which bandit is better but, instead, must work this out from trial and error by making selections in order to gain experience of the rewards available from the different bandits.

Useful insights into how humans or other animals might solve this type of problem has come from a branch of computer science known as reinforcement learning, which is concerned with building artificial algorithms for solving stochastic decision problems. The basic idea behind most reinforcement learning models is that in order to choose optimally between different actions, an agent needs to maintain internal representations of the expected reward available on each action and then subsequently choose the action with the highest expected value. Also central to these algorithms is the notion of a prediction error signal which is used to learn and update the expected values for each action through experience, just as in the Rescorla–Wagner learning model for Pavlovian conditioning described earlier. Consistent with the reinforcement learning framework, human imaging studies have found evidence for expected value signals in brain regions such as the medial and orbital prefrontal cortex and amygdala during the performance of simple variants of the *n*-armed bandit task (Figure 6). Moreover, prediction error signals have also been found in both the ventral and dorsal striatum and the prefrontal cortex during the performance of such tasks, consistent with the notion that such signals may be used to update action values as well as Pavlovian stimulus–outcome associations. These studies suggest that reinforcement learning

Figure 6 Expected value signals in the orbitofrontal cortex, medial prefrontal cortex, and amygdala during decision making: (a) illustration of payoffs available after the choice of the correct or incorrect stimulus; (b) areas of the medial orbitofrontal cortex, medial prefrontal cortex, and amygdala correlating with expected reward value (derived from a simple computational model) at the time of choice; (c) fMRI responses in medial prefrontal cortex plotted against expected value to illustrate the strong colinearity between fMRI signals in this area and expected value. The task is a simple variant of a two-armed bandit task called probabilistic reversal learning in which a subject chooses between two stimuli which pay out monetary gains and losses on a probabilistic basis. One stimulus is correct, in that the continual choice of that stimulus leads to an overall monetary gain, whereas the other stimulus is incorrect, in that the choice of that stimulus leads to an overall monetary loss. After a time, the contingencies reverse so that the advantageous stimulus becomes the disadvantageous and vice versa. Subjects have to keep track of which stimulus is correct and switch their responses once they deem the contingencies have reversed. In (a), a monetary gain of 25 cents is signaled by the presentation of a US quarter dollar coin, whereas the monetary loss of 25 cents is signaled by the presentation of a red cross superimposed over a quarter dollar. fMRI, functional magnetic resonance imaging. Adapted from Hampton AN, Bossaerts P, and O'Doherty JP (2006) The role of the ventromedial prefrontal cortex in abstract state-based inference during decision making in humans. *Journal of Neuroscience* 26(32): 8360–8367, Copyright 2006 by the Society for Neuroscience.

models may provide a useful analogy to at least some of the neural processes underlying decision making in humans.

Perhaps unsurprisingly, such models are unlikely to account for all aspects of human choice behavior. For instance, these models are unable to learn about higher-order decision rules, such as interdependencies between actions and other exogenous variables including time, whereas expected value representations in the medial prefrontal cortex have been found to encode these decision rules. Furthermore, existing reinforcement learning models may not adequately account for how humans solve the exploration/exploitation dilemma, in which a decision maker needs to balance the need to choose what is currently believed to be the best action with the need to sample other available actions just in case those actions turn out to be more lucrative. A recent study showed that regions of the anterior prefrontal cortex may become engaged when subjects switch between exploratory and exploitative action selection modes, but such a putative switching mechanism is not easily accounted for in current reinforcement learning approaches to this problem. Finally, simple reinforcement learning models may not adequately account for the behavioral distinctions between goal-directed action choice, in which actions are selected with reference to the current incentive value of the associated outcome (involving response–outcome associations), and habit learning, whereby an action is selected purely on the basis of a learned stimulus–response association without reference to the outcome which that response engenders.

Introduction

Rewards can be broadly defined as stimuli of positive valence that can influence behavior. They can be manifested through a variety of ways, ranging from appetitive goods to a mere congratulatory pat on the back, and can shape both short-term (e.g., receiving candy after homework) and long-term (e.g., receiving a degree after years of school) goal-directed behavior. Rewards can be observed impacting basic everyday behaviors, such as searching for nutrients, but also more complex social interactions, such as developing trust. The evolutionary function of rewards, therefore, is thought to consist of three primary purposes. First, rewards can induce an overall positive emotional state. Second, the appetitive and hedonic nature of rewards can elicit exploratory or approach behavior. Third, through associative learning, rewards can also serve to reinforce a behavior, or assign a positive value to a previously neutral stimulus or action.

In order to exert an influence on behavior, however, rewards must first be detected by the brain. Information about the various properties of a stimulus, such as its valence, magnitude, probability, and time of consumption, must be integrated to form a representation of the reward value or the value of the action necessary to obtain it. Through experience and a highly adaptive neural network, the brain is then able to show preference toward specific rewards, predict when such rewards will become available, and guide behaviors toward a positive outcome. Although such learning about rewards mostly has a positive influence on life, the neural systems responsible for reward-related processing can go awry, in turn leading to abuse of behaviors that lead to rewarding feelings and contributing to many social maladies. Thus, it is imperative to understand the neurobiology underlying the human reward system, specifically how rewards come to be represented in the brain and how humans learn about them.

Neuroanatomy of Reward Processing

Much of the knowledge about reward systems of the brain come from early theories and a rich animal literature, which highlight some basic ideas about the neural basis of rewards. For example, while information about the physical and chemical attributes of a potential reward is processed by the sensory system (i.e., first through visual, gustatory, olfactory, auditory, or tactile receptors, followed by distributed sensory cortical areas), such information does not initially carry any value to the organism without knowledge of its purpose or effect on behavior. Thus, the coding of a reward representation in the brain is an integrative process that takes into account the physical, but also the subjective, value of a reward with respect to an overall goal. Animal research has been fundamental in delineating a potential neural circuit involved in reward processing and goal-directed behavior, to form the basis of understanding the human reward system. While these elegant animal models and data that derived them are not fully described herein, the neural circuit concept provides an opportunity to highlight the underlying neuroanatomy.

A simple version of the neural circuitry that mediates reward processing involves different regions that have multiple inputs and outputs, with the primary components being areas in the prefrontal cortex, basal ganglia, amygdala, and midbrain nuclei that carry the modulatory neurotransmitter dopamine (Figure 1). In the prefrontal cortex, some reward-related responses have been reported in dorsolateral areas. However, a fair amount of research implicates orbitofrontal cortex as the key prefrontal region where sensory and affective information about rewards is integrated. The orbitofrontal cortex (encompassing predominantly Brodmann's areas 10, 11, and 47) receives sensory and visceral motor information and is hypothesized to mediate many functions that involve linking stimuli classified as reward with hedonic experience or affective value. The orbitofrontal cortex can be further subdivided into a medial and lateral portion, both with distinct functionality, as will be discussed later. The orbitofrontal cortex also has strong connections with mesolimbic structures such as the amygdala, located in the medial temporal lobe, and the striatum, the primary input unit of the basal ganglia. The amygdala, a structure classically considered to be involved in aversive learning, has also been shown to participate in other aspects of emotion processing, namely appetitive or reward learning. The striatum, in turn, due to its connectivity with motor structures, has mostly been associated with motor behavior, although more recent research also links the basal ganglia with cognitive and affective processing. The striatum can be subdivided into both anatomically and functionally distinct components: dorsal (consisting of the caudate nucleus and putamen) and ventral (including nucleus accumbens and ventral putamen) striatum. All three regions, orbitofrontal cortex, amygdala, and striatum, are innervated with dopaminergic input from

Figure 1 Brain regions involved in reward processing in the human brain. (a) Coronal view of the striatum and its components: caudate, putamen, and nucleus accumbens; (b) coronal view of the amygdala; and (c) sagittal view of the orbitofrontal cortex (approximately Brodmann's areas 10, 11, and 46) resting near the orbit of the eyes.

midbrain nuclei, such as the ventral tegmentum area and the substantia nigra. Dopamine, a neurotransmitter previously thought to be involved in representing a reward response, has more recently been linked not with the response to a reward, but instead with providing a teaching signal that helps the brain adjust expectations about the representation of reward value.

There are other neural structures that have been implicated in specific aspects of reward processing. Some of these other regions, which are not discussed at length herein, include the ventral pallidum, part of the basal ganglia complex, the thalamus, a relay station from the basal ganglia to diverse areas of the prefrontal cortex, the cingulate gyrus, and the hypothalamus. The basic circuit involved in human reward processing, therefore, involves the orbitofrontal cortex, amygdala, and the striatum, along with modulation by dopamine neurons.

Reward Representations in the Human Brain

Recent advances in technology have allowed researchers to confirm and extend basic findings from animal studies by looking at the human reward system using neuroimaging and neuropsychological methodologies. By means of similar types of rewards, such as food and liquids, this research has found a tremendous amount of overlap between species in terms of the neurocircuitry involved in reward processing. A reward such as food is known as a primary reinforcer – it is innate to an organism, and therefore is processed through similar neural pathways across species. However, due to social and cultural evolution, other types of reinforcers available for humans, chiefly money, are also thought to affect behavior through a similar circuitry. This class of reward, consisting of secondary reinforcers, has developed its reinforcing properties through associations with primary rewards (e.g., money, a secondary reinforcer, allows one to purchase food, a primary reinforcer).

Irrespective of the type of reinforcer, human neuroimaging and neuropsychological studies have suggested that regions of the brain –such as the orbitofrontal cortex, amygdala, and striatum – represent and integrate information about the value of rewards (Figure 2). Such representations are formed at time of reward delivery, when an unknown stimulus (i.e., the rewarding stimulus) is assigned value due to hedonic pleasure or satisfaction it provides. After learning an association between a reinforcer and a particular stimulus or behavior, the reward representation is then transferred to the earliest predictor of

Figure 2 Example of primary and secondary reinforcers and similarities in neural systems. Primary reinforcers (e.g., food and liquids) are innate to an organism while secondary reinforcers (e.g., money) gain their reinforcing properties through learning and associations with primary rewards. Despite the differences between primary and secondary reinforcers, there is some overlap in how information about the reward is processed in the brain. For example, activation in the striatum is observed in experimental paradigms where the incentive is either a primary or secondary reinforcer. vst, ventral striatum; cg, cingulate gyrus; ins, insula; y = Talairach coordinate reflecting coronal positioning. such reward. These new representations of expected reward value are constantly updated and, consequently, behavior is modified to maximize the availability of rewards.

Coding Reward Value

Once sensory information about a potential reward comes into the brain, a representation of the subjective value must be assigned to aid the dissociation between rewards and nonrewards. This type of representation regarding the affective value of a stimulus is thought to be coded in the orbitofrontal cortex. Activity in orbitofrontal cortex, for example, has been found during functional magnetic resonance imaging (fMRI) studies when comparing a stimulus of positive valence (e.g., a pleasant liquid) with a neutral stimulus (e.g., a tasteless solution). Similar results have been reported irrespective of sensory modality, using gustatory, olfactory (i.e., pleasant odors), and tactile (i.e., pleasant touch) stimuli. These findings also extend into more subjective, yet still sensory, reward representations, as coded by the auditory (e.g., pleasant music) and visual (e.g., beautiful faces) domains. A further dissociation within the orbitofrontal cortex has been suggested between the lateral and more medial portions. While lateral orbitofrontal has been linked with representations of negative stimuli (such as unpleasant touch, or loss of money), the medial orbitofrontal cortex has been implicated with processing stimuli with positive valence.

Neuroimaging studies have also shown that orbitofrontal cortex codes for representations of monetary rewards, concurrent with studies involving primary reinforcers. Some of these studies involve extensive activation in medial aspects of the prefrontal cortex. Further, patients with lesions in the orbitofrontal cortex demonstrate impairments in forming reward representations and updating the contingencies required to obtain such rewards, as evidenced by poor performance in probabilistic learning experiments that involve contingency reversals.

The comparison between an affective and a nonaffective stimulus, however, could also suggest that orbitofrontal activation may be due to the differences in sensory intensity between the stimuli, rather than coding for reward value. Yet, when human study

participants are presented with olfactory stimuli that differ in terms of valence (positive and negative) and intensity (high and low), activity in the orbitofrontal cortex is found to code for the valence of a stimulus, but not intensity (which is associated with amygdala activation). More support for the idea that the orbitofrontal cortex codes for representations of reward value, rather than just sensory properties of a stimulus, is observed during satiation. A hungry human, for instance, will show activation in orbitofrontal cortex when presented with two different food stimuli. After repeatedly feeding on one of the two stimuli, the activation will decrease for such food item due to satiation, but activation will persist for the other stimulus which still has rewarding value. Hence, the myriad of human data supports the existing animal models and suggests that the orbitofrontal cortex is an important structure involved in representing the value of a stimulus during reward delivery.

Expected Reward Value

There is more than one way that a reward representation can be coded by the brain. As discussed, a reward such as a food item can be processed in the orbitofrontal cortex. Yet, if an affective neutral stimulus is associated with delivery of the food item, then such stimulus comes to predict the reward. In this case, the neutral stimulus (which is no longer neutral) serves as a conditioned stimulus and provides an expected or predictive representation of reward value. This expectation of reward is created through learning (either via experience or verbal communication) and is observed in day-to-day life (e.g., pizza box predicts food reward for a hungry individual). The assignment of value to the conditioned stimulus that comes to predict reward occurs through an interaction of neural structures previously described, along with dopaminergic modulation.

Recordings from nonhuman primate dopamine neurons demonstrate that this class of neurons is sensitive to unexpected rewards, such as a drop of juice. Further, if a neutral stimulus, such as a neutral tone, is paired with the delivery of the juice reward (e.g., a pleasant liquid), dopamine neuron cell firing will cease to occur at the time of reward delivery. Instead, dopamine neurons will fire at the earliest predictor of a reward, in this example the neutral tone. This transfer of activity due to Pavlovian learning mechanisms highlights how reward representations can be transferred to any stimulus that has strong associative connections with a positive outcome or reward.

In humans, predictive reward representations can be observed in dopaminergic targets such as the orbitofrontal cortex, ventral striatum, and amygdala. Recent fMRI studies have suggested that the human orbitofrontal cortex codes not only for reward-specific representations, but also for conditioned stimuli that predict reward. Representations of expected reward value in the orbitofrontal cortex may be formed in conjunction with the ventral striatum and the amygdala (Figure 3). Activity in both of these structures, for example, has also been found during appetitive conditioning paradigms involving primary reinforcers such as pleasant liquids and odors. Further, patients with unilateral medial temporal lobe lesions (which include amygdala) are impaired in conditioned preference learning, where patterns are associated with food rewards. Unlike the orbitofrontal cortex, however, the ventral striatum and amygdala have been associated with coding the representation of reward value during the expectation or predictive phase of reward processing, rather than during actual reward delivery. This suggests an important role for these structures in learning about rewards and making predictions about potential rewards.

Representations of predicted reward can be observed in the human orbitofrontal cortex and ventral striatum with both primary (e.g., food) and secondary (e.g., money) reinforcers. Anticipation of monetary rewards, for example, leads to activation in the ventral striatum, since the stimulus inducing the anticipation carries a predictive representation of reward. Interestingly, the overlap between types of reinforcers is not observed in the amygdala, as conditioned stimuli that predict a monetary reward (i.e., a secondary reinforcer) do not usually yield amygdala activation. This potential discrepancy might be because of intensity differences between primary and secondary reinforcers, though limitations in neuroimaging methodology cannot be discounted. It is useful to examine neuropsychological investigations in conjunction with neuroimaging data, which do not imply causality. For example, one experiment found that patients with amygdala lesions did not show anticipatory responses to potential monetary wins and losses in a gambling game (i.e., the Iowa Gambling Task), although the complexities of such a task make it difficult to interpret the deficit as a failure to show predictive representations of value.

Adjusting Expected Values and Actions That Lead to Reward

The brain has a representation of reward value that, through learning, shifts to the earliest predictor of the reward. The conditioned stimulus then provides an expectation of reward. However, the brain must adjust the representation of the expected reward signal if a reward fails to occur (e.g., opening a pizza box but finding it empty). This is especially the case when a reward is contingent on a behavior, as an organism

Figure 3 Representations of expected reward value in the orbitofrontal cortex and amygdala during appetitive conditioning experiment. Two predictive stimuli are presented and one stimulus (conditioned stimulus 1, CS 1; orange color) is satiated midway through experiment, while the other stimulus (CS 2; light blue color) is not. Graphs represent differential blood oxygenation level-dependent (BOLD) responses (postsatiation break minus presatiation). (a) Activation of orbitofrontal cortex (OFC) to the devalued conditioned stimulus (CS 1) was decreased compared to the nondevalued conditioned stimulus (CS 2), suggesting that representations of expected reward value are constantly changing with motivational state. (b) The same pattern of results is observed in the amygdala. BOD, blood-oxygen level dependent. Adapted from Gottfried JA, O'Doherty J, and Dolan RJ (2003) Encoding predictive reward value in human amygdala and orbitofrontal cortex. *Science* 301(5636): 1104–1107, with permission.

has to quickly adapt and update action representations that will lead to rewards.

Dopamine neurons provide an illustration of how the nonhuman primate brain might signal a potential error in prediction. The role of dopamine in reward-related learning is thought to be a teaching signal that relays information about the representation of rewards. As previously discussed, these cells typically show learning-related activity demonstrated by a transfer in neural firing from the unexpected reward to the predictive cue. Notably, dopamine cells will also show a depression in neuronal firing when an expected reward is omitted. By signaling the presence of an unexpected reward and the omission of a predicted reward, dopamine is able to provide a reward prediction error signal that aids in goal-directed behavior.

In humans, the prediction error signal is observed in dopaminergic targets, but primarily in the striatum. Different portions of the striatum have shown evidence of coding for errors in prediction in neuroimaging studies. Using primary reinforcers, activation in the ventral putamen has been correlated with a prediction error signal. Using secondary reinforcers, the majority of studies suggest that the nucleus accumbens may be more involved. Although this separation within the striatum between primary and secondary reinforcers has been observed in some studies, it is not uniform and it may merely reflect a difference in type of paradigms or even particular properties of the reinforcer.

A more clear dissociation within the striatum is observed between dorsal and ventral striatum. As

previously described, the ventral striatum is involved in representations of expected reward, highlighted by activation to a predictive conditioned stimulus during appetitive learning paradigms. The dorsal striatum, in contrast, is important for specifically coding the representation of a reward which is contingent on behavior. This is illustrated in conditioning paradigms, where visual cues predict the delivery of rewards either noncontingently (Pavlovian conditioning) or contingently (instrumental conditioning) on choice behavior. Activation of the caudate nucleus, part of the dorsal striatum, is observed only during instrumental conditioning. Thus, the dorsal striatum, particularly the caudate nucleus, appears to be involved in the coding of action specific representations of reward value.

Modulation by Properties of Reward

Once reward-related information is detected by the brain and a representation is formed, such representation is constantly updated to reflect changes in the current value of the reward. This updating depends on the current state of the organism and the properties of the rewarding stimulus. For example, as previously discussed, a food reward will have a representation of value for a hungry individual. This representation of reward value, however, changes as the individual becomes satiated, suggesting that the motivational state of an organism can temporarily affect representations of reward and the neural circuitry involved in reward processing. Additionally, reward representations in the brain also take into consideration the properties of a reward, such as valence, magnitude, probability, and time of consumption.

Valence

Valence refers to the positive or negative quality attributed to a stimulus. For example, glucose water is a pleasant liquid solution considered to have positive qualities, while salty water is an unpleasant solution with negative qualities. Similarly, winning money and receiving positive feedback (e.g., pat on the back) are pleasant stimuli, while losing money and receiving negative feedback (e.g., reprimand) are unpleasant stimuli. Interestingly, the interaction between the valence of a stimulus and its reward value is not as clear-cut as the preceding examples suggest, leaving open questions for future investigations. For instance, although avoidance of a negative outcome such as losing money is generally a positive outcome, can it be considered a reward? What about receiving a small reward, a positive outcome, when a preferred larger one was available (i.e., regret)?

As previously mentioned, the representation of the value of a reward during delivery of such reward is coded in the orbitofrontal cortex. However, human neuroimaging studies also suggest that the human dorsal striatum is active during reward delivery when it is contingent on a behavior. Unlike more medial portions of the orbitofrontal cortex, the dorsal striatum does not create a representation of the reward value *per se*. Instead, it codes the differential activity between stimuli of positive and negative valence during trial-and-error learning, maintaining a representation of the outcome of goal-directed actions to help guide future behavior.

Magnitude and Probability of Reward

An affective stimulus can vary in terms of valence, but also magnitude. Although magnitude could also refer to the intensity of a stimulus, the primary definition refers to the amount or quantity of a reward. Changes in reward magnitude (e.g., increases in the expectation of reward or reward delivery) evoke predictive reward representations in orbitofrontal cortex and ventral striatum that grade parametrically according to increases in value (i.e., higher magnitudes, Figure 4).

Besides magnitude, an important component of the expected reward value representation is the probability of a potential reward delivery. A stimulus that is paired with a reward elicits a prediction of reward delivery. At times, however, the probability of receiving a reward is probabilistic. That is, there is a chance a reward will not be delivered. This is observed in everyday behavior, from extremes such as playing the lottery to hoping there is one more slice of pizza in the box. The probabilistic nature of reward is an important component of behavior, since if every attainable reward was predictable there would be no evolutionary need to explore or show approach behavior. Thus, all regions of the basic reward circuit are influenced by reward probability, as evidenced by expected reward representations parametrically varying in terms of how uncertain they are in regions such as the orbitofrontal cortex and striatum. For example, the striatum is found to be more activated during unpredictable, compared to predictable, delivery of primary rewards. More recently, the medial prefrontal cortex has been implicated in integrating information about the potential magnitude and probability of a reward, forming a representation of the expected value of a reward.

Time

Finally, a representation of reward value can be influenced by the time the reward is expected to be delivered. A reward that is available immediately is thought

Figure 4 Reward representations in the striatum are sensitive to magnitude differences. (a) Ventral striatum activation during anticipation of different magnitudes of monetary rewards. (b) Levels of blood oxygenation level-dependent response (represented by percent signal change) in ventral striatum varied based on different cues that represented monetary rewards of different magnitudes (ranging from $0 to $5.00). Adapted from Knutson B, Adams CM, Fong G W, et al. (2001) Anticipation of increasing monetary reward selectively recruits nucleus accumbens. *Journal of Neuroscience* 21(16): RC159, with permission. Copyright 2001 by the Society for Neuroscience.

to be more valuable than a reward available only in the future (e.g., a slice of pizza now vs. a week later). Recent investigations have suggested that the ventral striatum is more involved with processing immediate rewards, while prefrontal cortex regions are linked to evaluation of long-term rewards. This is supported by neuropsychological work with frontal-lesioned patients, who discount future consequences of their actions in a gambling game (i.e., larger losses) in deference to immediate rewards. Yet, more research is needed to fully understand the influence of time on the neural mechanisms of human reward processing.

Modulation of Reward System by Cultural and Social Factors

Together with findings from animal studies, recent research with humans has helped delineate a basic circuit involved in processing simple rewards such as food. Yet, human beings are much more complex and form reward representations through experience with social and cultural rewards which affect behavior. New fields of study are currently being developed to probe these more complex behaviors, which necessitate the merging of disciplines, as illustrated by social neuroscience and neuroeconomics. For instance, in humans, representations of reward value are also subjective; some like Coke and others like Pepsi, while some don't like soda at all. Studies have suggested that subjective preference for cultural rewards such as sugar-based liquids and even types of cars is represented in medial orbitofrontal areas.

Interestingly, the expected representation of social rewards seems to involve primarily the striatum. It is possible that the striatum, particularly the dorsal striatum, is more involved in processing social rewards because of the link between human interaction and action. Social rewards such as love, humor, and cooperation all yield positive feelings, and presentation of a stimulus that predicts such hedonic feelings (e.g., a picture of a loved one) leads to activation in the striatum.

These findings are strengthened by studies involving social and economic interactions, where an individual can either benefit or suffer from an interaction with another person. For example, in a trust game whereby reputations are built through experience, activation of the dorsal striatum is observed coding for a representation of expected reward value when a positive, trustworthy interaction occurs. To demonstrate how complex human nature is, however, such a signal can be influenced by previous information or biases that individuals have, rather than be driven by the presence or absence of rewards.

Finally, the complexities of the human reward system are also observed during abuse of rewards, as displayed by drug addicts, for example. The lure of drugs leads to exaggerated representations of expected reward values (e.g., craving) that can 'hijack' the brain's reward system. The influence of drugs on behavior will lead an addict to bypass natural rewards in favor of drugs, eventually deteriorating quality of life for the addict and those around him.

Summary

Rewards are incentives that influence behavior. The potential rewarding properties of a stimulus and its

effect on goal-directed behavior are coded in the human brain by an intrinsic reward circuit consisting of orbitofrontal cortex, striatum, amygdala, and dopaminergic modulation. Attributes such as a stimulus valence (positive or negative) are represented in these structures. The orbitofrontal cortex is chiefly-involved in assigning value to a stimulus during reward delivery. The striatum and the amygdala are involved in forming representations of the expected reward value of a stimulus, and constantly update such representations to reflect the current motivational state or changes in reward properties (e.g., probability and time of occurrence). The striatum, particularly the dorsal components, is also involved in forming action-specific representations of reward, monitoring the outcome of actions to maximize available rewards.

The human reward circuit processes both simple primary (e.g., food) and secondary (e.g., money) rewards. Current research aims to understand how the basic reward circuitry processes more complex cultural and social rewards, as displayed by subjective preference (e.g., different types of beverages) and human interactions (e.g., trust). Explorations of the simple and complex intricacies of the neural basis underlying human reward processing afford an opportunity to further our knowledge regarding goal-directed behavior, leading to appreciation and treatment of many of societal maladies associated with abuse of the reward system.

Reye Syndrome

D A Trauner, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

In 1963, RDK Reye, an Australian pathologist, described 21 cases of acute encephalopathy with fatty infiltration of the viscera in children. Over the next decade, the clinicopathological features of Reye syndrome became increasingly well recognized. The disease is biphasic, with an antecedent viral illness followed by sudden onset of encephalopathic changes. Reye syndrome afflicts previously healthy children. There is a high mortality rate, particularly in children who have progressed to a comatose state. At the peak incidence of Reye syndrome in the late 1970s, the disorder was the second most common cause of death in the pediatric age group from virus-associated central nervous system (CNS) disease in the United States, reaching a peak incidence of 0.8 per 100 000 in children under the age of 18 years. However, in the early 1980s the incidence of Reye syndrome began to lessen, and now is extremely rare, with only a few cases per year being reported. This article discusses demographic and clinicopathological features of Reye syndrome, current incidence, conditions with similar clinicopathological features, possible etiologies, and treatment and prognosis.

Demographics

Reye syndrome is almost exclusively a disease of childhood, with only rare reports of adult cases. Although children of all ages may develop this condition, there are peak occurrences at 4–5 years of age, and again in early adolescence. Most cases of Reye syndrome occur during the winter months, December through March. This parallels the incidence of influenza virus infections. In the United States, the disease is much more prevalent in Caucasians than in other races. Reye syndrome is more likely to occur in children living in rural or suburban areas. During the peak years of Reye syndrome in the late 1970s, there were clear geographical differences in incidence. The highest numbers of cases were reported primarily from the Midwest, with Ohio, Michigan, Iowa, Nebraska, Colorado, South Dakota, and Utah each having an annual incidence of 1–2.5 cases per 100 000 children under the age of 18 years. Only Georgia, in the southeast, had a similar incidence. These geographic differences have never been explained.

During the time that Reye syndrome had a high incidence rate, an interesting demographic difference was observed relating to age and race predilection. Whereas almost 90% of children who developed Reye syndrome after 1 year of age were white, approximately 50% of infants less than 1 year of age who developed the illness were nonwhite. Furthermore, infants tended to be from more urban areas, while the older children were more likely to live in rural areas. The reason for these differences has not been established. One speculation, however, is that infants living in poorer, inner city areas were likely to become exposed to certain viruses at an earlier age as compared to children living in middle class and more rural locales.

Clinicopathological Features

The typical case of Reye syndrome is preceded by a prodromal, usually upper respiratory, viral illness. Influenza B and A viruses have been linked with most of the case clusters of Reye syndrome, while varicella is the most common viral illness associated with sporadic cases. However, large numbers of different viral agents have been associated with sporadic Reye cases. The ill child is typically recovering from the prodrome when recurrent vomiting develops, followed within 24–48 h by the onset of encephalopathic symptoms (see Table 1). The earliest symptoms of CNS involvement include disorientation and agitation, with progression in some cases to delirium, stupor, and coma. Hyperventilation is a frequent sign, even in the early stages. In the most severe cases, children develop brain stem dysfunction, massive cerebral edema, and brain stem or transtentorial herniation. Mortality rate is high (~70%) in the severe cases. Death is almost always caused by massive brain swelling.

Reye syndrome is a multisystem disease. In the early stages, however, the most consistent laboratory abnormalities are related to hepatic dysfunction. Elevated serum transaminases are uniformly found, with no or minimal increase in bilirubin levels. Prolonged prothrombin time with minimal elevation of partial thromboplastin time is common. Blood ammonia concentrations are almost invariably elevated, at least early in the course of the illness. Hyperammonemia may be transient, however, and so the absence of a clear elevation of blood ammonia concentration may not rule out Reye syndrome. Hypoglycemia is present in approximately 40% of cases, and is more common in children under the age of 4 years. Other metabolic abnormalities commonly observed include

Table 1 Staging of Reye syndrome

Stage 1: Vomiting and lethargy
Stage 2: Disorientation, delirium, combativeness; hyperventilation; appropriate responsiveness to noxious stimuli
Stage 3: Obtundation or coma; decorticate posturing; preserved pupillary reflexes
Stage 4: Coma; decerebrate posturing; dilated pupils unresponsive to light; loss of oculocephalic reflexes
Stage 5: Respiratory arrest; flaccid quadriplegia; absence of tendon reflexes

elevated levels of creatine phosphokinase, plasma lactate, uric acid, and several amino and organic acids. Arterial blood gas determinations generally demonstrate a mixed metabolic acidosis and respiratory alkalosis, with the latter usually predominating. Cerebrospinal fluid (CSF) analysis is unremarkable, with the exception of hypoglycorrachia and elevated CSF pressure.

Acute pancreatitis is a less common but potentially severe complication of Reye syndrome. Abnormal elevations in serum amylase and lipase concentrations may be found. Severe hemorrhagic pancreatitis may be fatal. Renal dysfunction has been reported late in the course of the disease process, but may in part be related to vigorous treatment with hyperosmolar agents, and is usually reversible.

The hallmark pathological feature of Reye syndrome is the presence of diffuse, microvesicular fatty accumulation in the liver, kidney, and heart. Depletion of glycogen from the liver is a common feature as well. Ultrastructural changes are found primarily in the mitochondria of liver and brain. Swollen mitochondria with distortion of the structure of the cristae are typical ultrastructural features. Dilatation of the cisternae of rough endoplasmic reticulum and proliferation of smooth endoplasmic reticulum may also be found. Pathological changes in the brain include diffuse cerebral edema and mitochondrial damage similar to that found in the liver.

Conditions with Similar Clinicopathological Features

Reye syndrome is most likely not due to a single causative factor; rather, the symptoms may be produced by a number of different mechanisms and underlying conditions. Numerous cases of acute encephalopathy with 'Reye-like' features have been documented in children with inborn errors of metabolism, including disorders of mitochondrial metabolism, urea cycle defects, fatty acid oxidation defects, and other disorders of intermediary metabolism. Large numbers of children exposed to toxins, such as aflatoxin B1 in Thailand (Udorn encephalopathy) and hypoglycin A (from eating the unripe ackee fruit) in Jamaica (Jamaican vomiting sickness), have developed acute encephalopathies and hepatopathies identical to Reye syndrome. Insecticide exposure has been implicated in outbreaks of Reye syndrome in several case studies.

Etiology/Epidemiology/Incidence

Various medications taken during the prodromal viral illness have been implicated as possible causative factors in this condition. Only salicylate exposure, however, has been repeatedly demonstrated to have a strong epidemiological association with the development of Reye syndrome. Several state studies, beginning in 1980, documented a statistical association between aspirin and Reye syndrome. Two case control studies from the United States Public Health Service (PHS) also documented a strong statistical association between salicylate use and Reye syndrome, leading the investigators to the conclusion that there might be an etiological association as well.

The results of the epidemiological studies led to the placement of a strong warning label on aspirin bottles in 1986, advising parents not to treat their children with aspirin for viral illnesses. The use of salicylate-containing compounds for children with acute illnesses has dropped dramatically since that time. The incidence of Reye syndrome in this country began to decrease in the early 1980s, prior to completion of the PHS studies and several years prior to the warning labels on aspirin bottles. The incidence continued to decrease to the point that no more than two to four cases per year are currently reported.

Similar epidemiological evidence for an association between salicylate use and Reye syndrome has come from the United Kingdom and France. In Australia and Japan, however, no similar associations have been documented. A recent cluster of cases in India was not associated with a high incidence of salicylate use. In those cases, malathion was suggested as a possible trigger for the illness. An etiologic link between salicylates and Reye syndrome has also not been proved to date. One potential mechanism by which salicylates or environmental toxins might precipitate a Reye-like illness is by reducing the activity of mitochondrial enzymes involved in fatty acid oxidation, resulting in a large increase in circulating fatty acids. High concentrations of fatty acids have been shown to be toxic to mitochondria and to produce further mitochondrial dysfunction and metabolic derangements such as hyperammonemia. It has been suggested that a virus–toxin interaction, perhaps in a

genetically susceptible host, might be required for the development of Reye syndrome.

Beginning in 1976, the US Centers for Disease Control and Prevention (CDC) maintained a voluntary reporting system for Reye syndrome in the United States. Through the late 1970s, the incidence of Reye syndrome averaged approximately 400 cases per year. A peak was reached in 1980, with the highest number of cases (555) ever reported in one year. The number of cases reported to the CDC began to diminish in 1981, and after 1987 fewer than 36 cases per year were reported. Since 1994, no more than two to four cases have been reported per year. Many of the reported cases in recent years have been of teenagers who had taken salicylates, suggesting the possibility that salicylate use among adolescents should be avoided.

The decline and virtual disappearance of Reye syndrome may be related to a decline in salicylate use among children. It has been suggested, however, that this is an apparent decline, due at least in part to the heightened recognition of inborn errors of metabolism that previously mimicked Reye syndrome. Another speculation is that the viral agents responsible for triggering Reye syndrome have changed, such that they no longer produce the same toxic changes in liver and brain that induced Reye syndrome 40 years ago. All of these explanations may be correct. Virus–toxin interactions and virus–metabolic dysregulation interactions might have precipitated the metabolic changes necessary for the development of Reye syndrome.

Although the reported incidence of Reye syndrome in the United States and many other countries is quite low now, there are 'outbreaks' of what appear to be Reye syndrome reported intermittently from different parts of the world. India, for example, has had a number of clusters of what has been reported by the news media as a 'mystery disease' associated with flulike illnesses. However, the clinical features of this illness are identical to those of Reye syndrome, and may represent isolated clusters of Reye syndrome cases.

Treatment and Prognosis

The treatment for Reye syndrome consists of intensive supportive care, use of hypertonic glucose to treat the hypoglycemia, aggressive treatment of hyperammonemia, reversal of other metabolic abnormalities, reduction of increased intracranial pressure, and neuroprotective measures such as cooling. Numerous treatment protocols have been published. One commonly used protocol is outlined in Table 2.

Table 2 General management of Reye syndrome

- Admission to pediatric intensive care unit as soon as diagnosis is entertained
- Nasotracheal intubation if child reaches stage 3 or greater
- After intubation, controlled hyperventilation to maintain pCO_2 between 25 and 30 torr
- Intravenous glucose administration with 10–15% glucose solution
- Maintain serum glucose concentration between 150 and 200 mg%
- Intravenous insulin, 1 unit per 10 g glucose initially, adjusting dose to maintain serum glucose concentration between 150 and 200 mg%
- Intravenous L-carnitine administration using 50–100 mg kg^{-1} per day in three divided doses
- Intracranial pressure monitor placement for any child who reaches stage 3
- Intracranial pressure control using a combination of hyperventilation, osmotic agents such as mannitol, and neuromuscular blocking agents such as pancuronium bromide; intravenous barbiturates may be used if other measures fail to control intracranial pressure
- Reduction of blood ammonia levels can be achieved using neomycin enemas and lactulose by nasogastric tube, or by plasmapheresis or hemodialysis

As mentioned previously, a number of conditions can mimic Reye syndrome. Infections such as varicella encephalitis with hepatitis can produce some similar clinical and biochemical features. Salicylism, poisoning with *Amanita phylloides*, and fulminant hepatic failure from valproic acid use can all cause a Reye-like illness. Numerous inborn errors of metabolism may manifest themselves as an acute metabolic encephalopathy. The most common conditions in this category include genetic disorders of mitochondrial function, medium-chain acyl-CoA dehydrogenase deficiency as well as other fatty acid oxidation defects, systemic carnitine deficiency, hereditary urea cycle defects, and carnitine palmitoyltransferase II deficiency. The immediate treatment for these conditions during periods of acute metabolic decompensation is similar to the treatment for Reye syndrome, but long-term interventions are necessary to prevent recurrent episodes of acute decompensation with life-threatening encephalopathy.

The overall mortality rate from Reye syndrome is approximately 30%. If the severity of the illness at the time of admission is taken into account (based on a severity rating scale), mortality rates are lower for the milder stages of illness, but approach 90–100% if the child is in stage 5 coma at the time of hospital admission (see Table 1). Most of the deaths are caused by massive cerebral edema with brain ischemia or herniation. Other rare causes of death include

fatal cardiac arrhythmias and acute hemorrhagic pancreatitis with shock.

Survivors of the acute illness may have subtle cognitive and behavioral sequelae from their illness, although these consequences may not be apparent for many years after recovery. One recent study found that children who had developed Reye syndrome under 1 year of age, or whose acute illness had progressed beyond stage 2, were more likely to have adverse cognitive and behavioral outcomes. Approximately one-half of the children required some remedial help in school and exhibited problems with self-esteem. Given the marked metabolic derangements and the amount of cerebral edema that can occur with Reye syndrome, it is not surprising that cognitive sequelae are common following this illness.

Rho GTPases and Spines

H Zhang, University of Virginia School of Medicine, Charlottesville, VA, USA

© 2009 Elsevier Ltd. All rights reserved.

Dendritic spines are tiny protrusions on neurons that receive most of the excitatory synaptic inputs in the brain. Prior to spine formation during brain development, dendrites are covered with actin-rich, filopodia-like protrusions. These protrusions are believed to be actively searching for presynaptic partners, and once a contact is formed, the protrusion matures into a mushroom-shaped spine, which is rich in actin and essentially devoid of microtubules. Thus, the formation of spines requires extensive reorganization of the actin cytoskeleton, and it is likely that regulators of actin dynamics play a central role in spine development. Indeed, evidence is emerging that points to a key function for actin regulators, particularly proteins that participate in the Rho signaling pathway, in spine morphogenesis. This article focuses on the Rho GTPase signaling pathways that lead to actin reorganization and their effects on dendritic spine morphogenesis.

Rho GTPases and Actin Dynamics

The organization of the actin cytoskeleton is regulated by members of the Rho family of small guanine triphosphate (GTP)ases. The Rho GTPases are a subfamily of proteins that belongs to the Ras superfamily of small GTP-binding proteins, which cycles between an inactive guanine diphosphate (GDP)-bound state and an active GTP-bound state. Their activity is regulated by guanine nucleotide exchange factors (GEFs), which promote GTP loading and thereby activate these proteins; and GTPase activating proteins (GAPs), which enhance the intrinsic GTPase activity of these proteins and return them to the inactive state. Inactive GTPases are removed from the plasma membrane by guanine nucleotide dissociation inhibitors (GDIs), which form a 1:1 complex with GDP-bound forms of Rho GTPases and keep them predominantly in the inactive form until they are activated in response to stimulation. Active GTPases signal to downstream effector proteins and generate a cellular response (Figure 1).

There are 20 known members of the Rho GTPase family in mammals, seven in *Drosophila melanogaster*, five in *Caenorhabditis elegans,* and 15 in *Dictyostelium discoideum*. The best-studied members of Rho GTPases include RhoA, Rac1, and Cdc42, and their effects on the actin cytoskeleton are well characterized in fibroblasts. A constitutively activated mutant of RhoA induces the formation of contractile actin and myosin filaments known as stress fibers; constitutively active Rac1 promotes actin-rich fan-like surface protrusions called lamellipodia, which are composed of a highly branched network of actin filaments. Cdc42 promotes the formation of filopodia, which are fingerlike protrusions that are made up of parallel bundles of actin filaments.

Rho GTPases do not act on the actin cytoskeleton directly. Instead, they function through their downstream effector proteins, which then act on proteins regulating actin polymerization, actin filament assembly, or myosin contractility.

RhoA

The effects of RhoA on the actin cytoskeleton are mediated by Rho kinase (also known as ROK or ROCK), which promotes myosin light chain phosphorylation. Rho kinase can achieve this through two different mechanisms. First, it directly phosphorylates myosin light chain. In addition, Rho kinase also phosphorylates and inhibits myosin light chain phosphatase, thereby stimulating myosin light chain phosphorylation indirectly. Phosphorylated myosin binds to actin, thereby promoting actin bundling and the formation of stress fibers in fibroblasts.

In addition to acting on myosin, Rho kinase also phosphorylates and activates Lin-11, Isl-1, and Mec-3 (LIM) kinase (LIMK), which in turn phosphorylates and inactivates cofilin. Cofilin and its related protein actin depolymerizing factor (ADF) increase the rate of dissociation of actin subunits from the pointed ends of actin filaments. They also have F-actin-severing activities that increase the total number of shorter actin filaments. Thus, by inactivating cofilin, the RhoA–Rho kinase pathway serves to stabilize actin filaments.

Another known downstream effector of RhoA is mDia, which is the mammalian ortholog of *Drosophila* Diaphanous. mDia is a member of the formin family of proteins that functions to stimulate actin filament assembly. It is noteworthy that mDia also functions in aligning and stabilizing microtubules, suggesting that the functions of Rho GTPases extend beyond the regulation of actin dynamics.

Rac1 and Cdc42

The pathways downstream of Rac1 and Cdc42 that lead to actin reorganization are more complex. One of the common effectors of Rac and Cdc42 is p21-activated kinase (PAK). PAKs are a family of Ste20-like serine/threonine protein kinases. They contain a conserved C-terminal kinase domain and an

Figure 1 The Rho GTPases cycle between an inactive GDP-bound state and an active GTP-bound state. Their activity is regulated by guanine nucleotide exchange factors (GEFs), which promote GTP loading and thereby activate these proteins, and by GTPase-activating proteins (GAPs), which enhance the intrinsic GTPase activity of these proteins and return them to the inactive state. Inactive GTPases are removed from the plasma membrane by guanine dissociation inhibitors (GDIs), which form a 1:1 complex with GDP-bound forms of Rho GTPases and keep them predominantly in the inactive form. Active GTPases signal to downstream effector proteins and generate a cellular response. GDP, guanine diphosphate; GTP, guanine triphosphate; P, phosphate.

N-terminal regulatory domain. A highly conserved p21-binding domain (PBD) is localized within the N-terminal region. In its inactive form, PAK is folded onto itself. Upon binding of Rac/Cdc42 to PBD, a conformational change is induced, thereby allowing autophosphorylation within the kinase domain of PAK and the subsequent phosphorylation of its downstream targets. Activated PAK phosphorylates and inhibits LIMK1. PAK has also been shown to phosphorylate and inhibit myosin light chain kinase, thereby inhibiting myosin light chain phosphorylation. However, there is also evidence that PAK directly phosphorylates myosin light chain.

Another common downstream effector of Rac and Cdc42 is phosphatidylinositol-4-phosphate 5-kinase (PIP 5-kinase), which converts the phospholipid PI(4)P to PI(4,5)P2. PI(4,5)P2 has a variety of downstream targets that directly regulate actin dynamics. One of the effectors is capping protein, which caps actin filaments and stops their elongation. PI(4,5)P2 inhibits capping protein and facilitates filament elongation. In addition, PIP2 stimulates WASP (Wiscot–Aldrich syndrome protein), which causes the activation of the actin-related protein (Arp)2/3 complex. The Arp2/3 complex stimulates *de novo* actin polymerization and thereby promotes branch formation. Initially, PIP 5-kinase was thought to be a downstream effector of Rac. However, later studies found that PIP 5-kinase was activated downstream of Rac, Cdc42, and Rho, making it a potential convergent point downstream of Rho GTPase signaling.

In addition, both Rac1 and Cdc42 can activate insulin receptor substrate of 53 kDa (IRSp53). Activated Rac1 forms a ternary complex with IRSp53 and its downstream effector WAVE2. WAVE2 is a member of the WAVE/Scar family of proteins that activates Arp2/3. Thus, by activating IRSp53, Rac promotes actin filament branching that is necessary for lamellipodia formation.

By contrast, Cdc42 was reported to form a ternary complex with IRSp53 and Mena, a member of the Ena/vasodilator-stimulated phosphoprotein (VASP) family of proteins. The Ena/VASP proteins promote filament elongation by recruiting profilin, which is a G-actin-binding protein that accelerates the exchange of adenosine diphosphate (ADP)/adenosine triphosphate (ATP) on actin. In addition, they inhibit the activities of the Arp2/3 complex as well as capping protein. These actin-regulating activities of Ena/VASP result in longer and less-branched filaments, which fits well with the ability of Cdc42 to induce filopodia formation. However, a later study showed that IRSp53 co-localized with WAVE2 at the tips of both filopodia and lamellipodia, independently of Mena. Thus, it remains unclear whether the distinct effects of Rac and Cdc42 result from different downstream targets of IRSp53.

In addition to these common effector proteins, Rac and Cdc42 each have specific downstream targets, which may account for their differential effects on the actin cytoskeleton. Activated Rac binds the Sra-1 (specifically Rac1-associated protein 1)–cytoplasmic FMRP (fragile-X mental retardation protein)-interacting protein 1 (CYFIP1) complex, which contains Sra-1, Nck-associated protein (Nap1), Abl-interacting protein 2 (Abi2), and heat-shock protein C300 (HSPC300). The Sra-1 complex binds WAVE/Scar proteins. However, it is not clear how this interaction regulates the targeting and activation of WAVE proteins in response to active Rac.

In contrast to Rac1, the major downstream effector of Cdc42 is the WASP family of proteins. In its inactive state, WASP is folded onto itself through an intramolecular interaction between the N- and the C-termini. Cooperative binding of Cdc42 and PI(4,5)P2 relieves this interaction and activates it. Toca-1, a novel effector of Cdc42, is required for Cdc42- and PI(4,5)P2-mediated WASP activation and actin polymerization. The WASP family of proteins activates profilin, which promotes filament

Figure 2 Rho GTPase signaling in actin dynamics, Rho GTPases (purple) signal through their effector proteins (red), which then regulate proteins that affect actin filament extension, branching, or myosin contractility (green). Dashed line indicates indirect effects. Arp2/3, actin-related protein 2/3; IRSp53, insulin receptor substrate of 53 kDa; LIMK, LIM kinase; mDia, mammalian ortholog of *Drosophila* Diaphanous; MLC, myosin light chain; MLCK, myosin light chain kinase; MLCP, myosin light chain phosphatase; PAK, p21-activated kinase; PIP2, phosphatidylinositol 4,5-biphosphate; RhoA, Rac1, Cdc42, Rho GTPases; ROK, Rho kinase; Sra-1, specifically Rac1-associated protein 1; WASP, Wiscot–Aldrich syndrome protein; WAVE, WASP family verprolin-homologous protein.

elongation. Consistent with this, neuronal WASP (N-WASP) induces filopodia formation *in vivo*. However, it remains an enigma how WASP induces the formation of parallel actin bundles characteristic of filopodia when it also activates Arp2/3, which stimulates branch formation (Figure 2).

Signaling from Adhesion and Growth Factor Receptors to Rho GTPases

The Rho GTPases reorganize the actin cytoskeleton in response to a variety of extracellular stimuli. For example, cell–cell adhesion and cell-extracellular matrix adhesion both stimulate Rho GTPases through the engagement of different adhesion receptors, including cadherins, integrins, and Ig superfamily members. A variety of different growth factors also stimulate the activity of Rho GTPases. These adhesion and growth factor receptors target different GEFs and GAPs, which regulate specific Rho GTPases. To date, over 80 different GEFs and over 70 GAPs for Rho GTPases have been found. It is interesting to speculate that these GEFs and GAPs are targeted by different extracellular stimuli. They may also function to regulate Rho GTPases in different parts of the cell so that the activity of Rho GTPases is precisely regulated both temporally and spatially.

In addition to regulation by GEFs and GAPs, Rho GTPases can also be modulated by protein degradation through the ubiquitin–proteasome pathway. In migrating cells, the PAR (partitioning defective) polarity complex recruits Smurf1, an E3 ubiquitin ligase, to filopodia and lamellipodia. Smurf1 functions by locally degrading RhoA, thereby preventing RhoA signaling in protrusive parts of the cell. This provides a novel way of regulating Rho GTPase activity through controlling local protein levels.

Rho GTPases and Spine Morphogenesis

Because the Rho GTPases are central regulators of the actin cytoskeleton, it is conceivable that they play an important role in the morphogenesis of dendritic spines, which are extremely rich in actin. Recent studies have shown that Rho GTPases are indeed key regulators of dendritic spine formation.

Signaling through Rho

Two upstream regulators of Rho have been implicated in spine morphogenesis. One is oligophrenin-1, a Rho-GAP. Oligophrenin-1 is highly expressed in the brain and is present in dendritic spines in hippocampal neurons. Knockdown of oligophrenin-1 expression

causes a reduction in spine length in rat hippocampal slices, a phenotype mimicked by activating RhoA and rescued by inhibiting Rho kinase. Oligophrenin-1 interacts with the synaptic adaptor protein Homer, which is associated with both the metabotropic glutamate receptors (mGluRs) and the *N*-methyl-D-aspartate (NMDA)-type glutamate receptor. Glutamate receptor stimulation is thereby linked to Rho signaling through this interaction.

The second upstream regulator involved is the Rho-specific GEF Lfc. Like oligophrenin-1, Lfc is highly expressed in the brain. Interestingly, Lfc normally localizes to the dendritic shaft of cultured hippocampal neurons; however, on synaptic activation, Lfc translocates to dendritic spines in an NMDA receptor-dependent manner. Overexpression of Lfc results in shorter and smaller spines. Conversely, a C-terminal fragment of Lfc, which acts as a dominant negative mutant, causes the formation of longer spines. Taken together, these studies support a role for Rho in the negative regulation of spine neck length.

The effects of RhoA itself on spine morphology have been examined in several different systems. In all cases, a constitutively active version of RhoA decreases the density of dendritic spines and shortens the spine neck, indicating that RhoA negatively regulates spine formation. Consistent with this, inhibiting Rho activity using C3 transferase was shown to increase spine density and length.

These studies all point to a function of RhoA in the negative regulation of spine density and spine neck length. However, a recent study has made the story more complex. RhoA was shown to be associated with glutamate receptors at the spine membrane. Activation of ionotropic glutamate receptors leads to the dissociation of RhoA from these receptors and the subsequent recruitment of RhoA to mGluRs. This results in a decrease in local RhoA and Rho kinase activities, which leads to spine collapse. Based on these observations, RhoA was proposed to function in stabilizing dendritic spine morphology through Rho kinase. Interestingly, when Rho kinase was locally inactivated by uncaging a caged inhibitor, Y-27632, the spines retracted; however, in another study in which hippocampal slices were treated with Y-27632, no obvious changes in spine morphology were observed. Thus, further studies, especially those involving knockdown of endogenous proteins using short interfering RNA (siRNA), are needed to clarify the roles of RhoA and Rho kinase in spine morphogenesis.

Signaling through Rac

Several Rac GEFs have been implicated in dendritic spine morphogenesis. The first one is Kalirin-7. Kalirin expression in the adult rat is restricted to the central nervous system (CNS), with Kalirin-7 being the most abundant isoform. Furthermore, Kalirin-7 is enriched in the postsynaptic density fraction, where it interacts with several PDZ (Psd-95, Dlg, and ZO1) domain-containing proteins through its extreme C-terminal binding motif. In response to EphB receptor activation, Kalirin-7 translocates to synapses, where it mediates Rac activation. Overexpression of Kalirin-7 induces the formation of numerous aberrant spinelike structures, and the induction of these structures is dependent on its GEF activity. In addition, reduced expression of Kalirin results in decreased density of spines and a concomitant loss of pre- and postsynaptic markers. These results provide a pathway by which transsynaptic ephrin-EphB receptor activation leads to Rac-mediated actin reorganization.

A second GEF involved in spine formation is β PAK-interacting exchange factor (βPIX), which is a GEF for both Rac1 and Cdc42. βPIX localizes to synapses through its interaction with G-protein-coupled receptor interacting protein 1 (GIT1) and possibly the synaptic scaffolding protein Shank. Overexpression of βPIX causes the formation of multiple long, thin dendritic protrusions, whereas a GEF-deficient mutant of βPIX decreases spine formation. In both cases, a decrease in synaptic density was observed, suggesting that the activity of βPIX needs to be precisely regulated for synapses to form.

More recently, the Rac GEF tumor invasion and metastasis 1(TIAM1) has also been shown to be involved in spine formation. TIAM1 interacts with the polarity protein partitioning defective 3 (PAR-3), the EphB2 receptor, and also the NMDA receptor. Overexpression of TIAM1 causes the formation of multiple filopodia and lamellipodia-like structures, whereas knockdown of TIAM1 expression decreases spine density. TIAM1 phosphorylation is regulated by NMDA receptor activity in a calcium-dependent manner, thereby providing a potential mechanism by which NMDA receptor stimulation induces Rac-dependent actin remodeling in dendritic spines. In addition, activation of EphBr induces tyrosine phosphosylation of TIAM1 and its recruitment to EphB complex containing NMDA receptor. This makes TIAM1 a potential convergent point of EphB and NMDA receptor signaling.

Finally, a recently identified GEF for Rho GTPases, GEFT, has been implicated in spine morphogenesis. GEFT is highly expressed in the hippocampus, granular cells, and Purkinje cells of the brain. Ectopic expression of GEFT promotes dendritic spine formation in rat dentate gyrus explant cultures. However, because GEFT seems to show guanine nucleotide exchange activity for Rac1, Cdc42, and RhoA, at

this point it is unclear which Rho GTPases mediate the effects of GEFT on spine formation.

It is interesting to note that multiple Rac GEFs have been shown to be involved in spine morphogenesis. Loss of function of an individual GEF seems to be sufficient to cause defects in spine formation. It is interesting to speculate that each Rac GEF mediates the signaling downstream of different receptors and possibly synaptic adhesion molecules. Proper signaling through each pathway is necessary for spine morphogenesis, and abnormal signaling in any one pathway can cause defects in spine formation.

What are the effects of Rac1 itself on spine morphogenesis? Studies in various different systems have shown that mutating Rac1 to either the constitutively active form or the dominant negative form causes defects in spine formation. Activated Rac1 causes the formation of long, thin protrusions as well as broad veil-like protrusions on the dendrites in dissociated hippocampal neurons and hippocampal slice cultures. In cerebellar Purkinje cells of transgenic mice expressing constitutively active Rac1, dendritic spines were much smaller in size but more numerous. A dominant negative form of Rac1 causes the elimination of dendritic spines in both dissociated hippocampal neurons and hippocampal slices. Thus, it is likely that cycling of Rac between the active and the inactive forms is necessary for proper spine morphogenesis. Interestingly, activation of Rac1 is able to recruit α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors to nascent synapses, suggesting a mechanism by which regulated activation of Rac promotes spine formation.

Which proteins that mediate spine morphogenesis are downstream of Rac? Recent data show that PAK proteins and IRSp53, both downstream effectors of Rac, are involved in spine morphogenesis. Kinase dead versions of both PAK1 and PAK3 inhibit spine formation, much like the dominant negative mutant of Rac1. Similarly, perturbing IRSp53 function, either by knocking down endogenous protein expression using siRNA or by expressing a dominant negative mutant, reduces the density, length, and width of dendritic spines. However, the activated Rac1 phenotype is not copied by these effector proteins. Unlike active Rac1, which stimulates the formation of filopodia and lamellipodia-like dendritic protrusions at the expense of mature mushroom-shaped spines, activated mutants of PAK proteins, rather, stimulate spine formation. Similarly, IRSp53 promotes spine formation when overexpressed in hippocampal neurons. These data suggest that PAKs and IRSp53 are not the only downstream effectors of Rac1 in mediating spine morphogenesis and that additional effectors remain to be found.

Rac–Rho Reciprocity

Previous studies in nonneuronal cells suggested an antagonistic effect between Rac activation and Rho activation. Rac activation was shown to downregulate Rho activity and vice versa. However, how this occurs is not entirely clear. One possible mechanism is through a pathway downstream of Rac that leads to the activation of p190RhoGAP, which in turn inactivates Rho. Similar antagonistic effects are also observed in dendritic spine morphogenesis. Activated Rac promotes the formation of dendritic protrusions that are precursors of mature spines; whereas activated Rho inhibits spine formation, a phenotype reminiscent of dominant negative Rac. However, in this context, it is not yet known whether Rho inhibition is a result of Rac activation or the two processes occur independently.

The Rac–Rho reciprocity was observed in a recent study examining the role of p120 catenin in dendritic spine and synapse development. p120 catenin (p120 ctn) is an armadillo family member that associates with the juxtamembrane region of the cadherin family of cell–cell adhesion receptors. Conditional knockout of the p120ctn gene in the dorsal forebrain results in neurons with reduced spine and synaptic density. Further analyses showed that Rac activity was downregulated in these neurons; whereas Rho activity was upregulated. Activating Rac or inhibiting Rho was able to rescue the defects in p120ctn mutant neurons. Furthermore, overexpression of p120ctn results in the formation of multiple long thin dendritic protrusions, a phenotype reminiscent of neurons expressing constitutively active Rac. Interestingly, this phenotype can be almost completely rescued by expressing a constitutively active Rho, suggesting the possibility that the active Rac phenotype is a result of inhibited Rho activity.

Signaling through Cdc42

The role of Cdc42 in spine morphogenesis is less well defined. In the *Drosophila* visual system, loss of function of Cdc42 leads to a 50% reduction in the density of spinelike structures. However, in mouse cortical and hippocampal slices, neither constitutively active nor dominant negative Cdc42 has a major effect on spine morphology. In cultured hippocampal neurons, Cdc42 is activated downstream of EphB receptor tyrosine kinase. This process is mediated by the adaptor protein Numb and the Cdc42 GEF intersectin, and N-WASP appears to function downstream of this pathway. Interestingly, dominant negative Cdc42 seems to induce filopodia formation at the expense of mature mushroom-shaped spines. Consistent with this, a dominant negative mutant of intersectin induces

the formation of filopodia-like structures; however, the overall protrusion density is significantly reduced. These studies seem to be at odds with the ability of active Cdc42 to induce filopodia in nonneuronal cells. Clearly, further studies are needed to better explain the discrepancies among different systems and to better define a role for Cdc42 in dendritic spine development.

Rnd1 and Spine Development

Although there have been more studies focusing on the roles of RhoA, Rac1, and Cdc42 in spine formation, it is important to note that there are 17 other Rho GTPase family members in mammalian cells and that they are also likely to function in regulating dendritic spine morphogenesis. One example is Rnd1, which is mainly expressed in the brain. The expression level of Rnd1 is highest during the postnatal synaptogenesis period. Overexpression of Rnd1 results in the elongation of spines without significantly affecting spine width or density. Suppression of Rnd1 expression using antisense oligonucleotide causes the formation of headless protrusions at the expense of stubby or mushroom-shaped spines. These headless protrusions are largely devoid of PSD-95, a prominent protein that localizes almost exclusively to the postsynaptic density of excitatory synapses. This shows that these protrusions are immature spines. However, in contrast to the immature filopodia-like dendritic protrusions normally present on young neurons, the headless protrusions induced by Rnd1 antisense are much shorter in length, indicating that Rnd1 may be necessary for the elongation of filopodia. Although the exact mechanism for the effect of Rnd1 on spines is not clear, previous studies suggest that Rnd1 can inactivate Rho by binding to and activating p190RhoGAP. This is consistent with the data indicating a positive effect of Rnd1 on spine length and a negative effect of Rho on spine length.

Spatial Regulation of Rho GTPase Activation

An emerging theme is that Rho GTPases are probably activated in specific locations in the cell, and that global activation or shutdown of Rho GTPase activity is likely to cause pleiotropic defects in cellular processes. This is likely to be the case in dendritic spine formation as well because both constitutively active and dominant negative Rac1 cause defects in spine formation. Therefore, the activity of Rac1 is likely to be both spatially and temporally regulated for proper spine morphogenesis. In support of this, Rac1 is locally activated in dendritic spines. This has been demonstrated using fluorescence resonance energy transfer (FRET). FRET is a nonradiative transfer of energy from a donor fluorophore to an acceptor fluorophore. To visualize Rac activity in dendritic spines, a single chain FRET probe was used. This probe has yellow fluorescent protein (YFP), Rac1, the p21-binding domain of PAK (PBD), and cyan fluorescent protein (CFP) encoded on a single cDNA. Upon activation, Rac binds PBD, which brings YFP and CFP to close proximity, thereby allowing FRET to occur. Using this probe, it was shown that Rac is locally activated in a fraction of the spines and also at the base of the dendritic protrusions. The spines containing activated Rac are contacted by presynaptic terminals, showing that they bear synapses. It is tempting to speculate that the spines with activated Rac are undergoing synaptic remodeling.

How is the spatially regulated activation of Rho GTPases achieved? Because the GTPases themselves are diffusely distributed, one possible mechanism is through the targeting of GEFs and GAPs to dendritic spines by adaptor proteins. Both GIT1 and the polarity protein PAR-3 seem to function in this capacity. In each case, proper synaptic targeting of a RacGEF (βPIX for GIT1, and TIAM1 for PAR-3) by these proteins is essential for dendritic spine morphogenesis. Mislocalized GEFs cause aberrant Rac activation and the formation of multiple dendritic protrusions at the expense of mature spines. Thus, spatially restricted Rac activation is essential for normal spine development.

Downstream Actin-Regulating Proteins Implicated in Spine Morphogenesis

As previously stated, the Rho family of small GTPases eventually targets a variety of actin-binding proteins that directly regulate polymerization, depolymerization, branching, and bundling of the actin filaments. These proteins include profilin, ADF/cofilin, the Arp2/3 complex, capping protein, and myosin. These core proteins work together with their binding partners such as cortactin, WASP and WAVE proteins, Ena/VASP, and the lipid messenger PI(4,5)P_2. Several of these actin regulators have now been implicated in spine morphogenesis.

Profilin is a small protein that allows the elongation of actin filaments. In nonneuronal cells, profilin has been shown to stabilize the actin network. In cultured hippocampal neurons, profilin II shows increased localization to dendritic spines in response to NMDA receptor activation, which coincides with actin filament stabilization in the spines and inhibition of spine motility. In addition, fear conditioning drives profilin into spines *in vivo*. Taken together, these studies suggest that profilin is involved in activity-dependent synaptic plasticity that underlies memory formation.

In contrast to profilin, ADF/cofilin functions to depolymerize and destabilize actin filaments. Cofilin is usually enriched at sites of high motility and rapid actin reorganization. Recently, cofilin has been shown to localize to the peripheral part of the dendritic spines and rarely to the spine core, supporting the observation that the spine surface is the more dynamic part that undergoes actin-dependent shape changes. LIMK1, which phosphorylates and inactivates ADF/cofilin, is important for spine morphogenesis. LIMK1-knockout mice show abnormal spines, which have a thick neck and a small head as opposed to the normal mushroom-shaped spines. In addition, these mice show impaired spatial learning. Interestingly, LIMK1 mutations are associated with William's syndrome in humans, which is characterized by visuospatial cognitive deficits.

Cortactin is an F-actin binding protein that localizes to the peripheral membrane protrusions in nonneuronal cells. This localization is dependent on Rac activation. In addition to binding actin, cortactin also binds the Arp2/3 complex and stimulates its actin nucleating activity. In hippocampal neurons, cortactin localizes to dendritic spines, where it plays a role in spine morphogenesis. Knockdown of cortactin decreases spine density, whereas overexpression of cortactin results in longer spines. Cortactin also shows activity-dependent translocation in and out of spines, indicating a role in synaptic plasticity. However, whether these effects are dependent on Rho GTPases is not yet known.

Recently, WAVE1 was shown to regulate dendritic spine morphology through phosphorylation by the cyclin-dependent kinase 5 (Cdk5). Cdk5

Figure 3 Rho GTPase signaling in dendritic spine morphogenesis. Known Rho signaling pathways involved in spine morphogenesis are illustrated. Dashed lines indicate indirect effects. Question marks indicate proteins or pathways that are known to be involved in regulating actin dynamics in other systems, but have not been directly demonstrated in the context of spine morphogenesis. AMPAR, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor; Arp2/3, actin-related protein 2/3; Cdc42, Rac1, Rnd1, RhoA, Rho GTPases; Cdk5, cyclin-dependent kinase 5; EphR, Eph receptor; GIT1, G-protein-coupled receptor kinase interacting protein 1; GKAP, guanylate kinase-associated protein; IRSp53, insulin receptor substrate of 53 kDa; Lfc, Lbc (lymphoid blast crisis)'s first cousin; LIMK1, LIM kinase 1; mDia, mammalian ortholog of *Drosophila* Diaphanous; mGluR, metabotropic glutamate receptor; MLC, myosin light chain; NMDAR, *N*-methyl-D-aspartate receptor; N-WASP, neuronal Wiscot–Aldrich syndrome protein; PAK, p21-activated kinase; PAR-3, partitioning defective 3; PIX, PAK interacting exchange factor; PSD-95, postsynaptic density protein 95; ROK, Rho kinase; Shank, SH3 and ankyrin repeat-containing protein; TIAM1, tumor invasion and metastasis 1; WAVE1, WASP family verprolin-homologous protein 1.

phosphorylation of WAVE1 inhibits its ability to activate Arp2/3-mediated actin polymerization. Loss of WAVE1 results in a decrease in mature dendritic spines and a concomitant increase in filopodia-like protrusions. This effect is rescued by a nonphosphorylatable mutant of WAVE1 but not by a pseudophosphorylated mutant. Interestingly, Cdk5 was shown before to function as a neuronal-specific effector of Rac1. This provides a potential pathway by which Rac1 activation leads to filopodia-like dendritic protrusions in neurons.

Finally, myosin II, which binds and contracts actin filaments, is important for maintaining dendritic spine morphology. Inhibiting myosin II using blebbistatin disrupts spine formation in immature neurons and induces a loss of mushroom-shaped spines and the formation of filopodia-like protrusions in mature neurons. Similarly, knockdown of endogenous myosin IIb induces the formation of filopodia-like protrusions at the expense of mushroom-shaped spines. PAK and myosin light chain kinase (MLCK), both downstream of Rac and Cdc42, have been shown to function through phosphorylating myosin light chain (MLC) in regulating spine formation. In addition, Rho kinase, a major regulator of MLC phosphorylation, may also play a role. If this is the case, it places myosin as one of the convergent points downstream of Rho GTPases signaling in spine morphogenesis (**Figure 3**).

Rho GTPases and Mental Retardation

Mental retardation (MR) is a developmental disorder that is characterized by cognitive defects. On a cellular level, MR is associated with abnormalities in dendritic spine morphology, raising the possibility that mutations in proteins regulating spine morphology could cause MR. Indeed, three out of seven recently cloned genes that cause nonsyndromic MR (i.e., MR that is not associated with gross developmental brain defects) are directly involved in Rho GTPase signaling. These genes encode oligophrenin1, a Rho GAP; αPIX, a GEF for Rac and Cdc42; and PAK3, an effector for Rac and Cdc42. The fact that these proteins participate in different aspects of Rho-family signaling points to an important role for Rho GTPases in cognitive functions. Interestingly, both oligophrenin-1 and PAK3 have been shown to be involved in spine morphogenesis. In addition, βPIX, another isoform of PIX, is also essential for spine formation.

Several other proteins on the Rho pathway have also been linked to human genetic disorders that show mental retardation. For example, the FMRP, whose gene mutation is responsible for fragile-X syndrome, binds Sra-1/CYFIP, an effector for Rac. In addition, mutations of faciogenital dysplasia protein (FGD1), a GEF for Cdc42, cause Aarskog–Scott syndrome. Future studies will no doubt bring the Rho family of GTPases to the center stage of spine morphogenesis as well as cognitive functions such as learning and memory.

Rhodopsin

T P Sakmar and T Huber, The Rockefeller University, New York, NY, USA

Rhodopsin is the primary photoreceptor molecule of vision. Light striking a rhodopsin molecule in a photoreceptor cell of the retina is converted into a biochemical signal by a photochemical reaction. The signal is processed by other cells in the retina and sent to the brain. Two general types of photoreceptor cells exist in the vertebrate retina and are named according to their characteristic shapes: rods and cones. Rod cells are responsible for scotopic or dim-light vision, whereas cone cells are responsible for photopic or bright-light and color vision in vertebrates. Rod cells contain rhodopsin; cone cells contain photopsins, also known as cone pigments or color vision pigments. The photoreceptor cells of invertebrate species also contain rhodopsin, even though generally the anatomy of the invertebrate visual system varies dramatically from that of the vertebrate system.

The outer segment of the rod photoreceptor cell contains a stack of several hundred disks (Figure 1). These disks are derived from plasma membrane invaginations at the region close to the connecting cilium. The stack of disks is enclosed by the plasma membrane. The disk membranes are densely packed with rhodopsin. Cytoplasmic dynein mediates the vectorial transport of opsin-containing post-Golgi vesicles along microtubuli toward the distal region of the inner segment. The apical tip of the outer segment is constantly phagocytized by the adjacent retinal pigment epithelium (RPE), limiting the lifetime of rhodopsin to several days in the vertebrate retina.

Rhodopsin is a seven transmembrane (7TM) domain protein homologous to other members of the G-protein-coupled receptor (GPCR) family. Rhodopsin consists of the complex of a rod-type opsin with the chromophore ligand 11-*cis*-retinal acting as an inverse agonist. Photoisomerization of the chromophore converts the ligand in the all-*trans* form acting as the receptor agonist. The photoactivated receptor triggers a highly amplified signal transduction cascade. The dark-adapted rod cell is partially depolarized, causing steady release of neurotransmitters on the synaptic terminal. Light activation leads to hyperpolarization and reduction of neurotransmitter release.

The visual cycle (Figure 2) describes the retinoid pathway, including the light reaction in the photoreceptor cell and the reisomerization of vitamin A in the RPE. All visual pigments consist of an opsin protein plus a chromophore. The chromophore is a cofactor, which is linked covalently via a Schiff base bond to a specific lysine amino acid residue of the opsin protein. One of two retinoids serves as the chromophore for nearly all visual pigments. The chromophore in most vertebrate pigments is the aldehyde of vitamin A_1, 11-*cis*-retinal. The chromophore in some fishes and amphibians is the aldehyde of vitamin A_2, 11-*cis*-3,4-didehydroretinal, which contains an additional carbon–carbon double bond in the β-ionone ring. Photoisomerization of the 11-*cis* to all-*trans* form of the chromophore is the primary event in visual signal transduction, and it is the only light-dependent step. The absorption of a photon, a quantum of energy, by rhodopsin causes the photoisomerization. The wavelength of light that is maximally absorbed (λ_{max} value) is 500 nm (Figure 3). Although rhodopsin can absorb a fairly wide range of light energies, green light is most effective in activating rhodopsin due to the higher absorbance or photon capture probability. The physiological response to a single photoisomerization is independent of the wavelength of the photon causing the reaction. Upon photoisomerization of the pigment to the all-*trans*-retinylidene form, the receptor switches from the inactive receptor state (R), Meta I with a protonated Schiff base having a peak with a λ_{max} value of 480 nm, to the active receptor state (R*), Meta II with a deprotonated Schiff base and a characteristic λ_{max} value of 380 nm. The activating Meta I to Meta II transition depends on environmental factors such as temperature, proton activity, and the lipid environment. The R* is the active form of the receptor, which is able to transmit a biochemical signal as described later.

Rhodopsin is found primarily within the disk membrane of the rod cell (see Figure 1). The N-terminus of rhodopsin is in the disk lumen, or extracellular, whereas the C-terminus is intracellular, or cytoplasmic. The protein spans the membrane bilayer seven times, and the resulting 7TM helices of rhodopsin fold to form a pocket to accommodate the retinal chromophore (Figure 4). The chromophore-binding pocket resides in the membrane-embedded domain of the protein. The lysine residue that acts as the linkage site for the chromophore is conserved within the seventh TM segment in all visual pigments. In addition, a pair of highly conserved cysteine residues is found on the extracellular surface and may form a stabilizing disulfide bond. In many pigments, a carboxylic acid residue, which acts as the counter-ion to the positively charged protonated Schiff base, is conserved within the third TM segment. A cluster of serine and threonine residues is found in the C-terminal tails of most visual pigments. These sites become phosphorylated

Figure 1 A schematic representation of bovine rhodopsin within the bilayer of the disk membrane. The seven transmembrane helices form a binding pocket for the retinal chromophore. The rod cell consists of an inner segment and an outer segment. The outer segment contains a stack of disk membranes, which are highly enriched in rhodopsin. Other proteins of the biochemical cascade of the vertebrate visual system, including transducin, reside in the cytoplasmic space.

in response to light and provide a mechanism to attenuate the light response because a phosphorylated rhodopsin is prevented from transmitting its biochemical signal.

Visual pigments, including rhodopsin, are members of a large family of GPCRs. Bovine rhodopsin was the first GPCR to be sequenced by amino acid sequencing, the first to be cloned, and the first for which a high-resolution crystal structure has been reported. Bovine rhodopsin is 348 amino acid residues in length and is identical to human rhodopsin at all but 23 positions. The cloning of a β-adrenergic hormone receptor led to the identification of the structural homologies that now define the superfamily of GPCRs. Molecular cloning has identified hundreds of different but related GPCRs. It has been estimated that the human genome contains 865 genes encoding GPCRs. All GPCRs reside in cell membranes and consist of seven hydrophobic membrane-spanning domains. Thus, GPCRs may also be referred to as 7TM receptors. All GPCRs are involved in the transmission of biochemical signals across cell membranes, which includes sensory processes such as vision or olfaction and responses to hormones. Some receptors responsible for synaptic transmission of a neural signal, or for modulation of synaptic signaling, are also members of the GPCR family.

GPCRs become activated either by light in the case of rhodopsin or by binding to an appropriate agonist ligand such as a neurotransmitter or hormone. The activated receptor interacts with another class of proteins, called guanine nucleotide-binding regulatory proteins, or G-proteins. The G-protein transduces the biochemical signal to some cellular effector molecule, which ultimately affects cellular function, growth, or metabolism. Examples of cellular effector enzymes include adenylate cyclase, which produces cyclic adenosine monophosphate, and phospholipase C, which produces phosphatidyl inositides. Some G-proteins can interact directly with ion channels in the cell membrane. Transducin is the G-protein that interacts with the active Meta II photoproduct of rhodopsin. When it interacts with Meta II, transducin takes up a molecule of guanosine 5′-triphosphate (GTP), which allows it to activate a cellular phosphodiesterase that lowers the levels of cyclic guanosine monophosphate (cGMP), leading to a closing of cGMP-gated cation channels. The resulting hyperpolarization of the rod cell initiates the visual signal.

The molecular cloning of opsins from a variety of species has allowed detailed comparisons of visual pigments based on their structural, spectral, and biochemical properties. Pigment genes have been classified phylogenetically and models of pigment evolution have been proposed. The homology in the opsin family of genes indicates that divergent evolution occurred from a single precursor retinal-binding protein to form long- and short-wavelength absorbing prototypes. The long-wavelength prototype diverged

Figure 2 Photoisomerization of 11-*cis*-retinal to all-*trans*-retinal is the only light-dependent event in vision. The chromophore is covalently linked as a cofactor (11-*cis*-retinylidene) to a specific opsin lysine amino acid residue via a protonated Schiff–base bond. A salt bridge with a carboxylate counter-ion locks the receptor in the ground state. A single visible photon isomerizes the chromophore to the all-*trans* form with high quantum efficiency (~0.67). Hydrolysis of the photoproducts results in all-*trans*-retinal and the apoprotein opsin. The photopigment is regenerated from opsin and 11-*cis*-retinal, which is recycled in the dark reactions of the visual cycle (a) from all-*trans*-retinal. Vertebrate visual pigments contain one of two chromophores, 11-*cis*-retinal (vitamin A_1 aldehyde) or 11-*cis*-3,4-didehydroretinal (vitamin A_2 aldehyde), which contains an additional carbon–carbon double bond in the β-ionone ring. Typically, retinoids enter the cycle as all-*trans*-retinol (vitamin A_1) or as all-*trans*-3,4-didehydroretinol (vitamin A_2; shown in b).

to form red and green pigments. The short-wavelength prototype then diverged to form a blue pigment and the family of rhodopsins and rhodopsin-like green pigments.

Spectral Tuning of Rhodopsin and Cone Visual Pigments

Humans possess trichromatic color vision, or trichromacy. Most people can match any given reference color by combining the three primary colors. The three primary colors for additive color mixtures are red, green, and blue. In addition to rod cells, which contain rhodopsin, the retina contains three classes of cone photoreceptor cells. Each class of cone cell is sensitive to a specific wavelength of light. At the molecular level, human trichromatic color vision requires the presence of three cone pigments with broad overlapping spectral absorption. Each specific cone class contains only one type of photoreceptor molecule. The three types of cone photoreceptor molecules (red, green, and blue) are homolog of rhodopsin. The amino acid sequences of these opsins are approximately 40% identical to that of human rhodopsin. The green and red opsins are approximately 96% identical to each other and approximately 43% identical to the blue opsin. The spectral properties of human cone pigments have been studied by a variety of techniques, including psychophysical color matching and microspectrophotometry. In addition, the molecular cloning of the cone pigment genes has allowed the study of the molecular mechanism of spectral tuning and the molecular genetics of color vision.

Rhodopsin and the three cone pigments are each tuned to a characteristic λ_{max} but they all use the same chromophore, 11-*cis*-retinal. Despite the fact that retinal is the universal chromophore, the λ_{max} values of visual pigments must span the visible spectrum, which ranges from approximately 360 nm (ultraviolet) to 600 nm (deep red). Thus, a single chromophore allows all visible wavelengths of light to be detected. A spectral tuning mechanism exists so that

Figure 3 An ultraviolet-visible absorption spectrum of purified bovine rhodopsin shows a characteristic broad visible absorbance with a λ_{max} value of 500 nm. The 280 nm peak represents the opsin protein component. The 11-*cis*-retinylidene chromophore acts as an inverse agonist, effectively turning off the receptor. After exposure to light, *cis*-to-*trans* isomerization results in all-*trans*-retinylidene chromophore in the pigment. The all-*trans*-retinylidene acts as an agonist, triggering the transition from the inactive receptor state (R), Meta I with a protonated Schiff base having a peak with a λ_{max} value of 480 nm, to the active receptor state (R*), Meta II with a deprotonated Schiff base and a characteristic λ_{max} value of 380 nm. The R* form interacts with the rod cell heterotrimeric G-protein transducin, leading to signal transduction, and with rhodopsin kinase, leading to receptor phosphorylation and subsequent visual arrestin binding that terminates signaling.

a particular opsin protein can modulate the absorption spectrum of its retinylidene chromophore. Spectral tuning is possible because specific amino acid side chains of each opsin can interact with the chromophore and shift its λ_{max} value. For example, the human green and red opsin proteins display only 15 differences among their 364 amino acid residues. Of these 15 differences, seven amino acid changes are responsible for the observed 30 nm spectral shift in going from the λ_{max} value of the green to that of the red pigment. Most of this shift is caused by three amino acid side chains that contain hydroxyl groups: tyrosine, serine, and threonine.

Genetic variations in color vision may result from a mutation in one of the genes encoding a cone opsin. If the amino acid change affects spectral tuning in one of the cone pigments, then one of the cone types will contain a pigment with an anomalous absorption spectrum. Individuals with this genetic variation are called anomalous trichromats. The most common type of anomalous trichromacy is called red–green 'color blindness.' Red–green color vision variations predominantly affect males because the genes for the red and green opsin genes are found on the X chromosome. Severe color vision defects may result from complete deficiencies of one or more of the three cone opsin genes. Individuals who lack a functional red or green photoreceptor are called dichromats.

The Biochemical Cascade of Vertebrate Vision

Photoisomerization of retinal activates rhodopsin, allowing it to interact with a specific G-protein. The rod cell G-protein, transducin, transmits a biochemical signal from rhodopsin to a cellular effector molecule. Photoactivated rhodopsin catalyzes the exchange of guanosine 5′-diphosphate (GDP) for GTP by transducin molecules. A single activated rhodopsin can activate catalytically up to 500 transducin molecules. The activated transducin, with GTP in its nucleotide-binding pocket, then transmits a chemical signal to the effector molecule in the signaling cascade. The effector molecule in the vertebrate visual system is the enzyme cGMP phosphodiesterase. A single transducin molecule activates a single phosphodiesterase

molecule. However, each phosphodiesterase can catalyze the hydrolysis of up to 3000 cGMP molecules to GMP molecules per second. Thus, the biochemical amplification is as much as six orders of magnitude at the molecular level. The lowered levels of cGMP in the rod cell cause plasma membrane cation channels to close. A single photon causing retinal isomerization can affect the conductance of approximately 1000 plasma membrane cation channels.

Because the plasma membrane is selectively permeable to ions, which are electrically charged, an electrical potential difference exists between the inside and the outside of the rod cell. The potential increases as cation channels are closed and the influx of sodium and calcium ions, which carry positive charge, is slowed. The result is that the rod cell becomes hyperpolarized in response to light. The increase in potential varies proportionally with the strength of the light signal. The change in membrane potential is sent as an electrical signal from the plasma membrane to the synaptic terminal of the rod cell, where it is transmitted to other specialized cells of the retina.

A properly dark-adapted rod cell can detect a single photon. This extreme sensitivity is possible in part because of two important features of the visual system: (1) the stability of rhodopsin in darkness to thermal activation and (2) the high degree of signal amplification by the biochemical cascade of vision. It has been estimated that the spontaneous thermal isomerization of 11-*cis*-retinal in rhodopsin in darkness only takes place roughly once every 300–1000 years. In contrast (as presented previously), a single photon can theoretically cause as many as 1000 cation channels in a rod cell membrane to close.

Figure 4 A molecular graphics ribbon diagram of bovine rhodopsin prepared from the 2.2 Å crystal structure coordinates (PDB access number 1U19). The N-terminus (NT) and extracellular (or intradiscal) surface is toward the top of the figure, and the C-terminus (CT) and intracellular (or cytoplasmic) surface is toward the bottom. Seven TM (H1–H7), which are characteristic of G-protein-coupled receptors (GPCRs; also known as 7TM receptors), are shown. The TM segments are tilted with respect to the plane of the membrane bilayer. They are generally α-helical, but they contain significant kinks and irregularities. Three extracellular (E1–E3) and three cytoplasmic (C1–C3) loops connect the TM helices. Posttranslational modifications are the N-glycosylations on asparagines 2 and 15 (shown as several sugar residues: NAG, *N*-acetyl-glucosaminyl; and MAN, mannosyl), the palmitoyl thioesters at cysteines 322 and 323, the disulfide bridge between cysteines 110 and 187, and the 11-*cis*-retinylidene chromophore (RET) at lysine 296. The glutamate residues 113 and 181 play a central role in the ligand-dependent activation switch after photoisomerization that is relayed to the cytoplasmic switching microdomain, between glutamate 134 and arginine 135, in a highly conserved amino acid sequence motif, and glutamic acid 247 at the cytoplasmic end of helix H6.

Figure 5 Photoreceptor membrane phospholipids are unusually highly enriched in ω-3 polyunsaturated fatty acids, especially docosahexaenoic acid (DHA). Structures of (a) the monounsaturated phospholipid 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), and (b) the polyunsaturated phospholipid 1-palmitoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (PDPC), which contains DHA. Lipid–protein interactions with rhodopsin provide a model to understand why essential fatty acids of the ω-3 series are important for retinal and neural development and other key biological functions.

The light signal is turned off by a number of biochemical mechanisms. Light-activated rhodopsin becomes phosphorylated by a specific rhodopsin kinase enzyme. Visual arrestin binds to the phosphorylated form of the receptor that can no longer interact with the G-protein transducin. The active GTP-bound form of transducin has an intrinsic enzymatic GTP hydrolysis activity. Over time, the bound GTP is converted to GDP, and transducin returns to its inactive state. In addition, intracellular calcium levels drop after the cation channel of the rod cell closes. A fall in intracellular calcium concentration mediates photoreceptor cell recovery and adaptation. The process of adaptation allows the sensitivity of the retina to adjust based on the level of light in a visual scene. Adaptation is extremely important for a useful visual

Figure 6 Biomembrane model of rhodopsin in a POPC bilayer from molecular dynamics (MD) simulations. (a) Solvation of rhodopsin by the phospholipid bilayer and aqueous salt solution. Thermal motions on the nanosecond timescale are accessible by numerical simulations on supercomputers. Disordered acyl chains (cyan) are found in the fluid membrane interior. The seven transmembrane (7TM) helices span the membrane from both polar head group regions (orange). (b) Representative protein backbone conformations from the MD simulations (colored tubes) are overlaid with several crystal structures (gray). The arrows indicate conformational changes observed in the bilayer compared with the crystal structures. The TM region exhibits very small fluctuations compared with the cytoplasmic loop regions, shown in the lower part of the structure. (c) Approximate lipid–water interfaces corresponding to the hydrophobic region (gray) and head groups (cyan) of the bilayer. All helices, except some cytoplasmic parts of helices H3, H6, and H8, are confined by the lipid head group–water interfaces. (d) Protein interfaces analyzed by a novel generalized molecular surface method based on generalized Voronoi volume regions associated with aqueous salt solution (light gray), with the glycerophosphocholine head groups (light blue), the acyl chain ester group atoms (light purple), and the acyl chain hydrocarbon atoms (light green) of the POPC bilayer. The rhodopsin interfaces with the phospholipid acyl chain hydrocarbon atoms (red), ester groups (gray), glycerophosphocholine head groups (orange), and the aqueous solvent (yellow) are color-coded.

system because the magnitude of light varies widely in the environment. For example, bright sunlight and dim starlight differ in luminance by at least several orders of magnitude.

Lipid–Protein Interactions of Rhodopsin

Photoreceptor membrane phospholipids (Figure 5) are unusually highly enriched in ω-3 polyunsaturated fatty acids, especially docosahexaenoic acid. Lipid–protein interactions with rhodopsin provide a model to understand why essential fatty acids of the ω-3 series are important for retinal and neural development and other key biological functions. Molecular dynamics simulation of a computational biomembrane model (Figure 6) gives a detailed description of the solvation of rhodopsin by the fluid phospholipid bilayer and the hydration shell. Thermally excited motions on the nanosecond timescale result in relaxation of the protein in the membrane relative to the crystal structure. The lipid–water interface adapts to the protein and vice versa. The solvation interface analysis mapped to a secondary structure diagram of rhodopsin (Figure 7) demonstrates how the helices and loops are coupled to the polar head group interface of the bilayer membrane. The results of such coupling are, for example, hydrophobic matching phenomena involved in lateral organization of biomembranes.

Rhodopsin as a Model for G-Protein-Coupled Receptors

The human genome contains nine opsin genes, one rhodopsin and three cone opsins, as well as encephalopsin, melanopsin, peropsin, retinal G-protein-coupled receptor, and neuropsin. In contrast to these opsins, different photoreceptive proteins are found in archaea, bacteria, fungi, and a green alga, *Chlamydomonas reinhardtii*. They function as light-driven ion pumps or light sensors. Despite their 7TM fold, there is no evidence that these nonanimal opsins are structurally related to rhodopsin. GPCRs provide arguably the most important drug target family for the pharmaceutical industry. However, high-resolution crystal structure data are limited to rhodopsin and computational

Figure 7 A secondary structure diagram of bovine rhodopsin. Amino acid residues are depicted in single-letter code. The N-terminal tail and extracellular domain is toward the top and the C-terminal tail and cytoplasmic domain is toward the bottom. TM α-helical segments (H1–H7) and the cationic amphipathic helix H8 are shown in cylinders. The topology scheme of rhodopsin illustrates the protein residues associated with the different generalized molecular surface interfaces. Residues exposed to the bilayer hydrocarbon interior (the lipid–protein hydrophobic interface; yellow), head groups (the lipid–protein polar interface; green), and both simultaneously (orange) are color-coded. Squares indicate protein residues exposed to internal or external water. The charge states of the residues in the molecular dynamics model are designated by red or blue symbol frames.

modeling of other GPCRs is mainly based on homology to rhodopsin. These models are useful in the context of computer-aided drug design methods, such as docking, in combination with site-directed mutagenesis and high-throughput screening. Despite progress in crystallization of eukaryotic membrane proteins, it is expected that computational modeling approaches will remain the main source for GPCR structures in the foreseeable future.

Mutations in the Gene for Human Rhodopsin May Cause Disease

Retinitis pigmentosa is a group of hereditary progressive blinding diseases with variable clinical presentations. One form of the disease, autosomal dominant retinitis pigmentosa (ADRP), was linked to a mutation in the gene for rhodopsin. More than 70 different rhodopsin gene mutations have been reported in patients with ADRP. The mutations reported would result in alterations in all domains of rhodopsin: extracellular, membrane-embedded, and cytoplasmic. ADRP is characterized by a progressive death of rod and, sometimes, cone cells, resulting in gradual vision loss. The molecular pathophysiology of ADRP, namely how a defect in rhodopsin leads to rod cell death, remains to be fully elucidated.

Ribbon Synapses

B Odermatt and L Lagnado, MRC Laboratory of Molecular Biology, Cambridge, UK

Ribbon synapses are sites of contact between neurons specialized for the rapid transmission of signals by the calcium-triggered secretion of neurotransmitter. Although sharing many fundamental properties with chemical synapses throughout the nervous system, ribbon synapses possess several features that set them apart as being specialized for the transmission of sensory information. The defining morphological difference is the presence of an unusual organelle, the ribbon, which holds synaptic vesicles close to the active zone, the specialized region where vesicles fuse with the surface membrane (Figure 1). Functionally, neurons that transmit through ribbon synapses are distinguished by the nature of the electrical signal controlling neurotransmitter release. Conventional synapses convey information arriving as a 'pulse code'; action potentials lasting a few milliseconds trigger a transient burst of vesicle fusion and the amplitude of the action potential is fixed. In contrast, ribbon synapses transmit 'analog signals,' such as the intensity of light, over short conduction distances; the amplitude of the electrical signal varies continuously with the stimulus and so does the rate of vesicle fusion.

The use of ribbon synapses to transfer graded voltage signals is a key feature of information transfer in the first stages of vision and hearing. Ribbons occur in photoreceptors and bipolar cells in the retina and in mechanosensitive hair cells in the cochlea. Ribbon synapses also occur in the hair cells of the vestibular organs of balance and in neurons in the pineal gland that secrete melatonin in a circadian rhythm. In fish and amphibia, electroreceptors of the lateral line organ also transmit signals through ribbon synapses.

Why are graded voltage signals and ribbon synapses employed by sensory neurons? The answer probably lies in the fact that the maintenance of a high rate of continuous vesicle fusion, and the modulation of this rate by the stimulus, allows information to be transferred more rapidly than the pulse code of neurons firing action potentials. Theoretical studies indicate that spiking neurons with conventional synapses at the input stages of senses such as vision and hearing would limit the information that could be subsequently extracted by the neural circuitry into which they feed. The way in which the ribbon contributes to the maintenance of neurotransmitter release is not clearly defined; however, given that it holds a population of vesicles close to the active zone, it seems likely that it transports vesicles to sites of fusion during ongoing activity, perhaps in the manner of a conveyor belt.

The Structure of Ribbons

The term 'ribbon' was originally used to describe unusual structures observed in the synaptic pedicle of cone photoreceptors by making transmission electron micrographs of thin sections of the retina – a long osmiophiolic band extending to the surface membrane holding synaptic vesicles close to the active zone (Figures 1(a) and 1(b)). In three dimensions, the ribbon is typically a plate approximately 30–40 nm thick with a pentalaminar structure (Figure 1(c)). The shape and size of the plate varies between different species and between different photoreceptors within the same retina, as well as varying diurnally. Typically, the plate is 200–1000 nm tall and 200–2000 nm long. In rod and cone photoreceptors, the ribbon floats just above the plasma membrane on a second electron-dense structure, the arciform density, which in turn attaches to the underlying membrane. The arciform density is only 20 nm thick, so vesicles attached to the base of the ribbon also attach to the surface membrane.

The structure of ribbons is not fixed: In some cells, they exhibit a striking structural plasticity. In photoreceptors, for instance, ribbons become smaller in the light and then larger within 10 min of returning to the dark. Similarly, in mammalian pinealocytes, the size and number of ribbons is lower during the day through a mechanism of diurnal regulation. In retinal bipolar cells and hair cells of the ear, the ribbons tend to be significantly smaller than those in photoreceptors, and the arciform density is absent. In fact, the ribbons of hair cells have a different shape: They resemble a sphere and are also known as 'dense bodies' or 'synaptic bodies' (Figure 2). The functional implications of ribbons of different sizes and/or shapes have not been studied systematically, but it seems likely that they reflect adaptations for changes in synaptic strength or speed operating under different operating conditions of sensory neurons.

At all ribbon synapses, the synaptic vesicles are clear and small (30–45 nm in diameter) and contain glutamate as the principal transmitter. They attach to the ribbon all over its surface by multiple short filaments approximately 5 nm thick and 20–40 nm long (Figures 1 and 2). The packing of vesicles is

Figure 1 Structure of synaptic ribbons in the retina. (b) The ribbon from a bipolar cell terminal. The short filaments connecting vesicles to the ribbon are marked. (c) 'Side-on' view of a ribbon in a cone terminal showing the dense and regular arrangement of attached vesicles (within the dotted line). The dark ridge attaching the ribbon to the plasma membrane is marked by arrowheads and the postsynaptic elements are marked by asterisks. (a) Reproduced from Schaeffer SF and Raviola E (1978) Membrane recycling in the cone cell endings of the turtle retina. *Journal of Cell Biology* 79: 802–825. (b, c) Reproduced from Sterling P and Matthews G (2005) Structure and function of ribbon synapses. *Trends in Neurosciences* 28: 20–29, with permission from Elsevier.

often in a hexagonal array with a density up to 55%. A consistent feature of the synaptic terminal of these sensory neurons is that vesicles are found not just at the ribbon but also distributed through large volumes of the cytoplasm at a relatively high density. At conventional synapses, a reserve pool of vesicles can also be seen to congregate behind the active zone, but these do not number more than approximately 100 and they are not associated with a structure as large and well defined as the ribbon or dense body. It seems to be a general rule that the larger the synaptic terminal, the greater the number of ribbons at active zones, although these vary in size. For instance, rod photoreceptors in mammals typically contain just one large ribbon up to 2 µm in length with approximately 800 vesicles attached, whereas cones contain 10 or more smaller ribbons, each with less than 400 vesicles. An individual bipolar cell might contain 50 ribbons, although these will only be 200–300 nm in length with less than 100 vesicles attached. Hair cells are effectively one large synaptic terminal with small vesicles widely distributed throughout the cell and 10–20 ribbons attached to the basal end.

The Voltage Signal Controlling Transmitter Release

Rod and cone photoreceptors convert light into an electrical signal through the same basic mechanism: Absorption of light by the visual pigment in the outer segment activates a transduction cascade that results in the closure of cation-selective ion channels and hyperpolarization of the plasma membrane. At the synaptic terminal, this hyperpolarization leads to the closure of voltage-sensitive calcium channels and a reduction in the rate of vesicle fusion. Glutamate is therefore released at the maximum rate in the dark, and light causes a decrease that is graded with intensity. In rods, which are the more sensitive of the two classes of photoreceptor, the gain of this process is sufficient to signal the absorption of a single photon with a change in membrane potential of a fraction of a millivolt. The ribbon synapse can reliably transmit this small signal to postsynaptic bipolar cells and horizontal cells.

The ribbon in a rod or cone terminal is at the apex of a ridge forming a structure called a triad, in which

Figure 2 Structure of synaptic ribbons in hair cells. (a) A slice through the afferent synapse of a hair cell from the frog sacculus which has been reconstructed by electron tomography. Vesicles are attached to the ribbon (also known as the synaptic body) and are also docked to the plasma membrane immediately below. (b, c) Examples of the tethers linking vesicles to the ribbon. Adapted from Lenzi D, Runyeon JW, Crum J, Ellisman MH, and Roberts WM (1999) Synaptic vesicle populations in saccular hair cells reconstructed by electron tomography. *Journal of Neuroscience* 19: 119–132, with permission from Society for Neuroscience.

there are three postsynaptic elements: the processes of two horizontal cells laterally and the dendrite of a bipolar cell centrally (Figure 3(a)). The postsynaptic glutamate receptors on horizontal cells are of the AMPA type, but different classes of bipolar cells express different receptors, which confers on them electrical responses of different polarities. The bipolar cells receiving inputs from rods possess a metabotropic glutamate receptor (mGluR6) that leads to the closure of cation channels on binding glutamate. By decreasing glutamate release from rods, light causes the depolarization of these bipolar cells, which are also termed 'ON.' The polarity of the response in 'OFF' bipolar cells is inverted (i.e., they hyperpolarize to light) because these have AMPA and/or kainate receptors that pass cations when glutamate is released by photoreceptors in the dark. The organization of postsynaptic structures contacted by a bipolar cell terminal is similar, except that there are just two processes contacted by each ribbon, forming a dyad (Figure 3(b)). These two processes may be from amacrine cells (containing kainate receptors), the dendrites of ganglion cells (containing AMPA and NMDA receptors), or there may be one process from each cell type. The amacrine cells often make reciprocal synaptic connections back onto the synaptic terminal of the bipolar cell, and these release the inhibitory neurotransmitters GABA or glycine to modulate synaptic transfer from bipolar cell to ganglion cell.

In hair cells, deflection of the hair bundle toward its tall edge by a mechanical stimulus leads to the opening of cation channels and membrane depolarization. Conversely, displacement away from the kinocilium closes these channels and hyperpolarizes the membrane. Sound waves therefore cause oscillatory changes in membrane potential, the amplitude of

Figure 3 Electron micrographs of ribbon synapses in the frog retina. (a) A triad formed by a photoreceptor terminal and (b) a dyad formed by a bipolar cell onto two postsynaptic processes. Note that the photoreceptor ribbon is much taller than that in the bipolar cell. Figure 4 Rat inner ear hair cells contacted by afferent fibers. Two afferent boutons can be seen within the box at the base of the hair cell. One bouton has a glass pipette attached for electrophysiological recording. (Inset) Most inner hear hair cell synapses are served by a single synaptic ribbon. Reproduced from Glowatzki E and Fuchs P (2002) Transmitter release at the hair cell ribbon synapse. *Nature Neuroscience* 5: 147–154, with permission from Nature Publishing Group.

which varies with the loudness of the sound. In the mammalian cochlea, one inner hair cell might contact 10–30 afferent fibers that project into the central nervous system (Figure 4). In most cases, each fiber is contacted by just one synaptic ribbon, so the properties of the active zone directly determine the auditory signal that is transmitted. As in ribbon synapses in the retina, changes in membrane potential of a fraction of a millivolt cause significant modulation of the rate of vesicle fusion. A second key feature of the ribbon synapse of auditory hair cells is its ability to transmit signals at high frequency: Action potentials in the afferent fiber can be evoked at frequencies up to 300 Hz, whereas individual action potentials can remain phase-locked to a tone at frequencies up to 5 kHz.

Transient and Continuous Modes of Exocytosis

The fact that photoreceptors hyperpolarize to light, thereby closing calcium channels, suggests that they are capable of continuously releasing transmitter in the dark; otherwise, the light signal would not be transmitted. Evidence for this idea is shown in Figure 5(a), which is an intracellular recording from a horizontal cell in which the membrane potential indicates the rate of glutamate release by photoreceptors. Light flashes hyperpolarize the horizontal cell. Excess magnesium, which inhibits calcium-dependent exocytosis at the synapse, mimics the effect of light and blocks the response to a flash. The relatively depolarized potential of the horizontal cell in the dark must therefore be maintained by continuous transmitter release from photoreceptors in the dark, supported by a continuous cycle of exocytosis and endocytosis.

This vesicle cycle has been visualized in the terminals of rod-driven ('ON') bipolar cells from the retina of goldfish which have an unusually large synaptic terminal and, because of this practical advantage, have been intensively studied (Figure 5(b)). If the membrane dye FM1-43 is added in the absence of calcium, only the cell surface fluoresces because the dye cannot cross the membrane (Figure 5(b), b), but when the cell is depolarized in the presence of calcium, there is an immediate increase in fluorescence in the terminal as vesicles fuse with the surface and take up the dye. With time, there is a gradual accumulation of stained membrane retrieved from the surface by endocytosis until all the vesicles in the terminal carry the dye and the fluorescence reaches a maximum (Figure 5(b), d). Because exocytosis and endocytosis are balanced over timescales of tens of seconds, there is no net change in the surface area of the terminal.

The continuous mode of exocytosis is most obvious in ribbon synapses in the retina, and it is suited to signaling the intensity and duration of maintained stimuli. However, in some cases, ribbon synapses must signal rapid change, such as the onset of light or the frequency of a sound, and this is best done by a transient burst of neurotransmitter release similar to that which might be triggered by an action potential at a conventional synapse. Ribbon synapses can therefore also support short bursts of very rapid vesicle fusion. An electrophysiological method that allows exocytosis and endocytosis to be monitored with good time resolution is the capacitance technique, which measures the increase in surface area when vesicles fuse and the subsequent decline in area when this excess membrane is retrieved again. The vesicles docked to the plasma membrane under the ribbon can be released in a fraction of a millisecond after the calcium channels are opened, at rates up to many thousands of vesicles per second (Figure 6). Such a rapid response is expected in hair cells that transmit signals phase-locked to sounds of kilohertz frequencies, but it is also observed in retinal bipolar cells.

A key specialization enabling rapid modulation of exocytosis is found in the calcium channels that mediate calcium influx to trigger vesicle fusion. In all ribbon synapses, these channels are of the L-type, which are activated at relatively high voltages (beginning at approximately −42 mV) and which have very fast opening and closing kinetics. These calcium channels are tightly clustered in the active zone under the ribbon, very close to the docked vesicles. Over the voltage range that calcium channels are just

Figure 5 Continuous exocytosis. (a) The effect of magnesium on the membrane potential of a horizontal cell from the skate retina. Tick marks show the timing of flash stimuli, which cause a transient hyperpolarization. The downward arrow indicates the time at which high magnesium was applied to inhibit transmitter release, and this mimicked the effect of light to hyperpolarize the cell and gradually abolish the light response. The relatively depolarized membrane potential in the dark was therefore caused by the maintained release of neurotransmitter from photoreceptors. (b) A depolarizing bipolar cell isolated from the goldfish retina with a giant synaptic terminal (a). The fluorescence images in (b–e) show the distribution of the membrane dye FM1-43, first added in the absence of calcium (b) and then during maintained stimulation of exocytosis (c, d). When the dye is washed off the cell surface, the membrane compartments that have been retrieved by endocytosis contain the dye and can be visualized (e). The graph quantifies the increase in fluorescence in the terminal during the experiment. (a) Adapted from Dowling JE and Ripps H (1973) Effect of magnesium on horizontal cell activity in the skate retina. *Nature* 242: 101–103, with permission from Elsevier. (b) Adapted from Lagnado L, Gomis A, and Job C (1996) Continuous vesicle cycling in the synaptic terminal of retinal bipolar cells. *Neuron* 17: 957–967, with permission from Elsevier.

beginning to open, the amplitude of the calcium current is a very steep function of membrane potential so that minor changes in voltage cause major changes in the amount of glutamate released according to a power function. This voltage dependence does not appear to reflect a cooperative action of calcium in triggering release because the amount of exocytosis measured over timescales of hundreds of milliseconds has a linear dependence on calcium influx in both photoreceptors and hair cells. This fundamental property of the release apparatus is very different in conventional synapses, in which exocytosis is triggered by a highly cooperative action of calcium (Hill coefficients of 3 or 4). It has been suggested that the proportionality between vesicle release and calcium influx in hair cells contributes to the encoding of auditory stimuli by allowing the ribbon synapse to represent minor differences in sound intensity over a wide dynamic range, as well as accurately transferring variations in intensity with minimum distortion.

Closer analysis of signals in retinal bipolar cells demonstrates that there are two distinct populations of vesicles that can be released rapidly: fusion of docked vesicles is followed by release of a second group which is approximately four times the size of the docked pool and is depleted in approximately 1 s

Figure 6 Vesicle pools at the ribbon synapse of bipolar cells. The right-hand side shows the time course of exocytosis assayed by using FM1-43 to stain exocytosed vesicles: Three distinct phases are observed. The first group of vesicles to be released, the rapidly released pool (RRP), is thought to correspond to vesicles docked at the active zone, which are shown in red in the schematic diagram on the left. The second group of reserve vesicles shown in green correspond numerically with the vesicles attached to the ribbon projecting into the cytoplasm. The third and slowest phase of release is continuous and is supported by a population of vesicles distributed throughout the cytoplasm. Modified from Neves G and Lagnado L (1999) The kinetics of exocytosis and endocytosis in the synaptic terminal of goldfish retinal bipolar cells. *Journal of Physiology* 515: 181–202, with permission from Blackwell Publishing.

(Figure 6). The 1:4 ratio between the first and second phases of release correlates with the observation that approximately four times as many vesicles are attached to the portion of the ribbon projecting into the cytoplasm behind the active zone as those docked at the base of the ribbon. If the ribbon is indeed a conveyor belt transporting vesicles to release sites at the active zone, then these measurements indicate that it takes an average of 250 ms for a vesicle to be transferred from the ribbon to a release site and then fuse with the surface membrane. The third and continuous phase of exocytosis that follows is supported by a much larger pool of approximately 500 000 vesicles distributed throughout the cytoplasm (Figure 6).

Efficient Recycling of Synaptic Vesicles

Although synaptic terminals containing ribbons at the active zone tend to be large and contain many vesicles, the maintenance of transmitter release over the long term requires that vesicles be recycled within the terminal. At the ribbon synapse of bipolar cells, most, if not all, the vesicles fusing with the surface membrane collapse and merge, and there is no evidence that vesicles can connect transiently with the surface through a fusion pore that allows the release of transmitter ('kiss-and-run'). These collapsed vesicles are retrieved by at least three distinct modes of endocytosis. Electron microscopy demonstrates that chronic and strong stimulation of exocytosis in cones, bipolar cells, and hair cells is followed by bulk retrieval of large chunks of surface membrane, equivalent to several vesicles' worth. This process generates cisternae within the terminal, from which vesicles subsequently bud off. Capacitance measurements of higher time resolution show that briefer stimuli in bipolar cells and hair cells are followed by two other modes of endocytosis that are kinetically distinct. Fast endocytosis occurs in 1 s or less, whereas slow endocytosis occurs on a timescale of 10–20 s.

In bipolar cells, fast and slow modes of retrieval both take in membrane chunks similar to the size of synaptic vesicles, but by mechanisms that are molecularly distinct. Slow retrieval occurs by the formation of Clathrin-coated vesicles from the cell membrane and is similar to the process that internalizes membrane receptors in all types of cells. In contrast, fast retrieval is independent of Clathrin, but the molecular mechanisms of the process remain to be identified. The relative importance of fast and slow endocytosis depends on how strongly the synapse is stimulated: In bipolar cells, weak stimuli that only release docked vesicles are followed almost exclusively by fast retrieval, but as more vesicles are released at higher rates, an increasing proportion are retrieved by the slower, Clathrin-dependent process. The two mechanisms of vesicle retrieval are also distinguished by their dependence on calcium: fast endocytosis appears to be triggered by calcium influx at the active zone, whereas slow endocytosis does not appear to be directly calcium dependent.

Once vesicles have been retrieved from the cell surface, they must somehow find their way back to the ribbon and/or the active zone. At many conventional synapses, the cluster of vesicles held in reserve behind the active zone is restricted in movement because the vesicles are tethered to the actin cytoskeleton via the vesicle-associated protein Synapsin. In hippocampal synapses, for instance, only a fraction of vesicles are mobile, and these have an effective diffusion coefficient of approximately $3 \times 10^{-3}\,\mu m^2\,s^{-1}$.

However, vesicles in the synaptic terminals of cones and bipolar cells are almost all mobile, moving in a random fashion with an effective diffusion coefficient of approximately $5 \times 10^{-2}\,\mu m^2\,s^{-1}$. In the giant synaptic terminal of bipolar cells from goldfish, the cytoplasmic reservoir contains approximately 300 000 vesicles, and this degree of mobility would result in approximately 900 vesicle collisions s^{-1} against the ribbons and 28 000 collisions s^{-1} against the surface membrane. In comparison, continuous exocytosis can be maintained at rates of 500–1000 vesicles s^{-1}. The random motion of cytoplasmic vesicles therefore seems sufficient to maintain an efficient supply to the ribbon and plasma membrane during ongoing activity.

Molecular Aspects of Ribbon Synapse Structure and Function

The synaptic vesicle cycle is regulated by a large number of specialized proteins, many of which occur in the membrane of synaptic vesicles or at the active zone. The vast majority of these proteins are common to both ribbon and conventional synapses, but there are some significant divergences, presumably reflecting different specializations for maintained or phasic release of neurotransmitter. The most obvious difference is the ribbon itself, of which the major structural component is Ribeye (which is also the only specific component identified to date). Ribeye is the product of an alternative promoter in the *CtBP2* gene and consists of an A domain specific for ribbons – presumably responsible for its multimerization – and a B domain that is identical to CtBP2, a transcriptional repressor that in turn is related to 2-hydroxyacid dehydrogenases. Other ribbon-associated proteins, such as Piccolo, CtBP1, and RIM1, are thought to be involved in tethering synaptic vesicles to the ribbon and/or priming the vesicles for fusion at the active zone (Figure 7(a)). KIF3A, a kinesin motor protein, is also attached to retinal ribbons, providing some support for the conveyor belt model, in which primed vesicles are actively transported along the ribbon to the release sites at the plasma membrane.

In photoreceptors, the arciform density is connected to the ribbon via Bassoon, a large scaffolding protein that binds Ribeye and also anchors to the cell cytoskeleton. In a mouse deficient of Bassoon, there are free-floating unanchored ribbons in photoreceptor hair cells and fast synaptic transmission is severely reduced. Surprisingly, a very similar phenotype in cone photoreceptors could be found in the zebra fish *nrc* mutant, which is deficient for synaptojanin 1, a polyphosphoinositide phosphatase important for Clathrin-mediated endocytosis and actin cytoskeletal rearrangements at conventional synapses. Bassoon is

Figure 7 The distribution of different molecular components of a ribbon synapse. (a) The differential distribution of proteins defines two presynaptic compartments at a retinal ribbon synapse. The ribbon-associated compartment includes RIBEYE/CtBP2, CtBP1/BARS, KIF3A, Piccolo, and RIM1. The active zone compartment includes RIM2, Munc13-1, ERC2/CAST1, and an L-type calcium channel α_1 subunit. Bassoon localizes at the border between the two compartments. Postsynaptic glutamate receptors may be metabotropic (mGluR) or ionotropic (iGluR). (b) Freeze-fracture electron micrograph showing the array of particles in the membrane at the active zone of a hair cell from the frog sacculus. These particles are arranged in four distinct stripes and are a mixture of calcium channels (approximately 90) and calcium-activated potassium channels (approximately 40). (a) Reproduced from tom Dieck S and Brandstatter JH (2006) Ribbon synapses of the retina. *Cell Tissue Research* 326: 339–346, with permission from Springer Science and Business Media. (b) Reproduced from Roberts WM, Jacobs RA, and Hudspeth AJ (1990) Colocalization of ion channels involved in frequency selectivity and synaptic transmission at presynaptic active zones of hair cells. *Journal of Neuroscience* 10: 3664–3684, with permission from Society for Neuroscience.

not found in bipolar cell terminals, but all ribbon synapses contain Piccolo, which is similar to Bassoon in being a multidomain protein with a structural role at the active zone. Other proteins at the arciform density are RIM2, Munc13-1, and CAST1, which bind to each other and which probably play a role in docking and priming of vesicles before fusion.

The calcium signal that triggers exocytosis in ribbon synapses is generated by clusters of voltage-gated calcium channels at the active zone (**Figure 7(b)**). These channels are of the L-type ($Ca_V1.4$ in the retina and $Ca_V1.3$ in hair cells), which is an important distinction from the calcium channels at the active zone of spiking neurons, which are of the N-, P/Q-, or R-type. The activation of L-type calcium channels is inhibited by a number of neuromodulators within the retina, including adenosine, dopamine, and cannabinoids, all of which act through G-protein-coupled receptors on the surface of the terminal to alter the voltage dependence of exocytosis. A mutation in the pore-forming unit of the $Ca_V1.4$ channel produces congenital stationary night blindness, and these patients show disrupted transmission between photoreceptors and bipolar cells together with abnormal development of the synapse.

The SNARE complex, which mediates vesicle fusion with the plasma membrane, is very similar at ribbon and conventional synapses. In both cases, the v-SNARE on the synaptic vesicle is VAMP/Synaptobrevin 2, which associates with the t-SNARES on the plasma membrane – Syntaxins 1, 2, or 3 – together with SNAP-25. The SNAP receptor is modulated by Complexins; however, whereas conventional synapses contain Complexins I and II, ribbon synapses contain Complexins III and IV, implicating this molecule in the functional differences. It seems likely that the calcium sensor for fusion at all types of synapses is Synaptotagmin, a transmembrane protein in the vesicle of which there are many isoforms. Most conventional synapses contain Synaptotagmins I and II, which are also found in retinal ribbon synapses but not in hair cells, where Synaptotagmin VII is more usually found. Although it has been suggested that different Synaptotagmin isoforms with different affinities for Ca^{2+} ions may underlie variations in the functional properties of synapses, this idea remains to be tested. Calcium concentrations of 1 μM or less can trigger exocytosis at ribbon synapses of photoreceptors and bipolar cells, and this signal occurs on the spatial scale of a micrometer, being generated by the cooperative opening of many calcium channels distributed over the active zone (**Figure 7(b)**). Other proteins acting as calcium sensors for exocytosis may be the Ferlins, which are similar to Synaptotagmins. One of these, Otoferlin, has been suggested to be the major Ca^{2+} sensor triggering exocytosis in inner hair cells. Otoferlin localizes to synaptic vesicles at the ribbon, and on binding Ca^{2+} it interacts with Syntaxin 1 and SNAP-25. Mice deficient in Otoferlin are deaf, and exocytosis from inner hair cells is abolished. Otoferlin is also defective in a recessive form of human deafness.

Does the Ribbon Act as a Conveyor Belt?

Ribbon synapses possess several design features that allow the maintenance of continuous exocytosis in response to graded signals: large terminals with large numbers of vesicles and active zones, efficient retrieval of vesicles by endocytosis to maintain the cytoplasmic reservoir, and the rapid and unhindered movement of new vesicles to the ribbon and/or release sites at the active zone. The fact that the ribbon holds vesicles immediately behind docking sites at the active zone suggests that it aids this supply function by acting as a trap for vesicles moving randomly in the cytoplasm, like a piece of fly paper. Do captured vesicles move in a directed way from the ribbon to release sites on the surface membrane? The most direct evidence for the idea that the ribbon might act like a conveyor belt comes from work using total internal reflection fluorescence microscopy to image individual vesicles in the synaptic terminal of retinal bipolar cells. This approach demonstrates that active zones of exocytosis coincide with structures that hold vesicles just behind the plasma membrane until stimulation causes the transfer of these vesicles downwards. These structures are most likely to be ribbons holding vesicles 'in reserve' behind the active zone. The time required for transfer and fusion was estimated to be approximately 200 ms, which would be consistent with the kinetics of exocytosis shown in **Figure 6**. However, a definitive demonstration of the idea that the ribbon acts as a conveyor belt will require the direct visualization both of the ribbon and of vesicle movements toward the active zone in response to calcium influx. It will also be important to identify the molecules forming the filaments that tether vesicles to ribbons, which do not appear to be actin. Are synaptic vesicles attached to ribbons by a motor protein?

RNA Binding Protein Methods

P T Buckley and J H Eberwine, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Gene expression is regulated by a number of mechanisms from RNA transcription to protein translation. In eukaryotes, the primary forms of regulation at the posttranscriptional level involve the interaction of messenger RNA (mRNA) with RNA-binding proteins (RBPs) (Figure 1). More than 20% of annotated genes in the human genome encode proteins with nucleic acid-binding domains. This large number of molecules suggests a great level of complexity in the ways proteins and nucleic acids interact. The complexity of regulation may in part explain why the transcriptome of a cell does not always correlate with its proteome.

As the name for this class of molecules suggests, RBPs are proteins that can associate with and bind RNA molecules facilitating stages in RNA metabolism. RBPs are implicated in a wide variety of posttranscriptional events because RBPs associate and dissociate from RNA molecules at nearly all stages of RNA processing within the cell. Particularly in the case of mRNA, RBPs are of critical importance based on their diverse functions. A better understanding of these interactions will greatly impact the way gene expression is considered.

RBPs have been shown to function in RNA metabolism at all stages: transcription, splicing/alternative splicing, capping, polyadenylation, nuclear export, subcellular localization, stabilization, RNA editing, translation (as activators or repressors), degradation (in processes such as nonsense-mediated decay and RNAi), autoregulation (fragile X mental retardation protein-1 (FMR1) and human onconeural ventral antigen-1 (NOVA1)), and micro-RNA processing (miRNA). The profile of RBPs associated with a given RNA at any stage of processing is highly dynamic and can have varied consequences depending on the cellular context in which they are found.

RBPs can be found in both nuclear and cytoplasmic regions of living cells, suggesting their involvement in aspects of RNA metabolism associated with those regions. In the nucleus, RBPs associate with mRNA precursors (pre-mRNA), heterogeneous nuclear RNAs (hnRNA), and mature mRNA prior to export to the cytoplasm. The nucleus is the site of mRNA splicing, capping, and polyadenylation. Nuclear mRNA transcripts acquire a protein coat of cap and RNA-binding proteins allowing export and controlling functional fate. Nucleoli are membraneless regions within the nuclei of some cells and their primary function is ribosome biogenesis. Ribonucleoprotein (RNP) is also one of the main components of nucleoli and this region of the nucleus is thought to be the site of assembly for most cellular RNPs.

The assembly of RBPs and RNA transcripts are often thought of as existing as membraneless granules in the cytoplasm. Granules form upon mRNA export from the nucleus for a subset of transcripts. These granules are visible by light microscopy and can contain ribosomal subunits, translation factors, decay enzymes, helicases, scaffold proteins, and other RBPs. Granules are thought to be involved in the control of mRNA localization, stability, and translation of RNA cargo. At least some of the RBPs associated with mRNA transcripts in the nucleus are retained after export, although their functional role may alter depending on the cellular compartment in which they are found.

The cytoplasm is the site of mRNA translation upon association with the ribosome. Some mRNAs are immediately translated and processed following polysome assembly. Others are translationally delayed and transported or stored until developmental or environmental cues signal translation. All of these events involve the action of a host of RBPs that associate and dissociate from transcripts, and the RBPs associated with a transcript at a given time may govern mRNA fate. In polarized cells such as neurons, where large cytoplasmic volume can exist at great distances from the nucleus, RBPs become of particular importance. Transport of mRNAs to these regions requires the coordinated action of a complex system of RBPs called a RNP complex. Once localized into subcellular compartments, RNA processing, translation, and degradation can occur in response to synaptic stimulation.

RBP Structure

At the molecular level, RBPs have traditionally been identified by the presence of domains that are capable of binding RNA. These RNA-binding domains (RBDs) are often described as ribonucleoprotein domains or RNA recognition motifs. RBDs are highly represented in the genome, suggesting that a great number of proteins are involved in posttranscriptional regulation of RNA metabolism. Known RBDs include, but are not limited to, RNP consensus sequences (RNP1 and RNP2), K homology domains, zinc fingers (CCCH

Figure 1 Diagram of reported RNA-binding protein (RBP)/RNA molecular interactions. Colored objects represent RBP molecules, and black lines represent RNA molecules.

and CCHC), RGG boxes, DEAD/DEAH boxes, Pumilio/FBF (PUF) domains, Piwi/Argonaut/Zwille (PAZ) domains, and double-stranded RNA-binding domains (dsRBD) (**Table 1**). Aromatic amino acid residues in the RNP motif result in a stacking interaction with RNA molecules that are stabilized by lysine residues in the helical portion of the molecule. Nucleic acid binding is a result of the highly positive nature of lysine side chains and the negative character of nucleic acid phosphate backbones.

RBDs with clearly defined sequences can be found throughout eukaryotic genomes. Studies have shown a surprisingly large number of potential RBPs. Presuming that these gene products do indeed act as RBPs, then this large number of RBPs suggests a complex highly regulated cellular system for controlling RNA biology. RBPs with more than one known RBD have been shown to contain the same domain represented multiple times or different domains present in the same protein.

Some of these domains are suggestive of the functional role of the RBPs in which they are found. The most well understood of these are the RNA helicase activity of DEAD/DEAH box domains, the short single-stranded RNA (RNAi and micro-RNA) binding activity of PAZ domains, and the role of SM domains in the binding of snRNA in splicing and tRNA processing. Other domains indicate RNA binding without indicating in which aspect of RNA metabolism they may participate. Homologs from other species and mutations can also be informative of the role an RBP may play in RNA metabolism.

RBPs often bind regulatory sequences in the 3′-untranslated region (UTR) of mRNA, suggesting the ability to molecularly identify binding sites in RNA molecules. It is conceivable that these binding sites may be defined by primary sequences within RNA molecules or by structural motifs formed by RNA secondary structure or, more likely, a combination of the two.

Table 1 Basic characteristics of known RNA-binding domains

	RNP1, RNP2	*K homology*	*Zinc fingers*	*DEAD/DEAH boxes*	*PUF*	*PAZ*	*dsRBD*	*R3H*
Typical structures	One or more copy of a 90-aa sequence containing four strands and two helices arranged in an alpha/beta sandwich with a third helix present during RNA binding in some cases	One or more copy of a 70-aa sequence containing a beta–alpha–alpha–beta–beta–alpha structure (type 1) or alpha–beta–beta–alpha–alpha–beta (type 2), multiple copies may function cooperatively	Each finger contains a 25- to 30-aa domain composed of a beta–beta–alpha fold stabilized by a zinc ion, contains conserved C and H residues separated by highly polar and basic residues	Occurs as a helicase domain of the aa motif DExD/H	Occurs as a tandem repeat of six to eight domains	Five stranded mix of beta-sheets surrounded by helices, tertiary structure belonging to Rnase H family	70-aa globular domain with an alpha–beta–beta–beta–alpha structure	Contain a conserved arginine and histidine residue separated by three other residues, also display a conserved pattern of hydrophobic residues, prolines, and glycines
RNA target motifs	ssRNA, U1A proteins recognize stem/loop RNA structures	ssRNA, ssDNA	mRNA 3′-UTR, short runs of guanine residues	RNA secondary structures	UGUR motif found in the 3′-UTR of target mRNAs and flanking sequences (highly selective)	dsRNA	dsRNA	ssRNA
Example proteins	hnRNPs, snRNPs	hnRNP K, FMR1, NOVA	matrin, U2AF splicing factor, many transcription factors	Involved in RNA transcription, editing, splicing, export, translation and turnover proteins across all kingdoms	Pumilio (*Drosophila*), FBF-2 (*C, elegans*), other proteins found across all eukaryotic kingdoms	Dicer, Argonate	Adenosine deaminases, PKR, Rnase III	Present in proteins from a diverse range of organisms
Proposed functions	Splicing, alternative splicing	Nucleic acid binding and protein–protein interactions	Several subtypes capable of binding both DNA and RNA C2H2 and CCCH subtypes typically associated with RNA binding	Helicase activity involved in the unwinding of dsRNA	Translational repressors affecting mRNA translation and stability	dsRNA-guided hydrolysis of ssRNA	Binding of RNA duplexes	ssRNA binding as suggested by other domains in R3H containing proteins

RNA Targets

RBPs can regulate the metabolism of multiple RNA targets, as suggested by diverse effects seen in mutational analysis leading to misregulation of many RNA targets. The RNA targets of RBPs are notoriously difficult to identify. Most RBPs have multiple targets and mutant phenotypes can be difficult to tie to an individual RNA target. Identification of RNA targets is required to fully understand RBP function. Identification of RBPs that bind to known regulatory sequences is also critical to defining the mechanism of posttranscriptional control utilized by a given RBP.

In order to function properly, RBPs must specifically differentiate and recognize target from nontarget RNA. Specific recognition of target molecules could occur by sequence recognition, structural recognition, or both. Understanding the dynamics of this recognition would help in the identification of unknown targets of RBP interaction containing similar features. However, definition of an RNA sequence motif for RBP interaction may fail to reflect physiological interactions based on concentration, subcellular localization, and the requirement of multiple proteins for proper function.

Assays (discussed later) exist to identify RNA cargoes of RBPs, and educated guesses can be made based on phenotypic information gleaned from RBP mutants. Using *in vitro* techniques to attempt to assess *in vivo* associations between molecules requires a clear recognition of the limitations involved. *In vitro* methods of defining RNA targets of RBPs may alter the *in vivo* associations of RNA–protein complexes. RNAs associated with off-target proteins may be isolated as part of complexes. Immunoprecipitation (IP) experiments have been shown capable of generating complexes that form artificially *in vitro* via reassociation of molecules after cell lysis. These methods destroy the *in vivo* context and associations of RBPs and their targets, opening these molecules to new associations with molecules they would not encounter in normal cellular regulation.

RBPs are vulnerable to being bound by stretches of repeated sequences. Therefore, this type of binding is increased when these types of sequences are expanded in disease leading to altered function of RBPs. This is particularly true with splicing, where altered splicing patterns can be created upon nucleotide expansion.

RBP–RNA Cargo Identification

Identification of RNA targets of RBPs is key to understanding how RBPs posttranscriptonally control gene expression. By virtue of RBPs having multiple RNA targets, specific features of target versus nontarget RNA can be determined once cargoes for particular RBPs have been identified. Identification of the multiple RNA targets for an RBP can also yield insight as to the type of RNA metabolism that an RBP regulates, the mechanism or mechanisms used to control metabolism for a given RBP, and how RBPs exert coordinated control of RNA metabolism. A number of assays have been developed to analyze RBPs and identify target RNAs and are described here.

Immunoprecipitation

The most common assay used to identify RNA targets of RBPs involves the use of IP to isolate RNA–protein assemblies using antibodies to the RBP of interest. Once isolated, these assemblies can be screened by microarray to identify the RNA species captured with the RBP. Prior to the development of microarray techniques, RNA targets would have been identified by subtractive hybridization, cloning, and sequencing. Microarrays allow for a tremendous increase in the power of identification of targets.

The most significant limitation of these assays is the lack of specificity of the technique for both the antibody and the capture of nontarget RNAs. RNA molecules can be particularly 'sticky' and may be identified as targets despite having no specific interaction with the RBP under scrutiny. Cellular lysis steps can significantly alter the concentrations and context of RNA–protein interactions, leading to associations that are a consequence of the isolation technique rather than the biology of the molecules. RBPs also frequently associate with other proteins as part of multiprotein complexes. These proteins could provide additional sites of RNA interaction and binding and could in fact be other RBPs. Because these proteins would be isolated in the IP technique, any RNA cargo they interact with would incorrectly be seen as interacting with the RBP target of the IP.

Cross-Linking and Immunoprecipitation

A more recently developed technique, cross-linking and immunoprecipitation (CLIP), incorporates a cross-linking step in living cells to allow for isolation of *in vivo* RNA targets. Upon cross-linking, the RNA–protein complexes are isolated from the cellular extract by IP, and the associated endogenous RNAs are identified by microarray.

The ultraviolet cross-linking step incorporated into this technique was proffered to avoid some of the issues associated with the less selective traditional IP assays. However, since protein–protein cross-linking can occur, it is possible that nontarget RBPs and their cargoes are immunoprecipitated with the target RBP. Furthermore, the sensitivity of PCR makes it difficult

to ensure that small amounts of high-abundance mRNAs are not simply 'nonspecifically' associated with the IP complex and thereafter aberrantly identified as cargoes.

Yeast Three-Hybrid Screening

The yeast three-hybrid screen is an RNA target identification technique based on the yeast two-hybrid system used to detect protein–protein interactions. Phenotypic properties of yeast are used to detect and analyze RNA–protein interactions using two hybrid proteins along with a hybrid RNA molecule. A hybrid protein composed of a known RBP (with an RBD) is generated with a DNA-binding domain that binds to the promoter region of a reporter gene. Another hybrid protein is generated that is composed of a second RBD along with a transcriptional activation domain for the reporter gene. The RBDs of these proteins can bind the RNA sequences of the hybrid RNA molecule. As binding of the RNA molecule occurs, the DNA-binding and transcription-activating hybrid proteins are brought together and RNA–protein interactions are detected by expression of the reporter gene.

Antibody-Positioned RNA Amplification

In the antibody-positioned RNA amplification (APRA) technique, an antibody to an RBP of interest is covalently coupled to a single-stranded DNA oligo composed of a sequence of nonhomologous DNA, a restriction enzyme site, and a degenerate sequence. As the antibody specifically binds to the protein of interest, the oligo can anneal to mRNA cargoes in the vicinity. Priming from the oligo allows for directed *in situ* transcription. A second complementary DNA strand can then be synthesized, and the double-stranded DNA can then be digested away from the APRA construct, isolated, and amplified for analysis by microarray.

PNA-Assisted Identification of RNA-Binding Proteins

The peptide nucleic acid (PNA)-assisted identification of RNA-binding proteins (PAIR) assay provides the opposite type of information from the previously described techniques in that it allows for a means of RBP identification for any given RNA sequence rather than identification of RNA cargoes for a given RBP. In the PAIR assay, a PNA containing photoactivatable amino acids (AAs) in association with a cell-penetrating peptide (CPP) can be synthesized that is complementary to an RNA sequence of interest. After the CPP carries the PNA into the cell, the PNA anneals with its complementary sequence *in vivo* and the PNA is then crosslinked to proteins near where it bound by activation of the photoactivatable AAs. This PNA–RBP complex can be isolated and the PNA annealed to its target sequence immobilized on a bead which serves as a way to precipitate associated protein–RNA complexes. The proteins from these complexes can be isolated from the beads and target RNA for analysis by proteomic assays for identification.

The most significant limitation to exploring post-transcriptional processing in this way is the fact that an mRNA associating with any of these RBPs does not definitively show that those mRNAs are subject to the metabolic events normally associated with those RBPs (e.g., splicing enzymes may regulate translation not just splicing). A vast number of these proteins have secondary functions that are not completely understood, and a conclusion cannot be absolutely drawn without further investigation.

Global Regulatory Role of RBPs

RBPs are essential to regulating posttranscriptional gene expression. In addition to facilitating a number of mRNA processing events in the cell, RBPs are thought to be responsible for generating proteome diversity through alternative splicing and translational control of existing mRNAs. Many cell-specific RBPs are critical for phenotypic definition and are critical to developmental regulation.

RBP dysregulation has been implicated in a number of diseases and disorders. FMR1 disregulation is the cause of fragile X syndrome, the most common form of inherited mental retardation. CELF proteins are integral to normal heart and skeletal muscle development and in the pathology of myotonic dystrophy. NOVA autoimmune antigens are neuron-specific proteins involved in the pathogenesis of the neurodegenerative syndrome paraneoplastic opsoclonus–myoclonus ataxia.

Any dysregulation or mutation of RBPs can have dramatic biological implications for living systems. The RNA cargoes associated with the RBP and the metabolic function of the RBP can both be altered by impaired protein function. The repercussions of disrupting a single RBP can affect any number of systems, leading to disease. In the same way, altering the sequence of an RNA target can alter its interaction with any number of RBPs. These changes could be localized to regulatory and noncoding sequences within a transcript and still create a physiological effect in the same manner as a change in the coding sequence. Understanding the mechanism of binding and function of RBPs is essential to treating conditions impacted by RBP disregulation.

Introduction

Of all cells in nature, neurons have the most remarkable and diverse shapes. They vary from simple unipolar cells to highly complex cells, decorated with a profusion of projections that extend up to several centimeters and even a meter in the case of axons. This diversity in anatomical shapes generates myriad possibilities of cell-to-cell interactions, to form adaptable circuits through millions of synaptic connections. Far away from the cell body, synapses are functionally autonomous distinct subcellular domains; under constant remodeling and adaptation, they contribute to long-lasting changes in synaptic strength that are believed to play a role in neuronal development, learning, and memory processes. These changes rely on local rapid modulation of protein synthesis that is dependent on the presence of mRNA at the synapse. Logistic concepts arise on how to supply and functionally maintain territories and regions far away from the cell body. The majority of neuronal protein synthesis takes place in the somatic compartment and, as a result, the vast majority of the messenger RNAs (mRNAs) translated by the neuron are encountered in the cell body. However, approximately 5% of the mRNAs are also delivered either at presynaptic terminals or at postsynaptic dendritic spines, where these mRNA are translated into proteins that are required specifically in response to the local needs of the neuron. This transfer of mRNA provides a mechanism both for controlling the distribution of the corresponding protein and for regulating independently its level in individual axonal terminals or dendritic spines. The mechanisms of transport, targeting, and release of neurospecific mRNAs at the synapse are beginning to be unveiled, and involve motile macromolecular complexes that have been named RNA granules. These structures have been described as translationally silent ribonucleoparticles (RNPs), which contain mRNAs packed with RNA-binding proteins and ribosomes.

The Expanding World of Diverse Cytoplasmic RNA Granules

Originally, the term 'granule' referred to round-shaped cellular structures that, upon adequate staining, were visible using light microscopy. Granules were also subsequently seen under the transmission electron microscope as electron-dense structures. They were observed in dendrites as well as in axons, but their identities were either speculative or not documented. The possibility that some granules might contain mRNA was not considered until the 1980s, since the prevailing view was that all dendritic and axoplasmic proteins originated from translation of mRNA in the cell body, and were subsequently transported to the neuronal branches through mechanisms called 'long-range slow and rapid' dendritic or axonal transport.

The discovery of polyribosome aggregates beneath postsynaptic sites at the base of dendritic spines has changed our vision of how translation could also occur at the synapses, to regulate independently and rapidly protein synthesis in response to specific stimuli. Concomitantly, clues for the dendritic presence of extrasomatic mRNA were provided and it was established that *in vitro* protein synthesis also occurs in synaptosomes, and even in dendrites preparations, both isolated from neurons maintained in culture. The mechanism by which these mRNAs were targeted to the neuronal branches remained elusive until recently. Granules containing RNA have been documented in invertebrate neurons and also in fibroblasts, ovocytes, and oligodendrocytes. However, neuronal vertebrate RNA granules were only described in the 1990' as motile messenger ribonucleoprotein (mRNP) complexes encountered in the dendritic extensions of neurons. Although mostly studied in invertebrates systems, axonal RNA granules have also been characterized in vertebrate neurons.

RNA Granules, a Term Too General

Several types of RNA granules can be observed in all cells, including neurons. In addition to RNA detected by *in situ* hybridization, these structures can be visualized using immunofluorescent approaches with antibodies to known RNA-binding proteins. Also, they can be seen after microinjection of labeled RNA molecules, or after transfection with vectors coding for tagged-RNA-binding proteins as is the case for

Figure 1 Fragile X mental retardation protein, an RNA-binding protein that interacts with mRNA, is transported to dendrites in granule complexes. The protein, tagged with a green fluorescent protein, was expressed in rat hippocampal neuron in culture after transfection with an expression vector coding for the fusion protein. Granules, visible by epifluorescence microscopy, are observed as far away as 500 μm from the cell body. Reproduced from Davidovic L, Tremblay S, De Koninck P, and Khandjian EW (2005) Fragile X mental retardation protein: To be or not to be a translational repressor. In: Ju Sung Y and Denman RB (eds.) *The Molecular Basis of Fragile X Syndrome*, pp. 129–144. Kerala, India: Research Signpost, with permission from Research Signpost.

FMRP (Figure 1). The list of different proteins with affinity to RNA that appear as granules is increasing daily. However, since different RNA-containing granules have been described, it is worth trying to classify them into specific types.

Polyribosomes

Polyribosome structures are made of ribosomes connected by a strand of mRNA that runs between the large and small ribosomal subunits. A number of studies have shown that nonribosomal proteins, mostly RNA-binding proteins, associate with these structures referred often as aggregates, although the term 'clusters of polyribosomes' is more appropriate. These clusters can be visualized by electron microscopy as particles, but are not individually visible by conventional light microscopy because of its limited resolution of ~0.2 μm. However, clusters of ribosomes can be visualized under certain circumstances in neurons (see below).

Stress Granules

When a cell is submitted to a stress, such as heat shock, UV irradiation, oxidative stress, or hypoxia, it responds rapidly to contend with the insult. The amount of translating polyribosomes diminishes as the translational machinery is mobilized to treat only specific mRNAs, such as the heat shock mRNAs. Meanwhile, other mRNAs are removed, stored and stabilized in stress granules (SGs) as nontranslated mRNPs. SGs are formed with an aberrant eIF2–GTP–$tRNA^{Met}$ ternary complex and by recruitment of different RNA-binding proteins that are trapped with the mRNAs. In these SGs, the initiator tRNA is not loaded onto the 40S ribosomal subunit, and recruitment of the 60S large subunit is not observed. Once the environmental stress is relieved, stored mRNAs are released from the SGs, which vanish gradually while overall translation resumes.

Stresslike granules can also be induced and detected after transient expression of different RNA-binding proteins in all kind of cells. These structures are formed when the introduced RNA-binding proteins trap mRNAs, overloading the translation machinery that becomes overcrowded and easily visible under the microscope, since granules as large as 2–3 μm can be formed.

Processing Bodies

Processing (P) bodies are structures that can be visualized as dynamic granules. They contain mRNA and components of the nonsense-mediated decay pathway, and the 5′–3′ mRNA decay machinery, including decapping enzymes and endonucleases. They also contain factors involved in small RNA-guided gene silencing. The sequestered mRNAs can be stored transiently in a repressed state, to be later released from P bodies to undergo translation in the cytoplasm. Whether the RNA-induced silencing complexes (RISCs; see later) are part of these bodies is still not clear. While P bodies might be involved in local degradation or storage of specific mRNAs in dendrites, it is not known whether the whole complex, in the form of a granule, is translocated from the soma to synapses, or whether the complexes are assembled locally and transiently in the dendrites on demand. It is important to note that P bodies do not appear to contain ribosomes and therefore cannot be associated with the translation machinery.

miRNP and RISC Complexes

Consistent with the fact that mRNAs are maintained translationally silent in granules, several small noncoding RNAs that could behave as translation repressors

have been detected in granular structures. The brain-specific cytoplasmic RNA 1 (BC1), a 152 bp-long noncoding RNA polymerase III transcript, is also targeted to dendrites, suggesting that it could control the fate of certain mRNAs.

An intriguing question is whether control of translation in granules could rely on miRNA-mediated regulation of translation. This mechanism involves a class of small, 19- to 22 nt-long RNAs, termed microRNAs (miRNA), that can specifically repress translation of homologous mRNAs. Several recent reports suggest that neuron-specific miRNAs might act in nervous system morphogenesis. These miRNAs have also been found to target specific mRNAs into P bodies involved in mRNA storage and/or degradation.

It is not clear whether RISC, the macromolecular protein complex responsible for RNAi, would appear as a granular structure in microscopic observations of dendrites or axons. However, several RISC members are found in different types of granules, including the protein Argonaute and fragile X mental retardation protein (FMRP). At the molecular level, there is evidence that the RISCs affect mRNA transport to the synapse and the synthesis of synaptic proteins associated with memory in *Drosophila*. For example, miR-134, which localizes in the dendritic compartment, affects translation of specific mRNA that control dendritic spine size. Although preliminary, these observations suggest that miRNA/RNAi could play crucial roles in granule formation and functions in neurons.

Neuronal RNA Granules

As opposed to stress granules, which are seen only under stressful conditions, neuronal RNA granules are motile complexes that transport and deliver transcripts at distant sites in the cell. Once they arrive at their destination, it is inferred that they are docked to membranous or cystoskeletal structures, awaiting a signal to initiate translation. Biochemical evidence that these granules contain mRNA and ribosomes has been obtained after isolation from primary cultured neurons of a fraction of material sedimenting faster than polyribosomes, with coefficients above 1000 S (Svedbergs: $S_{20.w}$). Electron microscopy studies reveal that RNA granules are round-shaped structures that contain electron-dense material and tightly packed ribosomes. Their reported sizes range from 150 to 1000 nm, but the large aggregates appear as if several smaller granules had coalesced.

In addition to RNA granules containing ribosomes, it appears that other species of granular structures containing mRNA, but not ribosomes, can be detected in neurites. It has been suggested that these structures carry mRNA or/and other RNA species, to be delivered at specific sites either postsynaptically or in axons. These structures are apparently the supply cargoes required to replenish and feed the translation machinery with newly transcribed mRNA, as these molecules are turning over with various half-lives.

Characterization of Neuronal RNA Granules

Neuronal RNA granules are extremely heterogeneous in size, as determined by immunofluorescent studies using different antibodies to the protein associated with these structures. Also, they are heterogeneous in composition, since each can carry different types of RNA-binding proteins. However, some RNA-binding proteins co-localize in certain subpopulations

Figure 2 Axons from rat sympathetic (DRG) neurons growth culture contain RNA granules. Ribosomes were stained with anti-L7 serum (in red) and with monoclonal antibody 1C3 against fragile X mental retardation protein (FMRP), an RNA-binding protein (in green). The merged images show that FMRP is not associated with all ribosome-containing granules.

of granules (Figure 2). These observations strongly suggest that the protein composition of the granules is neither uniform nor universal. The identity and stoichiometry of the different components are subjected to high variability, and this variability is thought to determine the types of mRNAs to be transported, as well as the specific destination of the cargo.

To tentatively characterize neuronal RNA granules, biochemical approaches have been used. These are based on two main methods of separation: (1) isokinetic ultracentrifugation in sucrose density gradients to separate the subcellular components according to their sedimentation values (S) and (2) affinity chromatography, with specific antibodies or recombinant protein to isolate structures with their surrounding components.

Protein Components

Neuronal RNA granules contain RNA-binding proteins either associated with RNA transport and/or translational control, such as the members of the fragile X mental retardation protein family (FMRP, FXR1P, and FXR2P), CPEB, RNG105, Purα, Purβ, Pum2, TIAR, and TIA-1, and proteins specialized in the recognition of RNA dendritic or axonal targeting sequences, including the zipcode-binding protein-1 (ZBP1), SYNCRIP, MARTA 1, MARTA 2, and Staufen. Proteins involved in protein synthesis, such as elongation factors (e.g., EF1α, eIF2α, eIF2β and eIF2γ), are also found in RNP granules. Interestingly, they also contain proteins originally involved in nuclear posttranscriptional processes, such as RNA helicases (DDX1 and DDX3), heterogeneous nuclear ribonucleoproteins (hnRNP U, hnRNP A, and hnRNP B), and proteins involved in mRNA splicing, such as TLS, Sam68, Sc35, and polypyrimidine tract-binding protein-associated splicing factor (PSF). In addition to these specific proteins, RNP granules also contain, or at least are associated with, protein motors that are known to be involved in active transport (see below).

RNA Components

Electron microscopy analyses have revealed the presence in granules of electron-dense structures that react with the RNA stain SYTO-14. Granules also contain ribosomal RNA (rRNA) constituents of the ribosomal subunits. Due to the apparent high level of compaction of the ribosomes in the granule, it is inferred that the mRNA remains translationally incompetent. Further strengthening the hypothesis that RNA granules are repressed, it was shown that they contain little or no tRNA, a key component in translation.

Neuronal RNA granules are thought to be reservoirs of mRNAs that are transported into dendrites for subsequent site-specific utilization at synapses undergoing protein synthesis-dependent changes. To identify the mRNA content of the granules it is necessary to separate these structures from other RNPs, especially from polyribosomes. Different approaches are applied to enrich RNP granules, but these are mainly based on the different sedimentation properties between the various ribonucleoparticles present in the cell sap. It is not clear to what extent these RNP granules are pure, since they have not yet been fully identified at the biochemical level. The list of mRNA present in these RNP granules is expanding, with emphasis being put on specific mRNAs that direct the synthesis of proteins required in synaptic cytoskeleton remodeling (i.e., the microtubule-associated protein 2 (MAP2) and the activity-regulated cytoskeleton-associated protein (Arc)) and in synaptic functions (i.e.,CaMKIIα, neurogranin, voltage-gated potassium channel Kv1.1, and glutamate receptors). Other mRNAs encode proteins involved in translational control, including translation factors (i.e., elongation factor 1α, eukaryotic initiation factor 4E(eIF4E)) or RNA-binding proteins (i.e., cytoplasmic polyadenylation element-binding protein (CPEBP) or fragile X mental retardation protein). Finally, it is assumed that local translation of another class of mRNAs encoding transcription factors (i.e., the cAMP response element-binding protein, CREB) mediates short- and long-term changes in the repertoire of the genes expressed at the somatic level.

On the axonal side, several mRNAs have been identified, most of them encoding proteins involved in cytoskeleton remodeling, such as Tau and actin-depolymerizing factor (ADF), or in signal transduction, such as ephrin A2 (EpHA2) and importin β1. Other studies have inferred the presence of additional cytoskeleton-linked mRNAs (vimentin, cofilin), and several heat shock proteins mRNAs (HSP27, HSP60, HSP70), the products of which function as protein chaperones to control proper folding after protein synthesis.

Assembly and Sorting of RNA Granules: In the Nucleus or in the Cytoplasm?

To avoid ectopic translation in the cell body, the dendritic-targeted mRNAs have to be sorted from mRNA destined to somatic translation shortly after transcription and held in a translationally dormant state during transport to the appropriate destination (Figure 3). The presence of nuclear proteins such as hnRNP U, hnRNP A, and hnRNP B in some RNA granules suggests that the sorting or preassembly of the mRNA and

Figure 3 Model for sorting and trafficking of RNA granules. Once the 'decision' is taken in the nucleus, RNA granules are translocated onto microtubules and are transported to dendrites using motor proteins. On arrival at their destination, the granules are docked and wait for a stimulus, following which they unfold and resume protein synthesis on demand.

RNA-binding proteins in these granules may occur in the nucleus. In addition, RNP granules contain several RNA-binding proteins known to induce translation repression, such as FMRP, CPEBP, RNG105, Purα, Purβ, and p50, some of which harbor nuclear localization and nuclear export signals. These data strongly suggest that translation repression and mRNA transport within granules are tightly coupled. mRNAs could be sorted by means of the recognition of its cis-acting elements by specific RNA-binding proteins, to form mRNPs. The few known cis-acting elements are composed of a primary nucleic acid sequence and a secondary RNA structure that generate a specific RNA-binding protein recognition site. For example, the mRNA encoding β-actin is a well-known dentritically localized mRNA. Its targeting to dendritic spines or to the growth cones of developing neurites involves a specific interaction between ZBP1 and a 54-nucleotide zipcode sequence in the 3′-untranslated region (3′-UTR) of β-actin mRNA.

Another scenario can be proposed, based on new concepts about the continuous shuttling of mRNPs between hypothetical discrete cytoplasmic 'microdomains' and the translation machinery. In other words, decisions are taken in these 'centers,' whether an mRNA should be translated or be maintained as repressed mRNPs during its translocation at specific sites in the cell. Under certain physiological conditions, these structures merge, eventually to form granules large enough to be seen under the microscope.

Transport of Granules

The use of cytoskeleton-disrupting agents reveals that transport of neuronal RNA granules requires microtubules for rapid long-range axial transport and actin cytoskeleton for local dependent radial translocation locally at the synapse. Time-lapse videomicroscopy on hippocampal neurons harboring SYTO14-RNA dyed granules, green fluorescent protein (GFP)-labeled CaMKII 3′-UTR RNA, and GFP-Staufen enabled to visualize oscillatory (bidirectional) movements over short distances, or processive movements over larger distances in the direction of the growth cone and distal dendrites (anterograde). The oscillatory movement of granules has been attributed to fine local

adjustments within specific dendritic sites (i.e., clusters of synapses). RNA granules display an average velocity between 0.03 and 0.15 $\mu m\,s^{-1}$, compatible with active transport via kinesin and dynein. The kinesin I family (KIF5), and the kinesin II family (KIF3C) are thought to move a subset of granules toward distal processes, whereas dynein would move granules back to the soma. The direction of movement of RNA granules along microtubules appears to be determined by the balance of power between the conventional kinesin and cytoplasmic dynein in contact with each granule. However, due to the heterogeneity of the granules, the nature of the motors involved in their individual transports is not fully understood.

Interestingly, only a small portion of the tagged granules actually move within a neurite, and it is thought that these stationary elements might represent granules that have reached their final destination. Alternatively, it might be possible that stationary granules correspond to SGs that have been induced by high levels of the GFP-tagged proteins used, which could have trapped the mRNAs.

Derepression of Granules

When RNA granules have reached their final destination, they are docked pre- or postsynaptically until their translation is triggered by physiological and/or developmental stimuli, essentially determined by neuronal activity. Activity-dependent translation is triggered via a combination of mechanisms, including activation of the general protein-synthesizing machinery in dendrites and release from repression of specific mRNAs. It is likely that regulation also involves the selection of mRNA for translation and (maybe) competition between mRNAs for the limited available translation machinery at the synapse. Indeed, due to space limitation in the dendritic spine neck, where polyribosomes clusters are encountered, it is likely that a limited number of mRNAs is actually undergoing active translation at the synapse at the same time.

Prolonged depolarization of cortical neurons induces changes in the structure of granules, including apparent decondensation of the packed ribosomes, which can protrude outside the granules to be reshaped into polyribosomes. These changes are accompanied by postsynaptic polyribosome upregulation and a shift in the distribution of several dendritic mRNAs from the heavy-sedimenting granule fractions into actively translating polyribosomal fractions. Concomitantly, translation factors can either be immediately synthesized on the spot, or can be recruited into granules in response to synaptic activation. For example, brain-derived neurotrophic factor (BDNF) treatment of various neuronal preparations results in the redistribution of eIF4E to an RNA granule-rich cytoskeletal fraction. eIF4E linkage to cap structures mediates the recruitment of other translation factors to initiate translation. Inhibition of translation is likely to occur at this step. For example, the CPEB protein that localizes to dendrites and synapses binds to a specific cis-element in the 3′-UTR of CaMKIIα mRNA. CPEB forms a complex with the 5′-cap via interaction with Maskin, a protein that binds to eIF4E, to prevent the formation of the initiation complex and to keep the mRNA translationally dormant. When CPEB is phosphorylated, it facilitates polyadenylation and translation initiation by recruitment of polyA-binding protein (PABP) and eIF4G. Binding of eIF4G to the 5′ cap displaces Maskin from eIF4E, and enables translation of CaMKIIα mRNA. FMRP is also thought to regulate mRNA translation in dendrites by repressing translation initiation. Although the specific mechanism of FMRP action remains unknown, FMRP binds to several mRNAs via its multiple RNA-binding domains, and it has been described as a translation repressor. The fragile X syndrome (FXS), a cause of inherited mental retardation, results from the loss of FMRP. Mice and humans lacking FMRP exhibit changes in dentritic spines density and morphology, as these appear longer, thinner, and more tortuous than normal, looking immature and not fully differentiated. These observations are thought to be at the heart of behavioral and cognitive abnormalities, apparently due to altered local synaptic protein synthesis impairing proper connectivity between neurons. FXS is the only known human genetic inherited disease linked to alterations in synaptic translation and is therefore a great focus of attention in neurobiology.

Conclusion and Perspectives

Real-time fluorescence imaging has drastically changed our view and perception of the dynamics of RNA granules in neurons. It is now possible, in theory, to follow a single RNA granule, from its formation to its demise, and to monitor its complex paths of translocation. However, little is known about the signaling pathways and molecular mechanisms governing granule formation and decay. Since the discovery of polyribosomes at synaptic sites, recent studies have provided evidence linking synaptic plasticity to local protein synthesis. The presence of clusters of polyribosomes enables rapid triggering of local protein synthesis in response to exogenous stimuli. Logistically and energetically speaking, it seems that transfer of the whole translation apparatus, including ribosomes, to distal locations is

a more profitable operation than transferring bits and parts of this complex machinery. A second class of RNA granules lacking ribosomes would be necessary to replenish the translation apparatus, standing by for new rounds of translation with new mRNA transcripts. In parallel, the aging mRNAs would be addressed to P bodies, where they will be degraded. The model of the relationship between the different classes of these dynamic granules is certainly a simplistic and anthropomorphic view, and more studies are needed.

RNA-binding proteins, which are found in all neuronal RNA granules, play pivotal roles in regulating RNA metabolism. It is fascinating that among the 380 putative RNA-binding proteins coded in the mouse, 61% are detected in brain. Such high concentration of this class of proteins is certainly indicative of the high level of translation in the brain.

Rodent Aging

B Teter, University of California, Los Angeles, CA, USA

© 2009 Published by Elsevier Ltd.

Introduction

The study of aging has incorporated such vast theoretical and experimental effort that a review of brain aging must necessarily cover a wide conceptual landscape, from evolution to biochemistry, teleology to stochasticism, and genetics to environment. Aging, determined by the entire life history and its evolutionary determinants, is influenced by aspects of fitness, disease, reproduction, mutation, genetics, and random events. Since the brain and aging are the two most complex biological phenomena, it is not surprising that our understanding of brain aging is limited. In regulating and coordinating most somatic processes, the brain is a nexus of control systems linking organ systems and the environment, and while it is rarely the organ of pathological death, its degeneration may be intimately involved in inducing, synergizing, or failing to protect the development of terminal diseases of other organs. The brain, therefore, plays an important role in aging and in life span determination.

Normal aging in the brain, defined in the absence of diseases associated with neuron loss, is not itself associated with extensive age-related neuron loss, but is recognized as sublethal, functional neurodegeneration caused by increased vulnerability to metabolic stress and trauma. Brain aging is influenced by processes and events that begin with genetic and epigenetic contributions from the parents, acting during development, and accelerate in middle age. Aging can be defined to begin when neuron birth and differentiation is surpassed by neurodegeneration that eventually affects cognitive functional ability (approximately after age 10–20 years of human life for most functions).

Animal models of brain aging address select aspects of aging to varying degrees, including animals with phenotypically accelerated aging or prolonged longevity, engineered transgenic, mutant, and knockout models that focus on a single gene's role (and *in vitro* cell and organotypic systems proximally extracted from them), and interventions and environmental manipulations that attempt to modify specific behavioral, anatomic, cellular, or biochemical targets. However, the complexities of aging are not well elucidated in the reductionist approach of animal models. The translational extrapolation to improve the human condition is where animal models receive their greatest challenge and achieve their greatest relevance. Congruencies between humans and rodents justify such extrapolation, particularly at the cellular and gene expression levels. However, evolutionarily, humans and rodents evolved with different life histories (high entropy (equilibrium) and low entropy (opportunistic), respectively) that ultimately determine their respective chronological longevities. This profoundly impacts the strength of inferences drawn from rodent models for the human condition.

Rodents as Models of Aging

Rodent strains that vary in aging processes (qualitatively and quantitatively) and life span have revealed aspects of aging that control health and longevity. Inbred strains have similar or shorter life spans than hybrids (hybrid vigor), in part because they die from strain-specific disease patterns not active in hybrids. Therefore, the more diverse genetic background and greater interanimal variation of hybrids are more relevant to human populations.

It is important to distinguish the processes of aging, disease, and life span (death). 'Normal' aging is defined as time-related change in the absence of disease, yet both can be driven by the same processes and therefore difficult to completely experimentally (or conceptually) dissociate, for example, Alzheimer's disease and normal cognitive decline. Prepathological events play important roles in aging and longevity, including lifetime accumulation of 'events' involving inflammation, infection, and nutrition. Two aspects of brain development could establish the basis for later brain aging effects: genetic antagonistic pleiotropy and cognitive reserve. Antagonistic pleiotropy occurs when genes and events that are adaptively essential for brain development become deleterious with aging, for examples, the progressive decrease in brain plasticity at early ages which serves to focus the mind on the established (and, presumably, understood) environment that continues into adulthood resulting in cognitive decline with age, and age-related changes in inflammatory cytokines which modify responses to stress and reactive oxygen species (ROS) signaling and damage. In studying postdevelopmental influences on aging in mouse transgenic models, artifacts caused by transgene expression during development can be mitigated by the use of conditional-expression transgenics, where gene expression can be experimentally turned on in adult life. The use of cell type and tissue type-specific

transgene expression and controlled genetic knockout (using the Cre-lox system) mitigates global expression issues, as well as developmental issues.

Lifetime random events including spontaneous mutation and epigenetic events can explain variation in longevity of lab rodents and may model human longevity variation. Long-term strain inbreeding within an institution can result in genetic drift that may alter strain-specific phenotypes and responses to manipulations. This random variation can be exploited to develop models of premature brain aging even within an inbred strain, using prematurely aging littermates or substrains that are 'biologically' but not chronologically older (see the section titled 'Accelerated aging models and the oxidative stress theory of aging'), illustrating that the phenotypes of aging and death do not necessarily develop chronologically.

Some lab rodent husbandry practices create selective pressure against disease-sensitive individuals by invoking the mandatory, humane euthanasia of 'suffering' animals in longevity studies. For example, age-related ulcerative dermatitis in C57Bl/6 mice, exacerbated by dominance hierarchy aggression, leads to submissive mice being culled from the population and dominant mice being 'selected.' Further, social housing strongly influences stress levels, both increasing them in male cages and decreasing them in female cages, with effects on learning and memory. The addition of an enriched environment to standard housing conditions can reverse the age-related decline in neurogenesis in the dentate gyrus. Uncontrolled variation in state of the animals at the time of (and, particularly, immediately before) sacrifice can blur effects on immediate-early responses, for example, phosphorylation cascades.

In humans, medicalization of aging (prevention or delay of lethal diseases, including that by hygiene) has contributed to increased longevity, which has also allowed expression of older age-related diseases like Alzheimer's. This raises the profound issue that 'normal' aging is clearly changing in modern humans. A link between lifelong inflammation and nutrition drove the adaptive influence of human diet changes in the distant past to increase longevity (see the section titled 'Apolipoprotein E'); however, this is drastically changing with the recent obesity epidemic in some Western cultures that will actually reduce the expected average human life span. A similar disconnect between evolved life history and current lifestyle of diet and medicalization occurs in laboratory rodents where they age in a stable caged environment at various pathogen-free levels (which limits immune system development and response) and are fed *ad libitum* low-fat, high-calorie, antioxidant diets containing soy estrogens and other compounds that are increasingly recognized for their ability to mask effects or create experimental artifacts.

The Role of the Brain in Aging and Life Span

The brain is a nexus of control systems linking organ systems and the environment that regulates and coordinates most somatic processes. It evolved as a regulator of food acquisition, energy metabolism, stress responses, and reproduction. Lethal disease processes of other organs can be induced or synergized by neurodegeneration. The brain, therefore, plays an important role in aging and in life span determination, for example, brain-specific knockdown of insulin-like growth factor 1 receptor (IGF-1R) increased life span (see the section titled 'Retarded aging and longevity extension models').

Rodent Strain Differences

Rodent strains differ in the pace of behavioral changes with age, and while ultimately phenotypically similar, might implicate fundamentally different processes. The types of strain-specific effects that would best reveal genes regulating behavioral aging are those that differ in both the rate of age-specific mortality and the rate of behavioral decline. For example, strains with shorter life spans like 129/SvJ and FVB mice seem more behaviorally vulnerable (temporal or specific vulnerability) to age-related changes than longer-lived C57Bl/6J. Further, neuronal aging at the levels of cell structure and neurochemistry, while largely studied in C57Bl/6J, show strain specific differences in vacuolar neuritic dystrophy, Ca-binding proteins, inclusion bodies, neurogenesis, neuron cell number in the hippocampal dentate gyrus, various neurotransmitters, and responses to the toxin kainic acid and ischemia.

Behavioral test performance is notoriously strain dependent. Even sublines of the C57Bl/6 strain, the J and Nnia substrains, may differ in age-related decline in Morris water maze learning, and 129/SvJ mice are poor performers in part due to their visual pathology. Further, mice and rats do not perform the Morris water maze in identical ways, particularly regarding the performance parameter that is used in probe trials. As a further testament to the value of rodent models in predicting human responses, the rodent-specific behavioral test, the Morris water maze of learning and memory, has been adapted to a virtual (computer-based) task for testing congruent age-related deficits in humans.

Genetic Contributions

Genetic variation accounts for that about one-quarter of the variance in adult human life span. Several of the genes known to influence rodent life span have important effects in the brain, including insulin-regulated genes and *SIRT-1*, *daf2*, *age1* (PI-3-kinase), *pit1/prop1* (pituitary), growth hormone-related genes, *PARP-1*, and *apoE* (see sections titled 'Retarded Aging and longevity extension models' and 'Glial influences'), to name a few, and many other candidates identified by microarray analysis. Although some senescent phenotypes can be similar between humans and rodents, they are occurring over a 30-fold difference in time; is this simply a quantitative difference in rate or are mechanisms qualitatively different? Gene expression microarray analysis of genes whose expression changes with aging in rat, mouse, and human brain (in different regions) has shown a surprising degree of agreement across these species. Among the few hundred changing genes, as many as 33% were identical between rat and human. These and other genes were in concordant categories of aging-related inflammation, oxidation, and glial processes, as well as novel (not primarily aging-related) categories like developmental regulation, structural plasticity (including *apoE*), signaling, transcription factors, lipid metabolism, and protein processing. This conservation of genomic responses across short- and long-lived species strongly validates the relevance of rodents to study age-related genetic, and by inference, physiologic, changes.

Hormonal Control

Two brain regions that interact through neuroendocrine modulation of learning and memory, the hypothalamus and hippocampus, are particularly central to aging and the control of longevity. Hypothalamic control of gonadal, adrenal, and endocrine hormones impacts functions of and aging in the hippocampus.

The hypothalamus The hypothalamus is the central regulator of endocrine system homeostasis, integrating somatic growth and development driven by pituitary and gonadal hormones, stress responses driven by glucocorticoid hormones, and nutritional and metabolic signals, all central players in the neuroendocrine regulation of life span. The two organ system axes, the hypothalamic–pituitary–ovary (HPO) axis (or more generally, hypothalamic–pituitary–gonad (HPG) and the hypothalamic–pituitary–adrenal (HPA) axis, are dramatically affected by and mediate age-related changes in the brain and fundamentally regulate aspects of somatic aging and longevity. The aging hypothalamus shows gene expression microarray changes in several gene ontogeny categories of neuronal structure, signaling, stress response, and metabolism (also see sections titled 'Accelerated aging models and the oxidative stress theory of aging,' 'Retarded aging and longevity extension models,' and 'Glial influences').

The HPO axis regulates reproductive aging. There is a well-established tradeoff between longevity and reproduction (simplistically recognized by Aristotle as each act of sex shortening life). Reproductive aging is central to life history evolution and the pleiotropic effects of gonadal hormones on brain functions of both neurons and glia. Reproductive senescence is driven by oocyte depletion, which depends on rodent strain and strain hybridization, and on random variation in embryonic oocyte number. Caloric restriction retards ovarian aging by reducing or delaying reproduction (see the section titled 'Caloric restriction'); this may be a selected response, adaptive in times of famine to preserve reproduction for later times of feast when reproduction success is greater.

Human postmenopausal loss of estrogen drives some cognitive changes. Postreproductive female rodents differ from humans most significantly in their elevated estradiol levels. Brain control of and responses to reproductive aging have been investigated using both hormone and genetic manipulation models. Modeling the human postmenopausal estrogen loss in rodents by ovariectomy (OVX) and comparing this to estrogen replacement has shown that estrogen loss accelerates reproductive senescence. Estrogen receptor knockout and transgenic mice have shown the short- and long-term effects of estrogen exposure on neurons and glia. Additional key elements identified in rodent reproductive decline are the age-related decline in follicle-stimulating hormone (FSH), which alters communication between the hypothalamus and pituitary, and the age-related change in luteinizing hormone (LH) secretion and loss of gonadotropin-releasing hormone (GnRH) neurons and systems that control them, which alter the HPG axis.

The HPA axis controls developmental growth and stress responses. This axis controls the lifelong basal and stress-induced glucocorticoid hormone levels, which are elevated with age in several rat strains, but not in C57Bl/6J mice, perhaps reflecting species-specific pathologies. Modeling adrenal hormone action by adrenalectomy (ADX) largely but incompletely eliminates glucocorticoid production. A well-studied target of glucocorticoid action is the hippocampus.

The hippocampus Aspects of age-related changes in hippocampal structure and function are partly

understood in terms of their responses to glucocorticoid and gonadal hormones and their roles in longevity. Rodent models of age-related changes in learning and memory, as assessed by hippocampal long-term potentiation (LTP) and long-term depression (LTD), are dramatically different among rat strains, where F344 show increased LTD with age and outbred Long-Evans show decreased LTD. A canonical change across all mammals is the age-related decline in the *N*-methyl-D-aspartate receptor (NMDAR) subunit NR2B, which may contribute to hippocampal decline in LTP and learning.

Neuron number in the hippocampus is relatively preserved with aging across all mammals; small changes are relatively region specific and rodent strain dependent. Historically, conflicting data are attributed to nonstandardized cell counting methods. Therefore, hippocampal atrophy with aging is attributed to the neuron cell atrophy and neurite and synapse loss. Neurogenesis of immature hippocampal granule cells shows age- and exercise-dependent changes in rodent models.

The entorhinal cortex input to the hippocampal dentate granule cells degenerates with age in humans and rats, which causes compensatory neurite sprouting in the hippocampus. This is experimentally modeled in rodents, albeit acutely, by various afferent lesions, and this recapitulates aspects of normal aging, including modulation by estrogen and impairment in aging female rat. Age-related decline in sprouting is due to defects in the aged target to which the sprouting neurite synapses, not to defects in the aged sprouting neuron, as shown in the model of implanting superior cervical ganglion tissue near the hippocampus and reciprocally varying the age of the ganglionic tissue (neurite source) or the host (hippocampal target) animal.

Estrogen stimulates neuronal function at many cellular levels, including neurogenesis, sprouting of neurites and spines, and molecular pathways. For example, aged rats do not respond to estrogen with increased spine formation in hippocampal CA1 neurons, perhaps simply due to receptor downregulation. Glucocorticoids cause neuronal and glial changes in the hippocampus of humans and rodents that contribute to cognitive changes during aging. Modeling age-related glucocorticoid exposure in rodents includes both acute and chronic treatment (e.g., hormone pellet implantation in the brain), ADX, and genetic knockout of a cortisol-regenerating enzyme. Effects and correlates of these manipulations include hippocampal atrophy, neuron pyknosis (cell body atrophy) and cell loss (pyramidal neurons), decreased neurogenesis, glial activation (hypertrophy, altered gene expression including protective changes in glial fibrillary acidic protein (GFAP) and transforming growth factor β-1 (TGFβ-1), and gliogenesis (see the section titled 'Glial influences')), and concomitant learning and memory impairments. Glucocorticoids are also the target of paradoxical regulation by caloric restriction (see the section titled 'Caloric restriction'). Rat strains differ in age-related losses of corticoid receptors in the hippocampus. The effects of developmental experience and stress on age-related hippocampal impairments are modeled in a paradigm of neonatal handling and maternal deprivation that results in reduced cortical brain-derived neurotropic factor (BDNF) in the adult rat. Therefore, uncontrolled differences in lab rodent rearing could also contribute to contradictory reports of neuronal loss with aging.

Accelerated Aging Models and the Oxidative Stress Theory of Aging

Accelerating aging models, while showing phenotypes similar to normal aging, are not necessarily driven by the same mechanisms as aging. They display only a subset of normal aging phenotypes, underscoring the greater complexity of normal aging, and show a preponderance of only one or a few disease pathologies. For example, genetically autoimmune mice, which challenge the historical doctrine of brain immune privilege by the blood–brain barrier, show age-related cognitive disability in acquisition of avoidance response that is related to the age of onset of their autoimmunity (biological age), while their retention deficit is related to chronological age.

Oxidative Stress Models and ROS

Normal brain aging is associated with decreased homeostatic reserve (allostatic load) in the metabolic triad of mitochondria-ROS-intracellular Ca. ROS is a molecular example of antagonistic pleiotropy, being controlled during normal development for its signaling effects, for example, those regulating neuroplasticity, but becoming deleterious in brain with age, due to declining resistance to its detrimental actions and its increased production (free radical theory of aging); these differ between humans and rodents. There is an optimal ROS level; therefore, drastic reductions in ROS metabolism, either genetically or chemically with high dose chronic antioxidants, can block its beneficial activities. Genetic models of oxidative stress in the aging brain include knockout of the excitatory amino acid carrier-1 gene which impairs glutathione metabolism, knockout of the p66-Shc gene (an adaptor/signaling protein regulating ROS metabolism) which extends life span 30% and prevents increased emotionality and pain sensitivity, and knockout of the hexosaminidase B gene which models

the accelerated aging in human Sandhoff disease caused by lysosomal glycosphingolipid storage dysfunction, producing premature neurodegeneration involving microglia activation and oxidation, and which also partially responds to caloric restriction.

The Senescence-Accelerated Mouse

The senescence-accelerated mouse (SAM) was established by phenotypic selection of spontaneous, prematurely senile, and short-lived littermates of the AKR/J strain; SAM-prone (SAMP) and SAM-resistant (SAMR) littermates were separately inbred. The SAMP8 and/or SAMP10 show age-related learning and memory deficits, mood disorders, other cognitive impairments with associated biochemical and synaptic changes, peripheral amyloidosis, altered blood–brain barrier, region-specific brain atrophy (mostly in cortex, but not hippocampus), and neurotransmitter-specific (cholinergic) neuron atrophy. Cognitive impairments in SAMP8 are correlated with oxidative stress and are corrected by antioxidants, implicating fundamental, age-related oxidative stress mechanisms involving defense enzymes (superoxide dismutase (SOD), glutathione, catalase), with downstream effects on neurotrophic factor expression (glial-derived neuronal factor (*GDNF*), neurotrophin-3 (*NT-3*), nerve growth factor (*NGF*)), lipid peroxidation, protein oxidation (as detected by proteomics), and defects in energy metabolism. Microarray and specific gene analyses show involvement of oxidative and stress response genes, including those regulating signaling, energy metabolism, immune response, cytoskeleton (increased tau and its hyperphosphorylation), and decreased apoE and glucocorticoid receptor subunit expression.

Retarded Aging and Longevity Extension Models

Models that increase longevity may be more informative about aging mechanisms than accelerated aging models, because increased population life span is likely to be achieved by modulating multiple age-related mechanisms, particularly in hybrid or outbred strains that die of multiple causes (see sections tilted 'Rodents as models of aging' and 'Caloric restriction'). With the definition of normal aging that excludes disease, the distinction between slowing aging and inhibiting or delaying disease must be carefully considered, since preventing one relatively common lethal disease can apparently extend population life span without modifying fundamental aging processes.

Genetic Models

Several genetic models with increased longevity involve the insulin/IGF-1/growth hormone (GH) pathways, suggesting that chronological longevity is extended by inhibiting growth pathways and by increased protection from stress. Life span extension has been achieved in mice by genetic mutations in the genes including p66, *FIRKO* (insulin receptor), and *IGF-1R* (in females only). IGF-1 control of brain cell growth, neuronal myelination and sprouting, and astrocyte activation (including GFAP induction) in development and injury-response regeneration has been shown to depend on the cellular site of its expression, by comparing neuron-specific and astrocyte-specific inducible-expression transgenics. In mice, the specific role of brain expression of IGF-1R on life span and mortality was elegantly shown by genetic knockdown of the IGF-1R gene (by brain-specific Cre-lox-mediated heterozygous knockout), producing a brain hypo-sensitive to IGF-1 that had increased life span and decreased mortality.

The pituitary is specifically implicated in growth-associated longevity effects. Various hypopituitary long-lived dwarf mice (Ames and Snell) support the model of antagonistic pleiotropy in normal brain aging and age-related decline in cognition by counteracting this effect through delayed puberty. *GH* knockout mice have preserved learning and memory even with aging, while *GH* transgenic mice age faster with earlier puberty and faster cognitive decline. Dwarf and GH-resistant mice (*GH* receptor knockout) implicate multiple complex mechanisms and abnormalities, including insulin supersensitivity (decreased insulin and hippocampal *IGF-1* expression), ROS, lipids, carbohydrates, stress, and age-related disease. Many effects are gender, diet, and strain dependent.

Caloric Restriction

Caloric restriction (CR) is a well-established method of life span extension with significant, possibly contributing effects in the brain. CR may represent a more natural diet for rodents and *ad libitum* may cause overfeeding-induced stress (see the section titled 'Rodents as models of aging'). Its intense study has informed that energy metabolism (glucose and ketones), signaling pathways of insulin, IGF-1, and GH, and ROS metabolism impact fundamental aging processes as important subsets of normal aging changes. CR slows fundamental processes of aging that affect the rate of development of multiple diseases, although other mechanisms are implicated in brain. Life span extension by CR is influenced by strain-dependent pathologic diseases and lesions and by gender, including variation in reproductive aging and the hypothalamic and pituitary control of estrus cycling.

CR extends life span in all organisms up to rodents. However, in primates and humans, fundamental

differences in life history evolution and the set points of metabolic stability and ROS metabolism have argued against predicted efficacy. A human clinical trial was initiated in 2002 by the National Institute on Aging (NIA) (called CALERIE) which has shown some neuroendocrine and pyschophysiologic benefits. CR mimetics or intermittent (hormetic) CR may be much more practical for humans, in particular for brain aging. Mimetics of CR can target glucose, insulin, oxidation, and inflammation and can be quickly identified by their induction of short-term (8-week) CR-like gene expression profile responses. The NIA tests candidate compounds for mean and maximal life extension and/or health improvement in hybrid mice with genetic heterogeneity (HET mice) and pathologic diversity, which will include cognitive testing.

Many of the beneficial effects of CR can be linked to effects on the nervous system with specific effects on age-related changes in neuroendocrine and sympathetic systems, glia, vasculature (constriction and microvessel loss), hippocampal volume (gliogenesis, but not neurogenesis), synaptic efficacy, and neurotrophic factors, particularly BDNF. CR attenuates or reverses several age-related glial responses, including the increase in hippocampal astrocyte activation and *GFAP* expression (see section titled 'Glial influences'), the region-specific modulations in *apoE* and *apoJ* mRNA in hybrid rats, and microglial activation, by several mechanisms including reducing proinflammatory inducers like advanced glycation end products and promoting anti-inflammatory effects of cortisol on cytokine gene expression. Glucocorticoids are paradoxically increased with CR in rats in response to reduced plasma cortisol binding globulin, which suggests that the neuroprotective effects of CR (including increased BDNF and attenuated microglial activation) outweigh deleterious effects of increased glucocorticoids; however, generalizations are limited because rodent species differ in the relationship between age-related cortisol and cognitive impairment. Further, while CR protects some age-related neuron loss in the periphery (enteric and retinal, and motor neurons), effects of CR on brain neuron number, particularly in relation to elevated glucocorticoids, have not been assessed. Limited studies show that CR has opposite effects on different neuronal population in the hypothalamus, protecting the age-related loss of IGF-1R neurons but inducing the loss of other populations, and in the hippocampus, CR does not impact age-related decline in neurogenesis of granule cells but does promote the survival of newborn glial cells. CR impacts aspects of oxidation and stress responses, including inducing the neuroprotective actions of heat shock protein-70 (HSP-70) and attenuating its age-related loss that involves Ca, ROS, and cell death. Proteomics of CR effects in brain have identified the striatum and hippocampus as particularly benefiting, with lowered oxidized proteins. Several neurodegenerative disease models show beneficial effects of CR, including region-specific neurotoxicity of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridire (MPTP) (substantia nigra) and kainate (hippocampus), both dependent on BDNF. The BDNF knockout (conditional) mouse shows alterations in several CR-relevant systems including stress, glucose, and insulin.

A central question is whether CR impacts the same mechanisms that drive normal brain aging. Comparison of age- and CR-related gene expression profile changes in brain showed that most of the changed neurotrophic-like genes were dissimilar, suggesting that CR achieves brain effects and perhaps longevity by mechanisms distinct from or only partially overlapping normal aging. A gene that could be central to mediating CR effects on longevity and in models of age-related neurodegeneration is sirtuin 1 (*Sirt1*), the homolog of the yeast longevity gene *sir2*, which regulates genes involved in nutrient sensing, cell cycle, and DNA repair.

Glial Influences

Astrocyte and microglial phenotypes vary in a continuum from resting to reactive, playing both protective and deleterious roles in neurodegeneration and in aging. A major controversy is whether age-related changes in glia induce neurodegeneration or are simply a response to aging-induced neurodegeneration. The inability to co-localize activated microglia with neurodegeneration argues against the latter hypothesis, in some models. Microglial number and activation state increase with age across all mammals; in one strain (C57Bl/6NNIA), glial cells increased only in females. Astrocyte activity affects the permissiveness for neuroplasticity and repair in the brain, as suggested by the age-dependent activities of astrocyte genes *GFAP* and *apoE*. They act in membrane structure (GFAP) or in lipid trafficking and signaling (apoE), contributing to the multiple pathways for regeneration in the brain and its age-related manifestations, including the suppression of reactive gliosis by estrogen regulation of their genes.

Glial Fibrillary Acidic Protein

GFAP is an intermediate filament protein integral to cytoskeletal dynamics regulating the morphology and function of astrocytes including astrocyte reactive responses during aging. GFAP is consistently upregulated with age across rodents and humans and is a surrogate marker of aging in the brain, as indicated

by unbiased microarray analysis of various brain regions across rat, mouse, and human species. The conservation of transcription control elements in the *GFAP* promoter across rat, mouse, and human species implicates this gene in canonic features of brain cell aging across both short- and long-lived species. *GFAP* also responds in caloric restriction (see the section titled 'Caloric restriction'). Human and mouse GFAP protein have similar activities, as shown by the phenotypes of mice whose *GFAP* coding region is replaced by the human *GFAP* sequence.

In modeling the age-related increase in *GFAP* expression, *GFAP* overexpressing mice show an earlier onset of the gene expression profile changes that characterize normal brain aging in mice and age-related changes that suggest a temporal relation between astrocyte and microglial activation where the former precedes the latter. The profile of expression responses shows increased stress, immune activation, oxidation, and inflammation and decreased neuronal plasticity and development genes, indicating that increased *GFAP* expression can initiate a cascade of changes that affect all other cell types in the brain. Age-related phenotypic changes in astrocyte reactivity, including increased *GFAP* mRNA, persist in *in vitro* astrocyte culture and affect neurite sprouting of co-cultured neurons. This supports the direct role of age-related astrocyte dysfunction in neurodegeneration with age.

GFAP regulates neurite and synaptic morphology, since various means of reducing its expression increases neurite sprouting. *GFAP*-knockout (ko) mice show enhanced neurite sprouting and (in combination with vimentin-ko) show increased posttraumatic regeneration and neurogenesis, an effect reproducible in an *in vitro* lesion model. *GFAP*-ko mice show abnormal, late-onset myelination, which models aspects of the human disease (Alexander disease) caused by *GFAP* mutation. Estrogen downregulation of *GFAP* controls its activity in regulating morphologic changes of astrocyte end foot processes that displace hypothalamic neuron synapses or neurites that in turn regulate endocrine hormone release during the estrus cycle. Loss of gonadal hormones with age may result in increased reactive gliosis and reduced neuroplasticity, as shown in models of stimulated neurite sprouting in both *in vitro* and *in vivo* lesion recovery models using OVX and estrogen replacement.

Apolipoprotein E

ApoE is a major lipoprotein that primarily regulates lipid metabolism but has pleiotropic activities. Of the three common human alleles, *apoE2* is rare and is associated with increased longevity, *apoE3* is the most common, and *apoE4* strongly increases risk for several diseases and disorders, including cardiovascular disease and neurodegenerative disorders, particularly Alzheimer's disease (AD). Extensive human studies show apoE4 effects on milder and mid-life aspects of cognitive impairment, which are modeled in apoE4 transgenic mice.

Human *apoE* alleles evolved as part of changing life history evolution, where the ancestral *apoE4* allele was adaptive for the lower calorie, lower fat diet of early humans, while the common allele *apoE3* became adaptive with increased dietary meat by decreasing cholesterol metabolism. This may underlie the current pandemic of obesity-induced cardiovascular disease caused by the mismatch between current diet and exercise trends and the adapted apoE3 activities and maladaptive apoE4 activities in lipid metabolism. In addition to causing a decline in human longevity, this could also alter 'normal' human brain aging.

ApoE knockout and human isotype transgenic mouse models ApoE function has been studied using the *apoE* knockout mouse (*APOE*-ko) and transgenics expressing human apoE isotypes, usually on the background of mouse *APOE*-ko. While *APOE*-ko and rare humans lacking apoE develop to adulthood with relatively minor cognitive impairments, in the aging brain, compensatory pathways may become ineffective or insufficient, increasing the reliance on apoE activity to maintain plasticity, revealing defects in apoE4. *APOE*-ko begin to show neurodegenerative changes at 5–6 months, with defective LTP and loss of dendritic cytoskeleton and synaptic markers; some effects are background strain dependent.

A major issue in understanding apoE biology in the brain is defining which cell types produce apoE, which is determined by the transcription promoter regulation. Humans express apoE in both glia and at low levels in neurons. Mouse apoE is expressed in basal conditions only in glia, but can be induced in neurons by cytotoxic challenge. There is a critical functional trafficking and cellular localization difference between receptor-mediated uptake of apoE and actual production of apoE within the neuron. The human-like neuron expression of apoE is replicated in mouse transgenics driven by the human apoE promoter (human genomic promoter, HGp transgenics). To evaluate which cellular production site is relevant to detrimental effects of apoE4, transgenics driven by cell type-specific promoters limit expression to neurons using the neuron-specific enolase (NSE) promoter (NSEp transgenics) or to astrocytes using the GFAP promoter (GFAPp transgenics). The caveat with these mice is that the cell-specific expression of

apoE is either abnormally high in NSEp transgenics or unnaturally regulated in GFAPp transgenics. This caveat is partly addressed by the newest transgenics in which the endogenous mouse apoE promoter drives expression of the human apoE isotypes (the targeted replacement transgenics, TR). These mice are ideal in that they recapitulate the human brain region-specific levels of apoE, and equivalent levels among the three isotypes, but do not show the human-like neuronal basal expression of apoE.

All human apoE isotype transgenic mice (except TR) are maintained on the, *APOE*-ko background, which has severe peripheral hypercholesterolemia with a potential influence on brain and blood–brain barrier functioning. The brain cell-specific expression transgenics (GFAPp and NSEp) maintain the peripheral hypercholesterolemia, while the genomic transgenics (HGp) correct it; although TR mice are not on the, *APOE*-ko background, they show marked isotype-specific differences in peripheral apoE levels. *APOE*-ko show disturbed blood–brain barrier permeability and increased susceptibility to microvascular disease, which contributes to the more severe responses to acute ischemia and stroke models by, *APOE*-ko and apoE4 transgenics (HGp and TR), and which is relevant to similar responses in humans and to the regional glucose utilization defects seen in human positron emission tomography (PET) studies.

Considering the definition of 'normal' brain aging and the role of apoE isotypes, there is an important distinction in transgenic models between what is normal for a mouse (with mouse apoE) and what is normal for a human (defined by the phenotype of the common allele apoE3). Comparisons of wild-type C57Bl6/J mice with isogenic apoE3 transgenics (on, *APOE*-ko) have revealed some similarities in phenotypes, but also some very important differences indicating that mouse apoE is not consistently like human apoE3 or apoE4. However, some clear congruencies between apoE transgenics and humans have been identified, for example, apoE4 in elderly humans and middle-age transgenic mice both show reduced hippocampal neuron dendritic spine density.

Compared to, *APOE*-ko mice, apoE4 shows phenotypic gain-of-negative activities in inhibiting neurite sprouting, mortality from head injury, and amyloid deposition, and loss-of-function activities in inhibiting astrogliosis, age-related dendrite loss, age-related synapse marker loss, resistance to excitotoxicity, and defective LTP. For age-related memory loss, neuronal expression (NSEp) shows a loss-of-function while astrocyte expression (GFAPp and TR) show a gain-of-negative function. This phenotypic distinction has important implications for the design and administration of drugs that target apoE activity or expression in that a gain-of-negative function of apoE4 would be exacerbated by a drug that increased apoE expression, while a loss-of-function would be rescued. Indeed, pharmacologic attempts to correct age-related disease processes including cognitive disorders, for example, lipid normalization by statins, antioxidants, hormone replacement therapy, fish oil, insulin sensitizers, and other treatments for AD, have shown apoE genotype-dependent efficacy, where apoE4 are nonresponsive.

Effects of human ApoE isotypes on aspects of brain aging ApoE has pleiotropic effects on brain and neuronal functioning, including lipid metabolism, neurite sprouting, gender-specific effects, multiple signaling cascades, LTP, inflammation, oxidation, neurotoxicity, and neurotrauma. ApoE4 accelerates the age-related change in the differential distribution of lipids between cytofacial and exofacial leaflets of the bilayer, which affects membrane fluidity and lipid raft microdomains. Rodent models of brain aging should carefully consider dietary lipid composition for its effects both developmentally (maternal diet) and in aging, particularly the age-related reductions in the essential omega-3 fatty acid docosahexaenoic acid (DHA) (see the section titled 'Rodents as models of aging'). *APOE*-ko and apoE4 show defective neurite sprouting and other aspects of neuronal plasticity, including age-related loss of synaptic markers, shown at levels from *in vitro* neuron cultures to organotypic cultures of hippocampal slices (derived from apoE isotype transgenic mice), to *in vivo* reactive neurite sprouting responses in all the promoter forms of transgenic mice. This effect models aspects of human aging in cognitively normal individuals where dentate spine loss is greater, and compensatory sprouting (in AD) is reduced or nonexistent in apoE4.

Gonadal hormone regulation of the apoE gene and its interaction with the effects of the apoE4 isotype are a paradigm of life history evolution caused by adaptive changes in diet and reproduction (somatic theory of aging). Gonadal hormones, particularly estrogen, modify apoE4 effects, both in atherosclerosis and in cognitive disorders, resulting in a greater susceptibility of females in humans and in mice to the age-exacerbated impairments in learning and exploration seen in NSEp and GFAPp mice. This occurs in brain regions that undergo estrus cycle synaptic remodeling. Conversely, estrogen's neurotrophic effect of stimulating neurite sprouting is modified by the age-dependent increased apoE expression, as shown in a rat OVX/estrogen replacement model of sprouting where the absence of apoE (*APOE*-ko mice) prevents estrogen stimulation of neurite sprouting. In addition, effects of

male androgens on learning, memory, and recognition are altered by apoE4 as shown by castration studies (NSEp) and in androgen receptor functions.

Inflammation, like lipid metabolism, is a common feature of apoE-related mechanisms in both vascular and cognitive disease with the involvement of the common cellular element, the macrophage or microglial cell, respectively; however, it is important to distinguish between adaptive versus pathological effects. ApoE is generally anti-inflammatory, its production being repressed during the cytotoxic phase of the innate immune response and promoted during the repair phase, and inflammatory challenges including age-dependent changes in the HPA axis have more severe behavioral effects (memory and anxiety) in *APOE*-ko and apoE4 mice. Inflammatory effects of apoE4 (TR) implicate activated microglial and astrocyte production of ROS, glutamate, proteases, and inflammatory immune factors like interferon gamma (INFg), NO, tumor necrosis factor-α (TNF-α), and interleukin 1 beta (IL-1b), and their feedback regulation on apoE production, including regulation by anti-inflammatory factors TGF-β and estrogen, and reversal of anti-inflammatory effects of testosterone.

Neurotoxicity of apoE4 is linked to several of its other pleiotropic activities, for examples, proteolytic fragments of apoE4 are formed and are neurotoxic only when apoE4 is expressed in neurons (NSEp) but not in astrocytes (GFAPp), hyperphosphorylation of tau (NSEp), poor antioxidant activity (where $E4 < E3 < E2$), greater microglial activation, and differential effects on cell signaling including extracellular signal-regulated kinase (ERK) and AKT. BDNF and its signaling effects are implicated in apoE4 effects on cognitive responses to environmental enrichment and head trauma in transgenic models.

Conclusions and Relevance to Human Brain Aging

Rodent models of aspects of brain aging provide valid tools to understand the roles of select components and their interactions. However, studying the intersection of the two most complex biological phenomena is not well elucidated in the reductionist approach. Rodent models are strongly validated by the multiple levels of congruence with human brain aging, largely due to their common phylogeny. However, significant differences preclude the use of lab rodents to fully understand human aging, particularly fundamental differences in dietary energy sources and utilization, reproductive aging, and temporally accumulated stochastic events that feed evolutionarily established responses of antagonistic pleiotropy in middle and later ages. Differences even between and within rodent species and strains imply that human–rodent differences are much greater than is currently understood. Genetic manipulations intended to target adult-related processes can have developmental artifacts, particularly in gene knockout and quasi-controlled transgenics. Conditional knockouts and expression-controlled transgenics eliminate such developmental artifacts and control the temporal and dose-dependent influences of gene expression.

Introduction

Understanding the neural mechanisms of complex behavior, as well as the abnormalities in behavior that accompany psychiatric and neurologic disorders, represents one of the most formidable challenges in biomedical research today. Our very limited knowledge of the neural basis of behavior means that this endeavor must rely, to a unique extent, on *in vivo* studies. The human and mouse genome projects, coupled with an impressive array of molecular genetic technologies to manipulate expression of individual genes within the brain through mutagenesis and viral-mediated gene transfer, have provided unprecedented opportunities for investigating the influence of genes on behavior. In contrast, behavioral assays, and their application to large numbers of animals, have not kept pace in terms of throughput with the rapidly escalating use of genetic manipulations in mice. There is also a need for higher-throughput behavioral assays to screen increasing numbers of potential medications targeted to an increasing array of neural proteins. Similarly, the difficulty of current central nervous system (CNS) drug discovery strategies, where behavioral analysis of a potential medication comes late in the process, to develop psychiatric medications of fundamentally new mechanisms of action has led to the suggestion that behavioral testing should occur sooner. This, too, would require tests of increased throughput. Here, we briefly describe this challenge and review some of the innovative solutions that are in development to relieve the bottleneck in behavioral assessment. Such approaches may not only improve throughput but also provide new insights into the regulation of rodent behavior that are not approachable with conventional assays.

Types of Behavioral Assessments

Behavioral assays in psychopharmacology have been categorized into three classes: animal models of clinical disorders, behavioral screening tests, and behavioral bioassays. Animal models of clinical disorders are attempts to simulate symptom clusters characteristic of particular diseases. Screening tests are used to assess the impact of genetic and pharmacological manipulations on behaviors chosen to reflect particular behavioral processes of interest. For example, the forced swim test and elevated plus-maze are used to screen compounds and genetic mutations for their relevance to depression or anxiety, respectively. Alternatively, some behaviors are used as bioassays to assess the activity of particular neural pathways. Examples of such behavioral bioassays include circling behavior to test function of the brain's dopaminergic systems and head-twitch responses to serotonin receptor agonists as a measure of serotonin 5-HT2 receptor sensitivity.

Multiple behavioral assays have been used for decades to learn a great deal about the neural basis of behavior. It has become apparent, however, that there are fundamental limitations in their application to neural processes related to psychiatric and neurologic disorders and CNS drug discovery. Although *bona fide* animal models of neurologic diseases are becoming increasingly available as known disease-causing genetic factors are reproduced in mice, such models are not available for most psychiatric conditions because of the relative lack of knowledge of the specific genetic as well as nongenetic factors that cause these illnesses. In addition, it has become increasingly clear that accurate interpretation of individual behavioral tests can only be achieved in the context of a thorough set of behavioral assessments, as described in the next section.

Animal Models of Psychological Processes

Genetic and pharmacological influences on psychological processes must be inferred from their effects on observable behavior, but several factors complicate our ability to draw inferences about a rodent's psychological state from behavioral data (Table 1). The elevated plus-maze and Morris water maze are good examples of this. The plus-maze, a commonly used test of anxiety-related behavior, measures a rodent's avoidance of open or brightly lit places. In this test, animals are given a choice between narrow elevated platforms that are either walled or open. The predisposition of animals to prefer the walled arms is thought to correlate with anxiety state. The assay has some predictive validity for the identification of compounds with anxiolytic actions in humans. For example, benzodiazepines such as diazepam, which are anxiolytic in humans, increase the rodents' time in the open, brightly lit areas. Like many rodent behavioral assays, the plus-maze was originally validated in rats and more recently adapted to mice.

Table 1 Experimental approaches to behavioral assessment

Approach	*Advantages*	*Disadvantages*
Standard tests	Extensive pharmacological validation available Relatively simple and rapid to administer	Risk of data misinterpretation Limited etiologic and pathophysiologic validity Certain assays have low throughput Serial tests have very low throughput and require large numbers of animals
Batteries of standard tests	Pharmacological validation available Reduced numbers of animals required Data interpretation improved by assessing diverse behaviors	Limited etiologic and pathophysiologic validity Certain assays have low throughput Test order may confound results
Naturalistic assays	Behaviors assessed in a more ethologically valid context Reduces misinterpretations of behavioral responses Wide range of complex species-characteristic behaviors may be elicited	Low throughput May be time-consuming to establish assay conditions for certain behavioral processes Lack of widespread experience with these approaches for mice Requires extensive pharmacological validation
High-throughput screens	Capable of very high throughput Potential for detecting novel behaviors	Limited etiologic and pathophysiologic validity Some rely on limited tests, increasing incidence of false positives and false negatives Require extensive pharmacological validation
Quantitative home cage behavior analysis	Effects of handling and novelty minimized Assesses multiple behaviors over long time intervals Potential for detecting novel behaviors Relatively low labor costs	Need for chronic housing links throughput to number of available cages Requires substantial computational resources May be time-consuming to establish assay conditions for certain behavioral processes Requires extensive pharmacological validation

This is also the case for the water maze, a commonly used assay of spatial learning and memory. In a typical procedure, animals are placed within a circular pool of opaque water and must swim to a submerged platform. If the platform position remains constant, the animal's performance improves over the course of repeated trials, as indicated by reduced latencies to find the platform. Presumably, efficient performance in this task reflects a spatial memory process engaging a navigation strategy guided by visual cues. Spatial learning is verified in a subsequent 'probe trial,' in which the animal swims during a trial with the platform removed; preference for the prior platform location is viewed as a measure of spatial learning. Drugs that disrupt cognitive function impair performance in the water maze. However, the ability to demonstrate the converse – improvement of cognitive performance – is limited based on the current lack of availability of potent cognitive enhancing agents, with today's agents producing modest effects in the water maze, as they do in humans as well.

There are several sound reasons for the popularity of the elevated plus-maze and Morris water maze. Compared with other assays of similar psychological processes, these tests are simple and rapid to perform. The tests also have been pharmacologically validated with available agents, as mentioned previously. Moreover, a large literature addresses the contributions of neural circuits that regulate an animal's performance in these assays. Nevertheless, there are several limitations in the way in which such tests are sometimes interpreted. One limitation relates to a lack of accepted and standardized protocols. Interlaboratory variations often exist in both the testing apparatus and the procedures used. Often, results from one group cannot be compared to the results from another group because of such methodological differences. A second limitation is that the results of individual behavioral assays may be readily misinterpreted when they are conducted in isolation. For example, an undetected cognitive deficit interfering with the processing of contextual cues could cause abnormal performance in the elevated plus-maze. Potential perturbations of sensory perception (e.g., blindness), activity levels, or motor coordination could also lead to misleading results. Analogously, performance in the water maze can be influenced by many factors, including prior testing experience, motor impairments, abnormal stress responses, motivational state, visual problems, and perturbed thermoregulation. These considerations underscore the importance of not relying on any one assay in making a claim regarding the psychological basis of a behavioral phenotype. The evaluation of a diverse array of

behavioral domains improves the extent to which each individual assay may be correctly interpreted.

One common approach to obtaining a comprehensive behavioral assessment is to run cohorts of mice through batteries of multiple behavioral assays (Table 1). Examples include the SHIRPA protocol and PsychoScreen (PsychoGenics, Inc.; http://www.psychogenics.com), which involve an initial neurologic assessment followed by a series of standard tests of motor function, analgesia, stress responses, and cognition. Although this is a very important and useful approach, particularly given the limited numbers of mutant mice or amount of novel compounds typically available, behavioral test batteries present an additional set of caveats. First, they are time-consuming and labor-intensive, limiting their throughput, as discussed later. In addition, the extent to which prior behavioral testing influences test performance is often not examined. For example, studies have compared the performance of naive mice in the Morris water maze and elevated plus-maze with the performance of animals in which these tests were administered within the context of a behavioral battery. In one case, mice tested in the water maze within a battery did not show spatial selectivity for the platform location, whereas naive mice did so. In the elevated plus-maze, C57BL/6J mice displayed major differences in open platform time depending on whether they were tested within a battery or in the naive state. In the latter study, the test battery did not alter elevated plus-maze behavior in 129S2/Sv mice, indicating that testing order can interact with genetic background to further complicate the interpretation of behavioral phenotype data. Thus, limitations of individual assays and behavioral batteries of tests highlight the need for innovation.

Relevance of an Ethological Perspective

One way to improve the interpretation of behavioral tests is to consider them within an ethological perspective. As developed in the mid-twentieth century by investigators such as Konrad Lorenz, Niko Tinbergen, and Karl von Frisch, the discipline of ethology focuses on detailed analyses of the diverse sets of behaviors seen in animals in their natural habitats. Connotations of the term 'ethological' vary widely among investigators, and some would find it inappropriate to apply the term to studies in laboratory settings with genetically defined animals that do not exist in the wild. Regardless of whether the term may be applied to such studies, their interpretation may nevertheless be enhanced by insights that have been provided by ethology. Often, standard behavioral assays are considered in a rigid manner without regard to species-typical behaviors seen during testing. For example, mice placed directly on the open arm of the elevated plus-maze may show freezing behavior, recognized by ethologists as a characteristic response of rodents to threatening stimuli. Although this could result in increased open-arm time, it would be a mistake in this case to conclude that the animal showed reduced anxiety-like behavior. Ethological considerations can also complicate attempts to adapt rat behavioral assays for mice. As just one example, differences in the natural habitats of rats and mice have been implicated in the relatively poor performance of mice in the Morris water maze procedure. Given that rats may be better adapted to wet habitats, their superior performance in this task may relate more to task suitability than to cognitive differences.

An additional aspect of rodent behavior that is receiving increased attention relates to the fact that the behaviors of both rodents and humans are influenced by their social organization. For example, group housing of male mice can result in the formation of dominance hierarchies, which can affect many behaviors and provides an additional source of variability in behavioral studies. Attempts are underway to develop approaches to the efficient testing of interactions between same- and opposite-sex conspecifics. The value of considering social context is highlighted by work indicating that a rodent's behavioral adaptations (or maladaptations) to chronic social stress may be more relevant to stress-related disorders in humans than the various types of physical stress used in most studies.

Several groups are applying naturalistic approaches to the analysis of mouse behavior. For example, a population of mice was derived from the offspring of several laboratory strains that had been released into a 400 m^2 outdoor pen in western Russia and subjected to natural selection. Experimental subjects were captured in the enclosure, implanted with microchips for tracking, and re-released into the pen, which contained automated feeding monitors. The system enabled observations relevant to foraging strategies, social organization, and diurnal patterns of activity. A smaller modified version of this approach was used to reveal differences in foraging strategies in trkB receptor mutant mice. (TrkB is a neurotrophin receptor implicated in cognitive function and mood.) Such approaches provide opportunities for insights into mouse behavior that are not available under standard laboratory conditions.

Another example is the Mouse Defense Test Battery, used for assessment of anxiety-related behavior. In this assay, mice are placed in a test alley and approached with an anesthetized rat, a natural predator of mice that triggers unconditioned aversive reactions. A series of species-typical behaviors is assessed, including flight,

freezing, risk assessment (e.g., repeated episodes of extending and withdrawing the body in the direction of the threat), and defensive threat and attack responses. Factor analysis of these behaviors showed four factors that were differentially modified by a series of anxiogenic and anxiolytic drugs. Such approaches that more fully account for the variety of behaviors seen in mice in threatening situations hold promise for modeling several aspects of anxiety responses. However, practical challenges to implementing such naturalistic approaches for high-throughput screening have limited their widespread use.

Mouse Models of Psychiatric and Neurologic Disorders

A major determinant of the quality of an animal model of a human disorder relates to the degree to which it reproduces the disorder's pathophysiology. Mouse models have been particularly useful for studies of disorders whose underlying genetic causes have been identified in humans (e.g., neurodegenerative diseases such as Alzheimer's, Parkinson's, and Huntington's diseases, amyotrophic lateral sclerosis, hereditary ataxias, frontotemporal dementias, multiple sclerosis, and prion diseases). Mice with disease-causing mutations show some, but not all, of the neuropathological and behavioral abnormalities seen in humans, and these abnormalities have served as critical endpoints for assessing the potential clinical utility of novel therapeutic agents. These mutant mice have also been useful for genetically dissecting individual steps in the biochemical pathways responsible for disease pathogenesis. Most behavioral analyses of these models have focused on assays of motor function and cognition. It is noteworthy that many of these disorders also involve abnormalities in affect, diurnal rhythms, and impulsivity that may precede cognitive and motor symptoms. Accordingly, a study of mice with scrapie and bovine spongiform encephalopathy revealed impairments in circadian activity and open-field exploration prior to the onset of motor abnormalities. It is therefore likely that the application of comprehensive behavioral analyses to these models will improve their sensitivity and promote insights into the pathophysiology and treatment of these neurodegenerative disorders.

In striking contrast, the prospects of developing *bona fide* animal models for most psychiatric diseases are complicated by at least four major considerations. First, in comparison to neurodegenerative diseases, there is a relative paucity of definitive information regarding causal genetic factors, making the generation of mouse models difficult. Second, the precise contribution of environmental factors to the pathophysiology of these disorders remains poorly understood, precluding the production of convincing models through environmental manipulation. A third consideration relates to clinical diagnostic limitations: a great deal of heterogeneity exists among the symptom clusters of individuals sharing a common diagnosis (e.g., depression or schizophrenia), and many are not readily classifiable using standard criteria. Uncertainty regarding the clinical features of the human syndromes to be simulated obviously complicates the validation of animal models. Finally, many of the hallmark features of the human disorders pose a daunting challenge for the mouse psychiatrist. Unanticipated breakthroughs would be required to convincingly model phenomena such as guilt, religiosity, grandiosity, envy, delusions, hallucinations, grief, body image distortion, and multiple personality in the mouse.

One partial exception to these limitations is drug addiction, in which at least one of the key etiological agents – the drug – is clearly identifiable and key features of the behavioral pathology (drug self-administration) are readily measured in rodents. Progress has also been made in modeling cardinal symptoms of human addiction, such as drug craving, in rodents, although assessing whether a mouse 'wants' a drug remains challenging.

Although most behavioral models of psychiatric disorders, other than addiction, are unconvincing as disease simulations, they may nevertheless prove useful for exploring the neural basis of particular manifestations of these disorders. Thus, it is possible to model specific symptoms of a psychiatric illness (loss of appetite and disrupted sleep) even if modeling the entire syndrome is not yet feasible. In addition, many available behavioral tests have predictive value for potential medications. This can be illustrated by the forced swim test, an assay used to screen antidepressant compounds. Animals are placed in a water-containing cylinder from which they cannot escape. Initially, mice make apparent attempts at escape, but over time these give way to periods of immobility when they float at the water surface. This immobile state is proposed to reflect 'behavioral despair' – the loss of hope of escaping. Compounds that reduce immobility times have an increased likelihood of antidepressant efficacy in humans. Nevertheless, the etiologic and pathophysiologic validity of this test – that is, the extent to which the mouse resembles a depressed human, or the centrality of swim stress to human depression – is unconvincing, particularly because immobility could be viewed as an adaptive strategy in this experimental context. Therefore, if a mutation is found to result in decreased immobility time, it is risky to conclude that the mouse is 'less depressed.' A more conservative interpretation would

be warranted – that the animal has a behavioral abnormality associated with responsiveness to swim stress and antidepressants. Despite these limitations, the forced swim test has clear predictive validity, indicating that an understanding of its mechanistic basis may shed light on the function of neural pathways pertinent to the treatment of depression.

Behavioral Screening: The Problem of Throughput

The need for high-throughput behavioral screening procedures is illustrated by two endeavors: (1) the application of large-scale mutagenesis approaches for detecting genes that regulate behavior and (2) the use of behavioral testing for CNS drug discovery. Enthusiasm for chemical mutagenesis approaches has led to the establishment of international mutagenesis centers that include behavioral screening within their panels of phenotypic assays. The thousands of mutants produced yearly by these programs could provide an invaluable resource for the exploration of genetic influences on behavior. Currently, limitations in the availability of comprehensive behavioral test strategies that can be administered in a high-throughput manner create a substantial bottleneck with regard to our ability to use the valuable animal resources provided by these centers.

CNS drug discovery differs most from other therapeutic areas by its unique reliance on *in vivo* tests for target identification and validation as well as for compound selection and refinement. As stated previously, a comprehensive behavioral assessment, which is needed for accurate interpretation of behavior, is a very slow, costly, and sometimes subjective process. Consequently, at a time when the number of potential targets and the number of compounds directed toward these targets are rapidly increasing, behavioral screening has become the main bottleneck in CNS drug discovery.

Fortunately, there have been several improvements in the throughput of behavioral screening (**Table 1**). Several companies have developed semiautomated systems for measuring multiple behaviors, such as locomotor activity, fear/anxiety responses, and startle. The currently available devices, however, still must be better integrated into databases designed to coordinate the analysis of multiple behavioral responses in order to best predict clinical efficacy. Some private companies are moving in that direction. For example, Hypnion (http://www.hypnion.com) is developing a high-throughput system that monitors electroencephalograms, sleep, wakefulness, and several physiological variables in rodents. Their SCORE-2004 system uses a large database to predict efficacy and side effects of existing and experimental hypnotic and wake-producing agents. SmartCube (PsychoGenics), one of the most comprehensive approaches to date, works by compressing numerous tests into one by gathering comprehensive, detailed, and fully automated data into a large database and by implementing sophisticated data-mining algorithms to detect psychotropic drug activity. Mice are given a drug and placed in SmartCube for a designated time, during which they are presented with a sequence of stimuli. Videotracking and other automated measures are then processed by SmartBase, an intelligent database that, through sophisticated statistical analysis and data mining, identifies 'drug signatures' – for example, antidepressant, antipsychotic, or anxiolytic effects. Further research is needed to determine whether it will be possible to generate such drug signatures by a high-throughput method.

High-throughput behavioral tests could markedly increase the speed of compound screening and reduce the subjectivity inherent in many current behavioral tests. However, a key drawback must be overcome. The automated tests will probably pick up novel features of an animal's behavior that do not have the extensive predictive validity of standard behavioral assays. The elevated plus-maze, Morris water maze, and forced swim test, for example, may be labor-intensive, but they are time proven. Extensive pharmacological validation will be needed to convince a pharmaceutical company to pursue such a novel line of drug discovery. Likewise, to understand how a drug or mutation affects behavior, any finding from a high-throughput assay would require much more investigation in established and labor-intensive tests to elucidate the underlying behavioral and neurobiological mechanisms involved.

Quantitative Home Cage Behavioral Pattern Analysis

In addition to the high-throughput approaches to drug discovery described in the preceding section, efforts are also underway to apply information technologies for a comprehensive evaluation of the impact of experimental manipulations (mutations, environmental manipulations, and drugs) on mouse behavior. At the University of California at San Francisco, an initiative is under way for the collection and mining of data reflecting the diverse and spontaneous behaviors of mice in their home cages (**Table 1**). Animals are fully acclimated to housing in cages containing nest enclosures, food-intake monitors, lickometers, and activity platforms that record animal position and movement velocity with high temporal and spatial resolution.

Temporal and spatial organization of multiple behaviors are simultaneously assessed using a variety of computational approaches, revealing substantial heterogeneity in the manner in which behavioral patterns are influenced by single-gene mutations, drugs, and environmental manipulations. In association with the Jackson Laboratory Mouse Phenome Project Initiative, we have also observed that behavioral patterns vary markedly among the 16 genetically diverse inbred strains that have been examined to date. Such information will be useful as a basis to search for genes conferring strain differences and for the selection of optimal strains for the study of particular behavioral processes.

Several advantages may be associated with the use of quantitative home cage behavioral analysis. First, it helps eliminate the confounding effects of environmental novelty, as well as the impact of handling on stress and experimental variability. It also enables investigators to monitor behavioral processes regulated over longer timescales, such as circadian rhythms, patterns of ingestion, estrus cycle influences, and the gradual onset of pharmacological and genetic effects. In addition, it provides an opportunity to monitor the impact of experimental manipulations in the context of the integrated expression of multiple behavioral domains. Furthermore, hypothesis-independent data mining may reveal novel insights into the regulation of behavioral patterns. Once these behavioral patterns are established, environmental modifications may be introduced to explore additional domains of behavior (e.g., introduction of novel objects, predator stimuli, and running wheels).

On the other hand, several challenges may complicate the use of such approaches. For example, the establishment of stable behavioral patterns and the collection of sufficient data for modeling may require several weeks of monitoring. Large studies requiring analysis of terabytes of generated data require a substantial investment in computational resources. Furthermore, accurate interpretation of the functional relevance of some behavioral effects may initially require validation using standard assays.

Conclusions

The examples provided in this article reflect a growing appreciation within academic and industrial settings of the intricacies and importance of behavioral analysis. This is driving a proliferation of data acquisition and data-mining innovations that will bring comprehensive mouse neurobehavioral assessment into the information age and markedly enhance the value of rodent models for the study of psychiatric and neurologic disorders. Future research is needed to increase the throughput and consistency of such comprehensive behavioral analyses, as well as to incorporate ethological perspectives for an increasingly accurate view of rodent behavior. Such advances will greatly enhance efforts to relate genes to complex behavior and to optimally mine the genomic revolution for improved treatments of brain diseases.

Role of NO in Neurodegeneration

Y-I Lee, T M Dawson, and V L Dawson, The Johns Hopkins University School of Medicine, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Nitric oxide (NO) was first identified as endothelium-derived relaxing factor. NO is produced by many different cells in multicellular organisms, where it acts as an unprecedented biological messenger molecule. NO is synthesized by the enzymes NO synthases (NOSs), which catalyze the essential amino acid L-arginine into NO and L-citrulline. In the central nervous system (CNS), NO is an unusual neuronal messenger molecule in that conventional neurotransmitters are released by exocytosis from the nerve terminal, but because of its small size and ability to move through lipids, NO reaches its targets through diffusion. NO forms covalent and noncovalent linkages with protein and nonprotein targets. Conventional neurotransmitters undergo reversible interactions with cell surface receptors. NO is inactivated by diffusion away from its targets, by forming covalent linkages to the superoxide anion, or by scavenger proteins. In contrast, conventional neurotransmitters are terminated by presynaptic reuptake or enzymatic degradation. Because NO does not use conventional means for control of its biological actions, NO depends upon its small size, reactivity, and diffusibility more than any other biological molecule to exert its biological effects. NO is involved in a wide range of physiological processes, and under conditions of excess formation in the presence of superoxide anion it can mediate a series of pathophysiological actions. The multifaceted actions of NO in brain physiology include mechanisms related to development, synaptic function and neural plasticity, and neuronal survival and neuronal cell death.

NO in the Nervous System

NO is produced by a group of enzymes designated NOS. There are three members of the NOS family: neuronal NOS (nNOS), endothelial NOS (eNOS), and inducible NOS (iNOS). A fourth family member was proposed, mitochondrial NOS (mtNOS), but studies indicate that mtNOS is nNOSα – it is coded by the nNOS gene, and nNOS knockout mice do not have mtNOS. All the NOSs share between 50% and 60% sequence homology. In the nervous system, nNOS is expressed in neurons, eNOS is predominantly expressed in the endothelium of blood vessels, and iNOS is expressed in glial cells. nNOS and eNOS are Ca^{2+}-calmodulin-dependent enzymes that are constitutively expressed, although both isoforms can be induced following a variety of physiological and pathological stimuli. In contrast, iNOS does not require Ca^{2+}-calmodulin for activation and its regulation depends on *de novo* synthesis. Despite its highly diffusible nature, NO can exert very specific effects within the CNS and peripheral nervous system (PNS). Under physiological conditions, NO facilitates neurotransmitter release and uptake via neuron-glial communication, modulating the release of neurotransmitters, including glutamate, γ-aminobutyric acid (GABA), substance P, and acetylcholine. nNOS and eNOS are regulated via posttranslational modification, including phosphorylation, and nNOS levels are dynamically regulated through transcription. Cerebral blood flow is regulated through NO released from endothelial cells as well as autonomic nerves within the adventitia. NO may also regulate cerebral blood flow through activity-dependent activation of NOS in neurons that influence small cerebral arterioles. In the brain, nNOS is linked to the postsynaptic membrane near *N*-methyl-D-aspartate (NMDA) receptors via the postsynaptic density protein-95, and nNOS function is regulated through its interactions with the protein inhibitor of NOS (PIN) and carboxyl-terminal PDZ ligand of NOS (CAPON) (Figure 1). In the gut, NO functions as the nonadrenergic, noncholinergic (NANC) neurotransmitter where it mediates relaxation of smooth muscles associated with peristalsis. Penile erections are mediated, in part, through the neurotransmitter action of NO.

The diffusion properties and the short half-life of NO make it an ideal candidate for playing a role in nervous system morphogenesis and synaptic plasticity. In the nervous system, NO was first recognized as a messenger molecule that mediates increases in cyclic GMP (cGMP) levels that occur after activation of glutamate receptors, particularly those of the NMDA subtype. In this capacity, NO modulates long-term potentiation (LTP), which is essential for learning and memory. LTP is inhibited by administration of NOS blockers or genetic deletion of NOS isoforms, confirming the role of NO in synaptic plasticity. Nerve growth factor (NGF)-induced differentiation of pheochromacytoma cells (PC12) has been shown to be NO dependent with NO acting as a cytostasis factor. NO may play a role in the developmental processes of the nervous system, in that it is transiently expressed in the cerebral cortical plate during critical periods of neuronal development. NO is also critical for the neurite outgrowth and differentiation in murine cortical

Figure 1 NO signaling in the CNS. Glutamate activation of NMDA receptor results in stimulation of neuronal NO synthase (nNOS) which is functionally coupled to the NMDA receptor by PSD-95, a scaffolding protein. The tethering of nNOS near the NMDA receptor facilitates its activation by Ca^{2+} resulting in the generation of NO. CAPON binds nNOS and regulates its interaction with PSD-95 and thus regulates the generation of NO. NO diffuses between cells and can activate a number of cell signaling pathways in adjacent cells. NO can react with the heme center of soluble guanylyl cyclase (GC) activating GC to produce cyclic GMP (cGMP). NO can react with iron–sulfur (Fe–S)-containing proteins such as aconitase to regulate their activity. NO may S-nitrosylate (R-S-NO) proteins such as Ras or parkin, thus regulating complex cell signal cascades.

neurons. NO may play a role in the molecular maturation of adult spinal cord motor neurons and also in the initial pattern of connections in ocular dominance columns in the developing visual system. It has also been suggested to play a prominent role in the activity-dependent establishment of connections in both the developing and regenerating olfactory neuronal epithelium. Thus, NO may play an important role in synaptic refinement in the developing nervous system.

In the immune system, NO generated by iNOS is released in bursts of high concentrations and is a key cytotoxic weapon for the destruction of bacteria. The CNS immune cell counterparts, microglia and astrocytes, also have iNOS, which generates a burst of NO in response to injury and can contribute to neural injury. The expression of iNOS occurs following trauma, following stroke, or during neurodegenerative diseases and is thought to contribute to neural injury.

Although NOS is the main NO source, in some special situations this molecule can be synthesized by other mechanisms. NO can be produced by the xanthine oxidase pathway or by H_2O_2 and L-arginine in a nonenzymatic reaction or by the reduction of nitrites in acid and reducing conditions, such as occurs in ischemic tissue.

Figure 2 Physiological and pathophysiological NO signaling events.

NO Molecular Targets

There are several molecular mechanisms by which NO elicits cellular signaling (Figure 2). The unique chemical properties of NO facilitate its role as an important signaling molecule in the biological system by reacting directly with biological molecules or indirectly

following reaction with other reactive oxygen species. NO reacts with the ferrous ion in the heme complex in enzymes such as guanylate cyclase (GC), P450, and hemoglobin to form an iron nitrosyl complex. The binding of NO induces a conformational change in the protein structure activating these proteins. The prototype reaction is that of NO on GC leading to the production of cyclic guanosine-3′,5′-monophosphate (cGMP). cGMP is a second messenger that activates protein kinases. In the nervous system, NO was first recognized as a messenger molecule that regulates cGMP accumulation through activation of glutamate receptors, particularly those of the NMDA subtype. cGMP, in turn, binds to and activates a cGMP-dependent protein kinase (G kinase), which phosphorylates specific proteins on serine or threonine residues and also activates phosphodiesterase and ion channels. NO increases prostaglandin production by activation of cyclo-oxygenase, another heme-containing enzyme. Numerous enzymes (including *cis*-aconitase, NADH succinate oxidoreductase, and NADH ubiquinone oxidoreductase) that contain nonheme iron in iron sulfur clusters are also regulated by NO. NO also stimulates the RNA-binding function of the iron-responsive element binding protein in brain slices while diminishing its aconitase activity.

In recent years, the importance of protein S-nitrosylation of cysteine thiols by NO in physiological and pathophysiological actions has been appreciated. S-nitrosylation is a posttranslational protein modification that increases or decreases the activity of the target protein. Some known biological targets for S-nitrosylation include glyceraldehyde-3-phosphate dehydrogenase (GAPDH), caspases, transglutaminase, aromatases, mitochondrial aldehyde dehydrogenase, cyclooxygenase-2, G-proteins, p21-Ras, RAC1, cdc42, Dexras1, ERK, JNK, p38, and PKBa/AKT1. S-nitrosylation of the monomeric GTPase Ras activates this enzyme, triggering the MAPK and PI3K pathways in an NO-dependent and cGMP-independent manner. A recent study reports that NO donors promote HIF-1α accumulation via an increase in transcription and translation. It is not yet known how this occurs, but it is possible that these effects are due to activation of Ras and PI3K through NO-mediated nitrosylation of Ras. NO has inhibitory effects on cell cycle progression and promotes cell differentiation, in part due to activation of the retinoblastoma gene product (pRb) by S-nitrosylation. Nuclear factor kappa beta (NF-$\kappa\beta$), a transcription factor that induces iNOS expression, is inhibited by S-nitrosylation. Thus, NO inhibition of NF-kβ could be an autoregulatory feedback mechanism to regulate NO production. Another autoregulatory mechanism is the prevention of eNOS dimerization by S-nitrosylation, resulting in decreased eNOS activity. S-nitrosylation is also involved in the pathological activation of matrix metalloproteases in stroke and neurodegenerative diseases. NO regulates NMDA receptor activity through nitrosylation, thus reducing calcium permeability. One of the important features of S-nitrosylation is that the modification is reversible, and a specific protein sequence of acidic–basic motifs seems to be necessary. As usual, the modification is also selective, since only a specific cysteine is generally nitrosylated in a protein.

Oxygen and other free radicals can also react with NO to form reactive nitrogen oxide species and exertits effects on different biological molecules. Superoxide anion can react with NO to form peroxynitrite, a potent oxidant with many cellular targets. Peroxynitrite damages proteins by reacting with the tyrosine residues to form 3-nitrotyrosine. It can also induce lipid peroxidation and cause DNA damage. It is thought that many of the acute toxic effects of NO are mediated by peroxynitrite.

Neurotoxic Effects of NO

In the CNS, glutamate excitotoxicity due to activation of the NMDA receptor is mediated in large part by NO. Under physiological conditions, the binding of glutamate activates NMDA receptors in the postsynaptic neuron that result in Ca^{2+} influx, which in turn activates nNOS. Then NO either via cGMP or by S-nitrosylation suppresses NMDA receptor activity, thereby limiting further Ca^{2+} influx and thus protecting neurons. However, under pathophysiological conditions such as occur during stroke, trauma, or neurodegenerative stress, NO participates in neuronal damage through disruption of this system and generation of peroxynitrite that activates subsequent cell death cascades. NO regulation of the release of glutamate contributes to the initial toxic events. When NO concentrations are low, there is a decrease in glutamate release despite elevated cGMP levels. However, under increased NO production and excessive increases in cGMP levels, the inhibitory effect on glutamate release is reversed, and glutamate release is increased. Under the pathological conditions of excess glutamate release and NMDA receptor activation, activation of NOS leads to cell death. Excitotoxicity can be blocked by several classes of NOS inhibitors or by nNOS gene deletion. nNOS knockout mice are resistant to focal and transient global ischemia, suggesting a role for nNOS in CNS injury. The neuronal toxicity of NO is mediated by peroxynitrite, which inhibits mitochondrial respiration and manganese superoxide dismutage (MnSOD) activity,

thus establishing a feed-forward loop for peroxynitrite generation. Peroxynitrite damages DNA, which activates the nuclear enzyme poly(ADP-ribose) polymerase (PARP) that leads to the release of the cell death effector apoptosis-inducing factor (AIF) from mitochondria. AIF can induce phosphatidyl serine exposure on the plasma membrane, and in the nucleus it facilitates DNA cleavage and nuclear condensation (Figure 3). In addition, glutamate receptor-mediated excitotoxicity activates parallel cellular responses, resulting in the activation of proteolytic enzymes, lipid peroxidation, ROS and RNS formation, and activation of programmed cell death cascades. Under some conditions, NO can activate the ceramide–Jun kinase pathway and the NF-κβ–Jun kinase pathway, which regulate the expression of a large number of genes involved in both neuroprotection and neurotoxicity. The biological significance of NO stimulation of these pathways depends on the cell type and the environment. NO can also play a protective role via the blocking of caspases (cysteine–aspartate proteases), which form a complex family of proteolytic enzymes. It is not yet clear whether NO acts as a master regulator, determining which cell death pathway will be activated in neuronal injury, but these data are suggestive that NO production could direct neurons away from a classic apoptotic type of cell death and toward an excitotoxic form of cell death acutely and perhaps activate other apoptotic cascades in the late remodeling phase of neuronal injury and recovery.

Oxidative and nitrosative stress plays a pivotal role in ischemic-reperfusion injury during stroke. The increase of NO production in the presence of increased superoxide anion leads to brain damage. Brain ischemia triggers a cascade of events, including membrane depolarization, increase in intracellular Ca^{2+} concentrations via increase of extracellular glutamate concentration, and overstimulation of NMDA receptors, leading to activation of calcium-dependent nNOS. Released NO rapidly reacts with superoxide produced in excess during reperfusion resulting in peroxynitrite formation, and nitrosylation or nitration of proteins. Furthermore, ischemia or reperfusion eventually induces the expression of iNOS. This isoform is not normally present in the CNS, but it can be detected after inflammatory, infectious, or ischemic damage, as well as in the normal aging brain. Activation of nNOS or induction of iNOS mediates ischemic brain damage through mechanisms previously discussed. On the other hand, eNOS is thought to act as a neuroprotective agent by enhancing blood supply to the injured tissue. Therefore, NO generated by nNOS or iNOS contributes to injury following stroke, whereas NO generated by eNOS is protective by maintaining blood flow (Figure 4).

NO and Neurodegenerative Diseases

Abnormal activation of glutamate neurotransmission may contribute to neurodegenerative processes and

Figure 3 Mechanism of NO-mediated neurotoxicity. NMDA receptor (NMDA-R) activation causes an increase in intracellular calcium levels, which activates NOS, as well as other potential free radical-generating enzymes. These free radicals then damage DNA and also inhibit mitochondrial function, leading to more free radical formation. The damaged DNA activates PARP-1, which transfers ADP-ribose groups to nuclear proteins consuming NAD. NAD is resynthesized from nicotinamide (NAm), a reaction that consumes four high-energy equivalents of ATP. PARP activation also elicits the release and translocation of AIF from the mitochondria into the nucleus, initiating a caspase-independent cascade of cell death.

Figure 4 Dual roles for NO in brain ischemia. NO is involved in the mechanisms of neurotoxicity after cerebral ischemia. Following a stroke, the generation of NO can be either beneficial or detrimental to the brain depending on the which NOS isoform is activated and in which cellular compartment. NO generated from eNOS in endothelial cells provides protection by inducing vasodilation. Inhibition of eNOS can drastically increase stroke injury. NO produced by nNOS in neurons or iNOS in glia results in the formation of toxic peroxynitrite and cellular damage. Inhibition of nNOS or iNOS greatly reduces brain injury following stroke.

diseases such as Parkinson's disease (PD), Alzheimer's disease (AD), amyotrophic lateral sclerosis (ALS), and multiple sclerosis (MS). Neurodegenerative disorders are usually marked by a progressive loss of a selective group of neurons and are associated with aging. One of the common features of neurodegeneration is the presence of protein aggregates and increased indices of oxidative stress.

PD is a common neurodegenerative disorder characterized by impairment in motor function. It is another common age-related neurodegenerative condition associated with selective loss of dopaminergic neurons in the substantia nigra of the midbrain region. In PD, postmortem pathological studies have revealed mitochondria complex I dysfunction, reduced glutathione and ferritin levels, increased lipid peroxidation, nitrotyrosine immunoreactivity, and increased levels of iron. Genetically engineered animals reveal that NO generated by both iNOS and nNOS contributes to pathology. In the experimental 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) intoxication model of PD, NOS inhibition in wild-type mice or gene deletion of the iNOS or nNOS gene protects dopaminergic neurons. In PD patients, polymorphonuclear cells have increased expression of nNOS and increased NO production and accumulation of nitrotyrosine-containing proteins, reflecting an increase in nitrosative stress in these patients. Glial-derived neuronal factor (GDNF) is protective in animal models of PD, although its effect on patients remains controversial. GDNF action leads to the inhibition of nNOS activity and neurotoxicity. *R*-(–)-deprenyl (deprenyl) slows the progression of disability in early PD. Deprenyl prevents S-nitrosylation of GAPDH, which blocks the binding of GAPDH to Siah, preventing the GADH/Siah death cascade. In MPTP-treated mice, low doses of deprenyl prevent binding of GAPDH and Siah1 in the dopamine-enriched corpus striatum and it is neuroprotective.

PD is mostly sporadic, but rare familial cases are also found. Mutations in α-synuclein, parkin, DJ-1, PINK1, and LRRK2 have been linked to rare familial forms of PD. Point mutations or replication of α-synuclein results in autosomal dominant PD, which prompted intense investigation into the actions and pathobiology of this protein. The hallmark lesions of PD, the Lewy body, contain α-synuclein that is modified by nitration of tyrosine residues. It is possible that dityrosine cross-linking can generate stable oligomers that lead to aggregates. Both wild-type and disease-causing α-synuclein mutants can be nitrated, and the nitration induces the formation of α-synuclein inclusions with similar biochemical characteristics to protein extracted from human PD tissue. In addition to nitration, nitrosylation may also play a key role in both sporadic and familial PD, as there is a greater than twofold increase in S-nitrosylated proteins in PD. Parkin is an E3 ligase that adds ubiquitin on specific protein substrates by both K48 and K63 linkages. Disease-causing mutations and loss-of-function mutants lead to the accumulation of toxic parkin substrates in both mouse and humans. Parkin can be S-nitrosylated. This modification results in loss of function as an E3 ligase and inhibition of the protective function of parkin. In sporadic cases of PD, parkin is S-nitrosylated, suggesting that in the more common form of PD, parkin function may be compromised. While parkin and DJ-1 do not interact physiologically, under conditions of oxidative and nitrosative stress there is a gain of function and these two proteins interact. It is possible that this interaction results in the sequestering of DJ-1 into insoluble aggregates terminating its normal biological actions. The pathophysiological significance of this interaction between DJ-1 and parkin is not yet known but is an area of active scientific investigation. Actions of oxidative and nitrosative stress on PINK1 or LRRK2 await investigation.

AD is the most common chronic progressive neurodegenerative condition; it was originally described by Alzheimer about a century ago. Brains from AD patients are characterized by extracellular aggregates of amyloid β-peptide (Aβ) that form the neuritic plaques and intracellular neurofibrillary tangles due to the hyperphosphorylation of tau protein. NO can contribute to AD neurodegeneration in several

ways. Aβ fibrils are toxic, in part, by inducing ROS formation, which can produce peroxynitrite by reacting with NO. Increased expression of iNOS and eNOS in astrocytes has been associated with the presence of neuritic plaques indicating increased nitrosative stress in AD. Additional studies indicate that Aβ is critically involved in the induction of an inflammatory response through activation of astrocytes and microglia, eliciting subsequent production of inflammatory cytokines and neurotoxic factors, including NO, superoxide, and prostaglandins (via COX-2). Aβ deposition in brain vessels correlates with a decrease in the expression of eNOS in endothelial cells that can lead to decreased regulation of cerebral blood flow. In cell culture and experimental animal models, Aβ elicits NO-mediated excitotoxicity, neuroinflammation, and oxidative stress. Similar stress events are observed in patient tissue, implicating a role for NO in the progression of AD.

ALS is a neurodegenerative disease characterized by selective death of motor neurons in the cerebral cortex, brain stem, and spinal cord. The role of NO in ALS is controversial. There is evidence that nitrotyrosination induces motor neuron death and that there is irreversible inhibition of the mitochondrial respiratory chain in these cells, suggesting a role for NO. However, mice transgenic for the human disease-causing mutation in SOD-1 when crossed with the nNOS knockout mice did not derive any benefit and progressed to disease and death. On the other hand, treatment with a nonselective NOS inhibitor slightly decreased motor neuron degeneration in an ALS mouse model. It is possible that NO from different isoforms could contribute to progressive neurodegeneration in ALS and exacerbate disease progression. In postmortem tissue, there are reactive astrocytes that contain protein inclusions, express iNOS and COX-2, display nitrotyrosine immunoreactivity, and have a loss of the glutamate transporter, EAAT2. The combination of excitotoxicity and nitrosative stress could contribute to the development and acceleration of the disease.

Conclusion

NO is a multifunctional molecule that is needed for physiological functions, especially in the brain. NO has clearly revolutionized our thought about aspects of neuronal transmission. It is capable of regulating various body functions directly, via a cGMP-mediated mechanism or a cGMP-independent mechanism. NO is an important mediator of a variety of physiological effects in the nervous system; however, excessive NO production under pathological conditions could be destructive to the brain. Understanding the role of NO in these processes as well as the disposition and activation of NO will lead to a better understanding of the basic processes underlying normal and pathological neuronal functions, and hopefully to the development of selective protective therapeutic agents against neurodegenerative diseases.

Saccade–Pursuit Interactions

J-J Orban de Xivry and P Lefèvre, Université Catholique de Louvain, Louvain-la-Neuve, Belgium

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Saccades are typically evoked by target steps, whereas pursuit eye movements are initiated by a moving target of interest. These two types of eye movements have been studied separately for years because it was thought that pursuit and saccadic systems were independent and were controlled by distinct cortical and subcortical networks (see Figure 1). Initially, scientists developed paradigms to elicit one of the two types of eye movements without any disruption by the other; that is, saccades were directed to stationary targets and the Rashbass paradigm was used to elicit pure smooth eye movements. Indeed, if a visual target first steps in one direction before moving in the opposite direction (this typical motion of the target is called the Rashbass paradigm), the probability of occurrence of saccades is strongly reduced during pursuit initiation. In contrast, if a target suddenly moves from the center in one direction, a catch-up saccade (saccade made during pursuit of a target to reduce the position error between the eye and the moving target) is necessary to foveate the target.

The Rashbass paradigm is essentially used in species, such as primates, that have a pursuit gain close to unity (the ratio between eye and target velocity). This high gain allows primates to pursue a moving target smoothly. In contrast, the smooth eye velocity of cats saturates at lower velocities (around $25°s^{-1}$), and their pursuit gain is much more variable. As a consequence, cats usually rely on a combination of smooth and saccadic eye movements to pursue a moving target. In addition, cats have difficulties to make large saccades but, instead, usually perform series of small saccades to achieve large gaze shifts. During the intersaccadic intervals, postsaccadic slow eye movements directed toward the stationary target help reduce the residual error at the end of saccades. Thus, cats need a combination of both saccadic and smooth eye movements either to shift their gaze or to pursue a moving target.

After some preliminary observations of saccade–pursuit interaction in primates, major progress was achieved with cat studies. Indeed, the low gain of eye movements in this species forces the two subsystems to cooperate in order to foveate the target. Thereafter, scientists began to design new paradigms to test the hypothesis of cooperation between the two oculomotor subsystems in primates. We now focus on these paradigms and the evidence of interactions they provided. We first describe evidence for shared velocity and position inputs to the saccadic and pursuit systems. We then examine the different mechanisms that are common to both oculomotor subsystems. Finally, we review the brain areas that were proven to contain signals related to the planning and execution of both pursuit and saccades.

Velocity Input to the Saccadic System

In contrast with the classical view of independent saccadic and pursuit systems (see Figure 1), lesions and behavioral studies demonstrated that there is a velocity input to the saccadic system. Lesions in brain areas (the middle temporal area (MT) or dorsolateral pontine nuclei (DLPN)) that are known to be prominent for motion processing disrupt the accuracy of saccades to moving targets without impairing saccades to stationary targets. Furthermore, the accuracy of catch-up saccades during pursuit initiation and maintenance implies that target motion is taken into account in their programming. Finally, the Rashbass paradigm itself shows that a prediction about future target motion (based on target velocity) is taken into account by the saccadic system. Indeed, after an initial step, the target moves toward the center of the visual field and the oculomotor system predicts that no saccade is necessary to catch the target but, instead, that a purely smooth movement is sufficient. Indeed, if the saccadic system did not have access to motion signals, it would trigger a saccade to the target in the direction opposite to target motion. All these experiments contributed to the accumulation of evidence showing that motion signals play a role in saccade programming and trigger but did not discriminate which parameter related to target motion (target velocity or velocity error) is taken into account. Indeed, these two parameters are highly correlated during pursuit initiation because eye velocity is very small in comparison with target velocity.

The first evidence for a prominent role of the retinal slip (RS, velocity error) came from cat studies and was confirmed later in humans. Cat experiments took advantage of the large variability of pursuit gain in this species, which yields a large range of RS for the same target velocity. Because the pursuit gain of primates is much larger and less variable, an original paradigm involving both position and velocity steps of the moving target was used to elicit catch-up

Figure 1 Diagram of the traditional view of saccadic and pursuit systems. Blue boxes are part of the saccadic system. Red boxes belong to the pursuit system. Two-color boxes are part of both systems. saccades during pursuit of a moving target. This paradigm (ramp–step–ramp paradigm) consisted in a first ramp that was followed by a step of the target and a second ramp. During the step, both target position and velocity varied instantaneously and randomly before the second target ramp. The position and velocity steps created both position error (PE) and RS. To compensate for these errors, the oculomotor system combined catch-up saccades and pursuit responses.

In cats and primates, the amplitude of catch-up saccades results from the addition of two components: one related to PE that represents the proportion of PE that is taken into account by the catch-up saccade (on average, 90%) and another proportional to RS that compensates for target motion during the saccade. Some electrophysiological recordings suggest that the contribution of PE might be conveyed by the superior colliculus (SC), whereas the contribution of RS originates from the motion-processing pathway (through the MT).

The processing of the two components by different networks was confirmed by the asynchrony of signals related to PE and RS. This asynchrony has been demonstrated separately with the ramp–step–ramp paradigm in two dimensions, on one hand, and by the shape of catch-up saccade velocity profiles, on the other hand. The two-dimensional ramp–step–ramp paradigm yielded curved catch-up saccades (large differences between the initial and final orientation of saccades). The asynchrony between PE and RS could be inferred from the difference between initial and final orientations of saccades that were aligned with the PE and RS vectors, respectively (see Figure 2). Similarly, the asymmetry of the shape of the velocity profile of catch-up saccades highlighted the asynchrony between PE and RS. The acceleration phase was related to PE and the deceleration phase to RS. These two results show that PE is available to the saccadic system earlier than RS because in both cases saccades take first PE into account and subsequently RS.

In addition, it has been demonstrated that both PE and RS influence the mechanism leading to the initiation of a catch-up saccade (trigger system) during ongoing smooth pursuit (Figure 3). The combination of PE and RS determines the time-to-contact between eye and target (eye-crossing time: $T_{XE} = -\mathrm{PE}/\mathrm{RS}$),

Figure 2 Velocity input to the saccadic system. A curved saccade (blue circles) occurring after both position and velocity steps of the target (black solid lines) is presented in two dimensions. The target position just before and after the target step is represented by the open and closed squares. Before and after the saccade, smooth pursuit eye movements (solid blue lines) are present to track the target. The gray dotted lines represent isochronic lines that connect eye and target at the same moment in time. Red arrows give the position error (PE) and retinal slip (RS) orientation before the saccade; blue arrows give the initial and final orientation of the eye at the start and end of the saccade, respectively, and black arrows indicate the direction of motion of the pursuit target. (1) Start of the trial: The eye smoothly pursues the rightward moving target. (2) Target step: From target step to the onset of the saccade, PE and RS are evaluated. (3) The saccade is elicited with an initial orientation close to the orientation of PE. (4) The saccade ends with a final orientation close to the orientation of RS. (5) After the saccade, pursuit is engaged to the target and the eye is very close to the target, as shown by the isochronic lines after the saccade. T, target; E, eye.

that is, the time that the eye trajectory would need to cross the target at constant velocity, which is used as a criterion to switch from pursuit mode to saccade mode. As long as the value of this sensory parameter remains in the smooth zone (between 40 and 180 ms), no saccade is needed to track the target. However, when the eye-crossing time takes values outside the smooth zone (i.e., inside the saccade zone), the decision to trigger a saccade is taken because the smooth pursuit system cannot compensate anymore for the position mismatch between eye and target. Therefore, a saccade takes place, on average, 125 ms later.

Finally, it has been shown that the saccadic and smooth pursuit systems cooperate despite the absence of retinal signals. For example, when directing gaze toward the remembered position of a flashed target, the saccadic system is able to take into account the smooth eye displacement (the integral of smooth eye velocity). This has been demonstrated during ongoing pursuit of a moving target but also in the dark during anticipatory smooth eye movements. In this case, the estimation of the smooth eye displacement is based on extraretinal information about the smooth eye movement. Furthermore, it has also been shown that during the temporary occlusion of a moving target, the saccadic system takes into account and can compensate for the modulation of the smooth response in complete darkness. These observations are evidence for the role of extraretinal signals and the existence of a velocity input to the saccadic system.

In conclusion, the saccadic system has access to retinal information about relative eye and target velocity (RS), as well as to extraretinal information about smooth eye velocity. This velocity input is available later than the position input, and these signals are combined to estimate the eye-crossing time, which determines whether a catch-up saccade should be triggered or not. The velocity input used by the saccadic system originates from the motion-processing pathway.

Position Input to the Smooth Pursuit System

The first reports of a position input to the smooth pursuit system in primates were based on indirect evidence because stationary targets do not evoke smooth eye movements in this species. In contrast, cats use a combination of small saccades and slow correcting eye movements to shift their gaze to an eccentric stationary target. Thus, studies in this species provided direct evidence of a position input to the smooth pursuit system. In primates, new paradigms needed to be developed to address this question specifically.

PE, either induced by target stabilization on to the retina or by target steps during ongoing pursuit, gave the first evidence of a position input to the primate smooth pursuit system. Target stabilization consists in making the target move at the same velocity as the eye, which stabilizes the projection of the target on to the retina. The stabilization of the target with a small offset with respect to eye position evokes slow eye movements directed toward the target either during fixation or ongoing pursuit. Similarly, target steps provided evidence of slow eye movements in response to a position error. If during smooth pursuit the target steps but continues to move at the same speed, slow eye movements are modulated by the amplitude of the step (i.e., the amplitude of the position error).

However, in these studies, the influence of PE was not direct or could be perturbed by other factors, such as concurrent RS. The first direct evidence of a

Figure 3 Saccade trigger: (a) early-saccade trial; (b) late-saccade trial; (c) smooth trial (no saccade); (d) the evolution of the eye-crossing time (T_{XE}) versus time for the three trials; (e) T_{XE}, the time that the eye trajectory would need to cross the target at constant velocity. Panels (a)–(c) show the position versus time representation of eye and target (black traces) during three different trials of a ramp–step–ramp paradigm along the horizontal axis. This paradigm consists of a moving target (first ramp) followed by a target jump (position step, represented by the dotted black lines) and a change in target velocity (velocity step) occurring at the same time (time zero on figure). The target then continues to move at constant velocity (second ramp). In panel (a), the latency of the saccade is around 200 ms; in panel (b), the latency of the saccade is around 350 ms. Panel (d) shows how the decision to trigger a catch-up saccade is taken based on T_{XE}. The T_{XE} is represented until 125 ms before the saccade. The smooth zone corresponds to the values of T_{XE} that do not trigger catch-up saccades because the pursuit system can compensate for position error (PE). In contrast, the saccade zone contains values of T_{XE} that trigger a catch-up saccade. For the early-saccade trial, T_{XE} lies far from the smooth zone and the decision to trigger a saccade is taken quickly. In contrast, for the late-saccade trial, T_{XE} lies outside the smooth zone at target step but soon enters the smooth zone for 150 ms before leaving it. As soon as the parameter leaves the smooth zone, the decision to trigger a saccade is taken. Finally, for the smooth trial, T_{XE} quickly enters the smooth zone but never leaves it; therefore, no saccade is triggered. E, eye; RS, retinal slip; T, target.

position input to the pursuit system was provided by flashing a target aside from the pursuit target path (see Figure 4). In this paradigm, subjects pursued a spot moving along a straight line. During pursuit maintenance, a second target was briefly flashed aside from the target path. This flash created a position error with a component orthogonal to the target path. This component of position error generated by the flash evoked smooth eye movements orthogonal to the direction of pursuit, directed toward the flash and scaled to the position error created by the flashed target.

Apart from all the behavioral experiments conducted to assess the influence of a position input on the smooth pursuit system, it has been shown that the stimulation of the cat SC, an area classically involved in the saccadic pathway, produces such postsaccadic slow eye movements. In addition, it has been demonstrated that the saccadic and smooth pursuit systems share a PE signal at the level of the SC in primates. In this species, recordings in the rostral SC showed that it codes small PEs during both smooth pursuit and saccades. Apart from well-established role of the SC in saccades, this shows evidence for the implication of the SC in saccade pursuit interaction.

In conclusion, evidence from several behavioral studies shows that PE influences the smooth pursuit system. Moreover, SC was proven to be the place where both saccade and pursuit systems share the PE signal, highlighting the role of SC in saccade–pursuit interaction.

Common Mechanisms for Initiation and Cancellation

Up to now, we have shown that both systems share common inputs. Indeed, PE and velocity error are used by both oculomotor subsystems. These two subsystems may either process their inputs independently or share some processes in transforming visual inputs into motor commands. We now review which processes are likely to be shared by both systems.

Figure 4 Position input to the pursuit system: (a) horizontal and vertical position of the eye and the target are presented as a function of time; (b) velocity of the eye and the target are presented as a function of time. The inset represents a zoom of the vertical eye velocity profile. (1) The pursuit target starts moving rightward. (2) The pursuit target disappears. (3) A target is flashed for 10 ms above the target path (slight vertical offset, see the gray (black) star that represents vertical (horizontal) flashed target position). (4) The vertical offset of the flash elicits a vertical smooth eye movement, which is orthogonal to the pursuit path. E, eye; H, horizontal; T, target; V, vertical.

Figure 5 (a) Initiation mechanism; (b) corresponding eye position and velocity as a function of time. In panel (a), the initiation mechanism is represented by a linear rise to threshold process. After a given delay following target onset, the decision signal (black curve in no-gap condition) rises to two different thresholds (pursuit (P) in red and saccade (S) in blue). After the decision signal has reached a specific threshold, the corresponding eye movement is triggered (panel (b)). In the gap condition, the initial level of the decision signal is increased at target onset (gray curve).

Initiation

The latency of saccadic and pursuit eye movements have always been shown to differ. On average, the latency of saccades to stationary targets is around 200 ms, whereas the latency of smooth pursuit eye movements is around 100 ms. This discrepancy between smooth pursuit eye movements and saccades suggests that the initiation mechanisms are different. However, several paradigms have shown similar effects on the latency of both saccades and smooth pursuit. Their latency is shortened when the fixation point is extinguished prior to the appearance of the target (gap paradigm). The reduction in latency caused by the gap paradigm is very similar (around 50 ms) for both oculomotor subsystems. Neuronal correlates of the gap effect have been found in the SC for both types of eye movements when the buildup activity that occurs before saccade or pursuit is increased by the presence of a gap. Similar to the gap effect, the presence of a second moving target (a distractor) also modulates the latency of both pursuit and saccades in the same way (an increase in latency). Finally, when a first target is extinguished after the appearance of a new target (overlap paradigm), latencies of pursuit and saccades are comparable and highly correlated. These similar changes in latency suggest a common mechanism for the initiation of pursuit and saccades.

A linear rise to threshold model, in which a decision signal evolves toward a threshold, makes good prediction of saccade latency. As soon as this threshold is reached by the decision signal (see Figure 5), the intended action is initiated. In the case of saccade and pursuit initiation, a similar model can be used. A common decision signal linearly rises to two different thresholds (one for pursuit and a second higher one for saccades) to elicit eye movements. The crossing of one of the thresholds implies the trigger of the corresponding eye movement after some motor delay (different for pursuit and saccades). This model can account for the gap effect if it is assumed that the presence of a gap increases by the same amount the initial level of the decision signal and, hence, reduces the time needed to reach the threshold for both pursuit and saccades.

Cancellation

In a complex environment, it is often necessary to inhibit an action as circumstances that led to its

planning can change rapidly. In the oculomotor domain, a stop signal could be issued before the initiation of a movement, requiring the cancellation of the prepared eye movement. For both the saccadic and smooth pursuit systems, the probability of cancelation of the planned eye movement depends on the delay between the go signal (stimulus onset) and the stop signal. If the stop signal arises just after the go signal, the eye movement can easily be canceled; however, if it arises 200 ms later, it cannot. On average, the stop signal must be issued 60 ms before pursuit initiation for it to be canceled. Similarly, the interval between the stop signal and saccade initiation must be 80 ms to be efficient. In sum, it was found that it takes an additional 20 ms to cancel a saccade compared with smooth pursuit cancellation, suggesting that cancellation mechanisms are different for saccades and smooth pursuit.

At the neurophysiological level, cancellation of both saccadic and pursuit eye movements is mediated through omnipause neurons (OPNs, located in the brain stem). Indeed, OPNs exert an inhibitory control on the excitatory burst neurons that generate saccades, and their stimulation interrupts ongoing saccades. OPNs are also modulated during smooth pursuit eye movements, and their electrical stimulation reduces ongoing smooth eye velocity. Therefore, these results suggest that a common inhibitory group of neurons could regulate the cancellation of both saccades and pursuit. The common inhibitory neuronal population makes us think that there is a common cancellation mechanism, but it does not explain the additional delay required to cancel a saccade compared with canceling a pursuit.

Thus, the discrepancy between the cancellation delay for both saccades and smooth pursuit is probably not due to different cancellation mechanisms. Indeed, saccadic latency is measured with an eye acceleration or velocity threshold. However, 20 ms before saccade initiation, there is a point of no return for saccades. Indeed, around 20 ms before saccade onset, the OPNs are inhibited and excitatory burst neurons are activated. Therefore, under natural conditions, it is not possible to cancel saccades during this 20 ms interval. Such point of no return does not exist for pursuit. Therefore, when we take the point of no return into account instead of saccadic latency, the time needed to cancel any eye movement (either saccade or pursuit) is comparable (around 60 ms). In sum, the same inhibitory neurons could be involved in canceling saccades and pursuit eye movements. However, the details of the inhibitory process might differ between oculomotor subsystems.

Common Processes

In addition to shared inputs, saccade and pursuit systems share common processes. The initiation mechanism was proven to be common for saccades and pursuit on the basis of the similar modulation of saccade and pursuit latencies in different paradigms and on the basis of neurophysiological recordings in the SC. The proof of a common cancellation mechanism was yielded by a behavioral study on action inhibition and by a neurophysiological study in the brain stem. A third mechanism is also shared by saccadic and pursuit systems – the target-selection mechanism. This was demonstrated on the basis of target-selection paradigms and recordings in the SC (and not described here).

Other Brain Areas Subserving Both Saccades and Pursuit

In contradiction with the classical view of totally segregated systems (see Figure 1), the cortical networks of pursuit and saccades are anatomically overlapping. Among the cortical overlapping areas, some contain distinct neuronal populations for pursuit and saccades, such as the frontal eye fields (FEFs); others contain a neuronal population conveying both saccadic and pursuit signals, such as the supplementary eye fields (SEFs).

Subcortical areas generally contain a population of neurons subserving both saccades and pursuit. A subset of these subcortical areas that contain shared neuronal populations takes part in the descending pathway from the cerebral cortex toward the motor nuclei: the substantia nigra (SNr), the DLPN, the SC, and other brain stem regions (vestibular nuclei, nucleus of the optic tract, and interstitial nucleus of Cajal). Other areas containing neurons that convey both position and velocity signals take part in the ascending pathway that relays signals from premotor/motor nuclei toward cortical areas and/or form an internal feedback pathway of the ongoing eye movement: the cerebellum (vermis and fastigial oculomotor region) and the thalamus. On the other hand, the caudate nucleus (CN) contains two mainly segregated populations that convey pursuit and saccade signals separately.

Brain areas subserving saccades and pursuit contain either distinct neuronal populations for pursuit and saccades (the FEFs and CN) or a single population of neurons that conveys both pursuit and saccade signals (e.g., SNr, dorsal pontine nuclei, cerebellum, and thalamus), corresponding either to parallel or

shared brain structures. The current view of the saccade and pursuit networks has thus evolved toward a more integrated network, subserving both oculomotor systems (see Figure 6).

Conclusion

In recent years, our view of the interaction between the smooth and saccadic systems has completely changed. From the two separate networks, a more unified scheme of the oculomotor system has emerged step by step. In this article, we highlight all the inputs, processes, and brain areas that are shared by the pursuit and saccadic systems. We emphasize that, even though they are computed by different networks, PE and RS influence both oculomotor subsystems. Finally, we underline the integration of common initiation and cancellation mechanisms and the numerous brain areas involved in both subsystems, even if, for the majority of them, their precise role in the saccade–pursuit interaction needs to be further investigated.

Saccades and Visual Search

J M Findlay, University of Durham, Durham, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Visual search is a common visual activity that we engage in on a daily basis. For example, we spend time looking for a friend in the airport crowd, looking for our car in the parking lot, or looking for the tomatoes in the vegetable aisle at the supermarket. Indeed, it seems likely that visual search, and particularly the requirement to forage for food amid many nonfood items, has been a common form of behavior throughout evolutionary history. Exploration of the way in which visual search is conducted might therefore be expected to offer considerable insight into the workings of the visual system.

The extraordinary mobility of the eyes is well adapted to searching. The eyes move a few times each second, and these fast movements, known as saccades, direct the high-acuity foveal region to a succession of new visual locations for detailed inspection. Search is generally successful when the fovea is directed to the search target, since the high-resolution of foveal vision allows recognition that the target is located. The present article considers how the saccades that bring the eyes to the target are generated. Every saccade is a miniature behavioral act for which the brain makes a decision about the exact location in space to which the eyes should be redirected and a decision about the instant in time when the eyes should move. Saccades are sufficiently rapid that they cannot be guided by any visual information taken in while the movement is in progress, and so in general the saccade destination and trajectory are decided at the outset. The emphasis in this article is on human visual search, although the eye scans of monkeys trained in search tasks show considerable similarity to those of humans.

The major part of this article is devoted to consideration of eye scanning in rather artificial search displays consisting of a set of discrete items viewed against a plain homogeneous background. Usually one item is the search target and the remaining ones are nontargets, alternatively named distractors. Reference is first made to an important earlier tradition in which visual search was investigated with no explicit reference to eye scans. The final section discusses recent attempts to grapple with the additional factors that come into play when visual search occurs in more naturalistic visual scenes.

Search and Peripheral Vision

Consider the two tasks shown in Figure 1, each requiring search for a red cross. Figure 1(a) shows a display in which, for individuals with normal color vision, the target can be found with trivial ease. The target can be said to pop out of the display. In Figure 1(b), the search is clearly slower and more effortful. Around 1980, Anne Treisman suggested that, in the first case, the search was in some way carried out in parallel over the entire visual field, whereas in the second case, some serial attention-demanding process dealt with each item in turn. In support of the proposal she showed that, for displays of the type shown in Figure 1(a), the time to report the presence of a target was independent of the number of distractors present in the display, whereas for those of the type shown in Figure 1(b), the time increased linearly with the number of distractors present. For a number of years the distinction between parallel and serial processes formed the starting point for theories of visual search. It was proposed that search in the case of Figure 1(a) could be carried out 'preattentively' whereas searches such as in the case of Figure 1(b) required attention to focus on each item in sequence. It was also often believed that this attention scan could be achieved by a mental spotlight, and, for some years, these ideas were developed with little or no explicit reference to eye movements.

As empirical data accumulated, it became clear that, rather than a dichotomy, there is a continuum of visual search difficulty. Moreover, in the case of demanding searches such as those of Figure 1(b), several saccadic eye movements are normally required before the target can be found, whereas in the pop-out displays, a single saccade usually suffices to bring the eyes to the target. A critical factor is the ease with which the search target can be detected in peripheral vision. If a display is viewed briefly so that no eye movements can be made, the ease with which a target can be detected is dependent on the retinal location on which the target is projected. Detection becomes progressively more difficult with distance from the fovea (retinal eccentricity) and, in many cases, becomes impossible if the target is in the far periphery of vision. It is possible to define a functional field of view (sometimes termed the visual lobe) which describes the region where the target can be detected. Characteristically, this is shaped as a broad ellipse, centered on the fovea and extended along the horizontal axes. It is composed of two subregions. Within a central zone, the target can always be detected. This is surrounded by a transitional zone within which the

Figure 1 Demonstration of the distinction between preattentive and attentive search introduced by Anne Treisman. In both search displays the target to be searched for is a red cross. In (a) the target can be found easily and is said to pop out of the display. In (b) the search is more effortful and generally takes considerably longer.

Figure 2 Results obtained from a visual search experiment with displays similar to those of **Figure 1(a)** for parallel search and **Figure 1(b)** for serial search. The task was to make a two-choice response indicating whether or not a target was present, and the searcher's eye movements were recorded. The left-hand plot shows a typical search function, giving the response times to make a target present response (positive) or a target absent response (negative). The right-hand plot shows the average number of saccades made during the searches in the different conditions. Reproduced from Williams DE, Reingold EM, Moscovitch M, et al. (1997) Patterns of eye movements during parallel and serial visual search tasks. *Canadian Journal of Experimental Psychology – Revue Canadienne De Psychologie Experimentale* 51: 151–164, with permission from Canadian Psychological Association.

target may be detected sometimes, but not always. Further out in the periphery is a region within which the target is never detected.

For displays that are large enough to extend beyond the functional field of view, it is evident that saccadic eye movements may be necessary to find the target. Study of such cases also shows that a major factor contributing to the time taken to detect the presence of a target is the number of eye saccades that are made during the search. This relationship has been shown both in humans and in nonhuman primates. Figure 2 shows data from a study in which the task was to make a two-choice Yes/No response indicating the presence or absence of a target in displays similar to those of Figure 1. The size of the display varied from trial to trial. The left-hand plot in Figure 2 shows the search function, in which the mean search time is plotted against the display size. The right-hand plot shows the mean number of fixations made. The similarity of the two plots is very apparent.

Target Selection for Saccades

Figure 3 shows a plot of the saccades made in one trial of a search task in which an observer, initially fixating at the center of the display, was asked to move the eyes to locate a red cross. The display was visible for 1 s, during which time the observer made five saccades, the third being a small correction-like movement. Against each fixation is noted its duration in milliseconds. Analysis of saccades in this task

Figure 3 Example of an eye scan in a task in which the observer was asked to search for a red cross target. The observer initially fixated the center of the display, and the figures show the time in milliseconds for each fixation during the scan. Data from the study described in Findlay (1997); reproduced from Findlay JM (1997) Saccade target selection in visual search. *Vision Research* 37: 617–631, with permission.

revealed three important findings. First, if the target was in the inner ring, then it was frequently located with a single saccade. Second, saccades directed to the search target were made following a latency (time before making the movement) that was equal to, or slightly longer than, saccades made to distractors. Third, saccades made to distractors were more likely to land on elements sharing a common feature with the target than on elements with no feature in common (true for the second and fourth saccades in Figure 3, although not, in this case, for the first).

Similar findings emerged from several studies in the 1990s and were consistent with a view of brain function in relation to visual attention that was also developed in this decade. Visual processing in the brain occurs in a number of distinct cortical areas, in each of which the visual field (strictly hemifield) is represented in a retinotopic map. There are multiple cross-connections, often bidirectional, between these areas, but in each case the retinotopic mapping is maintained. This architecture promotes the operation of biased competition, a term introduced by Robert Desimone and John Duncan, who describe it as follows:

> Some kind of short-term description of the information currently needed must be used to control competitive bias in the visual system, such that inputs matching that description are favored in the visual cortex. (Desimone and Duncan, 1995: 199)

Visual cortical areas also connect in a retinotopically mapped way to three brain areas principally involved in saccadic eye movement generation, the frontal eye fields (FEFs), the lateral intraparietal area of posterior parietal cortex (LIP), and the superior colliculus (SC). The superior colliculus appears to be the brain center in which an irrevocable commitment to generate a saccade is normally made through the firing of a subpopulation of cells termed burst cells. Hence a plausible picture of saccade target selection in visual search is that the operation of biased competition results in a retinotopic representation in which neural activity codes similarity to the search target. The term salience map is often used to denote such a representation. A saccade is triggered when activity at some location on the salience map reaches a critical level. Because central regions of the visual field are exaggerated in each retinotopic map, proximity to the fovea is a further factor that combines with similarity to the target to determine the point of highest activity.

This general approach can account for each of the three findings from studies of saccades in visual search discussed at the beginning of this section. The approach maintains that visual information during visual search is always processed in parallel up to the point at which the decision is made to move the eyes. The antithesis to the approach is the alternative suggestion that some internal mental pointer (mental spotlight) is scanned around a number of locations during each fixation. The strongest evidence in favor of a fast-moving mental spotlight is the linear search functions of the type shown in Figure 2(a). As discussed previously, in the case of searches where eye movements are occurring, the linear increase in search time corresponds to an increasing number of saccades. Linear functions have also been reported in situations where eye movements are excluded, but it has been argued that these also can be accounted for in terms of the parallel processing approach. The argument runs along the lines that the target–distractor discrimination is a process of signal detection against noise. As the number of distractor (noise) elements increases, the task becomes more difficult and more time is needed to achieve a particular performance criterion.

While the general approach is widely accepted as an account of how saccade selection occurs when searching displays of the type shown in Figure 1, there is considerable debate concerning how the details of the biased competition process might be implemented. One issue concerns the degree of resolution possible. It is known that much of the visual information reaching the saccadic system is coded in a distributed form (large receptive fields; coarse or population coding). This form of coding does not preclude accurate localization in the case where a single isolated target is present. However, when two targets, or a target and a high-similarity distractor, occur in neighboring locations, the use of distributed coding can lead to the center-of-gravity phenomenon whereby an inaccurate first saccade lands between the two potential targets and is followed by further

corrective saccades. Another issue concerns how different features, which can potentially be selected for in different cortical maps, are reintegrated into an overall salience map. Thus, for example, one suggestion, that the salience map should be based on the squared Euclidian distance from the target in feature space, predicts that search for feature conjunctions should be more efficient than occurs in practice.

The salience map approach gives a clear description suggesting how bottom-up factors from the immediate stimulus display can be processed in a manner consistent with physiological findings. It is also straightforward in principle to see that top-down factors could be melded with these bottom-up factors through differential weighting in the final salience map. The influence of top-down factors will be discussed following a section considering the timing of the eye movements.

The Decision about When the Eyes Should Move

Our active vision system is capable of exquisite control of the duration of each eye pause, or fixation, between successive saccadic movements. This has been shown particularly clearly in studies of eye control during reading, where it is found that fixation durations are sensitively adapted to the difficulty of words encountered in the text. Similar effects occur in studies of visual search. Fixation durations in visual search tasks (typically 150–300 ms) are similar or slightly longer than those in reading and also increase when search is more difficult – for example, when the similarity between target and distractors increases.

In studies of reading, the relation between word difficulty and fixation duration has been found to occur both on a moment-to-moment basis, with longer fixations occurring on unusual or contextually improbable words, and on a longer term basis, with reading speed adapting to general text difficulty. An effect similar to the long-term adjustment has been noted in visual search for an oddity target (for example, a red target surrounded by a set of green distractors). If the color of the target to be found is known in advance, it is much easier to get the eyes on to the target than if the only information guiding search is that the target is different. Correspondingly, the latency to get the eyes under way is shorter in blocks of an oddity search task where all targets are of the same color than those when the target color changes unpredictably from trial to trial. Furthermore, if, in the latter case, a run of several trials occurs in which the target color remains constant, the latency is found to decrease during this sequence. This automatic priming effect of prior trials (termed priming of pop-out) shows how the system controlling when the eyes are moved can be adaptable in a flexible and efficient way.

Figure 4 Example of a search display used to study the influence of various factors on eye fixation duration during search. The search target was a complete ring with no gap. From Hooge ITC and Erkelens CJ (1998) Adjustment of fixation duration in visual search. *Vision Research* 38: 1295–1302.

How do factors relating to the immediate search display affect fixation duration? This question was thoroughly investigated by Ignace Hooge and Casper Erkelens using ingeniously designed search displays of the type shown in Figure 4. The search elements were Landolt C discrimination targets and the task was to search for an element that was a complete ring without a gap. The rings were of two thicknesses, fat and thin, and the observers knew that the target would always be a thin ring. Thus the fatter rings were always distractors, and could in principle be identified as such in peripheral vision. The task allowed independent control of the difficulty of the discrimination between fat and thin rings, available in peripheral vision, and the difficulty of discrimination between thin ring distractors and the target, for which foveal or near-foveal vision was required.

It was found that the fixation duration on distractors varied in a systematic way. Fixation durations were always shortest on fat ring distractors, and those on thin ring distractors became longer with shorter gaps and thus with the difficulty of the foveal discrimination needed to distinguish the distractor from the target. The width of the fat rings was varied between blocks of trials, thus varying the difficulty of the peripheral discrimination. This factor did not affect the fixation duration, although it did affect the proportion of times that fat ring distractors were fixated. The conclusion, supported by other studies, is that fixation duration depends on the information processing required in central vision, but is unaffected by what processing is carried out in the parafovea or periphery.

Pipelined Saccade Planning

The picture developed so far has shown how individual saccades may be programmed to be responsive to the

Figure 5 Sequence of displays used in a study by McPeek, Skavenski, and Nakayama, with eye scan traces superimposed. Displays always consisted of three elements and the task was to move the eyes to the odd-colored element, which could be either red or green. Immediately after the first saccade was initiated (switch frame) the display altered (two elements were interchanged). The traces show eye movements in a typical trial in which, although the first saccade landed close to the target location in the changed display, nevertheless a further saccade was made to the original target location. From McPeek RM, Skavenski AA, and Nakayama K (2000) Concurrent processing of saccades in visual search. *Vision Research* 40: 2499–2516.

immediate visual information. This basic pattern must now be supplemented in a variety of ways that allow more long-term influences to affect the eye scanning.

The first consideration is that more than one saccade can be planned at once. A particularly clear demonstration, made by Rob McPeek and collaborators, and termed by them pipelined planning, is shown in Figure 5. The task was an oddity search. On each trial three colored shapes arranged in a triangular array were presented, two red and one green, or one red and two green. The task was to move the eyes to the oddball target, a task that is in fact surprisingly difficult. On some trials, immediately after the eyes started to move, two of the elements were interchanged so the position of the oddball changed. In the case shown in Figure 5 the switch resulted in the target appearing at the destination of the initial saccade (panel b). However the eyes did not stop at this location but made a further saccade to the previous location of the target before a third and final saccade brought the eye back to the new target location. The implication is inescapable that the second saccade had been planned during the fixation before the first saccade. This was also demonstrated by the finding that the interval between first and second saccades was often extremely short. In this and similar demonstrations, the two saccades of interest are generated immediately following display occurrence. There is accumulating evidence that in this situation, one saccade is generated as a reflexive orienting movement responding to the rapid transitory visual stimulation from the display onset, while the other is a more volitional (intentional) movement. Saccades with short latency tend to be of the reflexive type and those with longer latencies are more likely to be volitional. It remains to be established whether such double planning is characteristic of search scanning generally. Fixations of short duration are often observed but these are most frequent before a small corrective saccade, without the selection of a new target.

How Are Saccades Distributed Over a Search Array?

In this section, processes are considered that contribute to search efficiency by distributing scanning to ensure that all parts of the search array are covered. It has been argued in the previous section that saccades are guided on the basis of the two factors derived from the immediate visual stimulation:

proximity to the current fixation location and similarity to the search target. A system that used these factors solely would encounter a problem if two items that were similar to the target were present in close proximity and at some distance from other potential targets. When item A was fixated, item B would be the most salient target, and when a saccade was made to B, then A would become the most salient. The system would be trapped into a salience loop. In the next two sections we consider how such loops are avoided. Obviously, what is needed is some form of memory for items already examined.

The phenomenon of inhibition of return (IOR) appears to be one attractive candidate for such a memory. IOR is a process whereby an item or location that has received attention is tagged in some inhibitory way so that return responses are slowed or rendered less likely. Ray Klein has proposed that it acts as a foraging facilitator, causing return saccades to be avoided. However, this has been disputed, since in fact, saccades returning to the immediately prior scanned item are quite commonly found in search scanpaths (3–4% of saccades is a typical figure), although return saccades to items further back in the sequence are rarer. A resolution of the conflict might be possible if IOR operated in a flexible way. It has been already shown that the time course of IOR is affected by the attentional demands of the material. Thus, rather than being generated automatically at a fixed time after the attention shift, IOR might operate in a manner sufficiently flexible that immediate returns to previously processed items were not precluded. Return saccades would then simply be a reflection of the fact that an item had been incompletely processed on first scan.

Other processes undoubtedly supplement IOR. It is evident that voluntary strategies are potentially available. For example, a regular array based on a rectangular grid could be searched with a raster-scan pattern, as in reading. Adoption of such a strategy ensures that the array is fully sampled and does not require a process such as IOR to avoid backtracking, but this is at the expense of abandoning any general guidance from peripheral vision. With less regular arrays, a similar regular scan could operate if the searcher were somehow able to use an imagined grid. In a recent study, a search task was given requiring search through a small- to medium-sized set of items (up to 12), all perceptually similar. Participants were free to adopt whatever search strategy they wished. Half the participants tested opted for a raster-like strategy. The other half generated a search which was almost as efficient, but they searched much more heuristically, making some use of the external overall contour of the array.

Learning of Contingencies

In the studies so far described, the search target might occur with equal likelihood at all locations within the display. This is, of course, not at all characteristic of more everyday search situations, where some parts of the scene would be very unlikely locations for a target. It might therefore be expected that, when a structured scene is being searched, such contingencies would influence search scanning.

Unsurprisingly, in situations where the target is likely to occur in one region, people are indeed found to concentrate their scanning in this region. However, an important discovery was that more complex contingencies can also be learned readily. These can be demonstrated even in unstructured displays and can occur without conscious awareness. In the late 1990s, Marvin Chun and Yuhong Jiang asked individuals to carry out a search task where the target was a T shape which could be in two orientations (rotated 90° clockwise or counterclockwise) and the distractors were L shapes in eight possible orientations. Target and distractors appeared at locations randomly chosen from a large set and their color was also varied. The task was to find the T shape and report its orientation. During the session, certain displays were regularly repeated. In comparison with displays not repeated, the search time on repeated displays became significantly shorter. When questioned following the experiments, participants showed no awareness that some displays had been repeated. This demonstration shows a learning process at work whereby a successful search for a target at a location in some way renders search more efficient for a target at this location when the display is encountered again. Furthermore, this learning is of an implicit nature, operating below the level of the searcher's conscious awareness.

A subsequent study by Matthew Peterson and Arthur Kramer repeated a similar experiment but in addition recorded the searchers' eye movements. They confirmed that searches were faster in repeated displays and showed that even the very first saccade made after a repeated display was presented was slightly more likely to land on the target than was the case for a novel display. The manner in which the implicit learning guided the eyes appeared to be precise. Over the first few search fixations, saccades were more likely to land on the target in the repeated displays than in the novel displays, but there was not any increased tendency to land on nearby distractors.

Searching in Coherent Scenes

In recent years several groups have developed eye recording technologies that allow gaze recordings to

Figure 6 Two examples of search tasks designed to study the ability to use high-level perceptual features to direct saccades. In each case the observers initially fixated centrally. (a) The task was to make a saccade to the intact face. (b) The task was to make a saccade to the frame that contained an animal. be made while individuals carry out typical real world tasks (e.g., tea making, food preparation). These show an enormously impressive ability to direct gaze sequentially at the appropriate items needed to complete the task, with fixations on extraneous distractor items being very rare. Although these tasks are not primarily search tasks, they contain search requirements and the findings show the very powerful extent to which stored knowledge about the environment can direct eye fixations. In contrast to the contingency learning discussed in the previous section, memory for coherent scenes is available for conscious recall, with the capacity for storage and retrieval of thousands of different scenes being readily demonstrated. It is beyond the scope of the current article to discuss how this form of scene context might guide individual saccades, but an issue that relates more closely to the theme concerns whether complex semantic information can be extracted from peripheral vision rapidly enough to guide the subsequent saccade. Figure 6 shows material from two studies that tested this possibility and led to different outcomes.

In both studies the observer fixated centrally and displays of the type shown appeared. The task was to make a direct saccade to the designated search target. In the first study, the target was a face and the distractors were scrambled faces. Naive participants initiated a saccade rapidly but these saccades did not land on the target more often than on a distractor. Training resulted in greatly improved performance, with subjects withholding the immediate saccade. In the second study, a scene containing animals was paired with a distractor scene without animals. The task was to move the eyes to the animal scene and careful controls were used to prevent the discrimination being possible on any simpler visual factors. In this task, high accuracy (~90%) was obtained with short saccade latency (~200 ms).

These studies give the flavor of current research in the area, in which increasingly realistic visual material is being used. There is now a challenge for neuroscientists to develop an understanding of the underlying brain processes that operate in these tasks so as to extend the accounts that have been developed successfully for simpler search tasks.

Saccadic Eye Movements

L Goffart, CNRS, Marseille, France

© 2009 Elsevier Ltd. All rights reserved.

The sudden appearance of an object in the visual field triggers an orienting shift of the line of sight (gaze) toward its location. This movement is an extremely rapid, steplike rotation of the two eyes – the saccade – which can sometimes be accompanied by a head movement. By positioning the object's image on the retinal region of highest acuity – the fovea – the saccade permits a more refined visual analysis of the object. But saccades are not exclusively aimed at objects that suddenly appear; scanning saccades are also generated when we explore the environment. In this case, saccade goals must be extracted from the visual scene based on their saliency or relevance for subsequent actions (e.g., grasping an object, heading toward a location, avoiding an obstacle, or reading the next word in a sentence).

Studying the neural control of saccades is a choice research theme for investigating how the central nervous system controls goal directed action, not only because the saccade is an essential movement used by vertebrates to spatially organize their sensory experience but also because it is a relatively simple model of the transformations that must be applied to sensory signals in order to generate motor commands for reaching a goal. This research is facilitated by the fact that eye movements can nowadays be recorded with very good spatial and temporal resolutions. Figure 1 illustrates the trajectory and the time course of a saccade aimed at a small target appearing in the peripheral visual field. The trajectory is shown by plotting the vertical versus the horizontal angular deviation (also commonly called position) of the eye (Figure 1(a)). The time course shows that, after a latency (reaction time) of approximately 150 ms, the change in eye orientation is extremely rapid (velocity profiles in Figure 1(c)) and ends with the maintenance of the eye in a new orientation (Figure 1(b)). It also shows that a secondary correction saccade sometimes follows the primary saccade.

This apparently very simple movement is the result of complex muscular and neural activities with a functional organization that is now fairly well understood. In this article instead of describing the path leading from the target-evoked retinal activity to the changes in muscle tension that rotate the eyes, we take the reverse path. Starting from the muscle contractions, we proceed upstream and present the neural mechanisms involved in generating the commands for saccadic eye movements.

Extraocular Muscles and Rotation of the Eyes

Saccades are elicited by the cooperative action of six muscles attached to the eyeball. These muscles are called extraocular muscles, to distinguish them from those located inside the eyeball which influence the diameter of the pupil or the lens curvature. Two pairs of muscles are involved during horizontal rotations of the eyes (i.e., rotations around a vertical axis through the eyeball): the lateral rectus (LR) and medial rectus (MR) muscles. Orienting the right eye toward the right is accomplished by the contraction of the LR and the relaxation of the MR (Figure 2(a)) while in the left eye the MR is contracted and the LR relaxed. Conversely, shifting the gaze toward the left is produced by MR contraction and LR relaxation in the right eye (Figure 2(b)) concomitantly with LR contraction and MR relaxation in the left eye. The muscles that contract are called the agonist muscles; those that relax are called the antagonist muscles.

The muscle contraction generates a torque which is delivered to the eyeball through tendinous attachments. Figure 2(b) shows the tension developed by the LR and MR muscles during a horizontal saccade. The agonist muscle tension waveform first shows a rapid rise in tension, which is followed by a quasi-exponential decay until a steady-state tension is reached that maintains the eye deviated in the orbit. For the antagonist muscle, the tension waveform shows a symmetrical pattern, with a sudden drop in tension followed by an exponential increase until the steady-state tension is also reached. These muscle tension recordings reveal that, after every saccade, the orientation of the eye is settled well before the agonist and antagonist muscle forces reach their final equilibrium. They also illustrate the three components of the innervation signal supplied to the extraocular muscles: a pulse, a slide, and a step component. The pulse and the slide quickly rotate the eyes and stop them abruptly against the viscosity of the muscles and orbital tissues, respectively. The step generates the force required to hold the eyes deviated in the orbit, overcoming the elastic forces that tend to drag the eyes toward their resting position.

Vertical movements of the eyes (rotations about a horizontal axis through the eyeball) are slightly more complex than horizontal ones because they are the result of a synergy between four other extraocular muscles. The joint contraction of the superior rectus (SR) and inferior oblique (IO) muscles of both eyes, combined with the relaxation of the inferior rectus (IR) and superior oblique (SO) muscles, rotates the

Figure 1 Oblique saccade: (a) spatial trajectory; (b) time course of eye position; (c) time course of eye velocity. The oblique saccade is initiated from a fixation stimulus located straight ahead (intersection between the axes in (a)) and aimed at peripheral target located 16° to the right and 8° upward (green diamond). Positive values of horizontal (H) and vertical (V) positions correspond to rightward and upward eye deviations in the orbit.

Figure 2 (a) Extraocular muscles of the right eye; (b) changes in LR and MR muscles tensions during a 16° horizontal saccade. Forces (black traces) are given as percentage of the maximum force (F_{max}). Upward deflection corresponds to muscle contraction; downward deflection corresponds to muscle relaxation. eyes upward. The bilateral contraction of the IR and SO, combined with the relaxation of SR and IO, rotates them downward. To date, there is no recording of the forces developed by these muscles during vertical or oblique saccades. Oblique saccades are generated by tensions simultaneously developed by the muscles rotating the eye horizontally and those rotating the eye vertically.

The Saccade Generators

The force generated by extraocular muscles is driven by the activity of motor neurons (MNs) located in cranial nerve nuclei III (oculomotor), IV (trochlear), and VI (abducens). The schema in Figure 3 shows the current view of the network of motor and premotor neurons which are involved in generating a rightward horizontal saccade (leftward saccades involve a similar neuronal network but located in contralateral territories of the reticular formation). The recruitment of MNs driving the agonist muscles is ensured by a population of excitatory burst neurons (EBNs) located in the ipsilateral pontine reticular formation (path p1). These EBNs drive the activity of abducens MNs innervating the LR of the ipsilateral eye. For contracting the MR in the contralateral eye, the EBN command is relayed to MNs in the oculomotor nucleus by internuclear neurons (INs), also located in the abducens nucleus. In parallel, EBNs activate a population of inhibitory burst neurons (IBNs) located in the ipsilateral medullary reticular formation and which inhibit the activity of EBNs and MNs in the contralateral side (path p2). The burst of ipsilateral IBNs thereby participates in the inhibition of MNs innervating the antagonist muscles (the LR of the left eye and MR of the right eye). In this way, the antagonist muscles relax while the agonist muscles contract. Some neurons in the IBN area also burst during contralateral saccades. If these neurons also inhibit contralateral MNs, the motor command sent to the MNs innervating the agonist muscles must be viewed as the combination of two inputs: an excitatory input from ipsilateral EBNs (path p1) and an inhibitory input from the contralateral IBNs (path p3).

The activity of EBNs and IBNs located in the left and right pontomedullary reticular formations is silenced between every saccade (e.g., when the eyes fixate) through the activity of another class of inhibitory neurons called omnipause neurons (OPNs), which are located in the nuclei raphe interpositus. These OPNs display a sustained activity which is interrupted every time a saccade is generated, irrespective of the amplitude and direction. Released from this sustained inhibition, EBNs and IBNs drive the MNs, which results in a saccadic eye movement.

During upward and downward saccades, different neuronal populations are involved. They are located in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), and their organization has not yet been completely elucidated. One major difference between the neural control of horizontal and vertical saccades is that the former are mostly driven by a unilateral excitatory input (from the ipsilateral pontine reticular region), whereas the latter are driven by a bilateral excitatory input from the left and right riMLF. The direction of oblique saccades is determined by the activation ratios between a unilateral horizontal saccade generator (left or right) and a bilateral vertical saccade generator (up or down). In normal healthy subjects, the examination of

Figure 3 Neuronal organization involved during a rightward saccade. Arrows indicate excitatory connections; connecting lines ended by a circle indicate inhibitory connections. The connecting lines have different colors for clarity. oblique saccades shows that both the horizontal and vertical rotations are initiated simultaneously, not sequentially (see Figure 1). Moreover, some observations show that the horizontal and vertical components are coupled – when the velocity of one component is reduced, the other component is also slowed down, thereby reducing the delay between the completion of horizontal and vertical components. Despite this component-stretching mechanism, the horizontal and vertical components may end at slightly different times. The analysis of saccades generated by neurology patients is very instructive in this matter. For example, in patients suffering from Niemann–Pick type C disease, the horizontal component precedes the vertical component, resulting in the completion of the vertical component well after the end of the horizontal component.

In Figure 3, the same network is involved for a horizontal saccade aimed at an object located 4° or 16° to the right. Additional mechanisms must be added to this network to generate saccades of different amplitudes and durations. In the next section, we describe what is known about how the central nervous system controls the amplitude and duration of saccades.

The Control of Saccade Execution

The Duration and Velocity of Saccades

In almost all studies, the duration of a saccade is defined as the time elapsed from when the eye velocity exceeds a certain threshold (e.g., $15° s^{-1}$) to when it returns below it. The duration of saccades increases linearly with saccade amplitude, ranging from 1° to 50° at a rate of approximately 2–3 ms deg^{-1} in humans (1–2 ms deg^{-1} in monkeys). For saccades less than approximately 30°, the velocity profile is bell-shaped (see Figure 1(c)), with a rapid rise to a peak value (acceleration phase) followed by a symmetrical decline in velocity (deceleration phase). For larger saccades, the velocity profile becomes skewed, with the duration of deceleration phase being longer than the acceleration phase. The peak velocity increases linearly with saccade amplitude until a value of approximately 15°, beyond which the increase in velocity begins to saturate to a maximum value as large as $700° s^{-1}$ ($900° s^{-1}$ in monkeys). These relationships between the amplitude and the duration or peak velocity of saccades are called the main sequences. Because their graphical shapes are relatively similar across healthy subjects, the main sequences have become a tool for studying the oculomotor deficits in brain-lesioned patients. Some authors have also suggested that common physiological systems are responsible for the generation of reactive saccades and voluntary saccades, as well as for the fast phases of optokinetic and rotatory nystagmi.

However, these duration–amplitude and peak velocity–amplitude relationships show considerable variability between subjects and even within the same subject. They are sensitive to alertness, motivation, and several other parameters such as saccade direction, initial deviation of the eyes in the orbit, and the testing conditions (i.e., whether the saccade is memory-guided or immediate). Saccade velocity also depends on the sensory nature of the target. Saccades toward somatosensory and auditory targets are much slower than saccades of comparable amplitude and direction aimed at visual targets. Saccades to moving targets are also slower than saccades of matched amplitude toward stationary targets and are characterized by a lower peak velocity and a prolonged deceleration phase. In some cases, a second peak eye velocity appears during the deceleration phase, presumably reflecting the late influence of a mechanism that compensates for the target displacement occurring before saccade end. Similar late reacceleration peaks are observed in saccades that accompany head movements during very large gaze shifts.

The Spatiotemporal Transformation

On the motor output side, the duration and velocity of saccades are defined by the temporal properties of MN activity. For saccades initiated from the straight ahead position in the orbit, different saccade amplitudes do not involve different groups of MNs; all MNs are recruited. Saccades of increasing amplitude are caused by increases in the duration of MN activity, the instantaneous firing rate dictating instantaneous saccade velocity (rate code). On the other side, at the sensory level, the code is topographic; targets at different locations in the visual field activate different zones in the retina. A topographical organization is found in several regions in the brain, including the intermediate and deep layers of the superior colliculi, the neurons of which are located two to three synapses from the motor nuclei. From a macroscopic point of view, the two deep superior colliculi (dSC) form a motor map, which appears to be in agreement with the retinal map, with the anterior (rostral) regions of both colliculi representing the foveal and perifoveal visual fields, posterior (caudal) regions representing the peripheral visual field, medial regions representing the upper visual field, and the lateral regions representing the lower visual field. In the dSC, neurons discharge a burst of action potentials prior to every contralateral saccade within their movement field (i.e., the range of saccade amplitude and direction that is preceded by a burst). Neurons in the rostral region discharge

maximally prior to small contralateral saccades, whereas neurons in more caudal regions burst before saccades of larger amplitude. Neurons located in the medial border burst prior to upward oblique saccades, and those located on the lateral border burst before downward oblique saccades. Interestingly, the electrical microstimulation of a particular site in the dSC evokes a saccade with amplitude and direction corresponding to those for which the stimulated neurons would maximally discharge. Thus, the amplitude and direction of impending saccades are almost fully determined by the location of active neurons in the dSC, although exceptions exist for some particular saccades.

One fundamental problem is to understand how the locus of collicular activity is converted into the MN firing rate. This transformation was initially considered to be performed by a putative spatiotemporal translator (STT) located in the cerebellum. This STT was viewed as a look-up table mechanism which associated a specific temporal pattern of motor activity with each locus of collicular activity. But, this explanation was not satisfactory because saccades generated toward the same target and from the same starting position can be slower in velocity (longer in duration), yet still have the same amplitude. A solution to this problem was proposed by David A Robinson in 1975 – the duration of saccades is determined by a negative feedback loop. According to this hypothesis, the saccade generators are driven by a motor error signal which results from the comparison between a reference signal, specifying the goal or desired state (e.g., desired eye orientation or desired change in eye orientation), and a feedback signal estimating the current state (current eye orientation or actual change in eye orientation). As long as there is a mismatch between these two internal signals, the motor error drives the saccade generators until the estimated current state matches the desired one. In this framework, the motor error is a dynamic command that changes as the direction of gaze is approaching that of the target. There is no need for an explicit STT; the duration of saccades is simply determined by the time taken to zero-out the motor error command. To date, the negative feedback loop has been the only hypothesis proposed for the spatiotemporal transformation problem. More recently, neuromimetic modeling taught us that the neuronal solutions to the computations involved in saccade generation (e.g., spatiotemporal transformation and component stretching) may not be explicitly performed by separate groups of neurons that neurophysiologists ought to identify. Instead, these computations are implemented implicitly, emerging from the activities of populations of neurons that are massively interconnected and distributed over several neural territories.

The Feedback Control of Saccades

One of the strengths of the negative feedback control is that it endows the oculomotor system with a high level of flexibility for the execution of saccades. If for some reason – pathological (e.g., spinocerebellar degeneration), experimental (functional perturbation by brief electrical microstimulation or by systemic/local injection of pharmacological agents), or natural (drop in vigilance or blink) – the saccade is executed with a velocity which is much slower than normal, its accuracy should be preserved as long as the feedback signal conveys information about the change in velocity.

The feedback signal can originate from several sources. The intrasaccadic visual signals (optic flow and/or target-elicited retinal trace) could participate in estimating the direction of the ongoing saccade. In patients affected by spinocerebellar degeneration, saccades are so dramatically slowed that saccades can even be redirected in flight toward a new target presented during the saccade. But in normal healthy subjects, most saccades are too short in duration for visual signals to influence their ongoing trajectory. Inflow signals originating from sensory receptors located in the orbital tissues or from extraocular muscle proprioception could also be involved in the feedback. But their elimination by sectioning of the ophthalmic branch of the trigeminal nerve does not affect the accuracy and velocity of saccades, nor does it affect the ability to compensate for unexpected changes in eye position prior to saccades toward flashed targets. The estimation of the ongoing oculomotor state could also be based on copies of commands sent to the MNs (efference copy). These outflow signals could originate from collaterals of the burst neurons that immediately drive the MNs. Interestingly, partial pharmacological inactivation of the region involved in the generation of the horizontal component of saccades barely affects the accuracy of the horizontal component of saccades, despite a dramatic reduction in velocity. This result, which demonstrates the feedback control of saccade accuracy also suggests that the number of active neurons influences the velocity of saccades.

The hypothesis of saccade accuracy being controlled by a negative feedback loop also predicts that a defect in estimating the current state should lead to dysmetric saccades. For example, an underestimation of the displacement performed by the eyes from saccade onset is expected to lead to hypermetric saccades (saccades larger in amplitude than required) because the motor error is canceled later than normally (i.e., until the time when the defective estimated displacement matches the desired displacement). Conversely, an overestimation of the actual displacement is expected to lead to

hypometric saccades (i.e., saccades that are smaller in amplitude than required). From this perspective, an optimal control of saccade accuracy requires a calibration of feedback signals such that they accurately represent the actual oculomotor output. A calibration is also required because the neural encoding of feedback signals is not necessarily commensurable with the signals encoding the desired state. Interestingly, one of the major structures involved in the visuomotor calibration of saccades, the medial-posterior cerebellum (composed of the vermal lobules VIc–VII and caudal fastigial nuclei), receives visual motion-related signals from pontine nuclei, proprioceptive signals from extraocular muscles, and eye position/displacement information from the nucleus prepositus hypoglossi/medial vestibular nucleus complex. In return, the output nuclei of the medial-posterior cerebellum, the caudal fastigial nuclei, send distributed projections to the territories housing the premotor neurons of the saccade generators. When the normal function of fastigial oculomotor region (FOR) is impaired, saccades become severely dysmetric.

The Adaptive Control of Saccade Accuracy

Saccade accuracy is also maintained by adaptive mechanisms that assess the error at the end of each saccade and modify the visuomotor transformation to reduce the error of the following saccade. These adaptive mechanisms have been studied in human patients and in monkeys with weakened muscles in one eye. When the subject monocularly views a visual target, saccades are accurate if the normal eye is used but are too small in amplitude when the weakened eye is the viewing eye. If the normal eye is patched and the subject is forced to use the weakened eye to look at visual targets, the amplitude of saccades gradually increases until they are nearly accurate. The fact that the amplitude changes are observed in both the weakened eye and the normal patched eye (which now makes hypermetric saccades) indicates that the adaptive changes affect a command that is issued for conjugate movements of both eyes. This flexibility of the oculomotor system to adjust saccade accuracy has also been studied in experiments in which the target is displaced to a new location during the ongoing saccade. Initially, saccades land near the initial target location, but gradually they land closer to the new one. Despite the plethora of studies characterizing the adaptive properties of the saccadic system, very few studies have tried to decipher the underlying neural mechanisms.

A mismatch between saccade amplitude and target eccentricity seems to also characterize saccades generated by newborns. When orienting toward a peripheral target, infants as young as 1–2 months of age frequently execute a series of consecutive saccades of approximately equal size, whether accompanied by the head or not. Although hypometric, the amplitude of saccades increases with the eccentricity of the target.

The Specification of the Desired State

Saccades are not exclusively aimed at visual targets. They can also be generated in the dark, toward sounds, and to stimuli applied to the skin surface. Localizing such stimuli is a much more complicated task. In the case of a somatosensory stimulus, estimating its location requires the knowledge of the stimulated body region (e.g., the index fingertip of the right hand) and of the posture of the limb on which the stimulus is applied. For auditory stimuli, they are localized on the basis of the interaural differences in intensity and timing of acoustic signals. The dSC seems to be the interface through which these different sensory signals have access to the saccadic motor system. Several saccade-related cells in the dSC are active prior to saccades to visual, somatosensory, or auditory stimuli, suggesting that the converging sensory signals are translated into oculocentric coordinates by the level of the dSC. But the differences in velocity observed among these different groups of saccades suggest that an error signal specifying the desired displacement is not the sole output signal that the dSC sends to the saccade generators. These differences could be due to different levels of firing rate in the population of active neurons or to different population sizes. It is indeed worth mentioning that regular visual saccades also have a reduced velocity and increased duration (accuracy relatively spared) during pharmacological inactivation either of small portions within the dSC or the source of one of its major cortical afferents, the frontal eye fields.

The locus of active neurons in the dSC is not sufficient for determining the amplitude and direction of impending saccades. Some studies show a mismatch between the amplitude and direction of saccades that are actually executed and those represented by the topography of active neurons in the dSC. Indeed, for the same target location, the amplitude and direction are very different between saccades to a permanent target and saccades to a memorized target location. The latter systematically end above the target location. Yet the same population of collicular neurons is involved in both saccade types, suggesting that the change in saccade accuracy is due to different neural activities below the level of the dSC. The same dissociation holds when we compare saccades toward stationary versus moving targets. The latter do not land

on the location where the target was initially detected. Some mechanism tries to compensate for the target displacement that occurred during the period preceding the end of the catch-up saccade. Chemical lesions of middle temporal (MT) cortical area or of its pontine target, the dorsolateral pontine nucleus (DLPN), two structures known to be involved in the processing of visual motion, impair the accuracy of saccades to moving targets without altering that of saccades to stationary targets. Because the DLPN is one of the major sources of motion-related visual signals to the cerebellum, the compensatory mechanism probably involves cerebellar oculomotor regions. Thus, the specification of the saccade goal presumably involves input from the dSC and the cerebellar oculomotor nuclei. Interestingly, for saccades to memorized targets and to moving targets, relationships exist between the accuracy and latency of saccades which may untangle the dynamics of the saccade goal specification.

A dependence of saccade endpoints on the latency has also been documented in studies testing saccades aimed at two stimuli that are simultaneously presented at close locations in the visual field. Under these conditions, the saccade endpoints are scattered along an axis joining the two target locations, characterizing an averaging process. This averaging depends on the relative properties of visual targets (size and energy) – the saccade landing position will be closer to the larger or the brighter target. Moreover, it mostly occurs for short latency saccades and not when the latency exceeds 300 ms. The time window of the averaging process can be delimited by presenting the two targets in a successive manner; short-latency saccades end at the location of the first target, whereas long-latency saccades end at the second target location. The amplitude transition function defines the averaging window that accounts for endpoints that proportionately change with saccade latency.

The Control of Saccade Initiation

Saccades are planned on the basis of information gathered during the time interval that precedes saccade onset. This reaction time is far longer than would be expected by adding the synaptic delays and nerve conduction times between the excitation of sensors and the contraction of extraocular muscles. It reflects the time taken to extract relevant signals from sensors; to make decisions about whether, and how, to respond to the stimulus; and to transmit a goal to the saccadic system. In response to the incoming information about a stimulus, a decision signal is supposed to rise from an initial level until it reaches a threshold level, at which point the saccade is initiated. A rate of rise that varies randomly between trials would explain the wide distribution of saccade latencies.

Several factors influence the latency of saccades. On the retinal side, latency depends, for instance, on the eccentricity of the target, on its energy, and on its contrast relative to the background. Saccade latency also depends on the presence and location of distractors and cues, as well as on more cognitive factors such as the probability of the target location, the amount of reward associated with the target, and the target valence.

Under certain experimental conditions, the distribution of saccade latencies is bimodal. The first mode, which can peak as low as 90 ms, designates the express saccades, whereas the second mode corresponds to regular saccades. The observation of express saccades is facilitated when a temporal gap separates the fixation target offset and second target appearance. Express saccades are suppressed when the deep superior colliculus is lesioned.

Conclusion

Saccadic eye movements are an important component of the animal's behavior for exploring and spatially organizing its sensory environment. They provide a useful tool for understanding how the central nervous system relates the sensorium with the motor repertoire. The neurophysiological approach's aim is to reveal the underlying neuronal organization. It helps us understand why and how the two eyes move together and at the same time and why and how it is possible to look in any direction and orient our gaze exactly to the location where a visual object has appeared. Further empirical research is required to determine the extent to which these basic neural mechanisms participate in the construction of spatial cognition and whether a similar organization underlies the control of other types of goal-directed movements.

Introduction

Sodium is vital for the existence of mammals and our appetite for sodium is undeniable. A fine example is that of the elephants and the caves of Mount Elgon, above the jungles of Kenya. Although it is common to see caves in a volcanic mountain, the way in which one of them, Kitum cave, has developed is unusual. For thousands of years, elephants, with little sodium (Na^+) in their natural diet, have supplemented their intake by 'mining' Kitum cave with their tusks. Antelope and buffaloes also supplement their diets by licking Mount Elgon's cave walls. Wild rabbits in salt-poor alpine areas of Australia have been observed to consume salt from pegs impregnated with sodium salt (NaCl) in preference to pegs impregnated with other non-sodium-containing salts or water. The attraction of wild gorillas and chimpanzees to natural salt sources has also been reported.

Sodium is crucial to numerous physiological functions, from maintenance of extracellular fluid volume, blood circulation, and neuronal function to reproductive success. Thus, sodium homeostasis is fundamental to mammalian life. Mechanisms have evolved to minimize sodium loss, and when sodium is lost it must be replaced. Sodium appetite is an innate drive or motivation to seek out and ingest sodium-containing substances.

The mechanisms involved in the control of sodium appetite are complex and rely heavily on receptor-mediated events. Because sodium ions and water are intimately connected within physiological systems, neuroendocrine mechanisms are needed to coordinate information regarding body fluid status and sodium concentration with the appropriate physiological and behavioral responses. The system includes the central nervous system, cardiovascular system, skin, adrenals, kidneys, and gastrointestinal tract. The biological relevance of sodium appetite emerges with much of the planet's land and, hence, vegetation is impoverished of sodium.

Increased sodium appetite and preference for sodium occurs in humans subsequent to salt loss. A demonstration of this is in the development of highly sophisticated salt trades in African desert dwellers and the medical literature abounds with reports of salt craving in conditions in which the function of the adrenal glands has been disrupted. Both congenital adrenal hypoplasia and Addison's disease (autoimmune destruction of the adrenals) lead to rapid demise, due to salt wasting, if untreated.

Most laboratory research has involved the study of rodents, ruminants, and primates in which sodium appetite in sodium deficiency can manifest as intake of an otherwise aversive high-sodium-containing solution.

This article discusses sodium appetite caused by sodium depletion primarily, but it also covers sodium appetite caused by stress and that observed during reproduction (Figure 1).

Sodium Appetite Induced by Depletion of Body Sodium

Depletion of body sodium, as would occur with diarrhea, profuse sweating, or dietary deficiency, results in a number of important physiological changes. Renal mechanisms are activated to minimize loss of body sodium. Activation of the renin–angiotensin–aldosterone system causes increased secretion of the adrenal mineralocorticoid hormone aldosterone that acts on the kidney to maximize reabsorption of sodium. A powerful, specific sodium appetite then develops. This appetite can be caused by a decrease in brain intracellular and cerebrospinal fluid sodium concentration, a decrease in plasma volume, or an increase in blood and brain levels of aldosterone and/or the peptide angiotensin II (Ang II). The appetite is a classic example of an innate neural organization generating a behavioral drive in the instance of a nutritional deficiency. The mechanisms responsible for the generation of this appetite for sodium are complex, and although much is now known, numerous gaps remain.

Factors Involved in Sodium Depletion-Induced Sodium Appetite

Brain Sodium Concentration Evidence to support the hypothesis that changes in the intracellular fluid sodium concentration within cells that subserve sodium appetite contribute to the sodium appetite following sodium depletion was based on experiments using slow intracerebroventricular (ICV) infusion of substances that raise or lower sodium and/or osmolality of the cerebrospinal fluid and surrounding brain nuclei. Sodium intake of sodium-deplete sheep was enhanced by decreasing and reduced by increasing the sodium concentration of the cerebrospinal fluid and

Figure 1 Factors influencing sodium appetite.

brain extracellular fluid, independently of peripheral sodium (i.e., the animal remained sodium deficient). Changes in osmolality did not influence sodium intake. Presumably, the changes in cerebral sodium concentration act on the neural mechanisms involved in the initiation and/or satiation of sodium appetite. Evidence obtained from sheep and cows suggests that cerebral sodium sensors subserving sodium appetite are some distance from the brain's ventricular system and are spatially different from those subserving thirst. A sodium channel (Na_X) thought to be the sodium sensor has been identified in rodents and is preferentially expressed in the circumventricular organs (i.e., circumventricular organs (CVOs), which are brain structures lacking a blood–brain barrier, such as subfornical organ (SFO), organum vasculosum of the lamina terminalis (OVLT), and area postrema (AP)). Increased sodium appetite is observed in mice in which the channel is absent.

Angiotensin II Ang II, an eight-amino-acid peptide, is formed in the peripheral circulation. The renal enzyme, renin, acts on its substrate, angiotensinogen, to form angiotensin I (Ang I), which is then converted to the biologically active Ang II by the action of angiotensin converting enzyme (ACE). Ang II is also formed in the brain, possibly from a precursor such as proangiotensin or preproangiotensin. Several receptor subtypes mediate the activities of Ang II, the best studied of which are type 1 (AT1) and type 2 (AT2). Administration of antagonists of the renin–angiotensin system, peripherally or centrally, has clearly shown that Ang II has a role in sodium appetite induced by sodium depletion. However, controversy exists regarding the relative contribution of Ang II generated in brain and that generated peripherally.

Peripheral administration of ACE inhibitors, such as captopril or enalapril, reduces sodium intake of sodium-deplete rats, sheep, cows, rabbits, mice, and baboons. Furthermore, the sodium appetite of the systemic captopril-treated sodium-deplete animal is restored to the appropriate level by intravenous, but not ICV, administration of Ang II. Importantly, it has been shown that the decrease in blood pressure caused by the administration of the ACE inhibitors is not the cause of the decreased appetite because the appetite is not restored by peripheral administration of phenylephrine at a dose that restores blood pressure. Since Ang II does not readily cross the blood–brain barrier, it is clear that one element in the genesis of the sodium intake of the sodium-deplete animal is mediated by peripherally generated Ang II acting in brain areas without a blood–brain barrier.

In addition to the role of peripheral Ang II, evidence suggests that central angiotensinergic mechanisms (i.e., brain Ang II) are involved in the control of sodium appetite of sodium-deplete animals. For example, administration of ACE inhibitors or Ang II receptor antagonists into the brain decreases the sodium intake of sodium-deplete rats. Whether or not Ang II has a direct influence on neurons subserving sodium appetite has still to be resolved.

Mineralocorticoid hormones The steroid hormones of both the mineralocorticoid (MC) and the glucocorticoid (GC; e.g., cortisol or corticosterone) classes appear to be involved in sodium appetite following sodium depletion, stress, or reproduction. Research has demonstrated that administration of aldosterone or deoxycorticosterone (DOC), another MC hormone, causes sodium appetite in rats, mice, rabbits, hamsters, and sheep. Curiously, the increase in sodium appetite caused by DOC appears greater than that caused by aldosterone, even though aldosterone is a more potent mineralocorticoid receptor (MR) agonist. Due to their lipophilic nature, steroid hormones cross the blood–brain barrier and increased brain levels reflect an increase in peripheral levels. One possible explanation for the difference between aldosterone and DOC in regard sodium appetite, however, is the observation that aldosterone does not penetrate the blood–brain barrier as well as DOC.

In rats, evidence suggests that the amygdala is important in steroid-induced sodium appetite. The amygdala has both MR and Ang II terminals and is the terminus for major gustatory projections from

the nucleus of the solitary tract (NTS) and parabrachial nucleus (PBN). Administration into the amygdala of aldosterone or DOC increases sodium intake in rats. Interference with MR, but not glucocorticoid receptor, formation in the amygdala (by antisense treatment) interferes with the expression of DOC-induced sodium appetite.

However, it is not clear how endogenous aldosterone can stimulate sodium appetite. That is, GCs have an affinity for MRs similar to that of aldosterone, but since the blood concentration of the GCs is 100–1000 times that of aldosterone, MRs are predominantly occupied by GCs. The answer seems to involve 11-β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), an enzyme that confers MR aldosterone specificity by converting active GC to an inactive form (e.g., cortisone). Interestingly, the amygdala does not have 11β-HSD2. Conceivably, aldosterone, a hormone produced in small amounts in the brain, is generated in the amygdala. Work has shown that some neurons in the NTS contain both MRs and 11β-HSD2. These neurons are sensitive to aldosterone; however, they become activated by sodium depletion even in the absence of increased aldosterone secretion. Although research is ongoing, it seems clear that determining a biological basis of sodium appetite will involve a better understanding of these cells.

In addition, sodium intake in rats is increased by 3β,5β-tetrahydroaldosterone (or 5α-tetrahydro-deoxycorticosterone), an A-ring reduced form of aldosterone (or DOC), a steroid that binds to GABAergic membrane receptors but not to intracellular MRs. Thus, mineralocorticoids can act on brain nuclei, particularly in the amygdala, to influence sodium intake through both genomic mechanisms (involving cytosolic MR) and nongenomic mechanisms via $GABA_A$ receptors.

It has been suggested that sodium appetite caused by sodium depletion is mediated by the synergy between aldosterone and Ang II. The synergy hypothesis is tested by concurrent administration of Ang II centrally and DOC or aldosterone systemically at doses that, individually, do not stimulate NaCl intake. Using this model, increased sodium appetite has been reported in rats and pigeons, but it could not be demonstrated in sheep or rabbits. Experiments have demonstrated synergy between Ang II and aldosterone in a primate.

Finally, adrenocorticotrophin hormone (ACTH), a peptide hormone associated with stress and reproduction, causes sodium appetite, which is partially (rabbits) or entirely (sheep and rats) dependent on adrenal hormones (i.e., it is partially or entirely eliminated in adrenalectomized (ADX) animals – animals without intrinsic MCs). However, sodium depletion-induced sodium appetite still occurs in ADX animals. Administration of GC hormones can cause and/or enhance MC-induced sodium appetite.

Central factors

Excitatory mechanisms. As noted previously, Ang II does not readily cross the blood–brain barrier. Thus, the role of circulating Ang II in salt appetite is most likely mediated by its influence on CVOs. In the sodium appetite of sodium-deplete animals, the role of peripheral Ang II acting in the lamina terminalis is suggested by the fact that sodium appetite is decreased or abolished in rats with lesion of the SFO, OVLT, or the anteroventral third ventricle (AV3V; a brain area including the ventral median preoptic nucleus (vMnPO) and OVLT).

Central Ang II-driven mechanisms are involved in neural pathways thought to subserve both physiological sodium appetite and thirst. Ang II and Ang II receptors have been identified in a number of different brain structures, including the hypothalamus (e.g., paraventricular nucleus (PVN) and supraoptic nucleus (SON)), the amygdala and bed nucleus of the stria terminalis (BNST), and the brain areas located on the midline of the front wall of the third brain ventricle (i.e., SFO, MnPO, and OVLT). There is an angiotensinergic pathway between the SFO and the PVN. Lesion experiments have implicated several brain areas with a blood–brain barrier in sodium appetite, such as MnPO, PBN, anterior and lateral hypothalamus, gustatory nucleus of the thalamus, nucleus accumbens, and amygdala.

Mineralocorticoids act on brain nuclei, particularly in the amygdala, to influence sodium intake through both genomic (involving cytosolic receptors) and nongenomic mechanisms. The synergy between the two major hormones of sodium deficiency (Ang II and aldosterone) might occur by (1) interaction between brain sites that are separately sensitive to Ang II (e.g., lamina terminalis) or aldosterone (e.g., amygdala); or, more directly, (2) interaction at the same brain site, for example, by aldosterone upregulating Ang II receptors, increasing Ang II binding to receptors and enhancing responses to receptor activation (e.g., increases in Ang II binding at AT1 receptors occur with administration (at the SFO and AP) of glucocorticoid and mineralocorticoid); or (3) the inhibition of central inhibitory mechanisms.

MRs are located in SFO, MnPO, OVLT, AP, NTS, periventricular brain regions, and some amygdaloid nuclei, but not in PVN or SON. Sodium appetite induced by treatment with DOC is enhanced, rather than depressed, in rats with lesions of the OVLT and is unchanged in rats with lesions of the SFO

or AV3V. Rats with lesions of the medial amygdala have impaired aldosterone- or DOC-induced sodium appetite, and the corticosterone potentiation of aldosterone-induced salt appetite is eliminated. Rats with lesions of the central amygdala or BNST show deficits in sodium appetite induced by DOC.

Inhibitory mechanisms. Brain activity in the OVLT and, to a lesser extent, the SFO is decreased subsequent to sodium intake, whereas sodium intake after sodium depletion has been shown to increase cellular activity (as measured by Fos expression) in the PVN or NTS. These observations suggest that the SFO, OVLT, PVN, and NTS may be involved in the inhibition or satiation processes related to termination of sodium appetite.

A number of neuropeptides have been shown to interfere with sodium appetite subsequent to sodium depletion. In some instances, Ang II, presumably in the neural system subserving thirst, stimulates the release of a neuropeptide that inhibits sodium appetite and Ang II may even inhibit sodium appetite through factors such as increased blood pressure.

Because Ang II is involved in both sodium appetite and thirst (i.e., for water), specificity of intake is achieved by the interaction of angiotensinergic mechanisms with other inhibitory systems. For example, in situations requiring the ingestion of water, stimulation of angiotensinergic thirst mechanisms causes the release of neuropeptides that inhibit or delay sodium intake. In situations requiring the ingestion of sodium, stimulation of angiotensinergic mechanisms involved in sodium appetite could cause the release of neuropeptides that inhibit or delay water intake.

Much evidence suggests that oxytocinergic cells in the PVN are involved in this inhibition of sodium intake. For example, treatments that stimulate sodium intake (e.g., sodium depletion and DOC) decrease OT levels, whereas treatments that decrease sodium intake increase OT levels. Interestingly, central administration of Ang II causes a small increase in sodium intake even though it increases pituitary release of OT. However, sodium intake is greatly enhanced by prior treatment with the central administration of an OT antagonist. Increased sodium intake after central administration of Ang II is also observed with DOC treatment. Administration of DOC also decreases Ang II-induced Fos expression in the PVN and SON.

Evidence suggests that other systems may also be involved in the inhibition of sodium appetite. Decreased serotonin in the raphe nucleus following ingestion of sodium after sodium depletion suggests that serotonergic cells in the raphe nucleus may be involved in inhibition of sodium intake. The administration of fenfluramine or dexfenfluramine, drugs that enhance serotonergic transmission, decreases sodium intake of sodium-depleted rats. Pharmacological blockade of the inhibitory serotonergic system or lesion of the dorsal raphe nucleus increases spontaneous sodium intake as well as the sodium intake of sodium-depleted rats. Injection into the MnPO of L-NAME, a nitric oxide synthesis inhibitor, stimulates sodium intake, suggesting an NO inhibitory system in the MnPO. Somatostatin, atrial natriuretic peptide (ANP), and a number of the tachykinins have also been shown to have an inhibitory effect on sodium appetite. These inhibitory peptides and/or their receptors have been identified in the CVOs as well as other areas implicated in sodium appetite.

Sodium Appetite Induced by Stress and Stress Hormones

The perception of a threat (stress) causes increased release of corticotrophin-releasing factor (CRF)/urocortin (UCN), which in turn causes release of ACTH from the pituitary. ACTH acts on receptors in the adrenal gland to cause the release of adrenocortical hormones. Stress or the hormonal consequences of stress (primarily release of ACTH and the adrenocorticoids) elicits sodium appetite (Figure 2). The

Figure 2 Stress and sodium appetite. Reproduced from Weisinger RS, Blair-West JR, Burns P, Chen N, and Weisinger HS (2004) Neurobiology of sodium appetite. In: Strickter E and Woods S (eds.) *Handbook of Behavioral Neurobiology: Neurobiology of Food and Fluid Intake*, 2nd edn., vol. 14, pp. 547–587, with kind permission of Springer Science and Business Media.

influence of the adrenocorticoids has already been discussed, and the influence of ACTH and CRF/UCN is discussed later.

One of the first demonstrations of stress-induced sodium appetite was made while attempting to fit wild rabbits with jackets designed for carrying small infusion pumps. This restraint of movement caused the rabbits to become agitated and over the course of several days a spectacular increase in sodium appetite was observed. Immobilized or restrained mice also manifest an increase in sodium appetite. 'Intruder' stress causes increased sodium intake in several rat strains, and crowding, a type of imposed social stress, has been shown to cause increased intake of hypertonic NaCl solution. Clonidine or reserpine (centrally acting sympathetic antagonists) blocks the increase in sodium intake, suggesting that the increase in intake is due to stimulation of the sympathetic nervous system. The mechanism by which stimulation of the sympathetic nervous system stimulates sodium appetite is not known.

Adrenocorticotrophic Hormone

Peripheral administration of ACTH causes a large increase in sodium intake in several species, including sheep, rabbits, rats, and mice. Sodium appetite following administration of ACTH can be eliminated by adrenalectomy and, therefore, probably involves the activity of adrenal hormones. In all of the animals tested with a cafeteria of hypertonic solutions of NaCl, KCl, $CaCl_2$, and $MgCl_2$, the appetite generated by ACTH administration is predominantly that of NaCl solution. In intact sheep, a large increase in sodium intake occurs after 2 or 3 days of ACTH administration. In ADX sheep, administration of a cocktail of hormones that are secreted from the adrenal gland during stimulation with ACTH (i.e., aldosterone, corticosterone, cortisol, 11-deoxycortisol, and deoxycorticosterone) causes an increase in sodium appetite which is similar to that induced by ACTH in intact animals. In intact rabbits, concurrent administration of cortisol and corticosterone, in doses that increase plasma levels to those observed in ACTH-treated animals, increases appetite by approximately half as much as that caused by ACTH.

ACTH-induced sodium appetite has been clearly demonstrated in ADX rabbits, maintained in good health with combined MC–GC treatment. The MC treatment was such that urinary sodium loss was minimized, whereas the GC treatment was such that blood ACTH was maintained at a basal level; blood glucocorticoids have a negative feedback control of ACTH secretion. When GC treatment was reduced such that blood ACTH was no longer maintained at basal level, sodium intake was increased. This evidence is consistent with the ability of ACTH to stimulate sodium appetite independent of steroid hormones and not due to sodium loss.

In rats, sodium intake (and output) is approximately equal to the rat's total body sodium by the fifth day of ACTH administration. ACTH also increased the sodium intake of both the SHR and WKY rats. In SHR rats, the increase was in addition to their already high-sodium intake. ACTH did not affect sodium appetite of baboons or pigs.

Corticotrophin-Releasing Factor/Urocortin

CRF, a 41-amino acid peptide, is expressed in neurons or terminals throughout the limbic system (e.g., hypothalamus and amygdala) as well as in systems associated with autonomic function (e.g., PBN and locus coeruleus). CRF is involved in the initiation of the behavioral and physiological responses to stress. UCN, also a 41-amino acid peptide, has a 45% homology with CRF and binds with high affinity to CRF receptors. UCN is expressed in many of the same brain areas as CRF, including those involved in body fluid and electrolyte homeostasis, and may contribute to responses previously attributed to CRF.

Administration of either CRF or UCN would be expected to increase sodium intake due to stimulation of sympathetic nervous system activity and ACTH secretion. Indeed, ICV administration of CRF increases sodium intake in rabbits while also causing a sustained increase in both cortisol and corticosterone. In experiments in sheep, however, prolonged ICV or intravenous administration of CRF or UCN failed to stimulate sodium appetite, despite increased secretion of ACTH. Furthermore, prolonged ICV infusions of CRF and UCN decreased need-free salt (and food) intake in sheep, mice, and baboons. The decrease in sodium intake in baboons was transient, but the decrease in food intake was sustained throughout the infusion period. Hence, there appear to be interspecies differences and the mechanisms responsible for the inhibition of sodium appetite are unclear.

Presumably, the inhibition of sodium appetite is caused by the influence of CRF on systems other than those influencing ACTH secretion or sympathetic nervous activity, such as oxytocin secretion. Clearly, the inhibitory actions of CRF and UCN need further exploration.

Angiotensin II

The increased sodium intake of restrained mice is prevented by treatment with captopril. This finding suggests that the appetite involves the renin–angiotensin system, which is known to be elevated under stress. It has been suggested that both peripherally generated and centrally generated Ang II can stimulate the

secretion of ACTH, the latter via its influence on CRF release from the PVN. Increased sodium intake in mice observed during cold stress has also been attributed to increased activity of the renin–angiotensin system. In mice, the increase in sodium intake caused by ACTH is not altered by treatment with captopril, and it appears that stress-induced Ang II precedes the increase in ACTH because stress-induced, but not ACTH-induced, sodium intake is blocked by captopril.

Brain Structures Activated by Stress or Stress Hormones

In crowded rats, Fos is increased in a number of brain areas, including the SFO, PVN, and amygdala. Increased Fos has also been reported in a number of brain areas (e.g., PVN, SON, locus coeruleus, BNST, midbrain raphe, NTS, amygdala, cortex, lateral septum, lateral preoptic area, anterior hypothalamus, LH, Barrington's nucleus, BNST, and striatum) in rats subjected to stress.

Sodium Appetite during Pregnancy and Lactation

Sodium intake is essential for reproductive success. In both rats and humans, plasma [Na^+] is decreased during pregnancy due to the actions of the hormone relaxin on the osmotic threshold for thirst and secretion of antidiuretic hormone. Despite the decreased plasma sodium concentration, retention of sodium is increased during pregnancy, with more than 55% of the sodium found in the products of conception. The reproductive process is a powerful stimulus of specific sodium appetite in several species. Increased sodium intake occurs in pregnancy and is then further augmented during lactation. ACTH seems to be part of the hormone complement necessary to induce this appetite. Treating rabbits initially with estradiol and progesterone and then with prolactin, ACTH, and oxytocin causes an increase in sodium intake similar to that seen during lactation. Thus, the behavior is primarily hormone induced, as distinct from it being determined by sodium deficiency caused by sequestration of sodium in the products of conception or loss of sodium in milk.

Ang II does not appear to have a role in the increase in water and sodium intake observed in pregnant rats because peripheral administration of losartan from day 2 to day 19 of gestation does not alter sodium intake.

Conclusions

The control of sodium appetite is as complex as it is vital to survival, involving neuroendocrine, behavioral, and multiple organ integration. As animals evolved, the challenges faced by each species varied, as did the mechanisms adapted to deal with those challenges. At the same time, presumably, the challenges imposed by sodium deficiency, stress, pregnancy and lactation, and the subsequent need to ingest sodium were integrated into the mechanisms required for survival in general. Thus, although the need for sodium and the ingestion of sodium may be common to most, if not all, terrestrial animals, it appears that in some instances different mechanisms have evolved.

Ang II has an important role in the control of sodium appetite. The relative contributions of peripheral and central Ang II to sodium depletion-induced sodium appetite are not completely understood. As sodium depletion increases, both peripheral and, presumably, central levels of Ang II increase. Peripheral Ang II, acting on AT1 receptors in CVOs, and brain Ang II, acting at AT1 receptors in brain structures with a blood–brain barrier such as the MnPO and amygdala, influence sodium appetite.

Increased blood levels of Ang II, caused by sodium depletion, stimulate the secretion of aldosterone. When the formation or action of Ang II is blocked, sodium appetite is decreased. Sodium appetite may be due to the increase in Ang II formation and concentration in the brain, possibly in synergy with the elevated blood levels of aldosterone. In addition, decreased cerebral sodium concentration may increase sodium intake by acting on sodium sensors or by increasing aldosterone secretion. Ang II, as a neurotransmitter, may have a role in these effects as well. Adrenocorticoid hormones may also contribute to sodium appetite by enhancing the central actions of Ang II or by acting directly on receptors located in the amygdala, BNST, and special cells in the NTS to cause sodium appetite. However, a role for adrenocortical hormones acting on receptors located in the lamina terminalis cannot be ruled out. Elucidation of these pathways and mechanisms will be challenging.

Inhibitory factors are important to the control of sodium appetite. Oxytocin and somatostatin are neuropeptides with some specificity with regard to body fluid homeostatic mechanisms (i.e., they inhibit sodium but not water intake). ANP, on the other hand, appears to have a universal inhibitory role in both sodium appetite and thirst. Brain serotonergic mechanisms appear to have an inhibitory input to sodium appetite.

Several peptides have been shown to influence sodium appetite, although their precise physiological role remains undefined. Although extensively explored, the pharmacoanatomical organization of the neural systems subserving sodium appetite is unclear. Regarding arousal of appetite, striking species differences have been demonstrated and are believed to reflect differing evolutionary selection pressures contingent on different

Figure 3 Central and peripheral factors involved in sodium appetite. Reproduced from Weisinger RS, Blair-West JR, Burns P, Chen N, and Weisinger HS (2004) Neurobiology of sodium appetite. feeding habits. It is also clear that different stimuli arouse appetite in different situations, with complex neurochemical organization within the brain underlying such behavior.

Stress and hormones associated with the stress response (e.g., ACTH and adrenocortical hormones) can cause sodium appetite. Although there is evidence in the rabbit for a direct effect of ACTH on sodium appetite, in rats and sheep the increased intake caused by ACTH appears to be mediated by its influence of the secretion of adrenocortical hormones. An increase in Ang II or activity of the sympathetic nervous system caused by stress also may stimulate sodium intake. The failure of CRF/UCN to stimulate sodium appetite is paradoxical and the mechanisms responsible are still to be discovered.

Increased sodium intake occurs during pregnancy and lactation. In rats, like humans, during pregnancy the plasma volume is maintained above normal level and plasma sodium concentration is maintained below normal level. Increased intake of sodium, which is required for the products of conception and reproductive success, is observed. The increase in sodium intake has been studied in the rabbit and appears to depend on the hormonal consequences of pregnancy and lactation, including ACTH. Thus, the sodium appetite could be generated, at least in part, by adrenocortical hormones utilizing mechanisms thought to contribute to the sodium appetite observed during stress or sodium depletion. Thus, notwithstanding the exceptions noted previously, in the main similar brain mechanisms (Figure 3) may be involved in the control of sodium appetite observed with sodium depletion, stress, pregnancy, and lactation.

Schizophrenia: Epidemiology, Clinical Features, Course and Outcome

W G Frankle, University of Pittsburgh, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Schizophrenia represents a brain disorder (or cluster of disorders) characterized by hallucinations, delusions, impairments in cognitive functioning, and blunted emotional relatedness. It ranks among the top diseases as a cause of disability in industrialized nations. With its onset in adolescence or early adulthood and the lack of fully effective treatments, it contributes greatly to the global burden of disease. In the United States alone, the direct and indirect costs of schizophrenia were estimated at $32.5 billion in 1990. In addition, it is associated with increased rates of general medical illnesses, including heart disease and diabetes, as well as frequent comorbid psychiatric illnesses such as substance abuse. Although significant advances have been made in the treatment of this disorder during the past 50 years, much remains unknown regarding the transmission, clinical course, and optimum therapy for this illness.

Epidemiology

Studies exploring the epidemiology of schizophrenia have been performed since the work of Koller in 1895 highlighted the heritability of this disorder. However, in the intervening century, the determination of epidemiologic factors relating to schizophrenia, such as incidence, population prevalence, and risk factors, has been disadvantaged by methodological problems not encountered in nonpsychiatric complex disease processes. First and foremost has been the issue of case identification. To date, as with all psychiatric illnesses, there are no biological tests to determine the disease state, and therefore clinical interviews, clinical observations, and self-reports form the basis for diagnosis. Moreover, shifting definitions have been utilized as diagnostic criteria for schizophrenia, confounding comparisons across studies and over time. With the development of standardized criteria for diagnosis in the 1980s, the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) and the tenth revision of the *International Statistical Classification of Diseases and Related Health Problems* allowed for structured interviews and agreed-on criteria for case identification, providing improved reliability in the diagnosis.

Prevalence and Incidence

The prevalence of a disease represents the morbidity of the disease in the population and is a combination of the incidence and the length of the illness. Although certain small populations exist in which the prevalence of schizophrenia has been found to be significantly increased or decreased compared with larger samples, the point prevalence rates across populations are, in general, similar, in the range of four per thousand, with lifetime morbidity rates in the range of seven to eight per thousand.

The incidence rate of a disease represents the risk of that disease's occurring at a point in time in a particular population. As the onset of schizophrenia is a relatively rare event, studies examining the incidence rate of schizophrenia generally use the point of first contact with mental health workers as the time of onset of the illness. This potentially represents a confound since the actual onset of symptoms frequently precedes contact with the mental health system by several years, a problem which some studies address by defining the time of onset retrospectively, although this is not ideal either. Incidence rates of schizophrenia across studies range from 0.07 to 7.1 per thousand per year. The WHO Determinants of Outcome study, published in 1992, was a ten-country study of schizophrenia which provided insights into the variability of this disease across cultures. Using a restrictive definition of schizophrenia, the WHO study found that there were no differences across countries in the annual rates of schizophrenia, with rates averaging around 0.10 per thousand annually. Given that the WHO incidence rates were similar across cultures, it would seem that factors such as climate and economic development of a country play little or no role in the risk for schizophrenia.

Moreover, there appears to be no difference between men and women in lifetime risk for schizophrenia. The lifetime risk for diagnosis of schizophrenia was determined to be approximately 0.13 per thousand in a study of first-admission cases by Häfner and colleagues. However, gender differences are apparent when comparing the age of onset of the illness. The age range of maximum risk for schizophrenia extends from 15 to 30 years old; for men the onset tends to occur about 4–5 years earlier than for women. As noted previously, first contact with mental health services is frequently delayed from the onset of the illness

and occurs between 25 and 35 years of age for both men and women. In spite of the age difference in onset between men and women, the core features of the illness are similar in both genders.

There are several other findings relating to the epidemiology of schizophrenia that remain interesting but are of uncertain significance. First is the finding of increased rates of schizophrenia in urban centers. At times this has been attributed to a 'drift' phenomenon; in other terms, individuals with schizophrenia may tend to migrate to urban areas. However, although Marcelis and colleagues in 1998 found a significant, positive correlation between the size of urban centers and the incidence of schizophrenia, they were not able to detect a difference between urban birth and urban residence. Another interesting epidemiological factor that remains unexplained is the highly replicated finding relating to season of birth. In the northern hemisphere, there is a 5–8% increase in schizophrenia births in the winter and spring compared with the other seasons. Finally, reports have repeatedly shown an increased prevalence of schizophrenia in immigrants compared with native-born individuals; however, methodological issues such as access to care, diagnostic difficulties due to language, and cultural issues confound the interpretation of these reports.

Risk Factors

Family history of the illness represents the single greatest risk factor for developing schizophrenia and was observed in the very first studies of this disease by individuals such as Koller and Kraepelin in the early twentieth century. The lifetime risk of developing schizophrenia for an individual with a first-degree relative who had the illness is 1–16%, compared with less than 1% in the general population. Individuals with a schizophrenic parent have a 15-fold increased risk of developing the illness; for siblings of an individual with schizophrenia, the risk of developing the illness is about tenfold greater than the general population. Second-degree relatives (nephews, nieces, grandchildren, and half-siblings) have approximate 3 times the rate of schizophrenia in the general population. The concordance rate for monozygotic twins ranges from 35% to 69%, depending on the study, while that for dizygotic twins is similar to that of siblings (0–26%). Adoption studies show that the risk of an adopted child's developing schizophrenia depends on the presence of schizophrenia in a biological parent rather than in the adoptive environment. Taken together, these findings indicate that genetic predisposition to schizophrenia is a risk for, but is not sufficient for, developing the illness and that environmental factors clearly play a role.

A variety of environmental factors have been examined as being potentially related to the development of schizophrenia; however, to date none have been demonstrated to be definitively causal. Among these factors are difficulties during pregnancy or birth, perinatal brain damage, and various early infections. Several studies have shown that obstetrical complications are associated with increased risk for developing schizophrenia, on the order of 3 times the risk of those without obstetrical complications. In one study, the most significant risk was represented by perinatal brain damage, which carried a sevenfold increase in risk of schizophrenia. Intrauterine exposure to influenza or central nervous system infections has also been associated with increased rates of schizophrenia, although more-recent work has not been able to replicate the findings related to maternal influenza infection.

Additional factors associated with the subsequent development of schizophrenia include poor premorbid adjustment, with few friends, isolative behavior, and lack of significant romantic relationships. However, as these patterns can be seen frequently in the at-risk age group of adolescence, their usefulness in predicting the development of schizophrenia is limited; furthermore, it is not clear whether these factors represent part of the illness prodrome or the risk factors.

Recent literature has implicated premorbid cannabis use as a risk factor in the development of schizophrenia. It has been evident for some time that the rates of cannabis use among individuals with schizophrenia are higher than those among the general population, but now, as reviewed by Arseneault and colleagues in 2004, a relatively strong association (odds ratio > 2) between premorbid cannabis use and schizophrenia has been observed, particularly when cannabis use occurs in adolescence. These data have led to an increased interest in the link between cannabis use or abuse and the pathophysiology and/or etiology of schizophrenia. Still other risk factors linked to the development of schizophrenia include low premorbid IQ, increasing paternal age, and epilepsy; however, no single risk factor has been shown to be causal in the development of schizophrenia. In conclusion, the transmission of schizophrenia is complex and likely involves multiple interacting genes which lead to a predisposition to the illness and that may combine with as yet incompletely identified contributing environmental factors.

Clinical Features

The current nosology of schizophrenia can be traced to the German psychiatrist Emil Kraepelin. Relying on his research, Kraepelin promoted the observation

that there was no specific clinical symptom or symptoms unique to the major mental illnesses but rather a specific pattern of symptoms and course which differentiated these disorders. Using this observation, he began to develop a classification system for mental illnesses which not only incorporated the clinical symptoms but also relied on criteria of age of onset, course, outcome, and prognosis to separate these disorders. It was with the publication of the sixth edition of his textbook in 1899 that Kraepelin separated the entity of dementia praecox from manic depressive illness. The term 'dementia praecox' (as 'demencé precocé') was first used by Benedict Augustin Morel in 1852 to describe the onset of dementia in young patients. Kraepelin defined dementia praecox as "subacute development of a peculiar simple condition of mental weakness occurring at a youthful age" and separated this entity into three forms – hebephrenic, catatonic, and paranoid (expanding on prior work by Hecker and Kahlbaum). The true advance by Kraepelin in this area came with his emphasis on etiology and outcome of the illness. He noted hereditary and premorbid personality as contributing to the appearance of dementia praecox, as well as suggesting that the presence of external factors, such as premature birth and/or obstetrical complications, might increase the likelihood of developing this illness. Most notably, he highlighted the underlying biological nature of the illness and the progressive, relapsing nature of dementia praecox.

The term 'schizophrenia' was introduced by the Swiss psychiatrist Eugene Bleuler (1908), who defined it as a group of psychoses characterized by alterations in thinking, feeling, and relatedness to the outside world. Bleuler noted four primary or core features of the illness, (1) looseness of associations, (2) affective flattening, (3) autism, and (4) ambivalence, which became known as 'the four A's' and were widely utilized as diagnostic criteria for schizophrenia. Bleuler considered these symptoms essential for the diagnosis, with the presence of additional, accessory features, including hallucinations and delusions, being secondary to the diagnosis. The four A's continued to be used in the diagnosis of schizophrenia until the work of Kurt Schneider, who in 1957 described first-rank symptoms of schizophrenia. These included audible thoughts; voices arguing, discussing, or commenting; somatic passivity experiences; thought withdrawal; thought broadcasting; and delusional perceptions.

Schneider's criteria shaped the current diagnostic definition of schizophrenia and have been largely incorporated into the DSM-IV, which uses a descriptive definition of the illness. The DSM-IV criteria define what have come to be known as positive symptoms and negative symptoms of the illness. Positive symptoms represent the psychotic features of the illness and include hallucinations, delusions, disorganized speech, and disorganized behavior. The negative symptoms of the illness are the absence of normal behaviors and include affective flattening, alogia, apathy, and avolition. In addition to clinical symptoms, the DSM-IV diagnostic criteria for schizophrenia requires impairment in function of one or more major areas, such as work, interpersonal relations, or self-care, defined as markedly below the level achieved prior to the onset of the illness. Continuous signs of the disturbance must persist for at least 6 months in order to meet the DSM-IV level of schizophrenia.

Although they are not specifically listed as a diagnostic criterion for schizophrenia, it has become evident that this disorder is associated with cognitive impairments. Of note, recent studies have demonstrated that it is the degree of cognitive impairment which is the best predictor of long-term outcome in individuals with schizophrenia. In general, the cognitive impairments seen in schizophrenia are most marked in the areas of memory and executive function, although mild-to-moderate impairment can be seen across all neurocognitive domains. The cognitive impairments tend to persist throughout the course of the illness, even during periods when the positive and negative symptoms have waned. The degree of impairment also appears to be relatively consistent early on in the illness; however, some individuals may experience a greater cognitive decline in later life. The striking lack of treatments available to address these cognitive deficits, combined with the association of these symptoms with poorer functional outcomes, has lead to the recent collaboration between academia, the National Institutes of Health, and the pharmaceutical industry on the Measurement and Treatment Research to Improve Cognition in Schizophrenia initiative to develop treatments for these symptoms.

Course and Outcome

It is now clear that, as noted by Kraepelin, the onset of the diagnostic symptoms of schizophrenia is frequently preceded by changes in functioning and behavior, termed 'prodromal symptoms.' These may include positive symptoms that do not rise to the DSM-IV level in severity or in duration, mood symptoms, cognitive impairments, or social withdrawal. Although useful, these prodromal symptoms exhibit significant overlap with the range of normal experience in the at-risk age groups, and so they cannot be used as diagnostic. Typically, the appearance of frank psychotic symptoms marks the onset of schizophrenia;

however, formal diagnosis and subsequent treatment are frequently delayed, on the average of approximately 1 year from the onset of psychosis. The first signs of the illness occur before the age of 30 in approximately 77% of individuals; nearly half the time, symptoms can be identified as having been present prior to the age of 20. Notwithstanding this fact, the majority of individuals diagnosed with schizophrenia achieve symptomatic recovery, with estimates as high as 75–85% achieving remission with treatment at 1–2 years in uncontrolled studies. Although definitions of remission vary, most studies have measured significant improvement in positive symptoms, with less improvement in negative symptoms, with treatment. Several factors have been identified as predicting elevated positive symptoms after treatment, including a longer duration of untreated psychosis, a greater degree and longer period of prodromal symptoms, and poor premorbid adjustment. Similar factors have been noted to predict higher levels of negative symptoms after 1 year of treatment.

Although most individuals experiencing a first episode of schizophrenia will achieve symptomatic recovery, nearly all will go on to experience at least one, and likely multiple, subsequent episodes. Relapse rates after the first episode range from 30% in the first year to 80% within 5 years. With each subsequent relapse, a significant proportion of individuals will not recover to the same degree as after the first episode of the illness and will experience persistent symptoms and/or cognitive impairments. This chronic, relapsing course of schizophrenia results in periods of relative remissions, rarely reaching the level of premorbid function, punctuated by acute exacerbation of the symptoms. This pattern of illness progression was noted by Kraepelin and appears to differing degrees across individuals diagnosed with schizophrenia, with more striking deterioration occurring in the early years of the illness and a relative stabilization of functioning in the later years. A number of large-scale studies have examined the long-term outcome in schizophrenia. These include studies such as the Iowa 500 Follow-Up Study, which, with a retrospective design and an average 35-year follow-up, examined 500 patients admitted to Iowa State Psychiatric Hospital between 1934 and 1944. Compared with patients with other diagnoses, those with schizophrenia had poorer long-term outcomes; however, approximately 20% of participants were symptom free at follow-up. Another example of this type of study is the prospectively designed Chicago Follow-Up Study, which has followed participants for up to 20 years. This study has also found that patients with schizophrenia had poorer outcomes than those with other psychiatric illnesses but that about 40% of those with schizophrenia demonstrated periods of recovery which could last several years. Comparisons between these and other studies of this nature are hampered by measurements used to assess outcome as well as the variability in the diagnostic criteria. Despite these factors, however, several points are clear. First, in all studies, a subset of patients with schizophrenia, in the range of 20–57%, demonstrate a good outcome, depending on the strictness of the criteria used in the diagnosis of schizophrenia (inclusion of individuals with some affective symptoms increases favorable outcome rates) and the definition of good outcome. Second, a small number, on the order of 6–8% of participants, met criteria for recovered at follow-up, meaning an absence of any symptoms. Finally, approximately 30% of patients with schizophrenia remain impaired, requiring long-term continuous treatment and experiencing few symptom-free intervals.

In sum, the clinical course of schizophrenia is highly variable, with the majority of individuals experiencing a relapsing course, which may include sustained periods of remission. In a smaller, but significant, number of individuals, the course of schizophrenia may be more chronic, with few, if any, symptom-free periods. In any discussion of long-term outcome, it is important to highlight the fact that schizophrenia is associated with a significant degree of mortality due to suicide. Suicide is the leading cause of premature death among individuals with schizophrenia, whose suicide risk is 8.5-fold that of the general population. Approximately 20–50% of individuals with schizophrenia will attempt suicide, and 4–13% have completed suicide.

Cross-Cultural Outcomes

Studies which have followed up the WHO Determinants of Outcome ten-country study samples have revealed some interesting differences in outcomes between developing and developed nations. A 2-year outcome study of this population found that in developing nations (Colombia, India, and Nigeria), 62.7% of individuals were remitted or in complete remission, with 35.7% experiencing continuous or episodic symptoms. Exactly the reverse was found in developed countries (Czech Republic, Denmark, Ireland, Japan, Russia, the United Kingdom, and the United States), with 36.8% remitted or in complete remission and 60.9% experiencing continuous or episodic symptoms. Several independent studies have also reported increased percentages of individuals with better outcomes in developing compared with developed countries. The reason for this difference remains unknown; possible explanations include differences in genetic variations, difference in social support

and social networks, and other environmental factors. Pharmacological management of the disease was used in only a small proportion of individuals in developing nations and therefore did not contribute to the improved outcome in this setting.

Treatment

Since the discovery of the antimanic and antipsychotic effects of chlorpromazine in the early 1950s, the mainstay of treatment for schizophrenia has been pharmacotherapy with neuroleptic medications (so termed by early researchers Jean Delay and Pierre Deniker for the properties of slowing motor activity and causing affective indifference and emotional neutrality). Earlier, therapies of questionable efficacy were employed, including application of tuberculin, insulin coma, and pharmacological agents such as opium, morphine, cocaine, or bromide. Since the introduction of chlorpromazine, numerous antipsychotic/neuroleptic medications have been introduced (on the order of 30 distinct compounds). The introduction of chlorpromazine was followed by haloperidol. Originally developed as an analgesic by Paul Janssen in Belgium but quickly found to have neuroleptic properties, haloperidol became one of the most widely prescribed medications after its introduction in 1959 (1969 in the United States). The work with chlorpromazine and haloperidol led to the development of multiple drugs screened to have properties *in vitro* similar to those of chlorpromazine and haloperidol. These medications have been termed the 'first-generation' antipsychotics, with about 15 different drugs being introduced in the United States from 1959 until 1975. Early preclinical research, along with subsequent brain imaging studies in humans, revealed a link between blockade of the dopamine D2 receptors and the ability of these medications to treat psychosis.

In 1975, clozapine, a drug with relatively low affinity for D2 receptors but relatively high affinity to serotonin 2a receptors (5-HT2a), was introduced in Europe but withdrawn shortly thereafter due to the risk of agranulocytosis associated with treatment. This medication was reintroduced in 1990 with hematological monitoring requirements, allowing for safer administration of the drug. Clinical studies have repeatedly demonstrated a superior efficacy for clozapine compared with the first-generation drugs, particularly in treatment of refractory patients. Moreover, clozapine is associated with fewer extrapyramidal side effects (EPS), which are prominent with the first-generation drugs due to blockade of the D2 receptors in the striatal brain regions. These two facts, increased efficacy with decreased EPS, resulted in clozapine being termed a 'second-generation' or 'atypical' antipsychotic and led to the development of additional medications (risperidone, olanzapine, quetiapine, and ziprasidone) with high 5-HT2a affinity relative to D2 affinity. At standard clinical doses, these medications appear to have lower rates of EPS than the first-generation drugs did, and they have also been classified as second generation or atypical antipsychotics. Although much work has been done to examine the efficacy of these second-generation drugs, with the exception of clozapine they demonstrate no clear superiority when compared with the first-generation medications. Moreover, despite the lower rates of EPS, additional side effects, most notably increased rates of impaired glucose metabolism and diabetes, have been observed with the second-generation antipsychotic medications.

While all currently available antipsychotic treatments have been determined superior to placebo in the treatment of the positive symptoms of schizophrenia, their effect on negative symptoms and the cognitive deficits can be described as minimal at best, with clozapine demonstrating the largest effect. This deficiency in adequate treatments for the negative and cognitive symptoms seen in this illness is a major shortcoming of currently available therapeutics for schizophrenia as the degree of cognitive impairment has been shown to be a predictor of poor functional outcome.

Although pharmacotherapy represents the main first-line treatment for individuals with schizophrenia, evidence has demonstrated that the best long-term outcomes are achieved in this illness using a multimodality approach. In support of this is the fact that many individuals with schizophrenia continue to have impairments in social, occupational, and cognitive function even after adequate treatment of the psychotic symptoms. In addition to pharmacotherapy, treatment systems may include family therapy, individual therapy, cognitive behavioral therapy, social skills training, employment training, or supported employment (albeit not all at the same time). These psychosocial interventions have been shown to enhance functional outcomes and the individual's quality of life.

Conclusion

Schizophrenia carries with it a significant morbidity, in terms of both the individual and the families affected and the population as a whole. Over the past half century, significant advances have been made in standardizing the diagnostic criteria and characterizing the course of this illness. However, it

remains clear that there is a large degree of inter-individual heterogeneity in the severity of symptoms, in the degree of between episode symptom remission, and in the response to treatment. Three main areas of focus hold potential for gaining a better understanding of this illness. First, the explosion of molecular genetic studies in the last 20–30 years, both at the population level and at the individual level, holds the promise of improving our understanding of the genes and genetic alterations which place an individual at risk for developing schizophrenia. Second, ongoing work aimed at further characterizing the contributory environmental factors linked to increased risk for schizophrenia may, in combination with genetic studies, allow better prediction and perhaps modulation of the risks for developing the disorder. Finally, the development of treatments, with targets beyond the standard dopamine D2 receptors, to address the cognitive deficits and negative symptoms of the illness could enhance the long-term outcome and improve the day-to-day quality of life for those with schizophrenia.

Schizophrenia: Genetics

© 2009 Published by Elsevier Ltd.

Introduction

Schizophrenia is a common psychiatric disorder with a prevalence of 0.5–1% among the general population. Symptoms include auditory hallucinations, paranoid delusions, disorganized speech and thinking, and social withdrawal. However, the disease is divided into several subtypes in which certain symptoms are more apparent than others; for example, the paranoid type is characterized by hallucinations and delusions in the absence of disorganized thinking. This wide spectrum of possible symptoms makes the determination of underlying genetic factors more complex, as does the fact that the symptoms overlap to a certain degree with those of other conditions, such as bipolar disorder. The symptoms may begin in early childhood, but the disorder typically becomes fully apparent during the late teens or early 20 s. For affected individuals there is no cure, and although therapy may alleviate some of the symptoms, the prospects for a full social and occupational life are limited.

The causes of schizophrenia are not yet definitively established, but the familial tendency of the disease and results from twin concordance studies suggest there is a strong genetic component. Until comparatively recently there was little information about the genes involved, even though a number of susceptibility loci had been identified. Schizophrenia is a polygenic disease and almost certainly results from the combined effects of several susceptibility alleles at different loci, together with the appropriate environmental stimuli. There has been renewed interest in identifying schizophrenia susceptibility genes in the last few years due to the development and application of high-throughput functional genomics techniques such as expression profiling, large-scale mutagenesis, and protein interaction analysis.

Genetic Epidemiology

During almost a century of epidemiological research into schizophrenia, a surfeit of data has built up to demonstrate that the disease is heritable. The disease has a far greater incidence among the close relatives of an afflicted individual than among the general population. Furthermore, the likelihood of developing the disease increases with increasing genetic similarity to an affected individual. Among monozygotic twins, the chances of one twin getting the disease when the other has already been diagnosed have been estimated to be as low as 11% in one study and as high as 28% in another, while these rates fall to 2–5% in dizygotic twins. The incidence of schizophrenia is also consistently higher among the biological relatives of adopted schizophrenics than among the adoptive relatives. Such studies present a strong argument for a genetic basis to the disease, although many environmental triggers have also been identified, including prenatal and developmental effects, social disadvantage, drug use, neural processes, and psychological mechanisms.

The Complexity of Schizophrenia

Schizophrenia is a complex disorder, both genetically and phenotypically. Genetically, schizophrenia is unlikely to be caused by single gene mutations. No gene has yet been discovered which alone, when mutated, is sufficient to cause schizophrenia. Furthermore, the pattern of inheritance of schizophrenia is not consistent with a disease caused by a single Mendelian trait. Although the risk of acquiring schizophrenia decreases in line with genetic dissimilarity to an affected individual, the decrease is rapid and nonlinear. The observed trend is consistent with multiple susceptibility genes, each having a small individual effect but a large combined effect. To complicate matters further, schizophrenia is a genetically heterogeneous disease. There may be a pool of susceptibility genes, from which a number of different combinations may lead to different subtypes of schizophrenia.

Clinically, schizophrenia manifests itself in a wide variety of symptoms. It is still not clear if schizophrenia, as currently diagnosed, represents one disorder or several related and overlapping disorders. A further complication is that there may be genetic overlap with other psychiatric disorders. That is, genes predisposing to schizophrenia may also be involved in other psychotic disorders that display similar symptoms. As with most complex psychiatric disorders, uncertainty over the clinical, phenotypic definition hinders the study of the genetic basis of the disease.

Techniques to Identify the Genes

Linkage Studies

Linkage studies are used to identify regions of a chromosome that may contain genes responsible for or contributing to a disease or that confer susceptibility

to a disease. Depending on the genetic background, a susceptibility locus in one family may appear to be a clear, disease-causing locus in another. Linkage studies identify genes that are closely physically linked to a particular marker or set of markers found on the same chromosome. The principle is that genes on separate chromosomes will undergo random independent assortment, while those on the same chromosome will tend to be inherited together depending on the physical distance between them and hence the likelihood of a crossover occurring during meiosis. Linkage analysis relies on the availability of heterozygous markers to track normal and disease alleles through a family pedigree and to identify potential recombination events caused by crossovers during meiosis. If a candidate gene is so tightly linked to a marker that recombination never happens or is a very rare occurrence, that marker is likely to be found very close to the disease gene or even within it and can be used as the basis for map-based cloning and eventual gene isolation.

Association Studies

Association studies are used to identify alleles that are present with greater or lower frequency in a group of individuals with a disease, as compared to the general population. Ideally entire genomes would be compared, but this is not feasible with the current state of the art. Instead, association studies for schizophrenia have focused on candidate genes, that is, those already implicated in the disease. Candidate genes may be implicated in two ways, functionally or positionally. Functional candidate genes are suspected, on the basis of their known or proposed function, of having a biological role in the development of the disease. Positional candidate genes are identified by linkage analysis or more occasionally through the analysis of chromosome aberrations in which breakage events affect a schizophrenia susceptibility locus.

Major Genes Implicated in Schizophrenia

The list of candidate genes implicated in susceptibility to or the progression of schizophrenia grows longer every month, particularly with the advent of large-scale functional studies based on messenger RNA expression profiling and proteomics. However, only a small proportion of these genes have strong experimental evidence linking them functionally to the disease; those with the greatest weight of evidence behind them are summarized in Table 1 and described in more detail below.

COMT

Catechol-*O*-methyltransferase (COMT) is an enzyme involved in dopamine metabolism, specifically the breakdown of the catecholamine neurotransmitters (dopamine, epinephrine, and norepinephrine). The *COMT* gene was first implicated in schizophrenia when it was found in a region of chromosome 22 (22q11) which is deleted in velo-cardio-facial syndrome (VCFS). Individuals with VCFS have approximately a 25% probability of developing schizophrenia. There is also evidence from association studies that the *COMT* gene is involved in schizophrenia, increasing the likelihood of the condition occurring spontaneously or following adolescent cannabis use.

The pathogenic mechanism is not precisely understood, but it may involve the effects of the gene on dopaminergic transmission in the prefrontal cortex. An SNP in *COMT* has been shown to affect cognitive tasks broadly related to executive function (abstract thought, response inhibition, rule acquisition). The resulting amino acid substitution (valine for methionine) produces an enzyme variant that metabolizes dopamine and other neurotransmitters four times faster than normal, thus reducing dopaminergic stimulation of the postsynaptic neuron. Consequently, neurons expressing this version of COMT show higher levels of activation during certain cognitive tasks since more action potentials are required to achieve the same level of postsynaptic stimulation.

DAO and *G72*

DAO encodes D-amino acid oxidase, which metabolizes the oxidative deamination of neutral D-amino acids, including D-serine. Another gene, named *G72*,

Table 1 Major susceptibility genes with functional links to schizophrenia

Gene	*Description*	*Chromosomal location*
COMT	Catechol-*O*-methyltransferase	22q11
DAO/DAOA	D-amino acid oxidase and D-amino acid oxidase activator	13q22
DISC1	Disrupted in schizophrenia 1	1q42
DTNBP1	Dystrobrevin binding protein 1	6p22
RGS4	Regulator of G-protein signaling 4	1q21–22
GRM-3	Metabotropic glutamate receptor 3	7q21–22
NRG1	Neuregulin 1	8p12–21

encodes D-amino acid oxidase activator (DAOA), which physically interacts with DAO. Through linkage and association studies, both of these genes have been shown to be associated with an increased susceptibility to schizophrenia. D-serine is predominantly confined to the forebrain, where *N*-methyl-D-aspartate (NMDA) receptors are enriched, and is thought to be an endogenous ligand for these receptors. It has been shown to potentiate NMDA receptor-mediated transmission by selective stimulation of the strychnine-insensitive glycine site of the NMDA receptor with an affinity similar to glycine, but no affinity for the inhibitory glycine receptor. Mutations affecting the activity of DAO and DAOA would modulate the level of available D-serine and therefore impact signaling through NMDA receptors in the forebrain. Despite this, no specific single-nucleotide polymorphisms (SNPs) have been found in either gene, which are also associated with bipolar disorder.

DISC1

Disrupted in schizophrenia 1 (*DISC1*) was first identified at the breakpoint in a chromosomal translocation involving chromosome 1. *DISC1* has since been implicated in schizophrenia through multiple association studies. The gene has also been implicated in several other psychological disorders, including schizoaffective disorder, bipolar affective disorder, and major depression. The gene product is known to bind phosphodiesterase 4B, which regulates cyclic adenosine monophosphate signaling and is thought to be involved in learning and memory processes.

The yeast two-hybrid system for identifying interacting proteins has revealed several proteins that bind DISC1. The first was fasciculation and elongation protein zeta-1, which plays a role in the control of axonal outgrowth and fasciculation. The two proteins were subsequently shown to be colocalized in the growth cones of hippocampal axons, and evidence suggests that the interaction is required for neurite outgrowth. Further studies identified additional binding partners Kendrin and DISC1-binding zinc-finger protein, the latter of which was shown to be expressed strongly in the hippocampus, olfactory tubercle, cerebral cortex, and striatum. This pattern was similar to that of pituitary adenylate cyclase, suggesting a role for the pituitary adenylate cyclase-activating polypeptide pathway in providing further insight into the basis of psychiatric disorders.

DTNBP1

The gene encoding dystrobrevin-binding protein 1 (DTNBP1), also known as dysbindin, was first identified as a candidate schizophrenia gene through linkage studies and then through multiple independent association studies although there were also negative results from such studies in certain population groups. Many SNPs have been identified, although all in noncoding regions, so their impact, if anything at all, is likely to be on expression rather than structure. The biological function of DTNB1 is to bind α- and β-dystrobrevin, which are components of the dystrophin $\bar{N}$ glycoprotein complex. Dysbindin also forms part of the biogenesis of lysozyme-related organelles complex-1. This complex controls cellular trafficking to lysozyme-related organelles and may be involved in the regulation of vesicular trafficking and dendrite branching. There is evidence from postmortem studies that dysbindin expression is decreased in the brains of patients with schizophrenia, particularly in the synapses of certain glutamatergic neurons within the hippocampus.

RGS4

Regulator of G-protein signaling 4 (*RGS4*) has been associated with schizophrenia through both linkage and association studies. Expression levels of RGS4 are significantly reduced in the prefrontal cortex of individuals with schizophrenia. Several SNPs have been implicated in the disease. The product of this gene functions to regulate effects at G-protein-coupled receptors, including dopamine and serotonin receptors.

GRM-3

The product of the metabotropic glutamate receptor 3 (*GRM-3*) gene is involved in the regulation of synaptic glutamate levels. It accomplishes this by controlling expression of the glial glutamate transporter, which functions to remove glutamate from synapses. *GRM-3* has been linked to schizophrenia through a number of association studies, and a number of SNPs have been identified which may confer susceptibility to schizophrenia. Studies have shown that inheritance of particular alleles of *GRM-3* can result in reduced expression of the glial glutamate transporter.

NRG1

NRG1 encodes neuregulin 1, a family of protein ligands produced by alternative splicing that act on the epidermal growth factor receptor family. Six different isoforms of neuregulin 1 have been identified thus far, with a diverse range of functions. Neuregulin 1–ErbB4 interactions are thought to play a significant role in the pathological mechanism of schizophrenia, and this may reflect increased availability of the ligand rather than any differences in structure. NRG1 has

been linked to schizophrenia through a number of independent linkage and association studies, including a study of the Icelandic deCODE database which yielded a high-risk haplotype at the 5′ end of the gene (SNP8NRG243177) that enhances the expression of Type IV NRG1 in the brains of schizophrenic patients.

Is Schizophrenia a Genetic Disorder of the Synapse?

Glutamate is a major neurotransmitter of the brain that functions through the activation of several types of receptor. Crucially, one type of glutamate receptor, the NMDA receptor, has been implicated in schizophrenia. Pharmaceutical inhibition of NMDA receptors, through use of the recreational drug PCP, for example, can induce many of the symptoms associated with schizophrenia. Drugs that enhance NMDA function, on the other hand, can relieve many of the symptoms of schizophrenia. Several of the genes implicated in schizophrenia, including *DTNBP1*, *NRG1*, *GRM-3*, *DAO/DAOA*, and *RGS4*, encode proteins that have the potential to influence the function of glutamatergic synapses. Dysbindin, for example, may affect the uptake of glutamate into synaptic vesicles. GRM-3 is known to regulate synaptic glutamate levels. NRG1 is released from glutamate terminals and can regulate NMDA receptors. DAO and DAOA may also regulate NMDA receptors indirectly, through their action on D-serine.

Although the evidence pointing toward a role for glutamatergic synapses in schizophrenia is promising, there are reasons to be cautious. The genes with the strongest evidence for a role in schizophrenia, particularly *NRG1* and *DTNBP1*, encode proteins with multiple functions, many of which could be involved in schizophrenia without directly involving glutamatergic synapses. On the other hand, the genes with the most direct biological roles in affecting synapses, such as *DAO*, *DAOA*, and *RGS4*, seem to be those with the weakest associations with the disease.

Summary

Several genes have been implicated in the development of schizophrenia. However, there remain concerns about the validity of the findings since no mutation predisposing to schizophrenia has yet been discovered in any of these genes. Among the variant alleles implicated in the disease, the genetic evidence is not definitive and is frequently inconsistent, with some studies reporting positive associations with the disease and others reporting negative associations for the same gene. In several cases, the susceptibility genes appear to have quantitative rather than qualitative effects, with mutations in regulatory regions either increasing or decreasing the amount of product available. This would help explain the absence of definitive structural mutations in such genes and would also explain why association studies in different geographical and ethnic groups sometimes come up with contradictory results, the implication being that compensatory mechanisms might be present to ameliorate such quantitative effects. For example, there is no association evidence between schizophrenia and DTNBP1 in Taiwanese families, perhaps because these families have an allele at a different locus which suppresses the effect of DTNBP1. However, these inconsistencies may also be a feature of the innate limitations of the techniques used (linkage and association studies), which are generally more suited to the identification of genes with large individual effects on a disease.

Schwann Cell Development

R Mirsky and K R Jessen, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Schwann cells, found in association with axons in peripheral nerves, are the main glial cell type in the peripheral nervous system (PNS). They exist in two quite distinct forms, either making myelin sheaths round large axons to speed impulse conduction or enclosing groups of smaller axons, holding them together in tight bundles. A mature peripheral nerve therefore consists of a mixture of myelinated and unmyelinated axon–Schwann cell units, usually referred to as nerve fibers. This article provides an overview of the development of Schwann cells from their origins in the neural crest. The generation of PNS glia parallels the formation of glial cells in the central nervous system (CNS). Nevertheless, many of the key molecules that control gliogenesis differ between the two systems.

The Schwann Cell Lineage

The neural crest is a transient group of cells that segregates from the dorsal neural tube and gives rise to a variety of derivatives, including autonomic and sensory neurons, chromaffin cells, glial cells including Schwann cells and satellite cells of the autonomic and sensory ganglia, fibroblastic cells, smooth muscle cells, and melanocytes (Figure 1). The majority of Schwann cells are derived from the group of neural crest cells that migrate ventrally through the anterior part of the somites, although it has been shown that Schwann cells in the dorsal roots are derived from a specialized group of cells called boundary cap cells that also give rise to some neurons and satellite glial cells in dorsal root sensory ganglia (DRG).

Mature myelinating and nonmyelinating Schwann cells arise from the neural crest via two intermediate stages, the Schwann cell precursor and the immature Schwann cell (Figure 2). Schwann cell precursors are the glial cells found in embryonic day (E) 14 or 15 rat nerves (mouse E12 or E13). Immature Schwann cells are generated from Schwann cell precursors and populate rat nerves from E17 or E18 (mouse E15 or E16) to approximately the time of birth, when myelination starts. At the immature Schwann cell stage, Schwann cells that by chance come to be associated with large axons receive axon-associated signals that instruct them to make myelin sheaths, and they adopt the specific gene expression profile appropriate for myelination. Mature nonmyelinating Schwann cells only appear approximately 2 weeks after myelination starts. These cells also express genes that differentiate them from myelinating cells and typically hold several small-diameter axons individually in troughs that run along the cell surface, forming unmyelinated (Remak) fibers.

Three major developmental steps define the lineage – that is, the transition from migrating neural crest cells to axon-associated Schwann cell precursors, the transition from precursors to immature Schwann cells, and finally the divergence of this population to form the two mature Schwann cell types found in adult nerves. At all stages, there is a continuous close association between these cells and axons. Also, it is a striking feature of all the cell types that they are highly dependent on survival factors, mitogens, and differentiation signals from axons. Another notable feature is plasticity, because much of the developmental sequence is readily reversible. For example, mature myelinating and nonmyelinating Schwann cells respond to nerve injury by reverting to a phenotype similar to that of immature Schwann cells, and Schwann cell precursors can be diverted, at least *in vitro*, to other neural crest derivatives. Only the transition from precursors to immature Schwann cells appears to be irreversible.

In vivo, rapid proliferation is a characteristic of all early stages of the lineage – namely, neural crest cells, Schwann cell precursors, and immature Schwann cells. In contrast, the onset of myelination is clearly linked with cell cycle exit, and both myelinating and nonmyelinating cells are quiescent in normal adult nerves. However, the cells retain the potential to proliferate because they reenter the cell cycle when they dedifferentiate in response to nerve injury. Apoptotic cell death is also a feature of developing cells in early nerves, whereas myelinating and mature nonmyelinating cells are resistant to apoptosis.

Markers of Schwann Cell Development

Each cell stage in the embryonic phase of the lineage can be defined by a distinct combination of differentiation markers (Figure 3). Additional criteria, such as morphology, relationships to other cells and tissues, and response to extrinsic signals, can also be used to define the cell types and to study the signals that are important in controlling progression from one stage to the next.

The markers can be divided into five different categories depending on expression patterns (Figure 3).

Figure 1 The neural crest. In a process known as neurulation, the neural plate, which is found along the dorsal surface of an embryo, gradually folds in on itself to form the neural groove. As the neural folds fuse to form the neural tube, the neural crest cells segregate from the tips of the folds. After taking up an initial position at the dorsal surface of the tube, the crest cells in the trunk region soon migrate along one of two major streams: in a lateral direction (1) to give rise to melanocytes in the skin, and in a ventral direction (2 and 3) to give rise to neurons in dorsal root sensory ganglia and glia (2) or glia, autonomic neurons, and chromaffin cells (3). Neural crest cells in the most anterior part of the trunk, the cardiac crest, also generate fibroblasts and smooth muscle cells, and the cephalic crest in the head region also forms the cells of cartilage and bone. The mechanisms that allow the apparently homogeneous population of crest cells to generate such diversity have been intensively studied. It is now considered likely that some neural crest cells are already committed to certain fates, whereas others are multipotent. Although some cells may enter lineages in a stochastic and undirected manner, a combination of positive and negative instructive signals probably plays an important part in directing neural crest cell differentiation. How migrating neural crest cells, which initially move through immature connective tissue on each side of the neural tube, end up as Schwann cell precursors in tight association with axons in early embryonic nerves is not clear, either in terms of their detailed migratory route or in terms of the signals that cause these cells to adopt an early glial phenotype. Reproduced from Jessen KR and Mirsky R (2005) The origin and development of glial cells in peripheral nerves. *Nature Reviews Neuroscience* 6: 671–682.

The first category, exemplified by the transcription factor SRY (sex determining region Y) box 10 (SOX10), includes molecules that are present at all developmental stages; the second, exemplified by the transcription factor activator protein 2α (AP2α), includes genes/proteins present at high levels in neural crest cells and Schwann cell precursors but which are downregulated in immature Schwann cells; the third category, of which cadherin 19 is the only known example, represents genes expressed only in Schwann cell precursors; and the fourth category represents genes/proteins expressed by Schwann cell precursors and immature Schwann cells but not by neural crest cells, such as brain fatty acid-binding protein, myelin protein zero (P_0), and connexin 29. The last category represents molecules such as S100 or glial fibrillary acidic protein (GFAP) that are present in high levels on immature Schwann cells but are low or absent from neural crest cells or Schwann cell precursors. It should be emphasized that the use of technologies such as Affymatrix that allow comparative analysis across the genome reveals larger sets of different genes, but which of these will be useful in the study of mechanisms that control development of the lineage remains to be determined.

Several additional criteria provide crucial information in analyzing Schwann cell development. Schwann cell precursors and immature Schwann cells, but not neural crest cells, share a feature characteristic of glial cells in both the PNS and the CNS, namely their close physical apposition with axons (neurons). Schwann cell precursors also differ from migrating crest cells in their response to survival factors and in being relatively insensitive to the neurogenic actions of bone morphogenetic protein (BMP) 2. They are also more sensitive to the actions of Notch and are strongly biased toward the generation of Schwann cells rather than other neural crest derivatives.

A striking difference between Schwann cells and Schwann cell precursors is the ability of Schwann cells to support their own survival in the absence of axons using autocrine survival circuits. The cytoarchitecture of the nerves at the stage when they contain Schwann cell precursors (E14 or E15) is also distinctly different from that of nerves containing immature Schwann cells (E17 or E18).

Figure 2 The Schwann cell lineage. Schematic illustration of the main cell types and developmental transitions involved in Schwann cell development. Dashed arrows indicate the reversibility of the final, largely postnatal transition during which mature myelinating and nonmyelinating Schwann cells are generated. The embryonic phase of Schwann cell development involves three transient cell populations. First are migrating neural crest cells, which are discussed further in the legend to **Figure 1**. Second are Schwann cell precursors. These cells express various differentiation markers that are not found in neural crest cells, including brain fatty acid-binding protein (BFABP), protein zero (P_0), and desert hedgehog (DHH) (**Figure 3**). At any one time, a rapidly developing population of cells, such as the glia of embryonic nerves, will contain some cells that are rather more advanced than others. Third are immature Schwann cells. All immature Schwann cells are considered to have the same developmental potential, and their fate is determined by axons with which they associate. Myelination occurs only in Schwann cells that by chance envelop large-diameter axons; Schwann cells that ensheathe small-diameter axons progress to become mature nonmyelinating cells. Reproduced from Jessen KR and Mirsky R (2005) The origin and development of glial cells in peripheral nerves. *Nature Reviews Neuroscience* 6: 671–682.

Gliogenesis from the Neural Crest

The generation of more differentiated cells from stem cells or cells that share some stem cell properties, including the neural crest, is a topic that continues to generate widespread interest. The consensus is that cell specification involves interplay between cell-autonomous intracellular signaling and extracellular cues arising from the niche in which the stem cell resides. The best evidence is that generation of Schwann cells and other glia from the neural crest involves both of these mechanisms.

The Role of SOX10 in PNS Gliogenesis

In the generation of glial cells from the neural crest, the transcription factor SOX10 is the most important player known so far, because it is the only gene known to be essential for this process. Initially expressed by all migrating neural crest cells, its expression persists in the developing satellite glial cells of the DRG, in Schwann cell precursors, and in Schwann cells of peripheral nerves. However, SOX10 is downregulated very early in neurogenesis. In line with this, neurons are initially generated in normal numbers in mice in which SOX10 has been inactivated. In contrast, satellite cells and Schwann cells fail to develop in these animals. In place of satellite cells (i.e., glia), the DRG contain a population of neural crest-like cells and nerve trunks also contain a few neural crest-like cells but no Schwann cell precursors, indicating that in the absence of SOX10 glial specification is blocked. Experiments using cultured cells also suggest that SOX10 plays a role in specifying and maintaining the glial phenotype. It may act in part by upregulating levels of the neuregulin receptor ErbB3, thus increasing the responsiveness of neural crest cells to the growth factor β-neuregulin-1. There is evidence that later in development, it acts in conjunction with other transcription factors such as KROX20 (EGR2) to regulate the promoters of genes that are crucial in myelination, such as P_0 and connexin 32.

β-Neuregulin-1 and the Neural Crest

β-Neuregulin-1, signaling through its receptors ErbB2 and ErbB3, is a growth factor that has multiple important functions throughout Schwann cell development. In neural crest cell cultures, it inhibits the development of neurons, a function that might lead indirectly to increased development of glia. Overproduction of neurons, however, has not been noted in mutants that lack components of the neuregulin signaling pathway, so it is not clear that β-neureglin-1 regulates neuronal numbers *in vivo*. When β-neuregulin-1 is added to migrating neural crest cell cultures, it increases the proportion of Schwann cells generated. Nevertheless, these cultures generate Schwann cells even in the absence of added neuregulin, and the same is true when the appearance of Schwann cell

Figure 3 Changes in phenotypic profile as cells progress through the embryonic Schwann cell lineage. Shared profiles are indicated by distinct colors. The boxes above indicate the changes in gene expression that take place during embryonic Schwann cell development. The gene expression shown here is based on observations of endogenous genes rather than on observations of reporter genes in transgenic animals. Note that Cadherin 19 (Cad 19) is exclusively expressed in Schwann cell precursors. Each developmental stage also involves characteristic relationships with surrounding tissues and distinctive cell signaling properties (boxes below lineage drawing). For instance, neural crest cells migrate through extracellular matrix. By contrast, Schwann cell precursors and Schwann cells are embedded among axons with minimal extracellular spaces separating them from nerve cell membranes, a characteristic of glial cells in the CNS and PNS. Basal lamina is absent from migrating crest cells and Schwann cell precursors but appears on Schwann cells. *In vitro*, β-neuregulin-1 (NRG1) only supports neural crest survival in the presence of extracellular matrix (ECM), although this is not required for the β-neuregulin-1-mediated survival of Schwann cell precursors and Schwann cells. Migrating neural crest cells also fail to survive in the presence of several factors that support the survival of Schwann cell precursors and Schwann cells, including combinations such as fibroblast growth factor (FGF) plus insulin-like growth factor (IGF), endothelin (ET) plus IGF, and platelet-derived growth factor (PDGF) plus neurotrophin (NT)-3 and IGF. Schwann cells also have autocrine survival circuits that are absent from Schwann cell precursors. *Proteins that also appear on neuroblasts/early neurons. ‡Markers that are acutely dependent on axons for expression. §Glial fibrillary acidic protein (GFAP) is a late marker of Schwann cell generation since significant expression is not seen until approximately the time of birth. GFAP is reversibly suppressed in myelinating cells. The early expression of GFAP has not been examined carefully in mice. ||Schwann cell precursors have been shown to be S100 calcium-binding protein (S100)-negative and Schwann cells S100-positive using routine immunohistochemical methods; however, low levels of S100 are detectable in many mouse Schwann cell precursors when the sensitivity of the assay is significantly increased. AP2α, activator protein 2α; BFABP, brain fatty acid-binding protein; DHH, desert hedgehog; ErbB3, neuregulin receptor; GAP43, growth-associated protein 43; L1, L1 adhesion molecule; N-cad, N-cadherin; OCT6, octamer-binding transcription factor 6; 04, lipid antigen; PLP, proteolipid protein; PMP22, peripheral myelin protein 22 kDa; P_0, protein zero; $p75^{NTR}$, p75 neurotrophin receptor; SOX10, SRY (sex determining region Y) box 10. Figure 4 The appearance of early cells in the Schwann cell lineage. (a) An electron microscopic image of a transverse section of a nerve in the hindlimb of a rat embryo at embryonic day (E) 14. Schwann cell precursors branch among the axons inside the nerve (large arrow) and are also found in close apposition to axons at the nerve surface. One precursor cell is undergoing mitosis (small arrow). Extracellular connective tissue space (turquoise), which contains mesenchymal cells, surrounds the nerve but is essentially absent from the nerve. These nerves are also free of blood vessels, and the axons are of smaller and more uniform diameter than those seen in mature nerves. Magnification, ×2000. (b) Schwann cells in a transverse section of the sciatic nerve of a rat embryo at E18, shown at the same magnification. In marked contrast to the nerve at E14, connective tissue spaces now branch through the nerve among compact bundles of immature Schwann cells and their associated axons (Schwann cell families; for example, see asterisk). Blood vessels (small arrow) and fibroblasts (e.g., directly above the vessel) have also appeared inside the nerve. One Schwann cell is undergoing mitosis (large arrow). Outside the nerve (in the uppermost part of the figure), connective tissue, which contains flattened fibroblasts of the early developing perineurium and two blood vessels, can be seen. Reproduced from Jessen KR and Mirsky R (2005) The origin and development of glial cells in peripheral nerves. *Nature Reviews Neuroscience* 6: 671–682.

precursors from neural crest cell cultures is monitored. Furthermore, in mouse mutants in which neuregulin signaling has been abrogated *in vivo*, satellite glia in the DRG are generated, although Schwann cell precursors are severely depleted. In these mutants, most neural crest cells fail to migrate ventrally below the level of the DRG to the sites where sympathetic ganglia are formed, resulting in underdeveloped (hypoplastic) ganglia. In summary, these data indicate that, in principle, β-neuregulin-1 is not required for the generation of glia from the neural crest, although it modulates this process by suppressing neurogenesis and by promoting migration of neural crest cells or early crest derivatives, particularly those that will form sympathetic ganglia. There is also evidence that β-neuregulin-1 accelerates the transition of Schwann cell precursors to Schwann cells.

Schwann Cell Precursors

In peripheral nerve trunks, Schwann cell precursors represent the first clearly defined stage of glial differentiation and are the cells from which the immature Schwann cells are derived. They represent the large majority of cells in the limb nerves of E14/E15 rats (E12/E13 mice). They are initially seen at the edge of early embryonic nerves but are later seen inside them as well. They communally surround large groups of axons with their sheetlike processes and divide the nerves into territories. At this stage, the nerves are compact structures that contain essentially no connective tissue and are not vascularized (Figure 4).

β-Neuregulin-1 and Schwann Cell Precursors

A vital role for β-neuregulin-1 in the Schwann cell lineage is indicated by the observation, mentioned previously, that Schwann cell precursors, and later Schwann cells, are absent or severely depleted in the peripheral nerves of mouse mutants that lack neuregulin signaling. This probably reflects the major role of β-neuregulin-1 as an essential survival factor and mitogen for Schwann cell precursors, although impaired migration might also have a role. Axonally derived β-neuregulin-1 is an essential survival factor and mitogen for Schwann cell precursors *in vitro* and it has been shown that the most important isoform expressed by axons is the membrane-bound β-neuregulin-1 type III (Figure 5). It is the major isoform present in DRG and motor neurons *in vivo*. In mice in which this isoform has been selectively eliminated, although peripheral nerves are initially populated by Schwann cell precursors, few remain after E14. *In vivo*, Schwann cell precursors die after nerve injury and this can be prevented by externally applied β-neuregulin-1. Taken together, this indicates that axonal β-neuregulin-1 type III is a key survival signal in embryonic Schwann cell development, being an essential survival factor for Schwann cell precursors.

Figure 5 Neuregulin-1. β-Neuregulin-1 seems to have exceptionally numerous and varied functions in Schwann cell biology. It is involved in neural crest migration and has been implicated in the specification of neural crest stem cells and shown to be essential for the survival of Schwann cell precursors. It is also involved in Schwann cell generation, proliferation, and survival. In postnatal nerves, β-neuregulin-1 is a positive regulator of myelin sheath thickness, but paradoxically, at least in experiments, it appears to drive the dedifferentiation of Schwann cells in injured nerve fibers. No other molecule has been proposed to be so comprehensively involved in the control of Schwann cell development. There are a surprising number (>15) of neuregulin-1 α and β protein isoforms. The schematic structures of the main isoforms found in the nervous system are shown here. Although splice variants without the transmembrane domain exist for all these isoforms, transmembrane isoforms (as shown here together with the products of a proteolytic cleavage in the juxtamembrane area) predominate in the nervous system. The epidermal growth factor (EGF) domain is found in all bioactive forms of neuregulin-1 and is sufficient for activation of ErbB receptor kinase. The type III β-neuregulin-1 isoform is expressed in axons and is the main regulator of survival of Schwann cell precursors and myelin sheath thickness. It is thought to have two membrane-spanning domains and to undergo proteolytic cleavage that generates a membrane-attached protein carrying the EGF domain. β-Neuregulin-1 shows high-affinity binding to two receptors, ErbB3 and ErbB4, whereas a related protein, ErbB2, acts as a coreceptor in ErbB3–ErbB2 and ErbB4–ErbB2 complexes. The former is the main receptor in peripheral glial cells. The action of axonal β-neuregulin-1 type III on ErbB3–ErbB2 in developing Schwann cells is probably the best established molecular signaling pathway between neurons and glia in the PNS. Reproduced from Jessen KR and Mirsky R (2005) The origin and development of glial cells in peripheral nerves. *Nature Reviews Neuroscience* 6: 671–682.

In vitro experiments show that in addition to its survival function, β-neuregulin-1 accelerates the transition from Schwann cell precursors to immature Schwann cells. This transition is also controlled by another signaling system present in embryonic nerves – endothelin. In contrast to neuregulin, endothelins negatively regulate Schwann cell generation, as shown by the observation that Schwann cells are generated prematurely in rats in which the endothelin B receptor is inactivated.

Notch and Schwann Cell Precursors

Notch transmembrane receptors and their ligands delta, jagged, and serrate are known to influence glial cell fate choices in the developing nervous system. In the CNS, the classical view of Notch signaling is that it acts to maintain neural stem cells in an undifferentiated state, but evidence suggests that it can promote the appearance of radial glia, astrocytes, and Muller cells. It also stimulates the formation of oligodendrocyte precursors while inhibiting their progression to myelinating cells.

The question of whether Notch instructively promotes gliogenesis from neural crest cells is still controversial. Notch activation in neural crest cells inhibits the generation of neurons *in vivo* and *in vitro*, whereas in cultures derived from a subpopulation of cells from E14 sciatic nerves it increases the number of GFAP-positive Schwann cells and the rate at which they are generated. There is also evidence that Notch, like β-neuregulin-1, acts on early glial cells, stimulating Schwann cell precursors to generate Schwann cells. Notch also promotes the proliferation of immature Schwann cells *in vitro* and *in vivo*. Although it is not settled whether the only actions of Notch are to accelerate lineage progression and stimulate proliferation, or whether Notch also directs crest cells to the glial lineage, there are strong parallels between the actions of Notch and β-neuregulin-1 in this system. Both signals suppress neurogenesis in

crest cells and stimulate Schwann cell generation from precursors and Schwann cell proliferation. It will be interesting to explore the significance of this in future studies.

Immature Schwann Cells

The switch from Schwann cell precursor to immature Schwann cell between E15 and E17 in rat (mouse E13–E15) involves a coordinated change in molecular expression and in the response of the cells to survival signals and mitogens. This is accompanied by architectural reorganization that involves the appearance of blood vessels and connective tissue in the nerve, eventually leading to the formation of basal laminae on the surface of individual Schwann cells. A distinct layer of perineurium also starts to appear at the nerve surface (Figure 4).

The mechanisms of cell survival also change with this transition. Schwann cell precursors are acutely dependent on β-neuregulin-1 for survival, whereas immature Schwann cells acquire autocrine survival mechanisms. This enables Schwann cells to support their own survival in the absence of axons, a mechanism that is likely to be important for axonal regeneration after injury. The autocrine survival factors that have been identified include a cocktail of insulin growth factor (IGF)-2, platelet-derived growth factor-BB, and neurotrophin (NT)-3, potentiated by laminin, and lysophosphatidic acid and leukemia inhibitory factor. This switch in survival strategy makes biological sense. Precursor survival is completely dependent on neuronally derived β-neuregulin-1, a property that may serve to match axon and Schwann cell precursor numbers and to keep precursors confined to developing nerves as they grow through body tissues to reach their targets. In contrast, the fact that Schwann cells can survive in the absence of axons ensures that if axonal injury occurs the surviving Schwann cells can provide essential factors to support axonal regrowth.

Little is known about the transcription factors that control the precursor to Schwann cell transition. Levels of activator protein 2α (AP2α) are high in precursors and decrease sharply in immature Schwann cells, and enforced expression of AP2α *in vitro* retards the transition. Endothelin also regulates the transition in a negative fashion, as mentioned previously.

As the cells transit from Schwann cell precursors to Schwann cells, developmental options narrow. Dedifferentiation of immature Schwann cells leading to the emergence of Schwann cell precursors has not been observed definitively, and Schwann cells in culture are resistant to signals such as BMPs and fibroblast growth factor 2 that can induce the generation of other neural crest derivatives from Schwann cell precursors.

Boundary Cap Cells Give Rise to Schwann Cells in Spinal Roots

Schwann cells in spinal roots have a different origin from the majority of Schwann cells in peripheral nerves. They are derived from boundary cap cells, a specialized set of cells that originate from the neural crest. These cells are found during embryonic development clustered in groups where dorsal and ventral roots enter and exit the spinal cord. They can be identified by the expression of the transcription factor KROX20 (EGR2) long before this gene appears in myelinating Schwann cells. Lineage tracing studies of the fate of these cells *in vivo* have revealed that they give rise not only to the Schwann cells of the dorsal and ventral roots but also to a small subset of nociceptive neurons and some satellite cells within the DRG. Few boundary cap cell-derived glia were detected in spinal nerves. Therefore, these findings do not affect the classical view that Schwann cells of limb nerves originate from migrating neural crest cells.

Functions of Schwann Cell Precursors and Schwann Cells

Trophic Support of Neuronal Survival

A major function of glial cells is to provide trophic support for developing neurons. In the case of Schwann cell precursors and immature Schwann cells, persuasive support for this view comes from experiments in which these cells have been deleted from peripheral nerves. In mouse mutants that lack SOX10, β-neuregulin-1 isoform III, or the neuregulin receptors ErbB2 or ErbB3, Schwann cell precursors and Schwann cells are depleted or absent owing to the importance of these molecules in gliogenesis and glial survival. Importantly, in these mutants most of the DRG and motor neurons that project into limb nerves die by E14 and E18, respectively, although they are initially generated in normal numbers. This suggests that an important function of precursors and immature Schwann cells is to provide essential survival signals for developing neurons. Impaired axon-target contacts may also contribute to sensory and motor death in the β-neuregulin-1 isoform III mutants.

Together with the evidence that axons provide essential β-neuregulin-1-mediated survival support for Schwann cell precursors that was discussed previously, these studies indicate that there is a discrete early phase of nerve development in which neurons and glia depend on each other for survival.

Morphogenesis: Maintaining the Normal Structure of the Spinal Cord, Nerve Trunks, and Neuromasts

An important morphogenetic role for the early glia of ventral roots has been revealed by studies using several mouse mutants, all of which have in common the absence of glial cells from nerve roots. In all of these mice, the cell bodies of motor neurons are displaced into the ventral roots. Comparable observations have been made in the chick. This indicates that an important function of boundary cap cells, or the Schwann cell precursors that are derived from them, is to maintain the normal location of motor neurons within the spinal cord.

Another morphogenetic function for immature Schwann cells and their precursors is that of holding peripheral nerve trunks together in a unified structure since in mouse mutants that lack these cells, large nerves separate into a number of smaller bundles. Remarkably, however, even without accompanying glial cells, the nerves initially grow out into limbs more or less correctly and find their way to their target areas. A morphogenetic function for neural crest-derived glia is also seen in the lateral line nerve of zebra fish, where developing glial cells (immature Schwann cells or their precursors) control nerve fasciculation and the formation of secondary neuromasts – organs that are specialized to detect water movements.

The Generation of Immature Schwann Cells and Endoneurial Fibroblasts

Lineage tracing studies have revealed an unexpected role for Schwann cell precursors. They show that the relatively small population of fibroblasts found within the nerve at birth (5–10% of total cells) arises from cells in the nerve that express desert hedgehog and p75 neurotrophin receptor ($p75^{NTR}$) and are therefore presumably Schwann cell precursors. This accords with the observation that not only Schwann cells but also fibroblasts appear in the nerve at the precursor–Schwann cell transition. It is also consistent with earlier experiments that demonstrated that, in principle, early PNS glia from rodents and bird nerves have the potential to generate cells other than Schwann cells since they can be induced to generate melanocytes in cell culture. A finding that provides an additional example of the unexpected developmental potential of early PNS glia concerns the boundary cap cells mentioned previously. These cells are tightly associated with axons and express glial-associated genes such as P_0 and KROX20, and they can therefore be regarded as having the phenotype of early glial cells. Nevertheless, these cells give rise not only to glia but also to some DRG neurons during normal development. This is reminiscent of the observation that early CNS glia, namely radial glia, generate both astrocytic glial cells and neurons, and it is in accord with the emerging concept that early glia can act as multipotent progenitors in both the developing PNS and the CNS.

The Transition from Immature Schwann Cells to Myelination

The transition from Schwann cell precursors to immature Schwann cells is essentially complete by E18, and at that time nerves have also acquired the basic tissue architecture known from postnatal nerves since they now contain relatively large extracellular spaces, connective tissue, fibroblasts, and blood vessels. At this stage, the Schwann cells, which have started to assemble a basal lamina, still ensheathe large groups of axons communally (Figure 4). Myelination starts approximately 3 days later, at approximately birth. This requires radial sorting, a process of radical change in the configuration of Schwann cells and axons that allows the larger diameter axons that will become myelinated to acquire a 1:1 relationship with individual Schwann cells, a configuration that is a prerequisite for myelin formation. At the same time as radial sorting is taking place, Schwann cell numbers are adjusted to the number of axons by controlling proliferation and survival. During this period, a number of signaling systems probably act together to prevent premature myelination.

Radial Sorting

This process, which allows individual Schwann cells to become associated with single large-diameter axons, is rapidly being dissected at the molecular level, although many aspects remain unclear. Defects in radial sorting are seen in the absence of laminin isoforms and in the absence of β_1 integrin. Radial sorting also fails in the clawpaw mutant mouse, which has a mutation in Lgi4, a secreted molecule of unknown function that belongs to a family of molecules, another member of which, Lgi1, complexes with Kv potassium channels and causes certain forms of epilepsy. Lastly, lack of a disintegrin and metalloprotease protein (ADAM)22 also causes sorting defects and severe hypomyelination. In the absence of laminin, or the laminin receptor

dystroglycan, Schwann cell proliferation is also impaired and apoptosis increased. Interestingly, these functions are unaffected by the absence of β_1 integrin.

Cell movement is a crucial component of radial sorting, and it is possible that factors that control Schwann cell migration in culture could also affect radial sorting. They include the growth factors β-neuregulin-1, IGFs, and NT-3, all of which promote migration, and brain-derived neurotrophic factor, which inhibits it. Levels of activation of the small GTPase Rac also appear to regulate Schwann cell–axon interactions, and in other cell types low levels of rac activation promote directionally persistent cell migration, whereas high levels promote random migration. There is also evidence that the p38 mitogen-activated protein kinase pathway is required just prior to myelination, perhaps for the correct alignment of axons and Schwann cells.

Control of Schwann Cell Numbers

During the process of sorting and myelination that occurs at approximately birth, it becomes important to match the numbers of Schwann cells and axons. By then, the period of neuronal cell death is largely over. This process is therefore controlled by a balance between rates of Schwann cell proliferation and death.

Experiments using cultured cells suggest that axons are the major stimulators of Schwann cell proliferation, an idea supported by the observation that *in vivo* Schwann cell proliferation decreases as Schwann cells lose contact with axons in transected nerves of newborn animals. In co-cultures of Schwann cells and DRG neurons, β-neuregulin-1 acts as a major axonal mitogen, but this has not been confirmed *in vivo*. Transforming growth factor (TGF)-βs are also potential mitogens that are present in developing nerves. Studies show that mouse Schwann cells that lack TGF-β type II receptor proliferate more slowly *in vivo* than normal Schwann cells, demonstrating that TGF-β is normally involved in regulating Schwann cell proliferation during nerve development.

Schwann cell survival in developing nerves is likely controlled by a balance between factors that support survival and those that promote cell death. Axonally derived β-neuregulin-1 and autocrine circuits provide survival support, together with laminin acting through dystroglycan receptors. Two signals that promote cell death have been identified *in vivo*, including TGF-β. Deletion of TGF-β type II receptors suppresses developmental death in E18 to newborn nerves, and cell death after newborn nerve transection is also lower in these mutant nerves. Signals acting through $p75^{NTR}$, possibly nerve growth factor, are required for the cell death that occurs after neonatal nerve transection but not for normally occurring developmental death.

The Onset of Myelination

Schwann cell myelination is a remarkable example of cell–cell interaction in which the association of an immature Schwann cell with a large-diameter axon induces a radical change in morphological and molecular phenotype. This leads to the formation of the myelin sheath and reciprocal changes in axonal membrane proteins, ion channels, and cytoskeleton that enable saltatory conduction along large nerves. The role of the basal lamina in promoting myelination is well established, although the molecular mechanisms involved are just beginning to be revealed.

The Role of β-Neuregulin-1 in Myelination

It has been shown that β-neuregulin-1 type III is one of the crucial axonal signals involved in controlling Schwann cell myelination. Mutant mice heterozygous for this isoform have thinner myelin sheaths, whereas overexpression results in thicker myelin sheaths and induces myelination of axons that would not normally be myelinated. β-Neuregulin-1 activates signaling pathways that positively regulate myelination, including the phosphatidyl inositol-3 kinase and protein kinase A pathways.

Myelin-Related Transcription Factors

The most important transcription factor involved in myelination is KROX20, which acts together with its partners, the NGF1-A-binding proteins 1 and 2 (NAB1/2), to upregulate a large number of myelin genes and proteins. The absence of KROX20 or, alternatively, the combined absence of NAB1/2, both of which are upregulated by KROX20, results in Schwann cell arrest at the 1:1 promyelin stage and failure to myelinate, indicating the central importance of the KROX20/NAB1/2 complex for gene activation and myelination. In humans, KROX20 (EGR2) mutations are associated with hereditary sensory and motor neuropathies. The octamer-binding transcription factor 6 (OCT6) and, to a lesser extent, brain 2 class III POU-domain protein (BRN2) control the timing of myelination. In mice that lack OCT6, myelination is severely delayed, probably because OCT6 is required for upregulation of KROX20 at the appropriate time in development, whereas BRN2 can partially compensate for loss of OCT6. *In vitro*, the transcription factor NF-κB and the Sloan–Kettering Institute proto-oncogene (SKI) are expressed prior to myelination, and in Schwann cell–neuron co-cultures lack of NF-κB or SKI in Schwann cells results in failure to myelinate.

Negative Regulation of Myelination

Although the onset of myelination is characterized by activation of promyelin pathways, studies indicate that signaling pathways that inhibit myelination also play a role in the timing of myelination. One of these inhibitory signals is the c-Jun N-terminal kinase (JNK) pathway. This pathway is active in Schwann cells of E10 to newborn nerves, where it is required for β-neuregulin-1 and TGF-β-induced signaling, at least in cultured cells. The pathway is inactivated as individual cells start to myelinate using a mechanism that depends in part on KROX20. In mice in which KROX20 has been inactivated, the JNK pathway is still active, proliferation remains high, and the cells arrest at the promyelin stage of development. When expression of JNK pathway constituents is enforced in cultured Schwann cells, myelination in neuron–Schwann cell cultures is blocked and myelin gene expression that would normally result from promyelin signals such as KROX20 is also blocked. The transcription factor SOX2 also promotes proliferation, inhibits myelination when overexpressed in Schwann cells in neuron–Schwann cell co-cultures, and remains high in mutant mice expressing low levels of KROX20 (EGR2). Similarly, Notch signaling, which, as mentioned previously, promotes proliferation in immature Schwann cells, is downregulated as cells start to myelinate *in vivo*, and in neuron–Schwann cell co-cultures enforced expression of Notch inhibits myelination. It is unclear how these apparently diverse inhibitory pathways are interlinked, and the details of how they interact with promyelin signals are just starting to be revealed.

Introduction

Along the entire length of mammalian peripheral nerves, axons of motor, sensory, and autonomic neurons are in close contact with Schwann cells (SCs), the main neuroglial cells of the peripheral nervous system (PNS). They were named after the German physiologist Theodor Schwann (1810–82), who founded modern histology by defining the cell as the basic unit of animal tissue structure, when he extended his cell theory of plant structure in animals with his 1839 publication, *Microscopic Researches into Accordance in the Structure and Growth of Animals and Plants*.

SCs are in intimate association and dynamic communication with neuronal axons thus influencing and regulating the development, maintenance, and function of peripheral nerves. They also play essential roles in the regeneration of peripheral nerves after injury and are capable of sustaining re-myelination of central nervous system (CNS) axons. They are therefore promising candidates for the development of transplantation therapies for repair of CNS lesions. Two major SC types are encountered in the adult nerves: the myelinating and the nonmyelinating SCs. Peripheral glia include more cell types than myelinating and nonmyelinating SCs. Perisynaptic glial cells or teloglia, found in the neuromuscular junction, as well as satellite cells of the peripheral ganglia are classified by some investigators as SCs. However, the consensus is that these cells are classified as non-SC peripheral glia and therefore they are not discussed here.

Myelinating SCs provide the myelin sheath of peripheral axons which is necessary for proper nerve function. The nervous system, both central and peripheral, relies on the myelin sheath for insulation and for decreasing membrane capacitance in the axon, thus allowing for rapid saltatory conduction and increased impulse speed to occur. Unlike oligodendrocytes, the myelinating cells of the CNS, each SC forms myelin around one axon only. For reasons that are not understood, only the larger diameter (typically >1 μm) axons of peripheral nerves are myelinated. A myelinated fiber is characterized by myelin internodes, which comprise the length of the myelin sheath generated by one SC, and short myelin-free areas, the nodes of Ranvier (Figure 1(a)). Myelinating SCs (Figure 2) are ultrastructurally distinct from their CNS analogs. The nucleus stains intensely, is flattened, and is oriented longitudinally along the nerve fiber. The cytoplasm of the SC is rich in organelles. A Golgi apparatus is located near the nucleus, and cisternae of rough endoplasmic reticulum as well as round mitochondria occur throughout the cell. Lysosomes, glycogen granules, multivesicular bodies, filaments, microtubules, and lipid granules can also be seen. Aggregates of dense heterochromatin are arranged peripherally.

Smaller axons (<1 μm) lie in troughs in the surface of nonmyelinating SCs (Figure 1(b)). The function of these cells is less well understood, but studies indicate that they are involved in the maintenance and function of unmyelinated axons and possibly nociception in the adult. The two types of SCs differ not only in their function, the type of axons with which they associate and their morphology, but also in molecular composition. Notably, myelinating SCs contain a set of myelin-associated proteins that are not expressed by nonmyelinating SCs.

Origins and Development of Schwann Cells

The two types of SCs, myelinating and nonmyelinating, found in adult nerves are derived from a single precursor cell type originating from the neural crest. This cell type matures in a stepwise process, giving rise to all SCs. First, SC precursors are generated by neural crest cells (at embryonic day (E) 14 or E15 in the rat) and associate with growing peripheral axon bundles, guiding their growth (Figure 3). In the limbs, these precursors are connected by adherens junctions and form elaborate scaffolds that serve as substrates for the developing growth cones as they advance to their targets. Expression of the adhesion molecule N-cadherin on SC precursors appears to be essential for their role as an axon outgrowth substrate.

SC precursors convert to immature SCs between E15 and E17 in the rat (Figure 3). This irreversible transition entails a phenotypic change in molecular expression and an altered response to survival signals and mitogens. It is also accompanied by a marked change in the cellular architecture of peripheral nerves. At E14 in rats, the nerves are compact structures consisting of axons and SC precursors (Figure 4). There is no significant connective tissue space and blood vessels are absent. SC precursors are found at the outer margin of the nerves, and inside them as well,

Figure 1 Schematic representation of peripheral myelinated (a) and unmyelinated (b) axons.

Figure 2 A large PNS axon (A) is surrounded by a myelinating Schwann cell. The SC nucleus is marked (N). Note the fuzzy basal lamina around the cell, the rich cytoplasm, the inner and outer mesaxons (arrows), the close proximity of the cell to its myelin sheath, and the 1:1 axon:Schwann cell relationship. Unstained collagen (C) lies in the endoneurial space. Reproduced from *Basic Neurochemistry*, 6th edn., with permission.

connecting to each other through sheet-like processes that communally envelope large numbers of axons. By E18, nerves are made up of irregular axon-immature SC bundles (similar to the 'families' found in newborn nerves) surrounded by connective tissue containing endoneurial fibroblasts and blood vessels (Figure 4). This basic architecture – comprising nervous tissue, connective tissue, and blood vessels – is retained in adult nerves.

On E18 in the rat, immature Schwann cells still ensheathe communally large groups of axons (Figure 3). However, for myelination to start soon after birth (approximately 3 days later), a process of radial sorting is required. During this process, which continues postnatally, the SC families of late embryonic nerves gradually become segregated into individual SCs, each associated with a single large-diameter axon. At the same time, SCs undergo a process of lateral elongation along the axon and secrete a basal lamina made up of mucopolysaccharides at their abaxonal surfaces. This radical change in cellular relationships, which results in a 1:1 relationship between axons and SCs, marks the promyelinating stage, is accompanied by changes in the molecular phenotype of the SCs, and renders them poised for myelination. Specific transcription factors, notably Krox 20, are upregulated and act to control myelination. Axon–SC contact is necessary for maintenance of the myelinating phenotype. Upon loss of axonal contact, as in the case of nerve injury, myelinating SCs revert to a nonmyelinating phenotype similar to that of immature SCs (Figure 3).

During embryonic development, as well as postnatally, numerous factors mediate specific aspects of the interactions between peripheral axons and SCs. Compelling evidence suggests that neuregulin-1 and its Erb receptors, belonging to the epidermal growth factor family of protein kinases, are key regulators of axon–SC interactions at every stage and for all SC types. The neuregulin/Erb signaling system is thus critical for SC biology and influences SC survival, proliferation, migration, and differentiation.

Myelinating Schwann Cells and the Myelin Sheath

At the promyelinating stage, as SCs start to wrap around the axon, the distance between two consecutive spirals (the extracellular gap) is 12–14 nm. At the myelinating stage, exclusion of the cytoplasm and compaction of the cytoplasmic surfaces results in the formation of compact myelin (Figure 2). Then the extracellular space is reduced from 12–14 to 2 nm, which is characteristic of compact myelin. Each SC is surrounded by the basal lamina it has secreted, which

Figure 3 Schematic representation of the major stages of Schwann cell development. Dashed arrows represent reversible processes. Adapted from Jessen KR and Mirsky R (2005) The origin and development of glial cells in peripheral nerves. *Nature Reviews Neuroscience* 6: 671–682, with permission.

Figure 4 Electron microscopic images (pseudo-color enhanced) and corresponding schematic illustrations of rat embryo peripheral nerves at E14 and E18, constituting hallmarks in the cellular architecture of peripheral nerves. At E14 (top left) the nerve is compact and is composed only of axons and SC precursors surrounding or interdigitating (large arrow) the axons. Division of an SC precursor is visible (small arrow). Extracellular connective tissue (in turquoise) and blood vessels are absent from the nerve. In sharp contrast, by E18 the nerve has been infiltrated by connective tissue and is now segregated into compact bundles of immature SCs and their associated axons ('SC families'). One such 'family' is depicted by the asterisk. Blood vessels are now also present (small arrow), whereas SC divisions can still be seen (large arrow). Reproduced from Jessen KR and Mirsky R (2005) The origin and development of glial cells in peripheral nerves. *Nature Reviews Neuroscience* 6: 671–682, with permission.

is approximately 20–30 nm thick and does not extend into the mesaxon. Myelination takes place during the first 2 or 3 weeks after birth in the rat. The mechanism by which SCs ensheathe the axon has been a subject of intense speculation in the past. In the PNS, the myelin spiral around a single axon may consist of up to 100 layers, a fact that has rendered the old 'jelly-roll' hypothesis, proposing that myelin

is laid down by a simple rotation of the Schwann cell nucleus around the axon, rather improbable (Figure 5(a)). In the CNS, such a hypothesis is precluded by the mere fact that a single glial cell can invest several axons with myelin. The prevailing hypothesis today is that ensheathment of the axon occurs by active progression of the inner (axonal) lip of the myelin lamella as it forms the myelin spiral (Figure 5(b)). As this movement progresses, the SC membrane on one side of the groove (in which the axon lies) comes into contact with the cell membrane on the other side of the groove. These parts of the membrane approximate and stay together and thus are seen, as the cell membrane lamella continues to wind around the axon, as a spiral of rings each made of double lines. Between adjacent double rings there is at first a layer of cytoplasm, but as the winding continues, the cytoplasm is squeezed back into the cell body.

The wrapping of the SCs around a short segment of the axon produces the myelin sheath, a lipid-rich layer formed by a greatly extended and modified plasma membrane (Figure 2). This membrane, since it is highly enriched in nonconductive ingredients and poor in conductive water-based media (cytoplasm), serves ideally as an effective insulant for the nerve fiber. The lipid component of the myelin sheath gives nerves a vacuolated appearance in histological stains. In myelinated axons, only the axon hillock and the terminal arborizations where the axon synapses with its target cells are completely devoid of the myelin sheath. Myelin and many of its morphological specializations such as the nodes of Ranvier and the Schmidt–Lantermann incisures, can be detected readily under the light microscope; however, much of our understanding of its organization is derived from studies carried out by other techniques offering higher resolution: polarized light, X-ray diffraction, and electron microscopy.

Along the myelinated fibers of the PNS, each internode of myelin is invested by one Schwann cell and each Schwann cell surrounds one internode (Figure 1). As discussed previously, this ratio of one internode of myelin to one Schwann cell represents a fundamental distinction between the SC and the oligodendrocyte, which is able to produce internodes at a ratio of 1:30 or greater. Another distinction is that the Schwann cell body always remains in close contact with its myelin internode, whereas the oligodendrocyte is not on an internode but extends processes toward them.

Under the electron microscope, myelin is visualized as a series of alternating dark and less-dark lines (protein layers) separated by unstained zones (the lipid hydrocarbon chains). This distinctive pattern of staining results from the way the myelin sheath is generated from the cell plasma membrane. The lighter (intraperiod) line represents the closely apposed protein coats of the outer aspect of the cell membrane; the darker (major dense) line corresponds to the fused inner protein coats of the membrane, formed as the cytoplasm has been squeezed out

(Figure 6). Examination of PNS myelin swollen in hypotonic solutions confirms this interpretation. Electron microscopy observation of such preparations reveals splitting at the intraperiod line, showing the continuity of its membrane junction with the extracellular space. With good perfusion fixation and tissue staining the intraperiod line is always visualized as a double line, indicating that the extracellular sides of the unit membranes are closely apposed but not fused, as was thought in the past. When studied in fixed preparations, PNS myelin has an average repeat distance of 11.9 nm (approximately 30% less than in the unfixed state), in contrast to 10.6 nm for central myelin. External to the myelin lies the greater part of the SC cytoplasm, bounded at its outer surface by the cell membrane and basal lamina of the Schwann cell (Figure 2).

The myelin sheath can be divided, by virtue of its composition and morphology, into two distinct domains – compact myelin and noncompact myelin – each containing distinct proteins. Compact myelin contains P0, the 22 kDa peripheral myelin protein PMP-22, and myelin basic protein (MBP). MBP which is positively charged is considered important in linking the two cytoplasmic surfaces, whereas P0 is crucial for stabilizing the intraperiod line by keeping a 2-nm distance between the apposing extracellular faces of two adjacent compacted myelin membranes. Noncompact myelin, found at the paranodal regions flanking the nodes of Ranvier and in periodic interruptions of the compact myelin called Schmidt–Lanterman incisures, contains myelin-associated glycoprotein (MAG), the gap junction protein connexin32 (Cx32), and E-cadherin. E-cadherin is localized to adherens junctions, whereas the localization of Cx32 coincides with the location of gap junction-like strctures. Adherens junctions and gap junctions are usually found between neighboring cells and their presence in the myelin sheath is atypical, as in this case they join adjacent layers of the same cell. Specific neuron–SC interactions that play an important role in the organization and function of peripheral nerves take place in the regions of noncompact myelin.

Noncompact Myelin

Nodes of Ranvier

Myelin is not a continuous structure but is interrupted at regular intervals by the nodes of Ranvier, constrictions named after the French pathologist and anatomist Louis-Antoine Ranvier (1835–1922), who first described them (Figure 7). These short periodical interruptions in the myelin sheath are regularly spaced along the axon at intervals of ~100 times the axonal diameter. The area of the nerve between two consecutive nodes of Ranvier, the internode, is ensheathed by myelin produced by a single SC. The nodal region, composed of both SCs and the axon, is a highly organized structure containing several distinct domains: the nodes, paranodes, and juxtaparanodal region, each characterized by an array of interacting cell adhesion molecules (CAMs), cytoskeletal proteins, and voltage-gated ion channels (Figures 8 and 9). This highly specialized structure, in terms of both morphology and molecular composition, is essential for saltatory conduction.

At the node there is no myelin. The nodal axolemma is characterized by a high density (>1200 mm^{-2}) of voltage-gated Na^+ channels (Nav 1.2 during development or Nav 1.6 in the adult) essential for the generation of the action potential during salutatory conduction (Figure 9). Na^+ channels co-localize with KCNQ2 K^+ channels, cell adhesion molecules such as NrCAM and neurofascin 186 (NF186), and cytoskeletal proteins, including the cytoskeletal-linking protein ankyring G and the actin-binding protein βIV-spectrin (Figures 8(b) and 9). These molecules as well as gliomedin, the glial ligand for NrCAM and NF186, interact to regulate channel clustering at the node. The nodal axolemma is in contact with microvilli emanating from the outermost regions of myelinating SCs. Several other morphogenetic proteins are present, contributing to the formation of the microvilli and the particular architecture of this specialized structure (Figure 9).

Figure 7 Low-power electron micrograph of a node of Ranvier in longitudinal section. Note the abrupt decrease in axon diameter and the attendant condensation of axoplasmic constituents in the paranodal and nodal regions of the axon. Paranodal myelin is distorted artifactually, a common phenomenon in large-diameter fibers. Reproduced from *Basic Neurochemistry*, 6th edn., with permission.

Just outside the center of the node lies the area of the paranode, in which the compact myelin lamellae open up into a series of cytoplasmic loops that spiral around the axon (**Figure 8(a)**). The length of the paranode is proportional to the axon diameter, ranging from 10–20 μm in smaller fibers (4 or 5 μm in diameter) to 80 μm in large fibers more than 15 μm in diameter. There, the cell adhesion molecules contactin (F3), paranodin (contactin-associated protein; Caspr) on the neuronal side and Neurofascin-155 (NF-155) on the glial side interact to stabilize the structure (**Figure 9**). The paranodal loops of SC are tightly attached to the axolemma, leaving an extracellular space of approximately 3 nm, in which the two membranes are joined by electron-dense structures – the paranodal or septate-like junctions. During development, these junctions are first generated next to the node and are formed gradually, as additional loops are attached to the axon in a spiral fashion. The paranodal junctions are thought to provide attachment of the myelin sheath to the axon, to electrically insulate the node from the internodal area, and to act as boundaries that limit the lateral diffusion of membrane components. Next to the paranode and distal to the node lies the juxtaparanodal region, characterized by the presence of K^+ channels Kv1.1 and Kv1.2 and their Kvβ2 subunit (**Figures 8(a) and 8(b)**). The adhesion molecule TAG1, which is expressed by both the axon and the SC at the juxtaparanode, as well as Caspr2, are crucial for the sequestration of K^+ channels (**Figure 9**).

There is one SC between every two nodes and fiber branching always occurs at nodes. The basal laminae of myelinating SCs at the nodes of Ranvier are continuous, and SC processes interdigitate so that the PNS myelinated axon never comes in direct contact with the extracellular space.

Schmidt–Lantermann Incisures, Lateral Loops, and Transverse Bands

The Schmidt–Lantermann incisures or clefts, named after the American pathologist Henry D. Schmidt (1823–88) and American anatomist AJ Lantermann (1855–1910), are recurring structures in peripheral myelinated axons. They represent regions where the cytoplasmic surfaces of the myelin sheath have not compacted to form the major dense line and thus contain SC cytoplasm (**Figures 8(a) and 8(c)**). These inclusions are present in each layer running spirally within the myelin, and they would therefore appear as tubes of cytoplasm in an unrolled myelin sheet. They transect the sheath at an angle of approximately 9°. Ultrastructurally, there is considerable variation in their number and width, which are related to the axon thickness; the density of the cytoplasm they contain, which is inversely related to their width; and the morphology of the rings that form their boundaries. Cx32 has been localized at the incisures, and the presence of gap junctions, along with adherens junctions and tight junctions, has been observed by freeze-fracture electron microscopy.

Similar tubes, in which the major dense line opens up to enclose cytoplasm, are located at the paranodal edges of the sheet and make up the lateral loops (**Figure 8(c)**). The lateral loops also contain Cx32. The presence of this gap junction protein in all uncompacted myelin structures and the electron microscopic observation of gap junction channels suggest that they act as routes of communication between turns of myelin of an individual SC for the transportation of electrolytes and metabolites, providing a path from the periaxonal cytoplasm all the way to the outermost part of the SC. The lateral loops form membrane complexes with the axonal

Figure 8 (a) Schematic illustration of a myelinated axon sectioned at the area of the node of Ranvier. Shown are the SC microvilli at the node as well as the SC lateral loops at the paranode. The lateral loops are kept in contact with the axon via specific protein–protein interactions (see also **Figure 9**). membrane called transverse bands. There are six to eight transverse bands per paranodal loop, spaced 25–30 nm apart. The transverse bands seal the myelin to the axolemma but provide, by the spaces between them, a path from the extracellular space to the periaxonal space, which separates myelin from the axon in the internodal area.

Nonmyelinating Schwann Cells

Some afferent and autonomic nerve fibers lack myelin sheath. These are the unmyelinated fibers and are smaller, since typically the diameter of an axon has to be larger than 1 μm for myelination to commence. After birth in the rodent, SCs diverge in myelinating and nonmyelinating cells. In contrast to oligodendrocytes, SCs surround both myelinated and unmyelinated axons. Although they are not ensheathed in a myelin structure, unmyelinated axons are nevertheless protected by SCs which are arranged in bundles (Remak bundles) so that they form a groove through which the fibers extend. In this manner, approximately 5–20 unmyelinated fibers lie protected by an SC at any given level. The protective cellular sheath enclosing a group of unmyelinated fibers thus comprises a series of interdigitating SCs arranged end to end along the bundle. Surrounding the external surface of SCs and covering the grooves where they open to the exterior is a basal lamina. Between the axolemma of each unmyelinated fiber and the SC membrane lining the housing groove is an intercellular space 10–15 nm wide. No nodal structures are present, and voltage-gated ion channels are considerably less ordered in the unmyelinated axon, spreading over the entire membrane surface. Nonmyelinating SCs (as well as SCs in culture) express a distinct and characteristic set of marker proteins, including the cytoskeletal glial fibrillary acidic protein (GFAP), the calcium-binding protein S-100, and p75 neurotrophin receptor (Figure 10).

There used to be a misconception that nonmyelinating SCs are there simply to take over myelination whenever the need arises. However, it has been shown that these cells play critical roles in neuronal survival, function, and axon maintenance while the axons support SC survival. As in the case of myelinating SCs, these reciprocal interactions are at least in part mediated via the neuregulin-1/ErbB signaling system.

Schwann Cells in Axonal Regeneration

In normal circumstances, the neuronal cell body maintains the axon through the axoplasmic flow. When even a small segment of an axon dies, the part of the axon distal to the injury undergoes a series of changes leading to its complete structural disintegration and chemical degradation. When myelinated axons distal to a site of injury die, their myelin sheaths also degenerate. This process is termed Wallerian degeneration because it was first described by neurophysiologist Augustus Volney Waller (1816–70). SCs carry out the first step in the removal of myelin by segmenting and then incorporating the degraded myelin. Recruited macrophages then join in. In the neuronal body, the rough endoplasmic reticulum disaggregates and the neuronal body swells. The cytoplasm becomes smooth as the organization of polyribosomes into Nissl bodies is temporarily disrupted and the nucleus is displaced toward the periphery of the cell. This process is called central

Figure 10 Confocal microscopy of SCs cultured from neonatal rat sciatic nerve. Cells were virally transduced to express, in this case, the green fluorescent protein, GFP (green, left column) and were immunostained for the characteristic SC markers *in vitro* (red, middle column): GFAP (A–C), S-100 protein (D–F), or p75 nerve growth factor receptor (G–I). Merged GFP/immunofluorescence images are shown in the right column. A fraction of SCs identified by the expression of marker proteins were transduced to express GFP (yellow, right column). Upon appropriate stimuli, these cells were induced toward a myelinating phenotype (J–L), as illustrated by their flattened appearance, production of new membrane expansions, and the expression of P0 peripheral myelin protein (red, K). Reproduced from Kenoutis et al. (2006), with permission.

chromatolysis and it reflects cytoskeletal reorganization and activation of protein synthesis in order to regenerate the axon. Cytoskeletal proteins and other materials flow down the axon and the proximal stump elongates at a rate of 1–3 mm per day. These changes begin within 24–48 h and reach a peak at approximately 2 weeks. SCs after myelin removal transiently revert from a myelinating to a nonmyelinating phenotype, and they start to divide and migrate forming longitudinally continuous columns (Bungner bands) between the severed ends. In this manner, they form tubes containing SC cell bodies and processes surrounded by a single basal lamina, thereby providing channels for growth cone navigation and axonal elongation. The presence and integrity of the SC basal lamina is essential for reinnervation. Wallerian degeneration was initially described in experimental axotomy. Neuropathies characterized by Wallerian degeneration include those that are caused by trauma, infarction of peripheral nerve (diabetic mononeuropathy and vasculitis), and neoplastic infiltration. SCs can myelinate and support the regeneration of not only peripheral but also central axons, both *in vitro* and *in vivo*. This beneficial SC property is being explored for the development of transplantation therapies for CNS repair after injury or in demyelinating diseases.

Schwann Cells *In Vitro*

Schwann cells can be cultured from neonatal peripheral nerves, after mechanical dissociation and enzymatic digestion followed by elimination of rapidly dividing residual fibroblasts with an antimitotic

agent (Figure 10). They can be maintained for weeks using proliferating media containing neuregulin-1 and a cAMP-elevating agent such as forskolin. In these culture conditions, SCs are nonmyelinating and appear mostly bipolar with a spindle-like shape, but they can also be tripolar. Cultured SCs have a molecular phenotype similar to that of nonmyelinating SCs (Figures 10(B), 10(E), and 10(H)). SCs can also be cultured from adult nerves, including human.

When culture conditions are switched from proliferating to myelinating by withdrawal of mitogens and exposure to higher concentrations of agents that elevate or mimic intracellular cAMP (forskolin, cholera toxin, and cAMP analogs), the morphological and biochemical phenotype of SCs changes dramatically, as it does *in vivo* at the onset of myelination. GFAP expression is downregulated and myelin protein expression is upregulated. SCs lose their bipolar appearance and become flattened as they produce large expansions of membrane in preparation for axonal ensheathment (Figures 10(J)–10(L)).

When in culture, SCs are amenable to genetic manipulation through viral transduction for the expression of exogenous proteins (Figure 10) with potential beneficial effects for nervous tissue regeneration. Such genetically modified SCs may be transplanted in the lesioned CNS to assist remyelination of central axons. This combination of gene and cell therapy approaches is currently attracting significant attention for CNS repair in demyelinating diseases or trauma.

Schwann Cells and Axon Relationship

R D Fields, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Vertebrates owe their evolutionary success to myelin. This multilayered wrap of electrical insulation speeds the conduction of impulses through slender axons. Without myelin, axons would need to be much thicker to carry impulses at the same rate. Evolution of myelin allowed miniaturization of nerve fibers and thus compaction of the nervous system into a brain of incomparable complexity – accelerating information processing in the nervous system of animals with backbones by magnitudes beyond the cerebral capabilities of the most evolutionarily advanced invertebrates. On a cellular level, myelin is perhaps the most intricate of all interactions between cells. Myelination requires cell–cell recognition, intercellular signaling, adhesion, motility, coordinated regulation of cell proliferation, differentiation, and synthesis of enormous sheets of insulating membrane, compacted into thin spiral layers in a manner unlike any other and with fine structural intricacies at the nodes of Ranvier to a molecular, crystalline level of precision, discernable only with the electron microscope. Myelin is unlike any other cell–cell interaction.

The cells that form myelin in the nerves of our limbs and trunk (peripheral nerves) are Schwann cells. In the brain, an entirely different type of cell, oligodendrocyte, with a distinct embryological origin, forms myelin. Schwann cells were first described in 1838 by the same pioneering biologist who conceived the concept of the cell as the basic building block of all life, Theodore Schwann. However, the purpose and origin of these peculiar cells were a mystery to him. Schwann cells coat axons like flattened pearls on a string, inspiring Schwann to speculate that they might form the nerve axon during fetal development by aligning and coalescing into a tube. In retrospect, this quaint idea appears naive, but the intimate interdependence of both axon and Schwann cell is now deeply appreciated.

Communication between Axons and Schwann Cells

Signals from axons are essential in regulating most Schwann cell functions, including proliferation, adhesion, migration, differentiation, and myelination. After an axon is damaged, Schwann cells respond to the loss of axon contact by de-differentiating. They lose their myelin and begin to proliferate and secrete growth factors to help guide the regenerating axon back to its target. The axon, in turn, is dependent on Schwann cells for its own integrity, structural development, and survival. In addition to providing structural support and electrical insulation, Schwann cells provide growth factors to axons, and they organize the arrangement of macromolecular ion channels into proper spatial domains along the axon membrane to support saltatatory conduction. Saltatory conduction describes the way an electrical impulse skips from node to node down the full length of an axon, speeding the arrival of the impulse at the nerve terminal in comparison with the slower continuous progression of depolarization spreading down an unmyelinated axon. Each node, situated between adjacent Schwann cells along the axon, is a bare segment of axon with specialized membrane properties for generating action potentials.

Embryological Origin of Schwann Cells

Schwann cells derive embryologically from the neural crest, which comprises multipotent cells migrating away from the dorsal neural tube. Neural crest cells differentiate into Schwann cell precursors, which migrate and proliferate along tracts of axons that have already extended into the periphery. The Schwann cell precursors then embark on a process of cellular differentiation into an immature Schwann cell to eventually become either a myelinating or a nonmyelinating Schwann cell. Only large-diameter axons, which conduct impulses at the highest speed, become myelinated. The slender, slow conducting fibers become bundled together and engulfed by massive, globular nonmyelinating Schwann cells.

Axon Signals Sustaining Schwann Cell Precursors

Early Schwann cell precursors are critically dependent on axon-derived signals for maintenance, proliferation, and differentiation. Axon contact stimulates proliferation of Schwann cell precursors, and neuregulin-1 (NRG-1) is recognized as one of the most potent axon-derived mitogens. Neuregulins are a family of growth factors that act as mitogens by binding the ErbB family of receptor kinases. The primary receptor for NRG-1 in Schwann cells is a heterodimer composed of ErbB2 and ErbB3, and mice genetically engineered to lack these receptors lose all Schwann cells on their peripheral axons. ErbB signaling is also

required to maintain the directed migration of Schwann cell precursors along axons. Genetic deletion experiments show that premigratory Schwann cells near the dorsal root ganglia fail to migrate out along the axons in the absence of neuregulin signaling.

The progenitors must proliferate as they migrate out along axons to produce sufficient numbers of cells to string the entire length of the axon, but precisely the correct number of cells is essential because this determines the number of nodes of Ranvier along the fiber. This is one of the important elements determining the conduction velocity and safety factor that will ensure the nodes are spaced closely enough for the wave of electrical depolarization to sustain a sufficient distance along the axon to activate the next node in sequence. As a limiting survival factor for Schwann cell precursors, NRG-1 helps establish the appropriate total number of Schwann cells on each axon. In a similar manner, transforming growth factor-β (TGF-β) also acts as a mitogen on Schwann cells at this stage to control the total number of cells.

Secreted factors inhibiting development are equally important to coordinate the timing of different development steps. Endothelins, AP2α, and bone morphogenic protein (BMP)-2 and -4 are examples of factors inhibiting the formation of Schwann cell precursors. Schwann cell precursors can also give rise to other types of cells, including neurons and fibroblasts *in vitro*. The remarkable plasticity of Schwann cells, recapitulated after nerve injury, aids in recovery from axon injury.

Differentiation to Immature Schwann Cells

Formation of immature Schwann cells from Schwann cell precursors is promoted by insulin-derived growth factor-2 (IGF-2), neurotrophin-3 (NT-3), (platelet-derived growth factor-β (PDGF-β), fibroblast growth factor-2 (FGF-2), Notch, and leukemia inhibitory factor (LIF) (**Table 1**). These factors can be produced by the Schwann cells and act in a autocrine manner when the axon signals are lost following injury.

TBF-β and the p75 neurotrophic factor induce programmed death of immature Schwann cells, and extracellular adenosine 5-triphosphate (ATP) and adenosine, acting on two different types of purinergic receptors (P2 and P1, respectively), inhibit Schwann cell proliferation and differentiation beyond the immature stage. ATP is released by axons firing action potentials, and adenosine is the end product of ATP degradation. This activity-dependent axon–Schwann cell signaling provides a mechanism for regulating the development of Schwann cells according to the state of functional activity in developing neural circuits.

The Schwann cell precursors are vitally dependent on axon survival signals, but mature Schwann cells can self-generate many of the essential survival factors in the absence of axons. Thus, these cells survive after the axon dies from injury. Indeed, the axon depends on the chain of surviving Schwann cells and the growth factors they secrete to grow back to its proper target. As discussed later, however, prolonged separation of Schwann cells from axons leads to detrimental changes in Schwann cells.

Myelination

Myelination begins after Schwann cells exit the cell cycle. In the promyelinating stage, just before beginning to form myelin, Schwann cells begin to increase expression of several myelin proteins, including myelin-associated glycoprotein (MAG) and myelin protein zero. The latter is the most abundant protein in peripheral nerve, and it is responsible for maintaining the compact layers of myelin together. A different protein, proteolipid protein, performs this function in central nervous system myelin.

The process of myelination begins by a Schwann cell first engulfing several axon segments at once (**Figure 1(a)**). These are sorted out until the cell selects only one axon segment to wrap with myelin (**Figure 1 (b)**). Formation of extracellular matrix is an essential early step in the process, and in cell culture, myelination will not commence until ascorbic acid is added to

Table 1 Growth and transcription factors affecting Schwann cell differentiation

	Schwann cell precursor	*Immature Schwann cell*	*Myelinating Schwann cell*
Promotes differentiation to this stage	NRG-1, Notch, FGF-2	Adenosine, ATP, β_1 integrin, c-Jun, Claw paw, Ets transcription factors, IGF, laminin, NRG-1, NT-3, SOX-2, p38, p75, TGF-β	BDNF, BRN-2, cAMP, GDNF, IGF, Krox20/NAB1/2, Erg2, laminin, NF-κB, NRG-1, Oct6, progesterone, PI3K-Akt, SKI
Inhibits differentiation to this stage	Endothelin, BMP2/4, AP2α		ATP, c-Jun, Notch, NT-3, PAX-3, SOX-2, TGF-β

Figure 1 Schwann cell–axon relations during remyelination of regenerated axons in rat sciatic nerve. After axotomy, Schwann cells (SC) provide trophic factors and extracellular matrix components (ECM) to guide regenerating axons to form appropriate connections. (a) Early events in remyelination by SCs can be seen in sciatic nerve regenerating after being severed. Cellular processes extending from SCs (white arrows) sort out unmyelinated axons (ax) from larger diameter axons (AX). The small-diameter axons will become engulfed together in bundles inside nonmyelinating SCs and remain unmyelinated. A single SC will become associated with one segment of a large-diameter axon and begin synthesizing multiple layers of myelin membrane around a segment of the axon (M). This will provide rapid, saltatory impulse conduction by insulating the axon and organizing the fiber into internodal and nodal domains having distinct types of ion channels. Basal lamina, synthesized by SCs (double black arrows), is necessary for sorting out large-diameter axons and initiating myelination. (b) A large-diameter axon in the earliest stages of myelination is shown ensheathed by a single wrap of SC membrane. (c) Another myelinated axon shows a later stage in which compact myelin is formed by wrapping multiple layers of membrane around the axon and squeezing the cytoplasm out from between the stacks of insulating membrane. Scale bar = 500 nm.

the medium to promote formation of the basal lamina (Figure 1, black arrows). Laminin-2 is a major component of basement membrane, and mutations in α_2 laminin cause dysmyelination. β_1 integrin is one of the laminin receptors on Schwann cells, and animals lacking this receptor fail to establish the one-to-one relation with axons. Dystroglycan, another laminin receptor on Schwann cells, is not vital for early stages of myelination, but it participates in organizing the Schwann cell structure at the node.

The factors initiating myelination are not fully understood, nor is it clear why Schwann cells only myelinate large-diameter axons. Just before Schwann cells begin to myelinate, nuclear factor-kappa B (NF-κB) is upregulated, and its activation and translocation to the nucleus is necessary to regulate transcription of genes essential for myelination. A number of transcription factors are involved in initiating myelination, including Krox20/EGR2, NGFI-1-binding proteins, Oct6, and BRN2. As might be expected, cell adhesion molecules have an important role in axon–Schwann cell adhesion and myelination. The cell adhesion molecules L1 and NCAM are expressed on nonmyelinated axons, and they are downregulated during early myelination. MAG, a cell adhesion molecule that promotes association between axon and myelinating Schwann cells, is upregulated immediately after the initial layer of myelin is wrapped around the axon (Figure 1(b)). Synthesis of myelin proteins increases, and the mRNAs for myelin proteins, such as myelin basic protein (MBP),

become concentrated at distal sites in Schwann cells to provide local synthesis of myelin membrane.

Wrapping the layers of myelin around axons and squeezing the cytoplasm out from between the leaflets requires extensive cell extension and motility, which are regulated by actin–myosin cytoskeletal dynamics (Figure 1(c)). The Rho kinase (ROCK) regulates actin–myosin mechanical transduction by activating Rho, and in the absence of ROCK activity, the single myelinating process of a Schwann cell splits abnormally to form many smaller internodes, with resulting deleterious consequences for nerve conduction.

Myelin is promoted by many growth factors, including glial-derived neurotrophic factor (GDNF), NRG-1, myelin basic protein (IGFs), brain-derived neurotrophic factor (BDNF), as well as the sex hormone progesterone and the extracellular matrix molecule laminin. Multiple intracellular signaling pathways are involved, notably PI3K-Akt and cAMP. Myelination by Schwann cells is blocked by Notch activation, the neurotrophin NT-3, as well as by extracellular ATP. The latter is released by axons firing bursts of action potentials. TGF-β also inhibits myelination. Neurotrophins such as nerve growth factor (NGF) promote neuronal survival, but NGF stimulates myelination by Schwann cells through an indirect effect on axons. Indirect signals from the axons must be involved because experiments have shown that Schwann cell myelination of types of axons that are not depend on NGF for survival is unaffected by experimental manipulation of NGF.

The thickness of the myelin layer is precisely regulated in proportion to the axon diameter. Axons of larger caliber have thicker myelin, but the ratio of axon diameter to total diameter of axons including the myelin sheath falls within a range of 0.6 to 0.7 (g-ratio), regardless of the diameter of a myelinated axon. How the Schwann cell maintains this strict proportionate myelin thickness to varying axon caliber is unknown, but the thickness can be altered experimentally. BDNF, p75 neurotrophin receptor, or neuregulin overexpression results in abnormally thick myelin. Conversely, if ErbB receptors in Schwann cells are eliminated after myelination has begun, the sheath does not develop to its normal thickness. Myelin on axons regenerated after injury is typically thinner than normal, however.

Node of Ranvier

Formation of the node of Ranvier involves forming adhesive junctions between the axon and the extreme edges of the Schwann cell membrane abutting the node. At this junction, the multiple layers of myelin wrapped around the axon each seal against the axon membrane stacking in a staggered sequence at the edge of the node, thus forming the paranodal domain. In dividing the axon into nodal, paranodal, and internodal domains, the Schwann cell also affects the precise localization of ion channels and adhesion molecules along the axon, which are essential for salutatory conduction.

An important adhesion complex in forming and maintaining the paranode involves the axonal protein Caspr (contactin-associated protein, also known as paranodin), together with another protein contactin, binding to the glial partner neurofascicn 155 (Nfasc-155) at the paranodal junction. Cross-links between membrane proteins and the cytoskeleton maintain the appropriate ion channels in the proper axonal domains. Sodium channel localization at the node depends on association with Nfasc-186/NrCAM together with AnkyrinG/betaIV spectrin to anchor the channels to the actin cytoskeleton at the node. The node forms by nucleation of macromolecules in the nodal membrane, which then act as anchors for clustering additional sodium channels. Potassium channels become localized lateral to the paranode (the juxtaparanodal region), anchored by Caspr2, an axonal protein similar to Caspr, which localizes sodium channels at the node.

Myelinated Schwann cells are postmitotic, so as the axon grows, the Schwann cells must elongate at the same time, and the distance between nodes increases as the animal grows. Cytoplasmic channels beneath the outer layer of the myelin sheath, called Cajal bands, are an essential route for mRNA translocation to distal regions of the Schwann cell. When these bands are disrupted by disrupting a complex of molecules linking basement membrane to the Schwann cell plasma membrane (the L-periaxin-DRP2–dystroglycan complex), Schwann cells are impaired in their ability to elongate during nerve growth. The internodal length is reduced and conduction velocity slows.

Axon Dependence on Schwann Cells

Most of the axons die in limbs of mice genetically modified to lack Schwann cells, indicating definitively that axons and immature Schwann cells depend on each other for survival at crucial points in development. Long-term disabilities in patients with demyelinating diseases, such as Charcot–Marie–Tooth disease, can lead to axon degeneration. Myelinating Schwann cells have been shown to affect the extent of neurofilament phosphorylation in axons. Through this regulation, myelinating glia reduce the rate of slow axonal transport, in turn shrinking the caliber of the axon.

Regeneration

Axon damage results in Schwann cell responses that reflect the close interdependence of these two cells. After axotomy, the portion of the axon distal to the damage degenerates, but the Schwann cells in the distal stump begin to proliferate and synthesize growth factors that sustain the survival of the Schwann cells and the axons. Survival of neurons and elongation of sprouting axons from the proximal stump of severed axons is sustained by factors secreted by the Schwann cells and the extracellular matrix that they form. These factors include NGF, BDNF, and LIF. These beneficial properties of Schwann cells have been exploited to promote regeneration of axons in the central nervous system in Schwann cell transplantation experiments.

Schwann cells that are chronically isolated from their axons, however, begin to lose the capacity to support axon survival and outgrowth. This is one of the major reasons for permanent paralysis and failure to restore function in patients with damage to long nerves. Axon regeneration proceeds relatively slowly, at a rate of approximately 1 mm per day, and the Schwann cells in the extreme regions of limbs lose their ability to sustain axon regeneration before the regenerating axons can reach them.

Terminal Schwann Cells

At the distal end of motor neuron axons, a specialized form of Schwann cell ensheaths the neuromuscular junction. Functionally, these perisynaptic Schwann cells resemble astrocytes in the brain. Terminal Schwann cells help maintain the physical integrity of the synaptic junction, but they also have receptors for neurotransmitters that allow them to respond to neurotransmission. In turn, they release neuroactive substances that regulate the strength of synaptic transmission. These Schwann cells are also intimately associated with the axon and respond dynamically to axon injury. After axotomy, the terminal Schwann cells become highly branched and provide a route for axon sprouts from surviving junctions to reinnervate the vacated synapse.

Conclusion

Myelin appeared suddenly in the earliest vertebrates, fully formed and equally developed in both the central and the peripheral nervous system, even though the axon sheathing is made by completely different types of cells in the peripheral and central nervous system. This sudden evolutionary advance is puzzling because comparative anatomy reveals no intermediate forms. Considering the intricate choreography of cellular differentiation, recognition, mutual dependence on survival, motility, and membrane synthesis involved in myelination, this situation is especially surprising. What is clear is that the evolutionary advantage of myelin catapults nervous system function in vertebrates far beyond the limits of the invertebrate nervous system, which shares with vertebrates very similar neuronal structure and function. This success of vertebrate organisms derives from the highly regulated and complicated cellular interdependence of axon and glia.

Schwann Cells and Plasticity of the Neuromuscular Junction

Introduction

The neuromuscular junction (NMJ) has served as a prototype synapse due to its relatively large size, simple organization, and easy accessibility. Similar to the chemical synapse in the central nervous system, the vertebrate NMJ is composed of three adjacent cellular components: the presynaptic nerve terminal, the postsynaptic specialization, and the synapse-associated glial cells. These synapse-associated cells are called perisynaptic Schwann cells (PSCs) or terminal Schwann cells at the NMJ (Figure 1). Previous studies on the NMJ have primarily focused on the roles of nerve terminals and postsynaptic components, while the role of PSCs has been largely overlooked. However, from the 1990s, a barrage of studies have revealed multiple roles of glial cells in synaptic function, formation, and plasticity at NMJs, as well as at central synapses. Emerging from these studies on synapse–glia interactions is the concept of the 'tripartite' synapse, which asserts that, along with the presynaptic nerve terminal and the postsynaptic specialization, synapse-associated glial cells should be considered as an active and integral partner of the vertebrate chemical synapse as well. In this section, we describe the key findings of synapse–glia interactions and the involvement of PSCs in the plasticity of the vertebrate NMJ and focus on the multiple roles PSCs play in synaptogenesis, maintenance, remodeling, and regeneration of the NMJ.

The General Characteristics of Perisynaptic Schwann Cells at the Neuromuscular Junction

In the vertebrate neuromuscular system, motor axons are wrapped around by myelinating Schwann cells, which are responsible for the saltatory conduction of nerve impulses; however, motor nerve terminals are capped by nonmyelinating PSCs instead. The existence of Schwann cells at the vertebrate NMJ was suspected long before the days of electron microscopy. Soon after the initial descriptions of vertebrate NMJs, Louis-Antoine Ranvier was the first to report clusters of 'arborization nuclei' in 1878. These nuclei accompany nerve terminal arbors at NMJs, and are distinct from muscle fiber nuclei. Subsequent histological studies identified these arborization nuclei as nuclei of teloglia, or terminal Schwann cells. The survival of these teloglia after nerve degeneration further suggests that they are non-neuronal cells. Electron microscopy studies in the 1950s and 1960s provided much detailed information about NMJ morphology, confirming the intimate association between terminal Schwann cells, or PSCs, and nerve-muscle contacts.

At the mammalian NMJ, PSCs do not invade the synaptic cleft between the nerve terminal and the muscle surface, and the exclusion may be attributed to laminin 11 in the synaptic cleft. At the frog NMJ, however, PSCs do extend finger-like processes looping around the nerve terminal in between active zones, and are colocalized with F-actin concentrated at the nonrelease domains of the frog nerve terminal. PSC fingers contain L-type calcium channels, but the function of PSC fingers, if any, is unknown. There are approximately three to four PSC somata per NMJ in both mammalian and amphibian muscles, and the PSC number correlates with the junctional size. PSCs are capped with basal lamina, which contain some molecules that are distinct from those in the synaptic cleft and in the extrasynaptic basal lamina of the muscle fiber. It has been suggested that the extracellular matrix associated with PSCs may play a role in guiding nerve terminal sprouts at the frog NMJ, although the molecular mechanisms remain to be studied (see below).

The advance in understanding the role of PSCs has been aided by the availability of several probes that can label them, although most of these probes are not specifically for PSCs as they can also label axonal Schwann cells. The most commonly used probe to label mammalian PSCs is an antibody to S-100, a calcium-binding protein. Recently, transgenic mice expressing green fluorescent protein (GFP) under the control of human S100B gene have been generated to reveal GFP expression in axonal Schwann cells and PSCs at living NMJs. Other probes – such as antibodies to glial fibrillary acidic protein (GFAP), neural cell adhesion molecule (NCAM), L1, LNX-1, growth-associated protein-43 (GAP-43), and the low-affinity nerve growth factor (NGF) receptor p75 – can also be used to label PSCs, although the latter two probes label PSCs only after nerve injury or blockade of nerve activity. Surprisingly, antibodies to myelinating glial markers – such as protein zero (P_0), myelin-associated glycoprotein (MAG), galactocerebroside, and 2′,3′-cyclic nucleotide 3′-phosphodiesterase – can also label PSCs even though they are nonmyelinating. The role, if any, of these myelinating markers in the differentiation of PSCs is not known.

Figure 1 The tripartite organization of vertebrate neuromuscular junctions (NMJs). (a–d) A frog NMJ fluorescently labeled with a monoclonal antibody, mAb 2A12, for perisynaptic Schwann cells (PSCs) (a, green); antineurofilament and antisynapsin I antibodies for axons and presynaptic nerve terminals (b, blue); and α-bungarotoxin (α-BTX) for postsynaptic acetylcholine receptors (AChRs) (c, red). Note that mAb 2A12 labels PSC somata (asterisk in (a)) and processes (arrow in (a)), but not Schwann cells along the axon (arrowheads in (a) and (b)). As seen in the merged image (d), the three components of the NMJ are closely aligned with one another. Scale bar in (d) applies to (a)–(c). (e–h) An NMJ in a transgenic mouse that expresses green fluorescence protein (GFP) in Schwann cells (e, green) and cyan fluorescence protein (CFP) in nerve terminal (f, blue). The NMJ is also labeled with α-BTX for AChRs (g, red). Note that GFP is expressed not only in PSC somata (asterisks in (e)) and processes, but also in Schwann cells along the preterminal axon (arrow in (f)). The tripartite arrangement of the NMJ is further demonstrated in the merged image (h). (i) Electron micrograph of a frog NMJ in cross section shows the PSC (S) with its electro-dense nucleus capping the nerve terminal (N), which is apposed to postjunctional folds on the muscle fiber (M). Scale bar = 1 μm. (a–h) Reproduced from *Journal of Neurocytology*, vol. 32, 2003, 423–1037, Special issue – the neuromuscular junction, Ko CP and Thompson W, Cover picture, copyright Spring with kind permission of Springer Science and Business Media. (i) Reprinted from Reddy LV, Koirala S, Sugiura Y, Herrera AA, and Ko CP (2003) Glial cells maintain synaptic structure and function and promote development of the neuromuscular junction *in vivo*. *Neuron* 40: 563–580, with permission from Elsevier.

In addition to the above probes, there are two probes available for selectively labeling frog PSCs: peanut agglutinin (PNA), which recognizes the extracellular matrix molecules associated with PSCs; and a monoclonal antibody (mAb) 2A12, which labels the external surface membrane of PSCs. One major advantage of these two probes is that they do not interfere with synaptic function and can thus be used as vital probes for PSCs in living frog muscles. Furthermore, mAb 2A12 combined with a complement treatment can be used to selectively ablate PSCs from living frog NMJs without destroying axonal Schwann cells. The application of this complement-mediated lysis provides a unique approach to test the necessary role of PSCs *in vivo* (see below). Unfortunately, neither PNA nor mAb 2A12 labels mammalian PSCs.

With the availability of these probes and the development of new tools such as calcium imaging, it is now possible to investigate synapse–glia interactions at the NMJ. For example, it has been shown that PSCs not only can sense synaptic activity by increasing their intracellular calcium levels but also are capable of modulating transmitter release when G-proteins or intracellular calcium levels are manipulated pharmacologically. Studies on the reciprocal interactions between PSCs and nerve terminals have also unraveled the multiple roles of PSCs in synaptic development, maintenance, and repair at the NMJ, as detailed below.

Role of PSCs in Synaptogenesis

The intimate association between PSCs and nerve terminals seen at adult NMJs has begged a question as to whether synapse–glia interactions also play an essential role in the development of NMJs. It has been shown that, during development, neuronal supply of neuregulin-1 (NRG1) is required for the survival of axonal Schwann cells as well as PSCs. Disruption of the neuregulin pathway by knocking out NRG1, or its receptor ErbB2 or ErbB3, in transgenic mice results in the absence of Schwann cells both in the peripheral nerves and NMJs. Despite the lack of Schwann cells in these transgenic mice, motor axons still project to their target muscles and form transient nerve-muscle contacts. These studies suggest that, during development, while axons are required for the survival of Schwann cells, Schwann cells are required neither for axonal navigation to target muscles nor for the initial formation of nerve-muscle contacts. Consistent with this suggestion is the finding that functional nerve-muscle contacts can be formed in *Xenopus* nerve-muscle cultures in the absence of Schwann cells. However, several lines of evidence suggest that Schwann cells are essential for the subsequent growth, maturation, and maintenance of developing NMJs. First, Schwann cells are present at normal NMJs soon after initial nerve-muscle contacts are formed. Second, the number of PSCs at the NMJ increases and correlates with the size of end plates during the period of rapid synaptogenesis. Third, in the transgenic mice that are deprived of Schwann cells, although initial nerve-muscle contacts are formed, the newly formed synaptic contacts cannot be maintained without the support of Schwann cells. This suggests a possible maintenance role of Schwann cells (see below). However, the specific role of PSCs at developing mammalian NMJs cannot be confirmed since axonal Schwann cells too are absent in these transgenic mice.

To examine the direct role of PSCs in synaptogenesis, repeated *in vivo* observations of tadpole NMJs have been conducted. They revealed that PSCs extend processes beyond nerve terminals, and the subsequent growth of nerve terminals, as well as the addition of synapses, occurs preferably along the preceding PSC sprouts. The necessity of PSCs at developing frog NMJs is confirmed using the PSC ablation technique. Repeated *in vivo* observations demonstrate that less synaptic growth and more synaptic retraction, including a complete loss of synapses in some cases, occur in tadpole muscles several days after PSC ablation. Therefore, PSCs and their sprouts play an important role in guiding extending nerve terminals and promoting synaptic growth, as well as maintaining newly formed NMJs in tadpole muscles.

The necessary role of PSCs in synaptic growth has also been implicated at mammalian NMJs. For example, although partial denervation in adult muscles results in sprouting of both nerve terminals and PSCs (see below), partial denervation in neonatal rat muscles does not induce nerve terminal sprouting. This result could be attributed to the apoptosis of PSCs following nerve injury in neonatal muscles. The withdrawal of nerve terminals seen in mutant mice lacking ErbB2 and ErbB3 is also consistent with a potential role of PSCs in the maintenance of developing synapses (although the involvement of axonal Schwann cells cannot be excluded). Furthermore, both exogenous application of NRG1 to developing rat muscles and induction of constitutively active ErbB2 in neonatal mouse Schwann cells activate the sprouting of nerve terminals and PSCs. Thus, NRG1-ErbB signaling provides an essential mechanism of how axons influence the development of PSCs.

However, the molecular mechanisms of how PSCs promote the growth and maintenance of nerve terminals at developing NMJs are not understood. It has been shown that Schwann cell-conditioned medium

promotes synaptogenesis in *Xenopus* nerve-muscle cultures. One candidate for mediating Schwann cell-promoted synaptogenesis in tissue cultures may be transforming growth factor (TGF)-β1. Whether TGF-β1 and other not-yet-identified factors also promote synaptogenesis *in vivo* remains to be explored. In addition to synaptogenesis, Schwann cell-derived molecules can enhance synaptic transmission in *Xenopus* nerve-muscle cultures. Application of Schwann cell-conditioned medium causes an acute increase in the frequency, but not the amplitude, of spontaneous synaptic currents by more than 100-fold. The identity of the Schwann cell-derived molecules responsible for enhancing transmitter release is currently unknown. Whether Schwann cells also enhance transmitter release at developing NMJs *in vivo* remains to be investigated.

Role of PSCs in Synaptic Maintenance at the Adult Neuromuscular Junction

Do PSCs also play a pivotal role in maintaining adult NMJs similar to developing NMJs? This question has been examined at frog NMJs using complement-mediated cell lysis, as described above for tadpole NMJs, to selectively ablate adult PSCs *in vivo*. Shortly after PSC ablation (within 5 h), neither the ultrastructure of nerve-muscle contacts nor synaptic transmission is affected. Thus, PSCs do not acutely modulate synaptic function and are dispensable for the short-term maintenance of frog NMJs, although PSCs are capable of modulating transmitter release by pharmacological treatments. In contrast to the lack of acute effect, partial or total retraction of nerve terminals is observed at frog NMJs 1 week after PSC ablation. In addition, transmitter release is decreased approximately by half. The overall muscle function as seen in the nerve-evoked muscle twitch tension is also reduced. These observations demonstrate that PSCs are essential for the long-term maintenance of NMJs. The mechanisms by which PSCs maintain adult NMJs are not known. The retraction of nerve terminals does not seem to be attributed to nerve degeneration as there are no signs of Wallerian degeneration – such as electron dense cytoplasm and swollen mitochondria – observed in retracting nerve terminals. The absence of global nerve terminal detachment after PSC ablation suggests that PSCs do not simply serve as mechanical 'glue' to attach nerve terminals with muscle fibers. Schwann cells have been shown to express a variety of trophic factors, including TGF-β1, and extracellular matrix (ECM) molecules. The potential involvement of these trophic factors and ECM molecules in maintaining nerve terminal structure and function remains to be determined.

Recent studies suggest that PSCs also play a similar maintenance role at adult mammalian NMJs. In a transgenic mice model, in which constitutively active ErbB2 is conditionally expressed in Schwann cells, PSCs sprout massively and nerve terminals also extend processes following PSC sprouts in adult muscles. Furthermore, when the expression of active ErbB2 is turned off, both PSC sprouts and nerve terminal sprouts retract. These findings suggest that PSCs can support nerve terminal growth and that activation of the neuregulin signaling pathway in Schwann cells is sufficient to induce nerve-terminal sprouting. However, it is important to investigate the necessary role of PSCs at adult mammalian NMJs using loss-of-function approaches, such as blocking the neuregulin-signaling pathway in PSCs or deleting PSCs *in vivo*. Unfortunately, the fact that the transgenic mice lacking Schwann cells die at birth precludes the study of PSCs' role in synaptic maintenance at adult mammalian NMJs. Since mAb 2A12 does not recognize mammalian PSCs, it cannot be used to ablate PSCs with the complement-mediated cell lysis approach in mammalian muscles. Recently, it has been shown that a subtype of anti-disialosyl antibodies that is found in Miller Fisher syndrome (MFS) preferentially binds and kills PSCs via membrane attack complexes at mouse NMJs. Despite the damage of PSCs following this antibody and complement treatment, both NMJ morphology and synaptic transmission in mammalian muscles are not acutely affected. This result is similar to the finding from frog NMJs following acute PSC ablation. However, no study on the long-term effect after PSC ablation has been performed in adult mammalian muscles. It would also be interesting to examine whether defects in PSCs may contribute to MFS or other neuropathies.

Role of PSCs in Synaptic Remodeling, Degeneration, and Regeneration

Remodeling

Mature NMJs are not static, but undergo synaptic remodeling throughout adult life. For example, extension and retraction of nerve terminals can be seen with repeated *in vivo* observations at frog NMJs in normal intact muscles. Similar to nerve terminals, PSCs are also very dynamic in frog muscles. Using PNA as a vital probe for PSC-associated extracellular matrix, it has been shown that PSCs and associated ECM often extend processes beyond nerve terminals, which grow along the preceding PSC sprouts. Similar dynamic behavior of PSCs and nerve terminals can occur even within minutes, as observed at adult toad NMJs *in vivo*. These results suggest that PSCs

guide nerve terminal growth during synaptic remodeling at adult amphibian NMJs. Although mammalian NMJs are relatively less plastic than amphibian NMJs, extension of short processes of PSCs and minor nerve terminal filopodia and lamellipodia has been seen at adult mammalian NMJs as well. The remodeling plasticity of mammalian NMJs is much more pronounced in androgen-sensitive muscles, and PSC number correlates with end plate size, which can enlarge or shrink in response to androgen treatment or castration, respectively.

Degeneration and Regeneration

After nerve injury, PSCs become phagocytic as they engulf the debris of degenerating nerve terminals and occupy the denervated end plate. Surprisingly, miniature end plate potentials can be recorded even at denervated end plates, albeit at a much lower frequency than those recorded from intact end plates. These spontaneous potentials at denervated end plates are thought to be caused by acetylcholine released from PSCs, but the functional significance of these Schwann cell miniature potentials remains unknown.

Besides being phagocytic, PSCs become very dynamic after nerve degeneration as PSCs sprout their processes profusely beyond the original end plate sites. PSC sprouting can also be induced by blockade of nerve activity. Regenerating axons not only grow along axonal Schwann cells but also extend nerve terminal processes along PSC sprouts. This indicates the importance of Schwann cells in promoting synaptic restoration. Furthermore, regenerating nerve terminals can follow PSC 'bridges,' which are formed by PSC processes between neighboring end plates, to innervate adjacent denervated junctional sites. Using mice that express GFP in Schwann cells and cyan fluorescent protein (CFP) in axons, it has been demonstrated that PSC sprouts induced by denervation guide regenerating nerve terminals. Similar results using vital probes to label PSCs and nerve terminals have also been found in frog muscles after nerve injury and regeneration. However, in contrast to mice, frog PSC sprouting is not induced immediately following nerve injury, but is triggered only upon the arrival of regenerating axons. Taken together, these findings from mammalian and frog muscles strongly suggest that PSC sprouts guide nerve terminal extension and play a central role in the reinnervation of the original junctional sites after nerve injury.

The importance of PSC sprouting in synaptic repair has also been shown in muscles after partial denervation. PSC bridges are formed as PSC sprouts extend from denervated end plates to contact innervated end plates following partial denervation. Consequently, nerve terminals from the innervated end plates grow along these PSC bridges to innervate the neighboring denervated end plates. Thus, similar to PSC sprouts induced by the total axotomy, PSC bridges can guide regenerating nerve terminal sprouts and help synaptic repair following partial damage of axons in adult muscles. The necessity of PSC sprouts in inducing nerve terminal sprouting has also been implicated. As discussed above on the role of PSCs in synaptogenesis, partial denervation of neonatal muscles does not trigger nerve terminal sprouting, which could be attributed to the apoptosis of developing PSCs following nerve injury. Furthermore, poor reinnervation has been reported in aging muscle as well as in *mdx* mice (a model for Duchenne muscular dystrophy), in which PSC bridge formation is impaired. Thus, PSC bridges likely are required for inducing nerve terminal sprouting.

The mechanisms by which PSC sprouting is induced following nerve injury are not fully understood. Activating neuregulin signaling pathway by expressing constitutively active ErbB2 receptors in PSCs can induce PSC sprouting, suggesting that the neuregulin-ErbB signaling pathway may play a role in PSC sprouting and nerve terminal sprouting at adult NMJs, similar to developing NMJs. It has been shown that nerve terminal sprouting can be induced by ciliary neurotrophic factor (CNTF) and insulin-like growth factor 1 (IGF-1). Whether these trophic factors, and other molecules such as GFAP, GAP-43, and p75, which are upregulated in PSCs after nerve injury or inactivity, mediate PSC-induced nerve sprouting is unknown. Nerve activity has also been shown to influence PSC sprouting. For example, although blocking synaptic activity by botulinum toxin or α-bungarotoxin induces sprouting of both nerve terminals and PSC processes, inactivity prevents the formation of PSC bridges in partially denervated muscles. On the other hand, direct stimulation or exercise of partially denervated muscles also impairs PSC bridge formation and nerve terminal sprouting. It is not clear how activity and inactivity can both inhibit PSC bridge formation following partial denervation.

In addition to their guidance role for regenerating presynaptic nerve terminals after nerve injury, PSCs may also modulate postsynaptic specializations by expressing neuronal isoforms of agrin. PSC-derived agrin may explain the appearance of AChR clusters underneath PSC sprouts in frog muscles following nerve injury and regeneration. In addition to agrin, PSCs also express neuregulin-2, which may promote AChR synthesis and synaptic differentiation at mammalian NMJs. Whether and how the postsynaptic role of PSCs may contribute to synaptic repair remains to be further examined.

Conclusions

Despite the traditional view of glial cells as a passive supporting player at chemical synapses, growing evidence has demonstrated that glial cells are an integral and essential component of synapses in both central and peripheral nervous systems. In this section, we have described the roles of PSCs during the formation, maintenance, and regeneration of the NMJ. Axonal navigation to target muscles and the formation of initial nerve-muscle contacts do not require the presence of Schwann cells; however, PSCs are essential for guiding extending nerve terminals and promoting synaptic growth, as well as maintaining developing NMJs. In adult muscles, while PSCs are dispensable for the short-term maintenance of NMJs, long-term absence of PSCs causes retraction of nerve terminals and reduction in synaptic transmission. This is possibly due to the lack of trophic support provided by PSCs. PSC sprouts guide nerve terminal sprouts during synaptic remodeling in intact adult muscles, as well as guide regenerating nerve terminals after nerve injury. NRG1-ErbB signaling is thought to play an essential role in the survival and sprouting of developing PSCs, as well as in inducing sprouting of PSCs and nerve terminals in adult denervated muscles. Similar to PSCs, astrocytes also play multiple roles at CNS synapses; therefore, synapses should be viewed as a tripartite structure, taking into account the contribution of glial cells in the formation, function, and maintenance of synapses. The molecular mechanisms by which synapse-associated glial cells contribute to multiple aspects of the synapse are not well understood. Identification of these mechanisms in the future will lead to better understanding of how synapses form, function, maintain, and repair.

Seasonal Changes in Night-Length and Impact on Human Sleep

K P Wright Jr., University of Colorado, Boulder, CO, USA

© 2009 Published by Elsevier Ltd.

Sleep Regulation and Seasonal Changes

Sleep in humans is primarily regulated by two factors, sleep homeostasis and internal circadian timing. In general, homeostatic sleep drive increases the longer we are awake and is dissipated during sleep. Most humans require 7–9 h of sleep each night to fulfill the homeostatic drive for sleep. An internal biological clock, located in the brain's hypothalamus, regulates sleep across the 24 h day. In humans and other diurnal animals, the biological or 'circadian clock' promotes sleep at night and wakefulness during the day. Specific brain regions are responsible for promoting wakefulness and others for promoting sleep, and these brain regions are primarily regulated by the sleep homeostatic and circadian systems. However, environmental factors can also influence sleep-wakefulness states. In humans, the timing, duration, and structure of sleep are reported to change across seasons. Specifically, bedtimes and wake times are reported to be later and sleep duration is reported to be longer in the winter compared to the summer. In addition, the total amount of rapid eye movement (REM) or dream sleep has been reported to be greater in the winter than in the summer. Why do these seasonal changes in sleep occur? The most common environmental factors that change with the season and influence the sleep and circadian systems are light and temperature. Seasonal changes in the hours of daily sunlight (photoperiod) and environmental temperatures occur at latitudes away from the equator. When the northern hemisphere is tilted toward the sun during summer, the photoperiod is longer and environmental temperatures are warmer, while at the same time the southern hemisphere is experiencing winter with a shorter photoperiod and colder temperatures. Near the equator, the photoperiod is relatively constant across the year, with approximately 12 h of sunlight and 12 h of darkness. At latitudes away from the equator, there are larger changes in the photoperiod across the seasons. For example, the city of Seattle in Washington State receives up to 16 h of sunlight each day in the summer and less than 9 h of sunlight each day in the winter. At the polar extremes, there are times when the sun never sets in the summer and never rises in the winter.

Influence of Environmental Factors on Sleep

How do environmental factors influence sleep? When we sleep, our senses are still active. Whether remembered or not, the sleeping brain responds to sounds, smells, pain, temperature, and even visual stimuli (e.g., light). The finding that sensory information can be processed by the brain during sleep provides a mechanism by which environmental factors disrupt sleep.

Temperature and Humidity

It is well documented that hot and cold environmental temperatures disrupt sleep. When it is too hot or too cold, the time it takes to fall asleep is longer, sleep is lighter, awakenings from sleep are more frequent, and REM sleep is reduced. REM sleep appears to be particularly sensitive to being disturbed by ambient temperatures that are too hot or too cold because brain thermoregulatory processes that maintain body temperature are altered during REM sleep.

Humans have constructed environments and developed technologies (e.g., heated homes) that reduce the influence of seasonal changes in environmental temperature on sleep. Sleep is best in a relatively cool environment. Thus, individuals who like warmer house temperatures in the winter should wear warmer cloths to bed; a house temperature that is too high may disrupt the sleep of others in the house. Assuming that heating in homes is adequate, the influence of cold temperatures on sleep is most commonly experienced when sleeping outside, such as in a tent during the fall or winter. In contrast, the influence of hot summer temperatures on sleep affects many more people, and as a result, there is widespread use of air-conditioning and fans to improve sleep at night. A high humidity environment has also been reported to increase the disruptive effects of hot ambient temperature on sleep.

Light Exposure

Exposure to light can acutely alter sleep. For example, exposure to light in the morning increases the ease of awakening, and exposure to light in the evening prior to bedtime increases the time it takes to fall asleep.

Influence of Seasonal Changes in Photoperiod on the Circadian Timekeeping System and Sleep

Seasonal changes in photoperiod alter the timing of the internal circadian clock, which in turn may alter

the timing of sleep. Light is the strongest environmental time cue for the circadian clock in humans. Exposure to light at night delays the timing of the internal circadian clock in a westward direction, and as a result, the circadian clock promotes sleep later the next day; whereas exposure to light in the morning advances the internal circadian clock in an eastward direction, and as a result the circadian clock promotes sleep earlier the next day.

The circadian clock regulates daily rhythms in many physiological functions such as alertness, performance, cardiovascular function, immune function, endocrine function, and sleep. One particular hormone that is strongly regulated by the circadian clock is the sleep-promoting hormone melatonin. Melatonin levels are typically high at night and low during the day. On average, humans go to bed approximately 2 h after melatonin levels begin to rise at night. The clock hour when melatonin levels rise or peak has been reported to be later during the winter than during the summer, and thus the time when the internal circadian clock promotes sleep is later in the winter than in the summer (Figure 1). This seasonal change in circadian timing is most likely related to the later time of sunrise in the winter. Changes in the timing of sleep and of the melatonin rhythm have also been reported to occur at research stations in Antarctica and in cities at latitudes away from the equator such as in northern Norway. In general, findings from most studies indicate a delay in the timing of the internal circadian clock during the winter. However, findings from some studies indicate a lack of synchronization between the internal circadian clock and the 24 h day. Lack of circadian synchronization occurs either when individuals are required to be awake when the levels of the sleep-promoting hormone are high or when individuals go to sleep later and awaken later each day and thus their sleep schedule cycles around the clock.

Figure 1 The daily pattern of melatonin is primarily regulated by the internal circadian timekeeping system. Melatonin levels are low during the day, increase on average ~2 h prior to habitual bedtime, and are high at night. Sleep quality is best at internal biological times when melatonin levels are high. The desire to go to bed later and to sleep in later in the morning during the winter is related to a shift in internal biological time, as represented by the delay in the timing of the circadian melatonin rhythm (dashed line). The phase delay in circadian timing may be related to the later sunrise in the winter. The solid line represents melatonin curve in the summer and the dashed line represents melatonin curve in the winter. The closed box represents sleep time in the summer, and the open box represents sleep time in the winter.

Many seasonal changes in physiology and behavior that are observed in nonhumans (e.g., seasonal reproduction, winter vs. summer coat color, and weight gain in hamsters) are primarily regulated by changes in the duration of high melatonin levels at night, which itself is regulated by changes in photoperiod. Melatonin is the primary biological signal regulated by the circadian clock to indicate to the rest of the body information about environmental photoperiod. In seasonal animals, the duration of high melatonin levels is longer during long winter nights than during short summer nights. The human circadian system is similar to that of other animals in that the human circadian system has the capacity to respond to seasonal changes in photoperiod with respect to the duration of high melatonin levels. In experimental studies, when participants slept in a sleep laboratory under simulated long winter nights (14 h of darkness) for 4 weeks, the duration of high melatonin levels was longer than during simulated short summer nights (8 h of darkness). Sleep duration was also longer during the simulated winter than during the simulated summer nights. However, outside of these experimental conditions, seasonal changes in the duration of the melatonin rhythm and of sleep in humans appear to be small. This is likely due to the widespread use of artificial lights before sunrise and after sunset. The use of artificial light may indicate to our circadian clock that we live in a near constant summer photoperiod year round.

Other Seasonal Changes That Influence Sleep

Other factors that may influence seasonal changes in human sleep include seasonal changes in health/sickness, environmental noise, and schedule-induced changes in sleep times. Seasonal exposure to foreign pathogens such as a flu virus in the winter or allergens in the spring can alter sleep. In response to being exposed to pathogens and allergens, cells of the immune system release proteins such as cytokines that alter sleep regulatory processes in the brain to promote sleep.

Physical activity levels are reported to be lower in the winter than in the summer. A reduction in physical activity levels can disrupt the quality of sleep. Environmental noise is more likely to disrupt sleep in the summer when sleeping with the window open (e.g., traffic noise or birdsong).

Last, seasonal changes in sleep timing may also be schedule induced. For example, the circadian clock in adolescents and young adults is reported to promote late bed and wake times. Specifically, levels of the sleep-promoting hormone melatonin are reported to rise later at night in adolescents and young adults as compared to children and older adults. During summer vacation, later bed and wake times can be accommodated; however, when school starts in the fall, the students are required to awaken earlier to accommodate the early school start times.

Winter Depression

Some humans appear to be particularly sensitive to seasonal changes in the environment. These individuals are at risk for developing winter depression, also known as seasonal affective disorder. Patients with winter depression report symptoms of depressed mood, irritability, loss of interest in performing activities, fatigue and sleep problems during the winter months, and lack of these symptoms in the spring and summer months. Sleep duration has been reported to be increased in the winter, although the increase in sleep time seen in patients with winter depression was not different than the increase in sleep time seen in nondepressed subjects. However, the amount of deep slow-wave sleep was reported to be lower and the number of rapid eye movements during REM sleep was reported to be higher in patients with winter depression during the winter months. Patients with winter depression are thought to be particularly sensitive to seasonal changes in light exposure. One hypothesis suggests that the phase delay of the internal circadian clock that occurs in the winter is a risk factor and/or underlying mechanism for winter depression. Another hypothesis suggests that a reduction in the amount of light exposure can increase the risk of winter depression. Why some people, but not others, experience winter depression in response to the circadian phase delay and/or changes in light exposure in the winter is unknown. Regardless of the underlying mechanism, the most common treatment for winter depression is exposure to bright light in the morning, although light exposure at other times of day and melatonin administration in the evening have also been reported to be effective.

Mechanisms of Seasonal Timing

It is adaptive for organisms to prepare for future changes in seasons so that biologically important physiological and behavioral responses occur at the optimal time of year. A number of environmental cues are used by various species to achieve seasonal timing. Of these, photoperiod is the most widely used cue, likely because it is readily detectable and is the most noise-free environmental signal for establishing seasonal time. Thus, although photoperiod may be of much less direct importance than factors such as food availability and temperature, in many environments it is the best single predictor of seasonal change. Most photoperiodic organisms employ circadian timing mechanisms to measure photoperiod (photoperiod time measurement (PTM)). This phenomenon has been most widely studied in birds, mammals, insects, and plants. In many organisms, including all mammals and birds studied to date, a biological circadian oscillator is involved in PTM.

Retinal Ganglion Cells Are Ultimately Connected to Pinealocytes via the Sympathetic Nervous System

In mammals, the photoperiod cue is received by the retinal ganglion cells and is transmitted through a multisynaptic pathway to the pineal gland and their primary cell type, pinealocytes. This has been most elegantly demonstrated using a retrograde transneuronal viral tract tracer, pseudorabies virus (PRV). PRV infects chains of functionally connected neurons labeled from the site of injection (end of the circuit) to its beginning. In brief, the circuit begins with retinal ganglion cells that ultimately project to the pinealocytes through the following neuronal chain: suprachiasmatic nucleus, hypothalamic paraventricular nucleus, intermediolateral horn of the spinal cord, and superior cervical ganglia (Figure 1).

The Pineal Gland Is Part of the Mammalian Photoperiodic Mechanism

In addition to the involvement of a circadian clock in PTM mammals, the pineal gland and its primary hormone, melatonin (MEL), are also key features of PTM. Once the neural signal that codes day length information reaches the pineal via the circuit described previously, it is transduced into a neuroendocrine signal in the form of the rhythmic secretion of MEL into the circulation. Pineal and plasma MEL concentrations are at their nadir during the light phase of the photocycle and at their peak during the dark phase. This pattern of MEL synthesis and secretion results from the regulation of the pineal gland by an endogenous circadian oscillator that is entrained to the light:dark cycle. Thus, the duration of the night is faithfully coded into the duration of MEL secretion and serves to trigger seasonal responses: Long MEL secretion durations signal 'fall/winter,' whereas short MEL secretion durations signal 'spring/summer' (Figure 2).

Photoperiodic mammals can be divided into two categories: Some species, such as the long day-breeding Syrian and Siberian hamsters, and several other rodent species, do not exhibit indications of seasonal change when held under a constant long day length in the laboratory. Exposure to the decreasing day lengths indicative of late summer is a necessary stimulus to induce a shift to the winter physiology/behavior that includes a complete inhibition of reproductive activity. Although an increase in day length can now stimulate a return to reproductive activity and other responses that are typical of spring/summer, this is not a necessary cue. Hamsters will 'spontaneously' return to a spring/summer physiological state after being held in short days for approximately 4 or 5 months, with the exact time depending on the species. The exact time of return to the spring/summer phase under constant conditions is apparently determined by the operation of an endogenous interval timer, the anatomical identity and underlying mechanisms of which are unknown. Regardless, the return to spring condition even under conditions of continuous short photoperiod is termed 'short-day photorefractoriness,' and this part of the seasonal timing mechanism appears to be a general characteristic of species with this type of annual cycle.

A second category of photoperiodic mammals includes those termed 'circannual.' These species exhibit repeated cycles of seasonal changes even when held under seasonally constant conditions (fixed day length and unchanging temperature). Under constant conditions, however, the circannual cycles generally have period lengths that are substantially shorter than 365 days. Under field conditions, day length cues are used to adjust the timing of the circannual mechanism so as to yield a true annual periodicity. The domestic

Figure 1 Using the pseudorabies virus, a transneuronal retrograde tract tracer, the multisynaptic pathway connecting the retina to the pineal gland was defined for the first time within an animal. Retinal projections via the retinohypothalamic tract (not shown) synapse on neurons in the suprachiasmatic nucleus (SCN). In turn, these neurons project to the hypothalamic paraventricular hypothalamic nucleus (PVN), then the preganglionic sympathetic neurons in the intermediolateral cell column (IML), then the postganglionic sympathetic neurons in the superior cervical ganglion (SCG), finally projecting to pinealocytes. Reproduced from Larsen PJ, Enquist LW, and Card JP (1998) Characterization of the multisynaptic neuronal control of the rat pineal gland using viral transneuronal tracing. *European Journal of Neuroscience* 10: 128–145, with permission.

Figure 2 Schematic of photoperiod transduction into durational melatonin signals by the pineal gland. Long days and short nights generate short nocturnal melatonin (MEL) durations of synthesis/secretion (left), whereas short days and long nights generate long nocturnal MEL durations of synthesis/secretion (right).

sheep has been the most thoroughly studied of photoperiodic, circannual mammals with respect to how photoperiod cues interact with the endogenous circannual timing mechanism. Sheep are short-day breeders and hence show reproductive activation and mating during late summer, with lambs being born the following spring. As with hamsters, sheep become refractory to continuous short-day exposure; ewes held under constant short days stop showing ovulatory cycles after several months, hence returning to the spring condition. Unlike hamsters, sheep also become refractory to long days. Ewes held under continuous long days – which are initially inhibitory to reproduction – eventually return to ovulatory cyclicity (hamsters held under continuous long day lengths remain reproductively active indefinitely). Thus, the circannual cycle of the sheep and the seasonal cycle of the hamster both include a role for photoperiodic responsiveness and an endogenous timing mechanism. Whereas both hamsters and sheep can show a spontaneous shift from winter to summer phase (short-day photorefractoriness), sheep show spontaneous shifts from summer to winter phases as well (long-day photorefractoriness). The presence of two distinct phases of 'spontaneous' change in the sheep (compared to a single spontaneous change in hamsters) may help to account for the expression of circannual cycles when this species is held under seasonally constant conditions.

The process of PTM appears to be essentially the same in sheep and hamsters, despite the fact that sheep are short-day breeders with true circannual

rhythmicity, whereas hamsters are long-day breeders that are not circannual. In both species, and in most mammals that have been studied, the duration of the nocturnal elevation of MEL secretion is roughly proportional to the length of the dark phase (or inversely proportional to day length). Thus, the duration of nocturnal MEL secretion contains information about the day length, and this information apparently is decoded and then triggers seasonally appropriate changes in target tissues either by direct effects (e.g., pars tuberalis) or via neural activation (e.g., white adipose tissue).

MEL Receptors Occur in the Brain and Periphery, but Stimulation of Specific Central Sites Appears Necessary for Seasonal Changes in Reproductive Status and Adiposity

Brain MEL receptors were first suggested by the binding of a radioactive MEL analogue (2-[^{125}I]-iodomelatonin; IMEL) to neural tissue. Only a few IMEL binding sites in the brain exist, although MEL binds extensively to many peripheral tissues. IMEL binds in the brains of a wide range of mammals (e.g., sheep; deer; goats; rabbits; laboratory rats; Syrian, Siberian, and European hamsters; white-footed mice; golden-mantled ground squirrels; guinea pigs; nine-banded armadillos; and humans) as well as nonmammalian vertebrates (Atlantic hagfish, lamprey, hedgehog skates, rainbow trout, and clawed toads). Across many mammalian species, one brain and one peripheral site consistently show IMEL binding – the suprachiasmatic nucleus of the hypothalamus (SCN) and the pars tuberalis (PT) of the pituitary gland, respectively. Many of these species show binding in both the SCN and the PT, although there are a few seasonally breeding species in which IMEL binding only is found in the PT (mink and skunks). Gene expression for one of the MEL receptor subtypes, the MEL 1_a receptor (mt_1 receptor) is present in the SCN of Siberian hamsters, laboratory rats, and humans, as well as the PT of the first two. Despite extensive studies of MEL binding sites, the specific functional roles of most of these sites have not been established.

Several Model Systems Are Used to Study Seasonal Changes

Studies of seasonal changes in endocrine-mediated events have revealed a number of interesting model systems that can be exploited to yield information of general application to both seasonal and nonseasonal species. Several of these systems are described next.

There Is a Similarity between the Mechanisms Involved in the Alternation between Breeding and Nonbreeding Seasons Compared with Mechanisms Leading to Puberty Onset

There is considerable similarity between the endocrine mechanisms that lead to a shift from the seasonal anestrous condition to breeding status and mechanisms involved in puberty onset. Two types of mechanisms have been found to account for the decreased secretion of the pituitary gonadotropic hormones (GTH), leuteinizing hormone (LH), and follicle-stimulating hormone (FSH), during seasons of anestrus. In some species, the hypothalamic–pituitary axis shows considerably increased sensitivity to the negative feedback effects of gonadal steroid hormones on secretion of pituitary GTH during seasonal anestrus. The consequence is that blood GTH concentrations are held at very low levels even in the presence of the decreased amounts of steroid hormones produced by the unstimulated gonads. In other species, GTH levels decrease during anestrus even in gonadectomized individuals, indicating that a steroid-independent or direct drive mechanism is responsible for the inhibition of GTH during anestrus. The same two types of mechanisms also have been described as operative in prepubertal mammals, with changes occurring at puberty that lead to an increase in GTH secretion much as similar changes lead to the shift from seasonal anestrus to reproductive activation with the onset of the breeding season. Interestingly, GTH secretion always seems to be largely steroid dependent during the breeding season; that is, during reproductive activation steroid negative feedback always exerts a powerful influence on GTH secretion. This negative feedback system is important for regulating the level of reproductive activity during the breeding season, as has been most clearly illustrated in studies demonstrating the important role of negative feedback to regulate the number of ovarian follicles that develop during an ovulatory cycle and, hence, the number of ova that will be released. During prepubertal development and during the season of anestrus, such precise titration of GTH activity is not required; rather, in these states it is presumably only necessary to achieve an essentially total inhibition of reproductive activity. This can be achieved either via greatly increased sensitivity of the negative feedback regulatory system or by a neural overriding of the system.

Pubertal mechanisms may be triggered at a particular age or in relation to attainment of a sufficient amount of utilizable metabolic fuels, usually lipid

stores. Seasonal activation of the reproductive system generally depends on environmental cues and/or the operation of endogenous timing mechanisms that are relatively independent of age or fat stores. Some cases of puberty incorporate both age-related and environmentally cued components. For example, Siberian hamsters will achieve active reproductive status (puberty) when 40–50 days old if raised in long days; however, if day lengths are short from birth, as in young born at the end of the summer breeding season, puberty will not occur until approximately 5 or 6 months of age, coinciding with the beginning of the next breeding season. The roles of steroid negative feedback and steroid-independent regulation of GTH during the juvenile and pubertal phases are similar to what is seen in seasonal reproductive cycles.

Neuroendocrine Regulation of the Preovulatory Surge of GTH

Considerable research has centered on determining the neuroendocrine pathways that regulate the timing of release of the preovulatory LH surge that is accompanied by an increase in FSH secretion of lesser magnitude. The amount of LH released is in excess of the amount required to lead to the ovulation of all mature follicles in the ovaries. The timing of preovulatory LH release is important in that it determines the time of actual ovulation – approximately 10 h after the LH surge in laboratory rodents – and ovulation time should most adaptively be bracketed by the time period when the female is most likely to mate. In mammals that are coitus-induced (or reflex) ovulators, sensory stimulation associated with mating triggers the release of LH so that ovulation will occur several hours later, when viable sperm are still present in the reproductive tract of the female. In spontaneous (or cyclic) ovulating species, a sharp increase in circulating estrogen, originating from newly matured ovarian follicles, is the endocrine stimulus that leads to release of the preovulatory surge of LH. Less emphasis has been placed on the ability of progesterone to delay the LH surge by one or more days; perhaps this is because in some species progesterone can actually advance the LH surge by a short period of time if administered early on the proestrous day, whereas progesterone administered earlier in the cycle may result in a 1- or 2-day delay of LH release. In rats and other cycling rodents studied in the laboratory, the LH surge occurs approximately 1 day after the initial large increase in circulating estrogen. In some species, the timing of the surge is further refined by the action of a circadian clock in the suprachiasmatic nuclei of the hypothalamus. For example, in laboratory rats and Syrian hamsters, the LH surge occurs during the early afternoon of the day after increased estrogen, with ovulation occurring at approximately midnight or slightly thereafter. This is presumably a time when these nocturnal and relatively nonsocial species are most likely to be successfully inseminated during an encounter with a male. The involvement of a circadian clock in the precise timing of LH release has been clearly demonstrated in studies showing that ovariectomized laboratory rats subjected to continuous administration of estrogen exhibit daily LH surges, occurring at the same time of day as the preovulatory surge that normally occurs only every fourth or fifth day.

Studies in the photoperiodic Syrian hamster have revealed an interesting variation on the theme of triggering LH surges by increased levels of estrogen. Syrian hamsters are long-day breeders and ovulatory cycles cease after 4–7 weeks of exposure to short day lengths (<12.5 h light/day). During the anovulatory phase of the annual cycle, female hamsters exhibit daily surges of LH. These surges occur during the early afternoon at about the same time as the preovulatory surges that occur during the breeding season, and the daily surges are of comparable magnitude to the preovulatory surges. These daily surges are expressed, however, even though estrogen levels are continuously very low. Indeed, the daily LH surges continue unabated in anestrous (short-day) females even following ovariectomy or combined ovariectomy and adrenalectomy. Curiously, daily LH surges are also observed in this species during lactation, another situation in which ovulatory cycles are suspended. It is not known whether the daily LH surges that occur in anestrous and lactating hamsters serve a physiological function. Syrian hamsters have extraordinarily regular, 4-day ovulatory cycles and have been well studied with respect to patterns of secretion of reproductive hormones, so the species may provide an interesting model in which to further examine factors that lead to the triggering of the preovulatory LH surge.

Seasonal Changes in Pelage Are Also Governed by Changes in Hormones Triggered by Alterations in the Photoperiod

Many temperate zone mammals undergo seasonal changes in pelage, molting their summer fur and developing a more insulative coat in the fall, with reversal of this process as spring approaches. In some species, the winter fur not only is more insulative but also may be different in color from the summer coat. One such species is the Siberian hamster,

which molts from a grayish-brown summer coat to a white winter pelage that no doubt provides camouflage during winters of heavy snowfall. Several studies in Siberian hamsters have demonstrated that circulating levels of the pituitary hormone prolactin determine what type of fur will be grown following a molt (Figure 3). Baseline prolactin levels are high during the summer and several fold lower during the winter. These seasonal changes in prolactin levels are determined by day length and by the action of the pineal hormone, MEL, as described later. When prolactin levels are artificially manipulated either by administering drugs that stimulate (e.g., pimozide, the dopamine antagonist) or inhibit secretion of the hormone (e.g., bromocryptine, the dopamine agonist) or by direct administration of prolactin or hypophysectomy to remove its source, the type of fur that is produced is always governed by the levels of prolactin. Thus, summer fur grows when prolactin levels are elevated, and winter fur grows when prolactin is decreased or absent. Many photoperiodic mammals show seasonal changes in prolactin that parallel those observed in Siberian hamsters – with high levels of the hormone under long days and low levels under short photoperiods. Seasonal changes in blood prolactin concentrations also have been implicated in seasonal pelage changes in mink, arctic blue fox, and red deer. Thus, prolactin may prove to be the hormone that usually regulates seasonal changes in fur quality.

It might seem strange that prolactin, which is known for its role in supporting mammary gland function (lactogenesis) in mammals, also should be the hormone that regulates the type of hair produced by hair follicles. Hair follicles, however, are one of a few types of integumentary glands in mammals, including sebaceous glands and sweat glands. Mammary glands are thought to have evolved as specializations of sweat glands so that there is an evolutionary connection between these two types of integumentary glands. Prolactin has also been reported to synergize with testosterone in the regulation of sebaceous gland activity in laboratory rats, suggesting a pattern of prolactin involvement in regulation of different types of integumentary glands and their derivatives, the mammary glands.

It may be that for some species prolactin has actions on hair follicles that are not limited to seasonal pelage changes. Laboratory rats develop a more bristly type of hair at the time of puberty compared to the softer fur of juveniles. Furthermore, hypophysectomy of adult rats results in a return to this prepubertal fine/soft fur. An increase in prolactin associated with achievement of puberty has been implicated in this change in pelage quality as well.

Finally, although prolactin has some documented effects on body fat, its role in the photoperiodic control of body fat appears minimal at best because manipulations of the hormone to produce long-day circulating physiological concentrations of prolactin in short days, and vice versa, do not in and of themselves create short-day- or long-day-like changes in adiposity, respectively.

Figure 3 Neuropeptide and leptin receptor gene expression in the hypothalamic arcuate nucleus of adult male Siberian hamsters fed *ad libitum* (ADLIB) in long days (LD) or short days (SD) or held in long days with restricted food to mimic short day body mass changes (LD-R). Means ± SEM as percentages of values in LD-ADLIB hamsters. Reproduced from Mercer JG and Tups A (2003) Neuropeptides and anticipatory changes in behaviour and physiology: Seasonal body weight regulation in the Siberian hamster. *European Journal of Pharmacology* 480(1–3): 43–50, with permission.

Seasonal Changes in Adiposity and Food Intake Are Also Often Regulated by the Photoperiod and Melatonin

Many animals exhibit seasonal changes in body mass, usually almost exclusively as changes in body fat (cf., collard lemmings). The patterns of seasonal changes in body fat fall into four major categories: (1) species in which body fat/mass increases in the short 'winter-like' days of the fall (e.g., Syrian hamsters and prairie voles) and then decrease, (2) species in which body fat/mass increases from spring to the beginning of fall and then decreases (e.g., Siberian hamsters, meadow and bank voles, deer, and domestic sheep, goats, and cattle), and (3) species that evidence photoperiod-controlled reproductive responses but show no body mass/fat changes (e.g., Turkish hamsters). Because the photoperiod induces a functional gonadectomy of these animals and because gonadal steroids have profound effects on body mass/fat, it may seem that the seasonal changes in body fat are simply secondary to the changes in gonadal steroids. This notion, however, is not supported because the majority of the photoperiod-induced changes in body fat occur independent of the gonads (i.e., they still occur in previously gonadectomized animals subjected to the photoperiod change).

There does not appear to be a hormonal intermediary of MEL for the photoperiod-mediated seasonal changes in adiposity because white adipose tissue lipolysis (fat mobilization) or lipogenesis (fat synthesis) are not triggered in isolated adipocytes (fat cells) by physiological doses of MEL in several species. Instead, at least in Siberian hamsters, it appears that MEL acts through a neural intermediary to decrease body fat in short days. Specifically, injections of PRV, the transneuronal viral tract tracer, into white fat combined with identification of MEL_{1a} receptor mRNA by *in situ* hybridization, reveal PRV + MEL_{1a} co-localization in neurons in brain sites that are part of the sympathetic outflow to white fat (e.g., suprachiasmatic anterior, arcuate, and paraventricular nuclei of the hypothalamus, reuniens/xiphoid, and paraventricular thalamic nuclei). These neuroanatomical data are supported functionally by the increased sympathetic drive to white fat in short-versus long-day-housed Siberian hamsters. Moreover, surgical or chemical denervation of the sympathetic nerves innervating white fat blocks short-day-induced decreases in body fat by Siberian hamsters.

In addition to seasonal body fat changes, often there are also corresponding changes in feeding; however, the changes in food intake do not completely account for the changes in body/lipid mass. In these cases, alterations in energy expenditure complete the accounting of the mechanisms underlying seasonal changes in body/lipid mass. The seasonal changes in food intake have most extensively been studied in Siberian hamsters, in which body/lipid mass most rapidly decrease during the first 5 or 6 weeks of short day exposure, but food intake only significantly decreases later, after approximately 7–12 weeks of short day exposure (**Figure 4**).

The mechanisms underlying these ultimate decreases in food intake by Siberian hamsters are not precisely known, but in laboratory rodents, changes in food intake are often triggered by alterations in orexigenic (increased feeding) and anorexigenic (decreased feeding) peptides. In Siberian hamsters, however, the well-established roles of these peptides in laboratory rats and mice often do not, at least superficially, hold. For example, in laboratory rodents, decreases in body/lipid mass are associated with increases in gene expression of the orexigenic

Figure 4 Siberian hamster (*Phodopus sungorus*) littermates treated identically except the animal on the left has been housed in long 'summer-like' days, whereas the animal on the right has been housed in short 'winter-like' days. Note the change to a white winter pelage in the short day-housed hamster.

peptides neuropeptide Y (NPY) in the arcuate nucleus and melanin concentrating hormone (MCH) and orexin A in the lateral hypothalamus. In addition, there are decreases in two anorexigenic peptides – leptin, mostly synthesized by adipocytes and secreted into the circulation, and arcuate nucleus cocaine- and amphetamine-regulated transcript (CART). In contrast, when short days trigger decreases in body/lipid mass in Siberian hamsters, these relations do not hold in that arcuate nucleus NPY gene expression and lateral hypothalamic MCH and orexin A do not change and arcuate nucleus CART decreases (Figure 5), but circulating leptin concentrations are decreased. In terms of the latter, when leptin is decreased in laboratory rodents, food intake is increased (as is arcuate nucleus NPY gene expression), but in Siberian hamsters food intake is decreased. Some of the disparity between the photoperiodic control of these peptides appears to be reconciled by embracing two views. The first is that unlike the fasting-induced body mass/fat-reduced laboratory rats and mice, the decreases in body mass/fat of short day-exposed Siberian hamsters are seasonally appropriate; thus, because these peptides serve to counteract deviations in body mass/fat, they might not be expected to be engaged because the short day decreases are not true 'deviations' from normal. Indeed, if Siberian hamsters are fasted to promote decreased body/fat mass in either long or short days, they show the same changes in these peptides as do laboratory rats and mice. Second, the unusual inability of decreased circulating leptin concentrations to stimulate food intake in short days and vice versa appears to be due to changes in leptin sensitivity. That is, long day-housed hamsters are leptin insensitive when circulating leptin concentrations are high, whereas short day-housed hamsters are leptin

Figure 5 Representation of mechanism by which mother hamster is thought to transmit photoperiod information to her fetuses. Photoperiod information received by the mother's eye is conveyed by a neural pathway (the retinohypothalamic tract) to the circadian pacemaker in the suprachiasmatic nuclei (SCN). Neural signals from SCN traverse a multisynaptic pathway to the maternal pineal gland to regulate the circadian rhythm of melatonin secretion. Maternal melatonin not only acts on target tissues in the mother but also crosses the placenta to act on similar targets in fetus. (The fetal SCN may be one of these targets.) The fetus does not yet have neural connections between the eye and SCN or between SCN and pineal. Hence, the fetal SCN/pineal unit does not generate a melatonin rhythm of its own. At approximately 2 weeks after birth, all appropriate neural pathways have become established and juvenile hamster (bottom) is able to generate its own melatonin rhythm, shaped by the prevailing photoperiod. The day lengths to which the juvenile is exposed will be either longer or shorter than those that were in effect during gestation, and both absolute day length and direction of change influence the trajectory of early reproductive development. Photoperiod information provided from the mother to the fetus may allow the juvenile to more rapidly assess the direction of change in photoperiod and, hence, to 'determine' the time of year. Reproduced from Goldman BD (2003) Pattern of melatonin secretion mediates transfer of photoperiod information from mother to fetus in mammals. *Science STKE* 2003(192): pe29 (DOI: 10.1126/stke.2003.192.pe29), with permission.

sensitive when circulating leptin concentrations are naturally low.

Photoperiod Information Is Transmitted from Mother to Fetus

It has been demonstrated that the photoperiod experienced by a female rodent during late pregnancy can influence the photoperiodic responses of her offspring. MEL passes from the maternal to the fetal circulation so that the rhythm of circulating MEL is similar in mother and fetus. In Siberian hamsters, there is strong evidence that the mother's MEL rhythm acts on fetal MEL target tissues and that this allows the fetus to establish a photoperiodic history that can influence its responses to the photoperiod experienced during forthcoming juvenile life. This early photoperiod history is a particularly important influence on juvenile testis development in male Siberian hamster pups that are born into 'intermediate day lengths' (~14 h of light (14L)). Males born to dams that experienced shorter day lengths (e.g., light:dark cycle 8:16) show relatively rapid testis growth when exposed to 14L postnatally, whereas males born to dams that experienced a longer gestation photoperiod (e.g., light:dark cycle 16:8) show slow testis development in a postnatal 14L day length. This mechanism may allow for rapid and appropriate adjustments with respect to reproductive development. Testis growth is rapid when the photoperiod is increasing, as it would be at the beginning of the breeding season, but is inhibited when the photoperiod is decreasing.

Seasonal Timing: Neural Mechanisms

M A Hofman, Netherlands Institute for Neuroscience, Amsterdam, The Netherlands

Introduction

The rotation of the Earth and the Earth's orbit around the sun result in daily and seasonal fluctuations in illumination, temperature, and humidity. It would be appropriate for an organism to have its internal organization and behavioral activity synchronized with this cyclic environment to provide an adaptive optimum. Periodic fluctuations, in fact, are found to be a fundamental feature of living systems and can be observed throughout the plant and animal kingdoms. Although a specific and constant phase relationship between the solar day and these rhythms is maintained, endogenous biological rhythms are not directly driven by the environmental light–dark cycle or by any other zeitgebers. Numerous chronobiological studies, in which environmental conditions were rigorously controlled, showed that organisms not only follow the rhythms of the diurnal and seasonal cycle but also possess their own intrinsic rhythm. This article focuses on the cellular and molecular mechanisms underlying the complex interaction between the circadian timing system and life in a photoperiodic environment.

The Biological Clock as Calendar

Suprachiasmatic Nucleus as Circadian Pacemaker

In mammals, the suprachiasmatic nucleus (SCN) of the hypothalamus is considered to be a critical component of a neural system implicated in the timing of circadian processes. The pacemaker of the SCN oscillates with a near 24-h period and is entrained to the diurnal light–dark cycle. The SCN is located on either side of the midline of the brain just dorsal to the optic chiasm. Since the discovery of the SCN as the site of the master circadian pacemaker, many attempts have been undertaken to unravel the mechanisms underlying its endogenous circadian rhythmicity. In particular, lesion and transplantation experiments of the SCN and *in vitro* slice studies have provided firm evidence for its biological clock characteristics. Furthermore, consistent with its role in circadian timing, investigations in rodents and nonhuman primates suggest that the SCN is the locus of the brain's endogenous calendar, enabling organisms to anticipate seasonal environmental changes (Figure 1).

Recent studies indicate that the biological clock is a multioscillator system, consisting of independently operating subdivisions located in the core and shell of the SCN. The core is located in the ventral region of the SCN above the optic chiasm, receives primary and secondary visual afferents, and predominantly contains neurons producing vasoactive intestinal polypeptide (VIP). The shell is located in the dorsal region of the SCN, largely surrounds the core, receives input mainly from nonphotic sources, and is composed predominantly of neurons containing arginine vasopressin (AVP). A similar topographic organization of SCN efferent projections was found, indicating that the nature of the signal conveyed to areas receiving core or shell projections varies as a function of the subdivision from which the innervation is derived.

Melatonin and Photoperiodic Time Measurement

In mammals, the SCN–pineal complex is the principal neural substrate involved in the regulation of annual cycles. In fact, many of the functions that exhibit seasonal cycles in mammals, such as sexual behavior, energy metabolism, food intake, and hibernation, are regulated by this timing system in the brain. Day length (photoperiod) has been shown to be the strongest synchronizer of seasonal functions in most species.

The periodic synthesis and secretion of the hormone melatonin exhibited by the pineal gland is generated by oscillators in the SCN and is communicated to the pineal via a complex multisynaptic pathway. Disruption of any portion of this pathway from the SCN to the pineal gland abolishes melatonin rhythmicity. These findings strongly suggest that the endocrine activity of the mammalian pineal is under neural control and receives a major input from the SCN. This means that, in addition to its role as a circadian pacemaker, the SCN may also be involved in the seasonal timing of a number of physiological and behavioral processes by regulation of the photoperiod-dependent changes in melatonin secretion (Figure 2).

Melatonin is secreted at night, and the duration of secretion is inversely related to day length; thus, photoperiodic information is encoded reciprocally in the duration of nocturnal melatonin secretion, which becomes longer in winter and shorter in summer. Several studies in hamster and sheep, employing a paradigm of timed daily infusions of melatonin in pinealectomized animals, indicate that photoperiodic information is indeed encoded in the melatonin signal. Thus, in both short-day breeding sheep and

long-day breeding hamsters, short-duration melatonin infusions led to the long-day responses typical for the given species, whereas long-duration infusions evoked responses that are associated with short days. These results suggest that day-length signals are encoded in the duration of nocturnal melatonin secretion. In other words, the circadian system regulates the pattern of melatonin secretion, and the melatonin pattern serves as a humoral signal that conveys day-length information.

It has been suggested that two light-entrainable circadian oscillators are responsible for regulating the duration of nocturnal melatonin secretion. Thus, a dusk oscillator may trigger the onset of melatonin secretion and a dawn oscillator might determine the termination of pineal activity. If the duration of melatonin secretion does indeed depend on the phase relationship between dawn and dusk oscillators, then there is a direct link between this mutual phase relationship and the endocrine coding of photoperiod via the duration of nocturnal melatonin secretion. It means that the circadian clock should exhibit sensitivity to phase resetting by melatonin during the crepuscular domains, times of the day which are most affected by changes in photoperiod. Indeed, the circadian clock in the SCN is most sensitive to melatonin levels at dusk and dawn.

The cellular and molecular mechanisms through which the melatonin signal is decoded to drive or synchronize photoperiodic responses remain unclear. Potential target sites in the mammalian brain, where the effects of melatonin are mediated via high-affinity melatonin receptors, are located in the pars tuberalis of the pituitary and in the SCN. The presence of melatonin receptors in the SCN suggests that melatonin feeds back to regulate circadian pacemaker function.

Seasonal Cycles in Humans

Most of the anatomical and molecular substrates of the system that encodes changes in photoperiod in the duration of melatonin secretion, and the receptor molecules that read this signal, have been shown to be conserved in monkeys and humans, and the functions of this system appear to be intact from the level of the retina to the level of the seasonal-dependent duration of the melatonin signal. Although photoperiodic seasonal breeding has been shown to occur in monkeys, it remains unclear whether photoperiod

and mediation of its effects by melatonin influence human reproduction.

Historical and experimental evidence indicates that human responses to seasonal changes in the natural photoperiod may have been more robust prior to the Industrial Revolution and that subsequently they have been increasingly suppressed by alterations of the physical environment. In fact, some observations in humans suggest that the seasonal fluctuations in pineal activity in modern urbanized human beings, who are living in an artificial photic environment, resemble that of mammals living under fixed light–dark conditions. It seems as if the extension of the natural photoperiod with artificial light to maintain long summer-type photoperiods throughout the year has significantly altered the temporal organization of many physiological and behavioral functions in humans.

During the past decade, several studies were conducted to determine whether variations in photoperiod and light intensity affect the morphology and neuronal activity of the human SCN by studying brains obtained at autopsy. The AVP- and VIP-producing neurons in the SCN, for example, were found to exhibit distinct seasonal oscillations with an asymmetrical bimodal waveform. The AVP cycle had a maximum in early autumn, a lower plateau in winter, a second peak in early spring, and a decline beginning in late spring, leading to a nadir in the period from May through July. The population of VIP-expressing neurons also reached a maximum in early autumn, a lower plateau in winter, a second peak in early spring, a short nadir in April to May, and another plateau in summer (Figure 3).

There is also convincing evidence for seasonal variations in monoamine concentrations in the human brain, based on postmortem studies and single-photon emission computed tomography (SPECT). Among the monoamines investigated, the level of serotonin (5-HT) in the human hypothalamus showed the most striking seasonal rhythm, with a maximum in autumn and a minimum in early winter. No corresponding seasonal fluctuations in the concentration of hypothalamic 5-hydroxyindoleacetic acid (5-HIAA) were found. Furthermore, the hypothalamic dopamine level showed a more complex, but less distinct,

Figure 3 Arginine vasopressin (AVP) neurons (red dots) and vasoactive intestinal polypeptide (VIP) neurons (green dots) in the human suprachiasmatic nucleus (SCN): (a) distribution; (b) normalized values of the seasonal cycles. Amsterdam: Elsevier, with permission from Elsevier.

seasonal profile, with two peaks and two nadirs, like the seasonal profiles found in the synthesis of AVP and VIP in the human SCN. How these periodic fluctuations in 5-HT and dopamine – neurotransmitters that innervate the SCN – are functionally related to the seasonal oscillations in the biological clock is not known.

Seasonal Affective Disorder

Seasonal affective disorder (SAD) is a condition of regularly occurring depressions in winter with a remission the following spring or summer. In addition to depressed mood, the patients tend to experience increased appetite and an increased duration of sleep during the winter. SAD is a relatively common condition, affecting 1–3% of adults in temperate climates, and it is more prevalent in women. The pathological mechanisms underlying SAD are incompletely understood. Certain neurotransmitters have been implicated; a dysfunction of the serotonin system in particular has been demonstrated by a variety of approaches. Furthermore, epidemiological evidence suggests that SAD and seasonal fluctuations in human reproduction are governed by a common biological process.

Although the role of the circadian timing system in SAD is not clarified yet, there are strong indications that the circadian pacemaker in SAD patients is delayed relative to the sleep–wake cycle. According to this phase-delay hypothesis, the symptoms of SAD should improve if the circadian rhythms can be phase advanced. There is some experimental support for this idea. SAD can be treated successfully with light therapy, in which the patient is exposed to 2000–10 000 lux for a period of 30–120 min daily during the late autumn or early winter. Other forms of light treatment and pharmacotherapy are currently being tested.

A Clock for All Seasons

Models of Seasonal Timing

Studies of the formal properties of photoperiodic mechanisms have revealed that most organisms use circadian oscillators to measure day length. Two types of paradigms – external coincidence (EC) and internal coincidence (IC) models – have been proposed to account for photoperiodic time measurements by a circadian mechanism. Both models postulate that the timing of light exposure, rather than the total amount of light (as in the classical model), is critical to the organism's perception of day length.

In the EC model for photoperiodic time measurement, light has two distinct and separate roles. First, light is the major diurnal zeitgeber for the entrainment of the circadian system; second, light is the photoperiodic zeitgeber for the entrainment of the biological clock to changes in day length. The model postulates that the photoinductive phase of the circadian cycle is subdivided in a relatively continuous fashion, enabling organisms to discriminate between small variations in day length. Light falling at one time point during the photoinductive phase might be interpreted by the circadian system as representative of a 12 h photoperiod light falling at a different time point might be interpreted as a 14 h photoperiod, and so forth. It is difficult to obtain a complete and precise role of the photoinductive phase, but it is clear that it is largely included within the portion of the circadian cycle where light is able to evoke phase shifts (i.e., the subjective night). For an EC system to discriminate unerringly among various day lengths, it is crucial that the organism be appropriately entrained to the 24 h light–dark cycle. Thus, a change in the phase angle between the circadian oscillator and the light–dark cycle might be expected to result in an alteration in the interpretation of day length.

In the IC model for photoperiodic time measurement, the phase relationship between two circadian oscillators varies as a function of day length. In the IC model, it is the degree of the phase difference between these oscillators that determines the type of photoperiodic response. Light is the zeitgeber for the entrainment of both oscillators. However, the two oscillators may be differentially phase shifted by a given light pulse, so that the phase relationship between them can vary depending on the parameters of the photic stimuli. The phase of each oscillator is also influenced via mutual coupling between the two oscillators, and the strength of the coupling relation may vary in response to a number of factors, including photoperiod.

The EC and IC models have frequently been treated as if they were distinct alternatives. The models are clearly different in that internal coincidence requires the interaction of two oscillators, whereas external coincidence requires only one. However, an IC system can behave in a manner fully consistent with the EC model. Thus, it could be that light falling during the photoinductive phase (EC) evokes long-day responses because that is the phase at which light produces differential phase shifts of two oscillators (IC), causing them to assume a long-day phase relationship to one another.

The Dual Oscillator Model

A hypothetical principle based on two coupled oscillators was proposed more than 30 years ago by Pittendrigh and Daan, who suggested that the mammalian circadian system consists of a morning oscillator (M) and an evening oscillator (E). One of the central

propositions of the original M–E oscillator model was that with M locking on the dawn and E on the dusk, the phase relationship of M and E in the coupled system reflects the day length to which the animal has been exposed. This 'clock for all seasons' could simultaneously be exploited to measure day length, and this information could be used to adjust adaptively to seasonal timing.

From a functional perspective the main attraction of the dual oscillator model, based on IC, remains that it accounts both for the adjustment of circadian organization to season and latitude and for the measurement of day length in photoperiodic responses. The mechanism of this neural calendar has remained elusive, however. Two main sets of facts, emerging from electrophysiological and molecular studies, now simultaneously suggest how the mammalian circadian clock may indeed be built from M and E oscillators, and how the phase relationship of these oscillators reflects the photoperiod, and thus time of year, to which an animal has been exposed.

In addition to the involvement of circadian oscillators in photoperiodic time measurement, there are other types of biological timing mechanisms that are generally associated with photoperiodism. Some photoperiodic species exhibit endogenous circannual rhythms when held for long periods of time under seasonally constant conditions, that is, constant photoperiod and temperature. For circannual rhythms, changes in day length may be viewed as a zeitgeber for entrainment of the putative circannual oscillator. However, the anatomical substrate for a circannual timing system has not been unequivocally identified in any mammalian species. Therefore, the concept of a circannual oscillator remains a hypothetical construct to explain the expression of circannual rhythms. It remains possible, however, that overt circannual rhythms result from interactions among multiple neural and endocrine systems rather than being a product of one discrete timing system, as for circadian oscillations.

Molecular Genetics of Biological Timing

Circadian Timing

As internal systems, circadian clocks arise from the expression and temporally regulated activity of specific genes and gene products. Over the past decade there have been significant advances in the understanding of the molecular basis of circadian clocks. A number of clock genes have been identified that play a key role in the generation of circadian rhythms. These clock genes are expressed in a circadian manner, with peak values at different times. The clock's core consists of autoregulatory feedback loops with oscillating levels of nuclear proteins that negatively regulate the transcription of their own genes and a positive feedback loop involving the rhythmic regulation of CLOCK–BMAL1 heterodimers.

Based on the oscillation patterns of the *Period* genes within the SCN (high during the day, low during the night), the mammalian clock was predicted to be a day-active clock (in which the oscillating components of the clock are at higher levels during daytime than during the night). However, analysis of the phase response curve (PRC) to light shows that the circadian clock is more greatly affected at nighttime than during the day (daytime is within a dead zone, during which light exposure has little or no effect on the phase of the clock). Thus, during the dead zone of the PRC, the oscillating clock molecules are abundant, and during the active phase of the PRC, these molecules are scarce. What follows from this is the prediction that this clock is phase shifted (and thus entrained) not by degradation of clock molecules following zeitgeber exposure but rather by the induced expression of clock molecules.

Seasonal Timing

Recently, the hypothesis was advanced that the circadian pacemaker in the mammalian SCN is composed at the molecular level of a nonredundant double complex of circadian genes (*Per1–Cry1* and *Per2–Cry2*). Each one of these sets is sufficient for the maintenance of endogenous rhythmicity and thus constitutes an oscillator, and each of these oscillators has slightly different temporal dynamics and light responses. The *Per1–Cry1* (or morning (M)) oscillator is accelerated by light and decelerated by darkness, and the *Per2–Cry2* (or evening (E)) oscillator is decelerated by light and accelerated by darkness. Changes in the activity of these M and E oscillators give rise to the adaptive tuning of the endogenous behavioral program to day length. In other words, the phase relationship of M and E in the coupled system reflects the day length to which the animal has been exposed. The phase angle between oscillator and zeitgeber tells us something about the oscillator's intrinsic period relative to the external 24 h period. This suggests that changes in day length involve changes in the intrinsic period of the two component cycles, whereas the external period remains at 24 h (**Figure 4**).

There must be some kind of coupling for the two components of the oscillating system in the SCN to maintain their mutual phase relationship under free-running conditions. In nature, the coupling force opposes the differential control of each oscillator by light because it acts to revert to this particular phase relationship from which the light responses pull

Figure 4 Dual oscillator model of photoperiodic timing proposed by Daan et al. In the cell nucleus, the transcription of the clock genes *Per* and *Cry* is promoted by the CLOCK–BMAL1 complex and suppressed by PER and CRY. The two hypothetical main pathways in the complex model are indicated as separate oscillatory loops, although they interact both via CLOCK–BMAL1 and via multimerization of PER and CRY between the loops. The two parts have slightly different temporal dynamics, leading to differences in the timing of expression of putative clock-controlled genes, indicated here as *m* and *e*. This, in turn, leads to two bouts of multiple-unit activity, M (morning) and E (evening), together inducing or suppressing behavioral activity during part of the 24-h period (lower part of the panel). The phase relationship of the M oscillator and E oscillator is thought to reflect the photoperiod to which an organism has been exposed.

the system away. There are various ways in which the coupling of these oscillators may be envisaged, depending on whether the oscillators are restricted to different populations of neurons in the SCN or whether they are co-localized in the same neuron. In the coupling interaction, it is likely that there is some degree of asymmetry in the strengths of the two oscillators.

At the moment, however, there is no clear evidence that one oscillator is more dominant in synchronizing the circadian clock with the 24-h day than the other. In nocturnal animals, however, under various photoperiods both pineal and SCN rhythms are locked to the morning light onset rather than to the evening light offset. It seems that in these animals, at least for the entrainment of circadian rhythms, the M oscillator is the dominant oscillator and the E oscillator the less flexible slave oscillator. Recent findings in fruit flies support this hypothesis, showing that the oscillators that control morning and evening peaks in locomotor activity reside in distinct neuronal cell populations and that the M oscillator resets the E oscillator once a day. In between these resets, the E oscillator free-runs with its own faster intrinsic period.

The data on human sleep–wake cycles under different photoperiods, furthermore, demonstrate that sleep onset and offset lock on to dusk and dawn along with the melatonin profiles, whereas both rhythms may become bimodal in their nocturnal distribution. These data, along with observations on the bimodal circadian profile of neuronal activity in the human SCN, lend support to the idea that eventually the M–E model will be applicable also to our own species.

Modeling the Molecular Calendar

The M–E model for photoperiodic timing understandably focuses very much on the novel molecular discoveries that support the dual oscillator view of the clockwork, and, as such, the notion of a molecular calendar in the SCN based on morning and evening oscillators is an attractive hypothesis. The M–E model, however, may be too simplistic in view of the complexity of the generation of circadian oscillations. The genetic details of the molecular calendar may be different from the models proposed so far, and other clock genes might be involved in the encoding of season by the circadian clockwork.

A complicating factor could be that there are species differences in the way photoperiodic modulations are encoded within the circadian clockwork. Recent findings, for example, support the conclusion that in sheep, unlike hamsters or rats, an EC model best explains the way photoperiod affects the temporal organization of clock gene expression in the circadian pacemaker, whereas an IC model best explains the way melatonin affects the phasing of clock gene expression in the pars tuberalis of the pituitary to mediate the photoperiodic control of physiological functions and behavior.

Although at present the details of how season is encoded by the circadian clockwork are not known, it is clear that there are properties in the behaviors of the clock genes that could be interpreted as M and E oscillators. The phase relationship of these oscillators or the temporal organization of the expression of their genes reflects the photoperiod, and thus the time of year, to which an animal has been exposed.

The dual oscillator model has obvious implications for the evolution of circadian timing. The rotation of the Earth provides two precise timing signals, sunrise and sunset, rather than a single one. It might well be that life that evolved on its surface has developed ways to exploit both signals, for the fine-tuning of its temporal organization over the 24 h as well as for adapting its physiology and behavior to the seasonal fluctuations in day length. Experimental data consistent with the model have formed the cornerstone of our understanding of how the duration of the nocturnal secretion of melatonin by the pineal gland encodes day length and how, at some level, the circadian waveform generated by the SCN is responsible for driving the pineal.

Finally, there is the intriguing question of whether humans have a seasonal timing system like their

circadian one. The distinct seasonal oscillations in neuropeptide expression in the human SCN, together with the seasonal rhythms in monoamine and hormone concentrations in the hypothalamus and other parts of the human brain, strongly suggest that humans, like other mammals, have a biological calendar.

Second Language Acquisition

Introduction: Second Language Acquisition and the Brain

Speaking a second language (L2) means having acquired a new inventory of phonemes (speech sounds), new words, and new inflectional and syntactic rules. Because this new knowledge must be stored somewhere in the brain, it does not require neuroimaging experiments to conclude that a bilingual speaker's brain must be in some way different from that of a monolingual speaker. The question is rather: Can the difference between the brain of a bilingual speaker and a monolingual speaker tell us something about the functional organization of a bilingual language system? Quite different answers are possible, ranging from 'more of the same,' meaning that at all processing levels the neural substrates for first language (L1) and L2 processing completely overlap, to 'radically different,' as suggested by early hypotheses that an L2 relies on the right rather than the left hemisphere of the brain. In between, there are hypotheses suggesting that L2s rely predominantly on a subset of L1 processes, such as storage and declarative processing, but not rule or procedural processing. Such hypotheses predict that a subset of the brain regions involved in L1 processing, namely those subserving rule or procedural processing, should not be recruited for L2 processing.

Neuroimaging studies on bilingual speakers are thus potentially of high relevance for our understanding of the functional architecture of a bilingual language system. At the same time, they face considerable methodological problems. In experiments involving a task, differences in neural activity patterns may be explained by general differences in task performance rather than the components of the task that the experiment was designed to assess. Given that most speakers are less proficient in their L2 than in their L1, however, equal task performance is rarely achieved. A second problem is that experimental variables such as 'age of L2 acquisition' are almost inevitably confounded with other variables such as 'L2 proficiency' or vice versa. Often, it becomes a matter of interpretation which of the observed neuronal activation differences are due to experimental variables and which are due to possible confounds. In this situation, comparisons across studies can be helpful because they may indicate which activation patterns or electrophysiological signatures are reliably found in certain tasks when performed in the L2, irrespective of particular L2 speaker characteristics. They may also show brain activity that is reliably found for subsets of studies testing particular types of L2 speakers.

This article therefore focuses on experimental tasks that have been used in a number of hemodynamic (i.e., positron emission tomography (PET) and functional magnetic resonance imaging (fMRI)) and electrophysiological studies of L2 processing, such that an assessment of the reliability of findings is possible. Where possible, we attempt to identify L2 speaker characteristics that seem to influence observed brain activation patterns.

Hemodynamic Correlates of L2 Acquisition

Hemodynamic studies on the neural correlates of L2 processing have been conducted on all levels of linguistic structure from phonology to discourse. At higher linguistic levels, most studies have investigated the processing of an L2 after years of learning rather than L2 acquisition as such. These studies provide evidence of changes in functional neuroanatomy that must have occurred at some time point during L2 acquisition rather than during the study. Experiments with true learning (longitudinal) designs are relatively rare and mostly found at the phonemic level.

Phonemic Learning

A number of studies have investigated the neural consequences of learning a novel phonemic contrast using within-subject training designs. These studies are very instructive because they illustrate a methodological problem of neurocognitive research on bilingualism and possible ways to overcome the problem. To detect neural correlates of phonemic learning, participants performing phoneme classification or recognition tasks were scanned with fMRI before and after a training phase (several hours spread over 1–4 weeks), during which they learned nonnative phonemic contrasts (e.g., Japanese speakers learning the English *r/l* contrast). All studies tested for differences between pre- and posttraining fMRI measurements. The number and anatomical location of regional changes in activation varied considerably across studies, but there were five regions that were

replicated across studies: the left and right posterior inferior frontal gyri, the left mid superior temporal gyrus (auditory cortex and planum temporale), the left superior parietal lobule, and the left caudate nucleus. According to the logic of the design, it is tempting to conclude that these regions are involved in the processing of the novel phonemic contrast. Note, however, that by definition successful training resulted in improved performance such that the two fMRI measurements were no longer comparable in this respect. Therefore, it cannot be excluded that the observed regions simply reflect unspecific effects, such as reduced attention or effort, lower error rates, and so forth. To be able to assess which of the observed activation differences were due to phonemic processing and which were unspecific effects of higher performance or even simple repetition effects, some studies included a control condition by training a second, easy phonemic contrast that was similar to a native language contrast. Because performance in this condition is sometimes even higher than that on the critical nonnative contrast, it is possible to interpret activation changes that only occurred in the critical condition as being specific for learning a nonnative contrast. When taking into account these additional data, commonalities between the findings of the different studies are further reduced.

Remaining regions that might be specifically recruited for learning a nonnative phonemic contrast are the left inferior frontal gyrus and the left caudate nucleus, but other data suggest that posttraining learner brain activation may be very much like native speaker brain activation. One possible reason for such seemingly discrepant findings is a potentially nonlinear relationship between learning and hemodynamic activation. The activation level of regions that are recruited for a difficult task (e.g., recognizing a nonnative contrast) may be initially high but fall off again after some level of performance is reached. This issue is further discussed later.

Word-Level Processing

The two most frequently used tasks for the study of word production are picture naming and word generation (typically generation of words that start with a given letter or fit semantially to a given stimulus word). Both tasks involve the core components of word production (lemma retrieval, word form retrieval, syllabification, and phonetic encoding) but differ with respect to the processes that are employed to come up with a lexical concept to be produced. No study comparing picture naming or word generation in the L1 and L2 of bilingual speakers has reported stronger activation when the task was performed in the native language. Stronger activation for the L2 has been reported in a small but reliable number of studies in the left (for word generation also the right) posterior inferior frontal lobe (**Figure 1**). Studies reporting stronger activation of this region in L2 picture naming had participants with later L2 onset and lower L2 proficiency compared to studies reporting no differences between L2 and L1 picture naming. Stronger activation of the left posterior inferior frontal gyrus was also found in a verb-generation study with quadri-lingual participants for languages that were learned later and spoken less proficiently. These results show that at a group level, L1 and L2 word production seem to engage the same cortical areas, and that L2 speakers with late onset or lower proficiency may recruit one or more of the areas more strongly. Note, however, that hemodynamic studies show all brain areas that are activated. They do not provide evidence of which brain areas are actually necessary for word production in individual speakers. Evidence for necessary areas comes from a study in which different cortical areas in fluent bilingual epilepsy patients were electrically stimulated prior to surgery. The patients performed an object-naming task in their first and their L2, and it was recorded whether electrical stimulation interfered with object naming or not. For every individual, this procedure resulted in a map of sites that were necessary for L1 picture naming, L2 picture naming, or both. Shared sites were found in all left peri-Sylvian regions. L1-specific sites were also found in both posterior frontal and temporal regions but more so in the frontal cortex. L2-specific sites were exclusively found in mid- to posterior temporal cortex and adjacent inferior parietal sites. These data show that although there may not be any L1- or L2-specific regions at a group level, there seem to be cortical sites in many individuals that are only necessary for word production in one of the languages. Moreover, the left inferior frontal cortex, which in hemodynamic studies has been found to be more strongly activated for L2 word production, does not contain L2-specific sites but, rather, L1-specific sites possibly subserving L1-specific processes. A possible interpretation might be that L2 speakers attempt to make use of processes that are in some way tailored to L1 word production (to the extent that L1, but not L2, word production becomes impossible without them). A good candidate for such a process seems to be postlexical syllabification, which is subject to language-specific constraints and engages Broca's area in L1 word production.

Most studies on bilingual word-level comprehension have used written stimuli and asked their subjects to perform some kind of semantic decision. Typically, control conditions involved nonlinguistic stimuli so that the observed activations may reflect

Figure 1 Schematic representation of brain areas reliably reported to be more strongly activated in L2 compared to L1 (based on a meta-analysis by Indefrey). Colors indicate the task in which stronger L2 hemodynamic activation has been found. Numbers in brackets refer to the number of studies reporting a brain area and the number of studies that examined this area. SMA, supplementary motor area.

all processing components involved in reading as well as semantic decision. Stronger activation for semantic decisions on L1 compared to L2 words has been reported for the anterior left middle temporal gyrus in late L2 learners with moderate to high proficiency. Stronger activation for semantic decisions on L2 compared to L1 words has been reported for the left posterior middle frontal gyrus, the left posterior inferior frontal gyrus (Broca's area (BA) 45), the left posterior inferior parietal lobule, and the anterior cingulate gyrus (Figure 1). The areas tend to be found in bilingual speakers with lower L2 proficiency, whereas there is no obvious influence of L2 onset or use. As in word production, areas of potentially stronger activation in L2 word comprehension are not L2 specific but are also observed in the native language. They are part of a modality-independent semantic system found to be activated during semantic decisions on both words and pictures. Anterior left middle temporal lobe activation, by contrast, has been found for semantic decisions on written words only, not on pictures, suggesting that a stronger activation of this area for L1 compared to L2 words may be due to L1-specific word representations at the graphemic or lemma level.

The processing of inflectional morphology in a L2 has been investigated with fMRI. Japanese learners of English were visually presented with English verb stems and had to choose between correct ('caught' and 'smelled') and incorrect past tense forms ('catched' and 'smold'). After a 2-month training involving explicit instruction on verb inflection, 13-year-old beginners of English showed activation of the dorsal left posterior inferior frontal gyrus (BA 44/45) when performing the task. The activation was stronger the better participants performed on the task. The area overlapped with the activation area observed when the same task was conducted with Japanese verbs. In a follow-up study, the same task was used on 19-year-old learners of English, who by this age

had 6 years of English instruction. Again, increased activation of left posterior inferior frontal gyrus (together with parieto-occipital and motor areas) was found when comparing the past tense task to a control task. A subgroup of high-performing advanced learners showed much weaker activation in the inferior frontal gyrus area, and the activation was also weaker in older compared to younger participants when performing the task with Japanese verbs. Taken together, the two studies suggest a change in the linkage between performance on a certain linguistic task and accompanying hemodynamic responses. The activation level of an area may initially be positively correlated with performance but show a negative correlation after years of practice. The positive correlation may simply reflect neural and behavioral consequences of the same underlying factor – the degree of effort put into the task. By contrast, a negative correlation may be explained by assuming that neural structures support the linguistic process involved in the task more effectively, which means that they must have in some way adapted to the process. Note, however, that 'adaptation' is not the only option to interpret reduced activation with better performance. Alternatively, a different but more effective brain region might have taken over or such a negative correlation might occur because the task is performed in a different, more effective way that no longer involves the original process.

Sentence-Level Processing

A number of studies have presented proficient bilingual speakers with spoken or written sentences. Although some regions have been reported as being more strongly activated in L1 compared to L2 sentence or story comprehension, no region has been reported in more than one study. Regions that have been reliably replicated as being more active in L2 than in L1 sentence comprehension are mainly found in the left posterior frontal gyrus (middle frontal gyrus, BA 44 and BA 47 of the inferior frontal gyrus, and the supplementary motor area; Figure 1). Stronger L2 activation of these regions has typically not been observed when subjects simply read or listened to sentences or stories, but it seems to depend on the use of additional judgment tasks. In particular, stronger L2 activation of BA 44 has been found consistently when bilinguals were asked to distinguish between correct sentences and syntactic violations. Another shared, but not distinctive, feature of the studies reporting stronger L2 activations seems to be late L2 onset (after age 10 years). In summary, the available hemodynamic studies suggest that proficient L2 speakers recruit the same cortical areas (but possibly stronger) for L2 as for L1 sentence-level comprehension.

We investigated changes in Broca's area activation in beginning Chinese learners of Dutch as an L2 for more than 1 year. Significantly stronger activation of Broca's area for listening to sentences compared to word sequences first emerged after 6 months of learning the new language, when the participants still scored in the low to moderate range of a standardized Dutch proficiency test. These findings suggest that brain regions involved in L1 syntactic processing are relatively soon also recruited for the processing of a new language.

Recruitment of similar brain areas for L1 and L2 sentence processing has also been observed in sentence production. Comparable activation levels for the two languages in frontal and temporal regions were found when bilingual speakers were asked to covertly report events of the previous day in their first and their L2s or when they generated sentences in a much better controlled task. Note, however, that in these studies differences between L1 and L2 in the exact localization of activation peaks in the frontal cortex (not in temporal cortex) were found, and these localization differences covaried with the age of L2 acquisition.

Electrophysiological Correlates of L2 Acquisition

The general picture that emerged from this overview of hemodynamic studies is that L2 processing involves the same brain structures as L1 processing but may be associated with greater activity. Complementary evidence for possible underlying processing differences may be provided in studies using electrophysiological measures such as the event-related potential (ERP) which are sensitive to the time course of neuronal activity. Past L2 research has mainly characterized L2 responses of speakers with preexisting L2 knowledge, whereas recent work has examined L2 learning.

Sublexical Processing

Studies of sublexical processing in bilinguals and learners have focused on the mismatch negativity response (MMN) observed in a passive listening task in which a sequence of standard sounds (e.g., syllables) are presented with an occasional mismatching sound. An MMN is taken as evidence that the brain has detected a difference between the two sounds. This technique has been used to examine whether native speakers and L2 learners show different electrophysiological responses to features of phonemic sounds that are distinctive in an L2.

Several studies have shown that an MMN response can be observed in both younger and older L2 learners, but that L2 learners who start relatively late show reduced amplitude MMN for L2 phonological contrasts.

Word-Level Processing

Several studies have compared L1 and L2 N400 responses to single words. The N400 is a negative brain potential deflection, peaking approximately 400 ms after stimulus onset, that is modulated by associative, semantic, or meaning-identity relations between a word and its context. Similar patterns of both associative and semantic priming have been shown in L2 N400 responses compared to L1 responses, but the pattern is modulated by L2 proficiency, with lower proficiency being associated with reduced conceptual but not associative priming. Current studies suggest that priming effects operate similarly in L1 and L2 single-word recognition, with some modulation by overall L2 proficiency.

Sentence-Level Processing

Although the priming effects that have been observed in L2 comprehenders suggest similar word-level semantic processing in L1 and L2, this does not necessarily mean that the semantic integration of words into a sentence context works equally well. Studies of L2 responses to semantic violations in sentence contexts have observed the N400 response to L2 violations, and most have shown a similar topographical distribution of this effect for L2 violations compared to L1 violations, sometimes with a delayed peak in the N400 response. Studies that have directly contrasted age of acquisition and proficiency have found that both age of acquisition and vocabulary proficiency make independent contributions to the longer latency of the N400 response in L2 readers. There is some variability in L2 response patterns, however, because no difference in the N400 violation response or a greater N400 violation response have both been observed. In most studies, however, the L2 N400 response in sentence contexts has been observed with a similar topography.

Two other electrophysiological violation responses are elicited by grammatical rather than semantic violations in native speakers. One is a late positive deflection (P600, or syntactic positive shift), and the other is a left anterior negativity (LAN) that is observed between 200 and 500 ms after a grammatical violation. L2 ERP studies have usually compared grammatical violation responses versus controls. Studies examining responses to phrase structure violations have demonstrated the P600 in early starting and/or proficient L2 learners, but the LAN has only been shown for relative high proficient L2 users, and some reports have also shown an atypical P600 in late L2 learners. Other studies have observed the P600 response for certain combinations of L1 and L2 pairs but not others. The existing patterns across studies are not easily reconciled, but it appears that L2 P600 effects are more likely to be observed if the L1 and L2 belong to the same language family (e.g., Western Germanic for German and Dutch), if one takes into account the proficiency of the speakers tested. The limited number of magnetoencephalographic L2 studies have revealed similar variability in responses to grammatical violations. Whereas some studies have shown relatively early (in time) L2 violation responses, others have not. Finally, comparisons of L1 and L2 responses to open- and closed-class words (without grammatical violations) have shown L1/L2 response differences for closed-class words in later-starting L2 learners even though similar responses to L1 and L2 open-class words have been shown.

Studies have examined violation responses in L2 learners as they acquire the L2. Similar to the results in learners with existing knowledge, P600 violation responses have been observed when learners have acquired L2 proficiency. Although no early (in time) components have been observed in learners, some studies have observed an N400 response to grammatical violations in L2 learners.

These results show that responses to grammatical violations in an L2 can be observed using electrophysiological techniques, but the exact form of the violation response varies greatly, more so than semantic effects. Two factors, age of acquisition and global language proficiency in the L2, appear to play an important role in the appearance of all of these responses.

Conclusions

Neurocognitive studies of bilingual language processing have indeed provided some answers to the question of how an L2 is implemented in the brain. First, one of the three hypothesis mentioned in the introduction, the 'radically different' hypothesis, can clearly be rejected. L2 processing does not use any new brain areas nor does it give rise to new electrophysiological effects that are not found in L1 processing. With respect to the other two hypotheses, the situation is more complex. Whether L2 processing uses the same processes and brain structures as L1 processing or just a subset seems to depend on the processing level, and hemodynamic and electrophysiological data are not always in agreement.

The available evidence for sublexical processing suggests no fundamental differences. Some nonnative phonemic contrasts can be acquired to a level at

which MMN responses and hemodynamic responses are indistinguishable from those observed for native phonemic contrasts. Insofar as nonnative contrasts elicited differential responses, these seem to be of a quantitative rather than a qualitative nature, such as a reduced MMN or a stronger hemodynamic activation of the left inferior frontal gyrus, which is also active for phonemic decisions in the native language.

Similarly, at the lexical level, electrophysiological and hemodynamic data are in agreement that there are no L1/L2 differences with respect to the type or location of responses. Brain responses may be modulated by proficiency in the L2, with lower proficiency being correlated with reduced electrophysiological semantic priming effects and stronger recruitment of primarily left posterior frontal regions. Note, however, that there is hemodynamic evidence for L1-specific processing of written words. It is also important to note that the overall observation of similar recruitment of brain areas for L1 and L2 lexical processing may only hold at the level of larger areas, but within those areas, L1 and L2 may be separated to some extent in every individual bilingual.

Although below the sentence level the available data generally support the 'more of the same' hypothesis, electrophysiological and hemodynamic data give different answers with regard to sentence processing. Whereas hemodynamic studies report similar L1 and L2 processing areas with age of acquisition-dependent modulations (stronger recruitment of Broca's area in comprehension and location of activation peak differences within Broca's area in production), electrophysiological studies suggest that one typical native language response to grammatical violations, the LAN, is less commonly observed in the L2. Also, it cannot be said that speakers who acquired an L2 early across the board show the P600 in the same way as native speakers (as might be expected from similar L1 and L2 hemodynamic activation patterns in early L2 learners). Whether or not a P600 is observed seems to depend on factors such as distance between languages and the exact type of violation in ways that remain to be more closely examined in the future. These electrophysiological data are the main source of evidence supporting the hypothesis that L2 processing may only use a subset of the processes that are engaged for the L1. Insofar as this holds true, L1/L2 differences seem to be restricted to the sentence level, most likely syntactic processing.

How, then, can it be that such differences do not seem to affect the set of brain regions that are hemodynamically activated in sentence processing? First, there are design differences that reduce the comparability of hemodynamic and electrophysiological studies. Hemodynamic studies used mainly correct sentences and within-subject L1/L2 comparisons, whereas ERP studies used grammatically violating sentences and L1/L2 differences were observed in group comparisons. Second, both the L1/L2 differences observed in ERP studies (scarcity of LAN or P600 in the L2) and the L1/L2 similarities in hemodynamic studies are negative findings, so it remains possible that evidence to the contrary will be found in the future. Third, and probably most important, the presence or absence of ERP components does not hinge only on certain neural populations being active or not but, rather, on their synchronous activity. It could be that what appears as a qualitative difference in the data is, in fact, a quantitative difference in the timing of neuronal activation. If L2 speakers were more variable with respect to the exact timing of the cognitive operations underlying, for example, the LAN response in native speakers, this ERP response might not be observable anymore, whereas the corresponding hemodynamic effect of neuronal activation might still be observable due to the much coarser temporal resolution of fMRI or PET.

In summary, the most parsimonious interpretation of the available neurocognitive data on L2 processing is a 'more of the same' account assuming that L2s are implemented in the same brain structures as the native language, but with quantitative differences in timing and strength of activation. Alternative views assuming qualitative L1/L2 differences, such as the 'subset' hypothesis, have some, although not conclusive, support from electrophysiological data but are not supported by hemodynamic data.

Segawa Dopa Responsive Dystonia

M Segawa, Segawa Neurological Clinic for Children, Tokyo, Japan

© 2009 Elsevier Ltd. All rights reserved.

Definition and Classification

Autosomal dominant (AD) GTP cyclohydrolase I (GCH-I) deficiency or Segawa disease is a dopa responsive dystonia (DRD) caused by heterozygous mutation of GCH-I gene, located on chromosome 14q22.1–q22.2. This disease was initially reported by Segawa as hereditary progressive dystonia with marked diurnal fluctuation (HPD). Prior to identification of the causative gene of HPD, this disease was called as Segawa syndrome with recessive type, which is clarified later as recessive tyrosine hydroxylase (TH) deficiency. In the 1990s, this was called as DRD. Recently, it is classified in DYT5 with recessive TH deficiency.

AD GCH-I deficiency is an autosomal dominantly inherited, generalized, postural dystonia with female predominance. The hallmarks of this disease included onset in childhood, diurnal fluctuation of symptoms, and marked and sustained response to levodopa. But some patients show action dystonia, ballistic dystonic movements, associated with postural dystonia from late childhood. AD GCH-I deficiency is characterized by the age dependency of the symptoms and clinical courses, and adult onset patients may start with tremor but without generalized dystonia or diurnal fluctuation. Other neurological conditions include psychiatric disorders, autism, depression, and migraine; furthermore, subjects with compound heterozygotes show hypotonia, failure in locomotion, and delay in mental and motor development in infancy.

Neuropathological studies revealed no degenerative changes. Neurohistochemistry shows decrease of the TH protein at the terminal of the nigrostriatal (NS)–dopamine (DA) neuron with predominance in the ventral area, which causes postural dystonia through the descending pathways of the basal ganglia. However, clinical, neurophysiological, and neuroimaging studies suggest the involvement of the NS–DA neurons projecting to the subthalamic nucleus (STN) with D_1 receptor for tremor and action dystonia. With lesions at the terminal, this disease shows diurnal fluctuation and age-related variation of symptoms.

Clinical Signs and Symptoms

Clinical symptoms are characterized by age dependency both in the initial signs and the clinical course. The ages of onset are childhood from 1 to 11 years, mostly ~6 years. The tremor disappears by passive stretching of the muscle, that is, it does not appear as cogwheel rigidity. However, there are patients who have onset in adulthood and some in ages older than fifties.

Childhood onset cases start with postural dystonia, dystonic posture of one of the lower extremities, mostly with pes equinovarus. There are patients who start with dystonia of one upper extremity at ages a little bit later. However, some patients show action dystonia, rigorous dystonic movements, besides postural dystonia. These appear later than postural dystonia from ~8 years. These are observed in neck and shoulder commonly as action retrocollis. Occurogyric crisis may associate with this. The occurrence of action dystonia is depending on the family. Postural tremor appears later in upper extremities with asymmetry, mostly after 10 years.

Adult onset patients start with hand tremor. They may show gait disturbance due to generalized mild rigidity. Some adult onset patients start with writer's cramp. Patients with onset after 50 years show tremor and generalized rigidity with bradykinesia similar to parkinsonism. These adult onset patients do not show the postural dystonia expanding to generalized dystonia. Asymmetry is a characteristic feature and is observed in dystonia, rigid hypertonus, and tremor irrespective of ages at onset.

Dystonia shows marked diurnal fluctuation, that is, aggravates toward the evening and recovers markedly or nearly completely in the morning after sleep. The fluctuation is also observed in tremor. But these fluctuations are mild or not apparent in adult onset patients.

In patients with onset in early childhood, the body length fails to grow normally with the onset of dystonia and becomes short stature in the late teen ages. This is not observed in patients with onset after adolescence. Locomotion or interlimb coordination is preserved and psychomental activities are not affected even in advanced stages.

Clinical courses are also characterized by age dependency. The postural dystonia of the lower extremity occurring in childhood expands to all limbs and develops to be generalized dystonia by the middle of the teen age and its grade progressively aggravates toward the early twenties. However, the

progression attenuates with age, and once the age has crossed 30 years, symptoms become stational. With the attenuation of the progression, diurnal fluctuation decreases its grade and becomes not apparent in the stational stage. However, tremor, with onset in early teen, expands all limbs and trunk with age and this progression is observed until 30 years. Writer's cramp or torticollis, that is, focal or segmental dystonia, may appear in adulthood.

Neurological Examinations

Muscle stretch reflexes demonstrate a rigid hypertonus, but there is no plastic rigidity, and repeated testing will produce fluctuations in the tonus. The tremor is a high-frequency postural tremor (8–10 Hz), but a parkinsonian, resting tremor is not observed. However, adult onset patients may show resting tremor of lower frequency. These clinical signs show asymmetry, but the pattern of involvement of the sternocleidomustoideus (SCM) differs between rigidity and tremor. That is, the side predominantly affected in the SCM is contralational to that of extremities in rigidity, while it is ipsilateral in tremor. However, in adult onset cases, the side of predominance of the rigid hypertonus is ipsilateral between the SCM and the muscles of extremities. Bradykinesia or postural instability appears with advancing symptoms of dystonia. However, freezing phenomena or the *marche a petit pas* of Parkinson's disease (PD) are not seen, and locomotion is preserved throughout the course of illness. The tendon reflexes are brisk and ankle clonus may be observed, but the plantar reflexes are flexor. Although some patients exhibit sustained dorsiflexion of the toe, this is 'striatal toe sign', not elicited by plantar stimulation, and is associated with basal ganglia involvement. There are neither cerebellar signs nor sensory disturbances. Psychomental activities are preserved normally.

Clinical Variation

Besides the classical type with generalized postural dystonia, there is a type associated with action dystonia. This variation is depending on the family and suggests existence of two types, that is, postural and action dystonia type. Ages at onset also show another phenotypical variation, that is, adult onset patients show tremor, gait disturbance, focal dystonia, or parkinsonism but without generalized dystonia and diurnal fluctuation. There are patients with paroxysmal dystonia, dystonic cramp, or oculogyric crisis. These symptoms are tended to be observed in patients with action dystonia. There are also intrafamilial variations, that is, there are families with anticipation in the ages at onset, while others show identical features or marked phenotypical variation irrelevant to the generation. Some patients show autistic features, depressive state, or migraine, and others, particularly in patients with compound heterozygotes, show hypotonia, failure in locomotion, and delay in mental and motor development. These symptoms are caused by serotonergic deficiency. These association are expected because GCH-I deficiency affects the 5-hydroxytryptophan (5-HTP), the coenzyme for synthesizing serotonin (5-HT) and observed in patients with marked deficiency of GCH-I. Thus, the heterogeneity of symptoms in this disorder appears to be related to age at onset, pathophysiological differences among families, and the grade of the involvement of the serotonergic neurons.

Treatment and Prognosis

In most cases, a dose of 20 mg kg^{-1} day^{-1} of plain levodopa without decarboxylase inhibitor alleviates the symptoms completely. Some patients starting treatment with plain levodopa before 10 years tend to decrease the response after ~13 years. Older onset subjects do not always respond to plain levodopa. To these patients, levodopa with decarboxylase inhibitor with doses of 4–5 mg kg^{-1} day^{-1} alleviates the symptoms completely. In a few patients, choreic movements develop by a rapid increase of dosage or by administration of a higher dose of levodopa in the initial stage of treatment. In patients with action dystonia, action retrocollis and oculogyric crisis may be aggregated by initial doses. In patients with compound heterozygote, aggravation of dystonia by initial dosage is prominent. In these patients, the unfavorable symptoms disappear with decrease of the doses. After titration to an optimal dosage by starting with smaller doses and by slowly increasing it, levodopa shows sustained and favorable effects without side effects. Levodopa is effective in almost all patients without any relation to the age of onset and the longevity of the clinical courses, and improves short stature, if administered before puberty.

Anticholinergic drugs may have a marked and prolonged effect, but do not afford a complete relief, either clinically or polysomnographically. It does not improve the tremor. Amantadine has proven beneficial for levodopa-related chorea. Tetrahydrobiopterin (BH_4) monotherapy is not favorable, but there are a few patients who show complete remission after administration of BH_4 in addition to levodopa. In a patient with compound heterozygote, administration of BH_4 is necessary for complete recovery.

Investigations

Biochemical Studies

Cerebrospinal fluid (CSF) examinations reveal low levels of homovanillic acid (HVA). But characteristic features are marked decrease (20% of normal levels) of both biopterin and neopterin levels. Moderate reduction of these pteridine metabolites is also observed (about 30–50% of normal levels) in CSF of asymptomatic carriers.

The activity of GCH-I in the mononuclear blood cells of patients is less than 20% of those in normal individuals, while asymptomatic carriers reached 30–40% of normal levels. Phenylalanine loading tests in both child and adult patients reveal a 6-hour increase in phenylalanine levels. In addition, the phenylalanine-to-tyrosine ratios remain at elevated levels during the postloading period, while biopterin levels decline. However, this test tends to show false negative results.

Neuroimaging Studies

Magnetic resonance imaging (MRI) and computed tomography (CT) scans of the brain show no abnormalities, while positron emission tomography (PET) scanning demonstrates normal or low normal [18F] dopa uptake levels. [11C] raclopride PET shows normal activity in symptomatic subjects. [11C] *N*-spiperone PET reveals mild increase in receptor binding. There is no increase in receptor binding in follow-up PET analysis after 7 months of levodopa therapy. Childhood onset patients with 30-year untreated courses and a 59-year-old patient with onset at 58 years showed no abnormalities either in [18F] dopa or [11C] *N*-spiperone PET scan. [123I] β-CIT SPECT scanning is normal in this disease.

Neurophysiological Studies

Polysomnographies (PSGs) reveal abnormalities in the phasic components of sleep. These changes include a decrease in the number of gross movements (GMs) and twitch movements (TMs) and abnormality in the pattern of occurrence of GMs against sleep stages.

These phasic components of sleep are modulated by the basal ganglia and the NS–DA neuron; of them, the numbers of TMs during rapid eye movement (REM) sleep reflect NS–DA neuronal activity. Sleep structure, percent sleep stages, and other parameters modulated by the brain stem aminergic neurons are preserved normally.

Normally, the number of REM-associated TMs decline with age and show decremental nocturnal variation with sleep cycle. In AD GCH-I deficiency, these ages and the nocturnal variations of the TMs are preserved, but the amount of TM declines to approximately 20% of normal values. Abnormalities of the patterns of GMs differ between postural dystonia and action dystonia type and that of the latter suggests DA-D_2 receptor supersensitivity.

Evaluation of saccadic eye movements reveals abnormalities in both visually guided and memory guided saccades, and implicates involvement of the both the direct and the indirect pathways. Besides hyperactive nigrocollicular inhibition associated with slowing in both memory and visually guided saccades, disinhibition of the superior colliculi has been postulated by failure in suppression of unnecessary saccade in memory-guided task.

Supracranial magnetic stimulation was normal, showing preservation of the corticospinal tract. Paired pulse magnetic stimulation showed normal short-interval intracortical inhibition of the motor cortex in postural type AD GCH-I deficiency. This suggests that reduction of GABAergic inhibition of the thalamocortical pathway may not contribute to generation of dystonia in postural-type AD GCH-I deficiency.

Brain Pathology and Histochemistry

Neuropathological examination reveals no demonstrable changes in the substantia nigra (SN) except decrease in the melanin, particularly in the ventral tier of the pars compacta. Histochemically, DA content is reduced in the pars compacta in the SN and striatum. Similar to PD, the reduction is greater in the putamen than in the caudate nucleus, and subregionally, more in the rostral caudate and the caudal putamen. In contrast to PD, AD GCH-I deficiency shows a greater DA loss in the ventral subdivision of the rostral caudate than its dorsal counterpart, and the activity and protein content of TH is decreased only in the striatum, while it is within the normal range in the SN.

There are marked reductions of total biopterin (84%) and neopterin (62%) in the putamen, despite normal concentration of aromatic acid decarboxylase, DA transporter, and vesicular monoamine transporter. A postmortem study on an asymptomatic carrier shows modest reduction of TH protein (52%) and DA (44%), despite marked reduction of striatal biopterin (by 82%).

Molecular Biological Studies

The causative gene of AD GCH-I deficiency is the GCH-I gene located on 14q22.1–q22.2. Although more than 100 independent mutations have now been identified in the coding region of GCH-I, the loci of mutation differ across families but are identical in one family. The rate of mutant GCH-I

mRNA production against normal RNA was 28% in a patient but it was 8.3% in the asymptomatic carrier.

Molecular analysis remains unable to determine mutations of the coding region of the gene in approximately 40% of subjects with AD GCH-I deficiency. In some of these subjects, abnormalities in intron genomic deletion, a large gene deletion, an intragenic duplication or inversion of GCH-I, or mutation in as yet undefined regulatory gene modifying enzyme function are suspected.

Pathophysiology

Although the pathogenetic mechanisms for dominant inheritance are unknown, a classic dominant negative effect and destabilizing effect have been considered. The ratio of mutant/wild-type GCH-I mRNA in lymphocytes is higher in an affected individual than an unaffected heterozygote, and varies depending on the locus of the mutation. Furthermore, the ratio differed among affected individuals in some families, depending on the locus of the mutation. Thus, the degree and the pattern of inactivation of normal enzyme by mutant gene differ among the locus of mutation and may cause inter- and intrafamilial variation of the phenotype as well as the rate of penetrance.

In AD GCH-I deficiency, the TH appears to be preferentially affected when compared to tryptophan hydroxylase. This could be explained by the difference in distribution of GCH-I mRNA in DA and 5-HT neurons, the destabilization of the molecule of TH, or impairment of axonal transport. However, the difference of K_m value for TH and tryptophan hydroxylase is most probable. With heterozygotic mutant gene, the BH_4 decreases partially in AD GCH-I deficiency. Thus, TH with higher affinity to BH_4 is affected rather selectively. In molecular conditions with marked decrease of BH_4, both tryptophan hydroxylase and TH are affected, producing symptoms induced by deficiencies of the 5-HT neurons.

Complete and sustained response to levodopa, especially given the absence of morphological changes, further suggests that the lesion in AD GCH-I deficiency is restricted to the NS–DA neurons. TH activity of the NS–DA neurons shows age-related decrement and circadian oscillation in the terminals, but these age- and state-dependent variations are not observed in the SN or the perikaryon of the NS–DA neuron. The onset of symptoms in the first decade of life with diurnal fluctuation and age related the clinical course correlates to the activities of TH in the synaptic terminals of the NS–DA neurons in the caudate. Neurohistochemical studies confirm the decrease of the TH protein and its activities only at the terminal, and the PSGs suggested that the TH activities at the terminal follow the decremental age and nocturnal variation of normal individuals with low levels but without progressive decrement of the activities. These features and the results of PET scan suggest that in AD GCH-I deficiency are not a progressive or degenerative disorder and the NS–DA neurons preserve their fundamental functions.

Study of GCH-I activity in stimulated mononuclear blood cells shows age-dependent, decreasing activity in the first three decades of life. Putaminal biopterin levels increase in postnatal period, reaching a plateau at 1–13 years of age, before declining in adulthood. These results imply that pteridine metabolism has a critical period beginning early in infancy and extending to early childhood and important roles of GCH-I and BH_4 for neuronal development in the first and the second decades of life.

As for the loss of striatal TH protein with normal preservation of it in the SN, following processes are considered. BH_4 may control protein stability rather than expression. Animal experiments revealed stabilization of TH protein by co-expression of GCH-I and loss of TH protein but not of TH mRNA in the brains of BH_4-deficient mice.

In the rostral caudate in particular, the medial/ventral portions, the striosomes/patches or D_1 direct pathways are more numerous, whereas in the dorsal/lateral portions the matrix compartment is more homogenous. Thus, histochemical findings suggest that the DA loss in AD GCH-I deficiency is more prominent in the striosomes/patches compartment, the terminal for the D_1 receptor. Clinically it is suggested that the D_1 direct pathways mature earlier than the D_2 indirect pathways. Dopa-responsive growth arrest seen in children with AD GCH-I deficiency is a reflection of the tuberoinfundibular D_4 receptor involvement. The D_4 receptor belongs to the D_2 receptor family, which, however, matures early among D_2 families. Thus, the DA neuron in which the DA synthesis is modulated by pteridine metabolism might regulate DA receptors that mature early in the developmental course.

Tremor is levodopa responsive but develops independently, from symptoms of dystonia. The side predominance of tremor is identical to dystonic hypertonus in the extremities while it is contralateral in the SCM. These suggest a different pathophysiology of tremor from that of dystonia and postulate the responsible lesion in the downstream of the striatum, the DA neuron innervating to the STN with D_1 receptor. This confirms unresponsiveness of tremor to anticholinergies. For generation of the rhythmic discharge of tremor, the circuits consisted of the STN

and two globus palliduses are considered. In addition, response of the tremor to stereotactic ventrolateral (VL) thalamic nucleus thalamotomy performed in the era before levodopa suggests involvement of the ascending pathway to the VL nucleus of the thalamus. Given that ascending pathways to the thalamus develop later than the descending pathways, increasing age may be a factor for development of tremor. Further support for the D_1 receptor-mediated hypothesis stems from the PET findings revealing preservation of function of D_2 receptors, and suggesting that the striatal indirect pathway does not play a role in the generation of symptoms. The PSG findings observed in patients with action dystonia could be explained by the hypofunction of the STN.

The 5-HT neuron involves in modulation of locomotion and postural tone as well as of behavioral function. The hypotonia and failure in locomotion observed in patients with compound heterozygotes are associated with deficiency of the 5-HT-regulated activities. Preservation of interlimb coordination or locomotion in AD GCH-I deficiency without symptoms of 5-HT deficiency may depend on the preservation of the descending output of the basal ganglia to the pedunculo pontine nucleus (PPN).

Two studies on penetrance estimating the ratio of symptomatic carries revealed just identical results, that is, for females 87% and 87% and for males 38% and 35%. Gender difference of the base levels of GCH-I in the mononuclear blood cells is yet to be confirmed. Thus, marked female predominance might depend on a genetically determined gender difference of the DA neuron.

The pathophysiology of AD GCH-I deficiency is postulated as follows. The decrease of the TH protein or DA in the ventral area of the striatum causes disfacilitation of the D_1 striatal direct pathway, and disinhibits the output projection of the internal segment of the globus pallidus and pars reticulata of the SN, which suppress the reticulospinal tract and the superior colliculus. These may cause postural dystonia with exaggeration of the tendon reflexes without extensor plantar reflexes and abnormalities in voluntary saccades. Whereas, with involvement of the DA neuron innervating to the STN with D_1 receptor, the ascending outputs to the thalamus are disfacilitated and develop tremor and action dystonia. However, action dystonia is observed in infants with recessive sepiapterin reductase deficiency; the projection of the descending output to the brain stem reticular formation could get involved in this process. This process also disinhibits of the superior colliculus and involves the failure in suppression of unnecessary saccade in memory-guided task. Focal and segmental dystonia observed in patients with action dystonia may be caused by dysfunction of the motor cortex due to disinhibition of the thalamocortical pathway. Considering the ipsilateral finging of the predominant side of involvement in SCM and extremities, this pathway may be preferentially involved in adult onset patients. These pathophysiologies are shown in Figures 1(a)–1(c).

Diagnosis

Confirming the diagnosis of AD GCH-I deficiency is usually not difficult in the setting of characteristic clinical symptoms. The estimation of GCH-I activity in peripheral nucleated cells is accurate, but technically complicated. Thus, estimation of neopterin and biopterin levels in CSF is most reliable for diagnosis.

Differential Diagnosis

All children with gait disturbance and limb dystonia with asymmetry should be evaluated for AD GCH-I deficiency. Other conditions with this clinical presentation may include Wilson's disease, Hallervorden–Spatz disease, hereditary spastic paraplegia, and cerebral palsy. AD GCH-I deficiency is often misdiagnosed as hereditary spastic paraplegia. The differentiation of AD GCH-I deficiency from these disorders is usually not difficult with careful clinical examination.

Cases with axial torsion dystonia, including early onset autosomal dominant torsion dystonia (DYT1), can be differentiated clinically from AD GCH-I deficiency by evaluating the side that is predominantly involved between the SCM and muscles of the extremities; the side of the SCM predominantly affected is contralateral to that of the limb muscles in AD GCH-I deficiency, while it is ipsilateral in dystonias with axial torsion. This difference in the side preference reflects involvement of the NS–DA neurons in AD GCH-I deficiency while involvement of the striatum or the pallidum in torsion dystonia. However, it should be taken care that AD GCH-I deficiency and also DYT1 may appear with focal or segmental dystonia without general dystonia in adolescence or adulthood. Besides biochemical and molecular biological studies, levodopa loading test is recommended.

Dopa Responsive Dystonia Other Than AD GCH-I Deficiency

This group includes recessive disorders of pteridine metabolism and recessive TH deficiencies (recessive DYT5). All of the inherited disorders of pteridine

metabolism develop levodopa responsive dystonia caused by decrease of BH_4 in infancy and early childhood as in AD GCH-I deficiency. However, they show postural hypotonia and psychological disturbances caused by deficiency of the 5-HT activities. Recessive TH deficiency shows ptosis, hyperperspiration, and psychomotor disturbances due to noradrenaline (NA) deficiency. However, some show almost identical features as AD GCH-I deficiency and respond well to levodopa. However, the diurnal fluctuation is not marked as AD GCH-I deficiency. For definite diagnosis, estimation of pteridine metabolites and catecholamine metabolites in CSF is necessary.

Dopa Responsive Dystonia Parkinsonism

All of juvenile parkinsonism (JP) appears as dystonia when it occurs in childhood to early teens. Although dystonia of JP responds briskly to levodopa, dyskinesia develops soon after levodopa is started. Among JPs, that caused by parkin gene (PARK2) is a particularly important disease to differentiate from AD GCH-I deficiency when it occurs in early ages.

In addition, some patients with AD GCH-I deficiency develop symptoms later in life (e.g., fifties and sixties). In this population, tremor and gait disturbance are the primary signs, and dystonia is absent or not prominent. In these patients, diurnal fluctuation is not observed and often misdiagnosed as PD. However, the tremor in these cases is mainly postural and their clinical features are milder with minimal progression. For definite diagnosis of PARK2, gene analysis is necessary.

Significance of Boundary Formation

The subdivision of the neural epithelium into domains with distinct regional identity is a crucial phase in establishing the highly complex organization of the central nervous system. This regionalization is initiated by localized signals that induce the spatially restricted expression of specific transcription factors, which in turn regulate which types of differentiated cells are generated within the tissue domain. At early stages the boundaries of regulatory gene expression can be fuzzy, but subsequently become very sharp. This sharpening is significant for two reasons: First, because it establishes a strict demarcation of regional domains that presumably contributes to the precision of subsequent tissue organization. Second, because some boundaries form a signaling center that further refines pattern by inducing new cell types. Since the distribution of the boundary-derived signal affects the location of the induced cell types, it is important that the signaling cells are precisely positioned by formation of a sharp interface.

Cell lineage studies have shown that there can be extensive intermingling within the neural epithelium due to the intercalation of proliferating cells. This raises the question of why such intermingling does not disrupt the formation and maintenance of precisely organized interfaces and signaling centers. One general mechanism to achieve this is the specific inhibition of cell intermingling between adjacent domains. Such territories within tissues that do not mix with their neighbors, termed compartments, were first recognized in studies of fruit fly development and shown to correspond to the domains of action of 'selector' genes that control regional identity. Clonal analyses and time lapse imaging have revealed a number of compartment boundaries in the developing central nervous system of vertebrates: between the cortex and lateral ganglionic eminence, the interface of the diencephalon and mesencephalon, between the zona limitans intrathalamica (zli) and adjacent dorsal and ventral thalamus, at the midbrain–hindbrain junction, and at the interfaces of hindbrain segments (rhombomeres). At some of these boundaries – the zli and midbrain–hindbrain junction – a signaling center forms that regulates patterning and differentiation of the adjacent territory.

Role of Cell Affinity in Boundary Sharpening

Important insights into mechanisms that inhibit cell intermingling came from studies showing that cell populations with different adhesive properties will segregate from each other after they are intermingled *in vitro*. Such segregation can be driven by quantitative or qualitative differences in homophilic cell-to-cell adhesion mediated by cadherins. These studies led to the concept that segregation is established and maintained by cells maximizing their contact with others for which they have the strongest affinity. Studies of the roles of cadherin family members with spatially restricted expression during development have confirmed the major role of these adhesion molecules in maintaining tissue organization. For example, the inhibition of cell intermingling between the cortex and lateral ganglionic eminence is mediated by R-cadherin and cadherin-6 that are expressed in these respective domains.

This article focuses on a second type of mechanism that restricts cell intermingling mediated by cell responses to signal transduction by Eph receptor tyrosine kinases and ephrins.

Interactions and Activation of Eph Receptors and Ephrins

Eph receptors are transmembrane receptor tyrosine kinases that bind to ephrin ligands. In vertebrates there are 14–16 Eph receptor tyrosine kinases and 8–9 ephrins that largely fall into two binding specificity classes: EphA receptors interact with ephrinA ligands that are anchored in the cell surface by a glycosylphosphatidylinositol moiety, and EphB receptors interact with ephrinB ligands that have a transmembrane and cytoplasmic domain. There are a few exceptions to these binding classes, for example, EphA4 that binds to ephrinB1 and ephrinB2 as well as all ephrinA ligands. Soluble ephrins do not activate Eph receptors unless they are artificially clustered, whereas Eph receptors are clustered and activated upon binding to membrane-bound ephrins. The clustering of Eph receptors triggers intracellular signal transduction, in part via tyrosine phosphorylation and activation of the receptor kinase domain, and also by kinase-independent mechanisms.

Remarkably, ephrins themselves have a receptor function and transduce signals upon being clustered by binding to Eph receptors. Consequently, Eph–ephrin

interactions mediate cell contact-dependent signaling that can lead to bidirectional cell responses. The mechanisms of ephrinA signal transduction are unclear, but for ephrinB proteins they involve phosphorylation of conserved tyrosine residues in the cytoplasmic domain by src family kinases.

Diverse Cell Responses to Eph–Ephrin Signaling

Eph receptor and ephrin signaling regulates a number of cellular responses, including proliferation, death, and migration. Of particular relevance to boundary formation are their roles in controlling cell migration by modulation of the state of assembly of the actin cytoskeleton and integrin-mediated adhesion. This involves multiple adaptor proteins that bind Eph receptors or ephrinB proteins on specific phosphotyrosine motifs (e.g., Nck, Grb4, RasGAP, Src), on a C-terminal PDZ interaction domain (e.g., Dishevelled), or on other motifs not requiring tyrosine phosphorylation (e.g., Ephexin). These adaptor proteins modulate the activity of a number of regulators of cell adhesion and the actin cytoskeleton, including Rho family GTPases, the Ras/mitogen-activated protein kinase (MAPK) pathway, and the planar cell polarity pathway.

One major role of EphA, EphB, or ephrinB activation is in cell contact-dependent repulsion in which there is disassembly of the actin cytoskeleton and collapse of cell membrane processes. Concomitantly, cell-to-cell attachment mediated by binding of Eph receptor to ephrin is disrupted by the endocytosis of intact Eph–ephrin complexes or the proteolytic cleavage of ephrinA protein, thus enabling the interacting cells to disengage. The repulsion response of migrating cells or neuronal growth cones to Eph or ephrinB activation prevents them from entering ligand-expressing territory, thus confining them to the correct pathway. Examples of such repulsive guidance in the vertebrate nervous system include the restriction of spinal cord motor axons expressing EphB receptors from the posterior half of somites that express ephrinB protein, and the inhibition of corticospinal axons expressing EphA4 from inappropriately crossing the ventral midline that expresses ephrinB3. A corollary of this role in guidance by contact repulsion is that Eph receptors and interacting ephrins are commonly expressed in complementary regions.

In contrast to such roles in repulsion, in other contexts Eph receptor or ephrin signaling can increase cell adhesion and promote the migration of cells or outgrowth of axons. For example, EphA–ephrinA signaling increases cell adhesion required for neural tube closure, and signal transduction through ephrinA5 promotes the targeting of vomeronasal axons to territory expressing high levels of EphA6. Furthermore, in some cells Eph receptor activation can lead to either repulsion or invasion responses. Switching between these alternative cellular responses contributes to the correct migration of axons during topographic mapping in the nervous system.

The nature of the cell response to Eph receptor activation depends at least in part upon the amount of clustering and/or the number of activated receptors. Unlike other classes of receptor tyrosine kinases, which are activated by dimerization, Eph receptors form higher order multimers upon binding to ephrin. The activation of some intracellular signaling components depends upon the amount of multimerization. Low levels of Eph receptor activation or clustering increase assembly of the actin cytoskeleton and integrin-mediated adhesion, whereas high levels of activation lead to disassembly of polymerized actin and decreased adhesion. This has been demonstrated most clearly for retinal axons that form a topographic map of connections by responding to a gradient of ephrinA ligands: low amounts of ephrinA stimulate axon outgrowth, whereas high amounts of ephrinA inhibit outgrowth. The nature of the cell response may thus depend upon the amount of ephrin ligand encountered. Alternatively, cell responses can be affected by mechanisms that modulate how much Eph receptor activation occurs in response to a given amount of ephrin. Examples of such modulatory mechanisms are the endogenous expression of truncated Eph receptors that inhibit Eph receptor phosphorylation, and the co-expression of ephrins and Eph receptors in the same cells, which leads to *cis* interactions and formation of inactive complexes. Cell responses may also be influenced by coactivation of Eph and ephrin signaling pathways within a cell, and by cross-activation of Eph receptor or ephrinB by fibroblast growth factor (FGF) receptor.

Roles of Eph–Ephrin Signaling in Boundary Sharpening

Repulsion at Boundaries

The clearest example of roles of Eph–ephrin interactions in the sharpening of boundaries in the nervous system has been uncovered in studies of the hindbrain. Expression of EphB and EphA4 receptor and their high-affinity ephrinB binding partners occurs in complementary sets of hindbrain segments, such that interactions occur at segment interfaces (Figure 1). The results of loss- and gain-of-function experiments

Figure 1 Expression of Eph receptors and ephrins in the zebra fish hindbrain. There is a largely complementary segmental expression of Eph receptors and ephrins that have high affinity for each other, for example, EphA4 and ephrinB3, and EphB4 and ephrinB2. This leads to interactions at hindbrain boundaries (indicated with arrows). There are some overlaps in expression, such as between ephrinB3 and the low level expression domain of EphA4 in rhombomere 2. Since this does not account for the role of EphA4 in regulating cell affinity within rhombomeres 3 and 5, other ligands may overlap with EphA4 in these segments.

in zebra fish embryos reveal that Eph–ephrin signaling is required for formation of sharp and straight interfaces between segments and that cell responses are regulated by signal transduction through Eph receptors and ephrinB proteins. Direct evidence for a requirement for bidirectional signaling comes from *in vitro* experiments in which Eph receptor and ephrinB-expressing cells are juxtaposed. Cell intermingling is restricted by signaling through full-length Eph receptor and ephrinB that mediate bidirectional activation at the interface. In contrast, cells expressing truncated Eph receptor – which acts as a ligand but cannot itself transduce signals – invade ephrinB territory, but ephrinB cells do not invade Eph receptor territory. Analogous roles of Eph–ephrin signaling in the segregation of distinct cell populations have been uncovered in mesoderm segmentation, the vasculature, limbs, and intestinal crypts. These findings, together with the complementary expression of Eph receptors and ephrins in many vertebrate tissues, suggest that Eph–ephrin interactions are widely used to stabilize tissue organization by mediating signaling across boundaries.

Activation within Domains

A role of Eph–ephrin activation at interfaces in restricting the mixing of cells predicts that Eph receptor function is required only at boundaries. For example, the expression of EphA4 in hindbrain segments r3 and r5 enables interaction with ephrins at the borders with adjacent even-numbered segments (Figure 1). However, mosaic knockdown of EphA4 leads to segregation of cells lacking EphA4 protein away from the central, nonboundary regions of these segments. Thus, EphA4 function is required throughout r3 and r5 to regulate cell affinity. These data suggest that EphA4 is activated by a co-expressed ligand(s). This is consistent with the findings, discussed previously, that overlapping Eph-ephrin expression causes low-level receptor activation that promotes cell adhesion.

Eph–ephrin activation thus contributes to the stabilization of boundaries by two mechanisms: by mediating bidirectional repulsion across the interfaces of cell populations and by regulating cell affinity throughout a cell population. This dual role could involve different levels of activation of the same receptor(s). Alternatively, there may be a different role of the two binding specificity classes, since although EphA and EphB receptors are both capable of triggering cell repulsion, in some tissues they mediate distinct cell responses.

Restriction of Communication across Boundaries

The formation of gap junctions between cells allows the passage of small molecules that may regulate cell phenotype, and the loss of such communication often correlates with the acquisition of a distinct cell fate. It is therefore intriguing that whereas cells within hindbrain segments are connected by gap junctions, there is a restriction to such communication across rhombomere boundaries. *In vitro* studies show that ephrinB and EphB receptor signaling each block the sharing of small molecules by gap junctions. Eph-ephrin signaling may thus regulate both the restriction of cell mixing and the inhibition of cell communication across the boundaries of hindbrain segments.

Relationships with Other Regulators of Boundary Formation

Eph–ephrin interactions have a major role in the restriction of cell intermingling in the hindbrain, but it is currently not known whether they contribute to the stabilization of other boundaries in the nervous system. Roles at other boundaries may be obscured due to overlapping expression and functions of Eph-ephrin family members. However, it is likely that other regulators of cell affinity are responsible for boundary sharpening or act in parallel with Eph receptors. This raises the question of the relationships between different signaling and adhesion systems implicated in boundary formation.

Notch and Boundary Formation

The inhibition of cell mixing between the zli and thalamus is regulated by lunatic fringe, a glycosyl transferase that by glycosylating the Notch receptor modulates the strength of its binding and activation by ligands. This situation has a parallel in the fruit fly wing imaginal disc, in which the restriction of cell mixing between the dorsal and ventral compartments requires differential activation of Notch in boundary cells and adjacent cells. The restriction of cell mixing in the wing disc involves transcriptional targets of the canonical Notch pathway and modulation of the actin cytoskeleton by a noncanonical pathway. How Notch receptors regulate boundaries in the developing nervous system is not known, but interestingly in somitogenesis Notch regulates the formation of morphological boundaries via the upregulation of EphA4 expression.

Cadherins and Cell Sorting

In view of evidence that Eph-ephrin signaling and cadherin-mediated adhesion can each restrict the intermingling of cell populations, it is possible that one or the other mechanism acts at specific boundaries, for example, at hindbrain boundaries and the lateral ganglionic eminence–cortex boundary, respectively. Alternatively, these mediators may synergize by acting in parallel at boundaries and/or modulate each other's activity. Indeed, E-cadherin is required for the correct cell surface localization and activation of EphA2. Furthermore, strong cadherin-mediated adhesion requires interaction with the actin cytoskeleton, which could indirectly be modulated by the regulation of cytoskeletal assembly by Eph-ephrin signaling.

Integrins and Boundary Stabilization

Eph receptor activation can lead to the promotion of the integrin-mediated adhesion of cells to extracellular matrix. A potential connection with boundary formation has been revealed by genetic studies of the segmentation of mesenchymal paraxial mesoderm to form epithelial somites. The formation of somite boundaries requires EphA4–ephrinB2 interactions at the interface of presumptive somites that induce the generation of polarized epithelial cells. The subsequent maintenance of sharp interfaces between somites requires integrin $\alpha 5$ and the accumulation of fibronectin at boundaries. Thus, Eph–ephrin interactions and integrin-mediated adhesion are both required and potentially have connected roles in the stabilization of boundaries. This situation may have a parallel at hindbrain boundaries where there is an accumulation of extracellular matrix in the spaces between cells.

Perspectives

Eph receptors and ephrins have versatile roles in the establishment and maintenance of tissue organization by regulating cell repulsion and adhesion responses. They can act at boundaries or within tissue domains to maintain sharp interfaces or in gradients to position cells or axonal connections at appropriate locations. Elucidation of how the level of Eph receptor clustering and other mechanisms control the restriction or invasion of cells remains a key challenge. There is increasing evidence for cross-talk with other classes of receptors that may modulate cell migration, as well as cell proliferation and death, and it is important to understand how intracellular signal transduction by these multiple receptors is correctly integrated.

Segmentation: Spinal Cord Segmentation and A–P Somite Patterning

G M W Cook, K E Lewis, and R J Keynes, University of Cambridge, Cambridge, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Segmentation, the process of tissue subdivision into a periodic pattern of repeated elements, is a key strategy in animal development. It can expand body size, by increasing segment size and/or number, and it promotes tissue diversification, by enabling variation and differentiation of individual segments independently of others in the series. Accordingly, it appears to have evolved convergently several times in different animal phyla. The nervous system is no exception to this rule because the anatomy of the adult vertebrate nervous system shows clear evidence of its segmental origins, most clearly in the hindbrain and peripheral nervous system (PNS) of the trunk.

Intrinsic Segmentation of the Spinal Cord

As discussed elsewhere, the early neural epithelium of the developing hindbrain is subdivided into a series of repeat units, or rhombomeres, causing both motor neurons and interneurons of the hindbrain to be arranged segmentally. The PNS of the trunk region is also manifestly segmented, with aggregates of primary sensory neurons, or dorsal root ganglia, and associated spinal nerves (mixed motor and sensory) placed at regular, repeated intervertebral positions in relation to the segmented vertebral column. In most vertebrates, however, there is no direct evidence for any intrinsic segmental patterning within the spinal cord, unlike the hindbrain. Distinct subpopulations of motor neurons that occupy specific motor columns are specified at particular anterior–posterior (A–P) axial levels (e.g., lateral motor column neurons at limb levels and visceral/sympathetic motor neurons at thoracic levels). However, these differences reflect a subdivision of the A–P axis into broad regions rather than a more fine-grained, regular periodicity of different neuronal types, and similar subdivisions of interneurons have not been described.

Segmentation of Motor Neurons in the Zebra fish Spinal Cord

An important exception to this lack of segmentation in the vertebrate spinal cord is the zebra fish embryo, in which the first spinal motor neurons to form, primary motor neurons (PMNs), are located in a segmentally reiterated pattern along the A–P axis. Zebra fish have three different PMN subtypes: rostral primary (RoP), middle primary (MiP), and caudal primary (CaP) (Figure 1). One PMN of each subtype innervates the myotome (developing musculature) derived from each successive somite (mesoderm segment alongside the developing spinal cord), with the exception that approximately half the hemisegments (one hemisegment = one somite's length of one side of the spinal cord) initially have two CaP-like PMNs, one of which is called variably present (VaP) and usually dies. Each PMN subtype is uniquely identifiable by its soma (cell body) position relative to the overlying somites and by its axon trajectory. MiP and RoP somata, for example, are positioned adjacent to the somite boundaries, whereas CaP somata lie adjacent to the middle of each somite. CaP axons project into ventral myotome, MiP axons project into dorsal myotome, and RoP axons project into medial myotome. Such a fine-grained, reiterated pattern of distinct motor neuron subtypes has not been described in other vertebrates, although this may be because there are many more motor neurons in the species that have been examined to date, and distinct types of individual cells have not yet been recognized.

The tight spatial correspondence between the reiterated pattern of zebra fish PMNs and the overlying somites has long suggested that signals from paraxial mesoderm might specify different PMN subtypes. Consistent with this, transplantation experiments have shown that environmental signals can specify zebra fish PMN subtypes. For example, when a MiP is transplanted 2 or 3 h before axogenesis to a position where a CaP normally develops, the transplanted cell forms a CaP-like axon and initiates expression of a CaP-specific gene marker *islet2*. Studies of CaP and MiP specification have shown that zebra fish mutants which either lack somites or have very narrow somites form PMNs with hybrid identities, again suggesting that somite-derived signals specify the different PMN subtypes. This has been confirmed using cell transplantation to create genetically mosaic embryos: CaPs and MiPs were correctly specified in embryos where wild-type somites surrounded mutant neural tube but not in embryos with wild-type neural tube but lacking somites.

In addition, either morphological somite boundaries or some aspects of A–P somite patterning are required for the correct segmental spatial organization of PMNs. Zebra fish mutants that lack morphological

somite boundaries and aspects of A–P somite patterning form normal numbers of CaPs and MiPs, but the precise alternation and spacing of these cell types is lost and PMNs on the two sides of the embryo form out of register with each other. This shows that PMN subtype specification and spatial organization are separable aspects of PMN patterning, and it suggests that these somite segmentation mutants are lacking signals that normally fine-tune or maintain the precise segmental organization of different PMN subtypes. However, none of these somite signals have been identified at the molecular level.

Figure 1 Zebra fish MiPs and CaPs form in different positions, express different genes, and have different axon trajectories. Lateral views of a five-somite length of zebra fish trunk 18–20 h postfertilization (hpf) (top three pictures) and 26–30 hpf (bottom picture). In all cases, dorsal is up and anterior is right. MiPs express *islet1* and line up with overlying somite boundaries (top), whereas CaPs and VaPs express *islet2* and are found adjacent to the middles of the overlying somites. Red dotted lines indicate somite boundaries. The alternation of these different PMN fates can be seen in the third picture, in which MiPs are only labeled by nuclear Islet antibody staining (small brown circles indicated by asterisks) and CaPs and VaPs are labeled with both nuclear Islet antibody staining and *in situ* hybridization to *islet2* RNA (blue cytoplasmic staining indicated by white arrows). In all three pictures dorsal Rohon–Beard sensory neurons also express *islet* genes. The bottom picture shows ZNP1 antibody staining, which labels axons. MiP axons extend dorsally (white asterisks) and CaP axons extend ventrally (white arrows).

Segmentation of Interneurons in the Zebra Fish Spinal Cord

As with motor neurons, in most vertebrates there is no evidence for a segmental pattern of spinal cord interneurons. The main exception is again the early zebra fish embryo. At least one morphologically identified interneuron class is segmentally organized in the early embryonic zebra fish spinal cord, and several transcription factors that are good candidates for being expressed by particular classes of spinal cord interneuron are initially expressed by irregularly spaced cells along the A–P axis of the spinal cord, suggesting that there may be an imprecise segmental arrangement of other interneuron classes (Figure 2). For example, ventral lateral descending (VeLD) interneurons are, at least initially, segmentally arranged: at 24 h of development, the cell bodies of one or two VeLDs can be found just dorsal to PMNs on each side of the spinal cord. In contrast, Rohon–Beard sensory neurons and commissural primary ascending interneurons do not seem to be segmentally arranged, even at this early stage. Circumferential ascending interneurons express the transcription factor Engrailed, and expression occurs initially in a roughly

Figure 2 Transcription factors that are good candidates for labeling different interneuron classes in the zebra fish are expressed in an imprecise segmental pattern early in development. Lateral views of a five- to six-somite length of zebra fish trunk at approximately 20 hpf showing RNA expression of *evx1*, *eng1b* (*engrailed1b*), and *vsx1*. Each blue circle is an individual neuron showing cytoplasmic staining. In all cases, dorsal is up and anterior is right; dashed lines demarcate the ventral edge of the spinal cord.

segmented pattern in the spinal cord, although at later stages it becomes more continuous. This is reminiscent of *islet1* and *islet2*, which are initially expressed by PMNs but are then also expressed by later-forming secondary motor neurons, at which point expression along the A–P axis occurs in a more or less continuous row of cells and is no longer obviously segmental. A similar result is also observed for *chx10*-expressing interneurons (at least some of which are circumferential descending interneurons). Interestingly, these imprecise segmental patterns resemble the imprecise spacing of PMNs seen in A–P somite mutants, suggesting that early forming neurons in the zebra fish spinal cord may have a stochastic/imprecise intrinsic periodicity, and then some neurons are more precisely aligned with the overlying somites by signals from the somites. One possibility is that these somite signals set up segmental differences in cell adhesion along the spinal cord. This would explain why some neurons have such precise segmental distribution (they respond to differences in cell adhesion) and others do not (they are refractory to these differences). If this hypothesis is correct, then the CaP/MiP results discussed previously suggest that these cell adhesion signals should be disturbed or lacking in somite segmentation mutants.

Segmentation of Spinal Cord Neurons in Chordates and Protochordates – An Ancient Phenomenon in Chordate Evolution?

There is evidence from anatomical studies that other teleosts, lampreys, and *Amphioxus* have spinal cord motor neurons and/or interneurons that are arranged segmentally with a period equal to that of the myotome/somite series. This suggests that the segmentation seen in the zebra fish spinal cord reflects an evolutionarily ancient segmentation of the primitive spinal cord that has either been lost in tetrapods or is obscured by the larger numbers of cells (in amniotes – reptiles, birds, and mammals) or by the displacement of the somites relative to the spinal cord (e.g., amphibia such as *Xenopus*). In this context, it is notable that even in zebra fish, the spinal cord appears less obviously segmented as the embryo develops; the only clearly segmental neurons that have been observed are those that form early in development.

Peripheral Nerve Segmentation in Amniote Vertebrates

As mentioned previously, there is no direct evidence for any intrinsic segmental patterning process within the spinal cord of amniote vertebrates, yet their peripheral spinal nerves are manifestly segmented. How does this arise? In particular, since the amniote spinal cord is encased by a flexible, weight-bearing vertebral column that gives it necessary mechanical protection, how do the spinal nerves, which must make essential interconnections between the central nervous system and the tissues and organs of the body, navigate their way through this developing column? How do they avoid being buried in bone and cartilage, and how do they achieve their final position between adjacent vertebrae in the intervertebral foramina, unperturbed by bending movements of the vertebral column throughout the life of the animal? The answer lies in the relative positioning of their earliest precursors – migrating neural crest cells and the growth cones of outgrowing motor and sensory axons – and the segmental pattern of the mesodermal somites that develop alongside the developing spinal cord and construct the vertebral column.

Somite Segmentation

Somites bud off sequentially from the mesenchymal 'paraxial' mesoderm, lying on either side of the neural tube, in a rhythmical sequence, arising as pairs of epithelial spheres that flank the neural tube and accumulate in a progressive A–P (craniocaudal) direction. The segmentation process is driven by a clock mechanism, intrinsic to paraxial mesoderm cells, that involves *Notch*, *Wnt*, and *Fgf* signaling, the details of which are beyond the scope of this article. Each somite then generates a diverse set of tissues (Figure 3(a)). The mesenchymal sclerotome arises from the ventromedial somite cells, triggered by signaling proteins such as sonic hedgehog and noggin secreted from the midline notochord and floor plate and characterized by expression of transcriptional regulators such as *Pax1*, *Pax9*, and *cFkh-1*. Together with cells from the midline notochord, the sclerotome differentiates into the vertebral column. The dermomyotome derives from the remaining dorsolateral somite, differentiating into axial dermis and skeletal muscle, whereas a further group of cells between the myotome and the sclerotome, the syndetome, provides the tendons that attach segmental muscles to vertebrae.

Peripheral nerve segmentation is critically dependent on the sclerotomes. When somites first appear in the embryos of birds and mammals, neural crest cells simultaneously migrate from the dorsal neural tube and navigate the somites in two broad streams. One is dorsal, between the ectoderm and somites, and provides skin melanocytes. The second stream penetrates ventrally, its earliest cells migrating between adjacent somites to a final position alongside the dorsal aorta, where they contribute to the sympathetic ganglia. Once the sclerotome appears, however,

Figure 3 Development of spinal nerve segmentation in amniote vertebrates. (a) Schematic diagram showing the early components of the developing PNS (the neural crest, sensory axons from the dorsal root ganglion, and motor axons from the ventral neural tube/spinal cord) and the derivatives of the somite (dermomyotome and sclerotome). The dermomyotome is largely removed on one side to show the subdivision of the sclerotome into anterior (A) and posterior (P) halves, and the dashed line shows the A–P boundary within the sclerotome. Migration of neural crest cells (large red arrows), development of the crest-derived dorsal root ganglion, and growth of spinal motor and sensory axons are restricted to the anterior half-sclerotome. (b) Whole mount of a chick embryo at 3.5 days of incubation, stained with zinc iodide and osmium tetroxide. Motor axons extend from the neural tube on one side of the embryo and grow exclusively in the anterior (left) half of each sclerotome of the somite series. Arrows mark the boundaries between neighboring somites. From Kuan C-YK, Tannahill D, Cook GMW, and Keynes RJ (2004) Somite polarity and segmental patterning of the peripheral nervous system. *Mechanisms of Development* 121: 1055–1068.

crest cells selectively invade the anterior half of each sclerotome while avoiding the posterior half-sclerotomes (Figure 3(a)). Many of these cells will aggregate alongside the spinal cord as the segmentally arranged dorsal root (primary sensory) ganglia and alongside the aorta as the sympathetic ganglia, whereas others differentiate into peripheral nerve Schwann cells. Soon after crest cells begin to penetrate the anterior half-sclerotomes, motor axons project from the motor pools of the ventral neural tube through the sclerotomes and, like the crest, their growth cones show the same exclusive preference for anterior versus posterior half-sclerotome (Figure 3).

Peripheral nerve segmentation is not an intrinsic property of the neural tube. Instead, experimental analysis in the chick embryo has shown that it is dictated by the A–P polarity of the sclerotomes. In particular, whereas A–P reversal of a short length of neural tube does not reverse the position of axon outgrowth within the sclerotome, when the presomite mesoderm is similarly reversed, motor axons grow through the original anterior (now posterior) half-sclerotomes. Supporting this conclusion, both axon outgrowth and sensory ganglia are unsegmented after surgical construction of multiple anterior half-sclerotomes *in ovo*.

Besides PNS segmentation, the A–P subdivision of the somite is critical for the formation and/or maintenance of sclerotome boundaries. Transplantation experiments in chick embryos have shown that anterior cells are nonmiscible with posterior cells, and that

confrontations between them generate boundaries. The A–P somite polarity is also important in the segmental patterning of the vertebral column since each half-sclerotome contributes to positionally distinct elements of each vertebra. Placing axons in the anterior half-sclerotomes ensures that the spinal nerves and dorsal root ganglia will be sited in the intervertebral foramina, where they are isolated from movements of the adjacent vertebral elements.

Spinal nerve segmentation appears to be determined by the A–P sclerotome polarity in all reptiles, birds, and mammals. These terrestrial vertebrates require a weight-bearing vertebral column to be constructed early in development, and the polarized sclerotome is, accordingly, a prominent component of the somite. In fishes, the sclerotome is only a minor somite constituent during the establishment of PNS segmental patterning, and the mechanism of PNS segmentation is discussed above. Classical experiments have also shown the dependence of amphibian PNS segmentation on somite segmentation but have not resolved which somite component may be critical in these vertebrates.

Molecular Determinants of the A–P Subdivision of the Somite

Studies have shown that the generation of somite A–P polarity is linked to the clock mechanism that underlies somite segmentation. According to one model, polarized expression of the transcriptional regulator, Mesp2, in the future anterior half-somite causes arrest of Notch activity in this somite domain and subsequent generation of anterior identity; Notch activity continues in the future posterior half-somite where Mesp2 is not expressed, resulting in posterior identity and a boundary between A–P somite domains. Consistent with this, loss of the Notch ligand, Delta1, causes loss of A–P somite polarity and a single, anterior somite identity, whereas loss of Mesp2 likewise generates a single posterior identity. It remains unknown, however, what determines the anterior restriction of Mesp2 expression. Several other transcriptional regulators have been identified that show polarized expression domains in the somite, such as the T-box transcription factor Tbx6, the homeobox transcription factors Meox1 and Meox2, and the bHLH transcription factor paraxis. Identifying how these interact with other transcriptional regulators involved in establishing A–P polarity, as well as with Wnt and Fgf signaling, remain an important challenge for future research.

Molecular Basis of Peripheral Nervous System Segmental Patterning

In principle, the preference of crest cells and growth cones for anterior half-sclerotome might reflect attraction by molecules from anterior half-sclerotome and/or repulsion from posterior half-sclerotome. Several extracellular matrix proteins, including laminin, fibronectin, collagens, thrombospondin and tenascin-C, are expressed by neural crest cells and/or anterior half-sclerotome cells, and these are likely to promote migration of the crest in the anterior half-sclerotome. However, there is no evidence that these proteins determine the preference of the crest or axon growth cones for anterior half-sclerotome. Work has concentrated largely on the repulsive activity of posterior half-sclerotome cells for migrating crest cells and growth cones, and this system was among the first to provide strong evidence that cell–cell repulsion plays a major role in axon guidance and the construction of the nervous system.

Using the growth cone collapse assay to detect contact repulsion of axon growth, detergent extracts of chick somites have been shown to cause collapse of primary sensory axons and motor axons growing on laminin *in vitro*. The main repulsive mechanism is likely to be contact repulsion rather than long-distance (chemo-) repulsion. Detailed observations of interactions *in vitro* between motor axon growth cones and posterior half-sclerotome cells are consistent with contact repulsion. Moreover, chemorepulsion is not seen in collagen gel co-cultures of posterior half-sclerotomes with primary sensory axons, whereas chemorepulsion of these axons by the notochord and dermomyotome is readily visible under identical conditions. The posterior half-somite has been shown to express a variety of candidate repulsive systems that might mediate spinal nerve segmentation, and these are now considered in turn.

Eph/ephrin signaling Several members of the Eph receptor tyrosine kinase family and their ephrin ligands, initially implicated in the repulsive guidance of retinal axons projecting to the optic tectum, show polarized expression patterns in the sclerotome. Ephrins are subdivided, according to their mode of attachment to the plasma membrane, into ephrin-A ligands (attached via a GPI anchor) or ephrin-B ligands (with a transmembrane domain and cytoplasmic tail). Their cognate receptors (EphA and EphB) bind ephrin-A and ephrin-B ligands, respectively. Within each subclass, a receptor can bind to more than one ligand and vice versa, and signaling can be bidirectional; with some exceptions, there is little cross-talk between the two subclasses.

Eph/ephrin signaling has been implicated in the contact repulsion of neural crest cells by posterior sclerotome cells. EphB3 is expressed by migrating neural crest cells in chick anterior half-sclerotome, whereas the ligand ephrin-B1 is expressed reciprocally

in posterior sclerotome; in the rat, EphB2 and ephrin B2 are expressed similarly. Moreover, these studies have shown that addition of soluble ephrin-B to chick trunk explants disrupts segmental migration of the crest, and that avoidance by crest cells and motor axons of immobilized ephrin-B *in vitro* is also blocked by soluble ephrin-B. Surprisingly, however, defective spinal nerve segmentation has been reported neither in an EphB2/EphB3 double knockout mouse nor in an ephrin-B2 null mutant, perhaps because of functional redundancy in this signaling system or because additional repulsive systems operate in the sclerotome. There is also evidence that EphA4/ephrin-A5 interaction promotes crest and axon migration in anterior half-sclerotome, showing the 'bifunctional' nature of this signaling system.

F-spondin Another molecule with bifunctional properties in PNS segmentation is F-spondin, which belongs to the thrombospondin type 1 repeat (TSR) superfamily and acts as a floor plate attractant for chick spinal commissural axons. F-spondin is expressed throughout the sclerotome with the exception of the region corresponding to the early migratory pathway of neural crest, suggesting a repulsive role in crest migration. Consistent with this, crest cells migrate into posterior half-sclerotome after *in ovo* microinjection of anti-F-spondin antibodies into the embryo trunk, leading to expansion of dorsal root ganglia. F-spondin also inhibits outgrowth of cultured motor axons, although paradoxically it is reported to promote the outgrowth of rat primary sensory axons. Another member of the TSR superfamily, thrombospondin-1, acts as a permissive rather than repulsive molecule for neural crest migration. It is expressed on the myotome basal lamina, adjacent to the stream of ventrally migrating crest cells, and it promotes neural crest migration and adhesion *in vitro*.

Semaphorins Sema3A was originally identified as a secreted repellent protein causing collapse of chick primary sensory axon growth cones, and it is expressed selectively in the posterior half-sclerotome, albeit at low levels after the initial phase of neural crest migration. Its coreceptor, neuropilin-1, is expressed reciprocally on migrating crest cells in the anterior half-sclerotome, and crest cells migrating *in vitro* avoid stripes of Sema3A-Fc. For several reasons, however, it is unlikely to be a critical determinant of PNS segmentation. These include the finding that explanted posterior half-sclerotomes show no chemorepulsive activity for cultured sensory axons, and that there are no abnormalities of spinal nerve segmentation in mouse null mutants for Sema3A or neuropilin-1. On the other hand, zebra fish SemaZ1B, which is closely related to Sema3A, has been implicated in the segmental outgrowth of motor axons in this species.

Expression of another semaphorin, Sema3F, is also restricted to posterior half-sclerotome, and migrating crest cells express its coreceptor neuropilin 2 (Npn2). Strikingly, in both Sema3F and Npn2 mutant mice, anterior-restricted crest migration is replaced by uniform migration in the sclerotome, whereas somite polarity is otherwise unchanged. This system is therefore a good candidate for mediating segmental crest migration in the somites, but it is also clear that other mechanisms must be critical for generating the final segmented pattern of spinal nerves; despite the loss of segmental crest migration, segmented dorsal root ganglia and spinal nerves still develop in these mutant mice.

Peanut lectin-binding glycoproteins The search for molecular differences between anterior and posterior half-sclerotome was pioneered by the use of plant agglutinins: Among a panel of lectins, only peanut agglutinin (PNA) showed a preferential binding to posterior half-sclerotome cells in the chick embryo. PNA has a specificity for Galβ1–3 GalNAc residues, but binding is inhibited upon sialylation. Subsequent use of jacalin, a lectin whose binding to Galβ1–3 GalNAc is not blocked by sialylation, also showed preferential binding to posterior half-sclerotome cells, indicating that differential sialylation does not account for the differences in glycosylation between anterior and posterior half-sclerotome cells detected by PNA. The biological significance of this differential glycosylation is not established, but experiments conducted with detergent extracts of somites have shown that all the growth cone collapse-inducing activity present in these extracts is removed by absorption to immobilized PNA. In addition, two PNA-binding glycoproteins of molecular weight 48 and 55 kDa are localized in the posterior half-sclerotome, and antibodies raised against these proteins can also be used to remove all of the growth cone collapse-inducing activity present in detergent extracts of somites. The addition of soluble PNA to explant cultures of chick embryo trunks permits crest cells to enter both halves of the sclerotome, confirming a role for PNA-binding glycoproteins in establishing PNS segmentation. Molecular cloning of PNA-binding proteins will enable a more detailed understanding of the role of these proteins in spinal nerve segmentation.

Other molecules Several other molecules are expressed selectively in the posterior half-sclerotome

and are candidate contact repellents. T-cadherin is a GPI-linked cadherin that inhibits motor axon outgrowth *in vitro*, but its role in mediating axon segmentation *in vivo* remains unclear. Chondroitin sulfate proteoglycans (CSPGs) implicated in PNS segmentation include collagen IX and versican, and the study of versican illustrates well the potential difficulties in interpreting molecular function in this system. Versican is initially expressed throughout the sclerotome, becoming progressively confined to the posterior half as the dorsal root ganglion compacts in the anterior half. However, this redistribution may be a consequence rather than a cause of segmental crest migration since expression remains uniform following ablation of the crest. Also, when versican-coated micromembranes are implanted into the crest migration paths *in ovo*, crest cells are attracted to them rather than repelled. Like the ephrin/Eph system discussed previously, versican may regulate crest migration in a bifunctional manner, depending on which isoforms are expressed where and when.

Surround Repulsion

In addition to their A–P segmental pattern, spinal axons also adopt a particular dorsoventral trajectory. Each differentiating primary sensory neuron initially emits short extensions in random directions before producing definitive growth cones at its dorsal and ventral poles, which then grow in a bipolar fashion (Figure 4). Again, the chick embryo has provided a valuable model system for investigating how this trajectory is sustained. The influence of the tissues surrounding the dorsal root ganglia can be studied by placing tissue fragments adjacent to a dorsal root ganglion embedded in a collagen gel, the latter acting as a medium for stabilizing gradients of any diffusible molecules released from the tissues. Using this system, ectoderm, dermomyotome, and notochord have been shown to secrete potent sensory axon growth repellents. When a dorsal root ganglia, which would normally extend axons radially in a collagen gel, is sandwiched between a fragment of dermomyotome and notochord, axons extend in a polarized trajectory reminiscent of the bipolar orientation seen *in vivo*. Such experiments suggest that opposing gradients of chemorepellents cause axons to extend along the path of least repulsion, a phenomenon termed 'surround repulsion.'

CSPGs and Sema3A are expressed by the notochord, and Sema3A is also expressed by the dermomyotome. Neutralizing antibodies have shown that Sema3A and neuropilin-1 mediate dermomyotome and notochord repulsion. Studies with Sema3A- or neuropilin-1-deficient mice have indicated, moreover,

Figure 4 Surround repulsion of sensory axons. The schematic diagram shows a transverse section through the chick and mouse embryo trunk at the level of an anterior half-sclerotome. Diffusible repellents are secreted from surrounding tissues and determine the dorsoventral growth trajectory of primary sensory axons (black arrows) extending from dorsal root ganglia neurons (black circles) in the sclerotome (Sc): ectoderm (magenta arrowheads), dermomyotome (Dm; green arrows), floor plate (blue arrows) basal plate of neural tube (NT; red arrows), and notochord (Nc; purple arrows). The left half of the diagram shows normal development. The right half shows the consequence of loss of function of sema3A/neuropilin-1; repulsion from the midline is now unopposed, causing some sensory axons to project aberrantly toward the dermomyotome (black arrow to the right).

that dermomyotome repulsion is substantially due to this molecular system since sensory axons extend toward the dermomyotome in these mice (Figure 4). Evidence suggests that Sema3A acts as one component of a surround repulsion mechanism in this system. The lack of aberrant axonal projections toward the notochord in these animals (Figure 4) is not surprising because sensory axon repulsion by the notochord is only partially blocked by soluble neuropilin-Fc, and retinal axons, which are insensitive to Sema3A, are still repelled by the notochord. This suggests that the notochord secretes a number of different repellents that contribute to surround repulsion in this system.

Conclusions

During vertebrate evolution, segmentation of the trunk nervous system has transformed from an early type in which the positioning of motor and sensory neuronal cell bodies was determined by somite-derived signals and in which sensory and motor axons extend independently in the space between neural tube and somites. In birds and mammals, the polarized sclerotome forces motor and sensory spinal axons to segment together in register with the developing series of vertebrae. It is likely, then, that

during the amphibian–reptile transition a new mechanism evolved, alongside the expansion of the sclerotome, to align spinal motor and sensory axons together along the A–P axis. This transformation may have incorporated substantial molecular redundancy into the process of segmental patterning of spinal axons. It is possible, for example, that the cell types involved – neural crest cell, anterior or posterior sclerotome cell, motor axon, or sensory axon – express independent cues that mediate their segmentation. The search for further molecular mediators of spinal nerve segmentation should help to distinguish between this possibility and the alternative – that one molecular system, still to be identified, orchestrates segmentation *in vivo*.

Seismic and Vibrational Signals in Animals

P M Narins and N Losin, University of California, Los Angeles, CA, USA

Introduction

Substrate-borne vibrations are a potentially important but largely unexplored signal class for communication in terrestrial animals. The detection of seismic stimuli is a phylogenetically widespread phenomenon, with known examples in every terrestrial vertebrate class. Many of these cases involve animals using seismic cues to evade predators, to locate prey, or to detect environmental changes. Although this is not considered true communication, these cases are worth further investigation since sensitivity to substrate-borne vibrations is often the scaffolding preceding the evolution of intra- or interspecific seismic communication.

The phylogenetic distribution of seismic communication *sensu stricto* is less clear. Well-documented examples of intra- and interspecific seismic communication occur among the mammals, with a few amphibian examples as well. It seems probable, however, that future discoveries will substantially broaden the range of taxa in which seismic communication is known to occur. The two most common methods of creating these signals are percussion and direct coupling of vocalizations with the ground. In the sections below, we will describe recent advances in our understanding of both seismic sensitivity and seismic communication proper in several vertebrate taxa.

Seismic Signal Generation

Percussion can produce both short- and long-distance seismic cues. A spider jumping on a web, foot-drumming in the kangaroo rat and Cape mole rat, head banging in the termite and blind mole rat, and chela drumming of male fiddler crab are examples of close-range percussion-induced signals.

The white-lipped frog (*Leptodatylus albilabris*), a terrestrial amphibian endemic to the neotropics, produces seismic vibrations concomitant with its air borne acoustic signals. During calling, the posterior portion of the frog's body is often buried in the muddy substrate, while the head and forelimbs are above ground. The seismic signal component is created while vocalizing when the frog's rapidly expanding vocal sac strikes ('thumps') the substrate impulsively. Such substrate-borne vibrations might simply be a natural consequence of the sound production mechanism in this species, but in fact males of *L. albilabris* can detect and respond to these vibrations. The sacculus in the inner ear of *L. albilabris* exhibits the highest sensitivity to substrate-borne vibrations of any terrestrial vertebrate studied. The frequency corresponding to the maximum saccular sensitivity in *L. albilabris* and the frequency spectrum of the seismic component of its vocalization match closely, suggesting that the thumps may be important for communication. Moreover, in response to either audio playback of the conspecific call or seismic playback of the vibrational call components, males of *L. albilabris* reliably modify the timing of their own vocalizations. This is the clearest demonstration of seismic communication in any anuran amphibian.

Seismic detection is not limited to adult anurans. Embryos of the red-eyed tree frog (*Agalychnis callidryas*) respond to particular vegetation-borne vibrations by hatching. The eggs of this species are laid on vegetation overhanging water so that on hatching, tadpoles drop directly into the water below. Aquatic predators may await in abundance, so it pays to delay hatching until the embryos are as mature as possible. Egg mass strikes by oophagous snakes trigger hatching *en masse*, up to 30% earlier than undisturbed clutches; other intense vibrational disturbances, such as rainstorms, do not induce hatching. Vibrations from snake attacks typically exhibit a slower temporal pattern than do rainstorm vibrations; vibration playback experiments have shown that snake recordings induced significantly more hatching than rain recordings. Stimuli that mixed snakelike and rainlike characteristics elicited intermediate levels of hatching. The *A. callidryas* embryos' sophisticated seismic detection and discrimination capabilities, although not an example of true communication, suggest that the use of substrate-borne vibrations in this group may be much more widespread than is currently recognized.

Many mammal species are known to thump their feet against the ground, and in some species these simple thumps may be rapidly repeated in complex 'drumming' sequences. These signals are best known in the Rodentia such as *Dipodomys* and *Georhycus*, but they are likely more widespread. Many kangaroo species are known to thump their feet; eastern gray kangaroos (*Macropus giganteus*) foot thump when confronted by predators. It is not clear for whom these signals are intended; two possibilities are predators or conspecifics.

Among the rodents, foot drumming is widespread, and these signals are known to propagate seismically between individual burrows. For example, individually distinctive drumming sequences have been found in the banner-tailed kangaroo rat (*Dipodomys spectabilis*). Evidence suggests that the animals may use these signals for individual recognition; drumming sequences are learned early in life and are modified with experience so that they differ from those of close neighbors. When an individual moves to a new territory, it may adjust its drumming sequence to be more recognizable among its new neighbors.

Some species, including kangaroo rats, also drum interspecifically at potential predators, particularly snakes. Snakes are highly sensitive to substrate-borne vibrations, so this antipredator behavior is often an effective signal, causing the snake to retreat. While foot-drumming signals are known to propagate through the soil, it is unknown whether conspecific recipients detect the substrate-borne vibrations directly (via somatosensory or auditory mechanisms) or via air borne vibrations created at the soil–air interface of their burrow walls. In either case, the animals are exploiting properties of seismic transmission, but more work needs to be done to understand the sensory capabilities of these organisms.

Massive terrestrial mammals may generate high-2 amplitude percussive signals; examples include foot thumping in kangaroos, trunk banging in the Asian elephant, and body slamming of male elephant seals. Although the propagation of these particular signals has not been measured through the ground, a man jumping generates a seismic disturbance that is measurable at a distance of 1 km. Locomotion of large mammals also produces ground-borne vibrations; examples include a stampede of bison or an elephant mock charge which ends in foot-stomping behavior. A running herd of zebra or giraffe generates propagated seismic waves which are distinctive at the species level and which could provide information to a predator at a distance.

The coupling of vocalizations with a substrate and the separate propagation of signals along the surface of a particular substrate, be it a plant stem, the forest floor, or open savannah, have the potential for short and long-range transmission. Distance traveled and propagation velocities of the signals depend on signal frequency and energy level as well as the properties of the substrate.

Seismic Signal Propagation

Maximum transmission efficiency of seismic energy occurs in the frequency band between 10 and 40 Hz, precisely the range in which many animals communicate seismically. In areas with little or no anthropogenic seismic noise, the 20 Hz channel is relatively noise free, save for vibrations associated with thunder or earth tremors, making it a reasonably quiet communication band. In general, for species that generate percussive substrate vibrations or low-frequency vocalizations that couple to the ground, communication signals are produced that often exhibit a spectral peak near 20 Hz and propagate along the surface of the earth as Rayleigh waves. The velocity of these seismic signals depends on the propagation velocity in soil and may be either slower or faster than the velocity of their acoustic signal counterpart. Moreover, depending on physical and environmental limitations, the seismic component may propagate within or potentially beyond the range of the airborne component.

Both airborne and substrate-borne (seismic) waves are subject to interference and alteration due to environmental factors. Variables such as wind and temperature influence airborne sound propagation, whereas the soil type and heterogeneity are among the environmental variables affecting the propagation of a seismic signal. Airborne sound waves spread spherically rather than cylindrically, attenuating more rapidly (losing 6 dB for every doubling of distance) than ground surface waves such as Rayleigh waves (losing 3 dB for every doubling of distance), which all else being equal, favors the long-distance propagation of seismic waves.

Seismic Signal Detection

The signal source intensity and attenuation during transmission, together with the sensitivity and depth of receptors in the receiver and the threshold at which the receptor will be stimulated relative to the frequency and strength of the stimulus define the active space of seismic communication signals. Detection of these signals depends on the expectation, motivation, sensitivity, and decision-making ability of the receiver, as well as the *in situ* condition – for example, the environmental backgound noise level and the signal trajectory.

There are at least two pathways for detecting seismic signals, either through bone-conducted acoustic detection or through somatosensory reception. Mammals that employ bone-conducted seismic detection have enlarged ossicles, the malleus being particularly hypertrophied, which facilitates independent oscillations of the middle ear bones relative to the skull due to inertia. This is true for species such as the blind mole rat as well as the elephant, but nowhere is this more evident than in members of the family Chrysochloridae (golden moles), which have the

largest malleus relative to body size of any animal. Moreover, recent molecular data place the Proboscidia (elephants) and the golden moles in the same clade – the Afrotheria – which also includes the Sirenia (manatees and dugongs), Hyracoidea (hyraxes), Tubulidentata (aardvarks), and Tenrecomorpha (tenrecs and otter shrews).

In elephants, vibrations travel from the substrate through the feet, up the legs and shoulders, and into the middle ear cavity, or in the case of some marine mammals and small rodents, straight through the skull. Another pathway for seismic signals in small terrestrial mammals is directly from the substrate to the skull. This is facilitated, for example, in the golden mole *Eremitalpa* by head-dipping behavior (in which the animal stops its forward motion and inserts its head in the sand) and in the blind mole rat *Nannospalax* by placing the head against the burrow wall; both behaviors appear to improve substrate–skull coupling.

Vibrations of the middle ear ossicles lag behind the skull motion due to the inertia of the hypertrophied ossicles as well as the displacement of the ossicular center of mass from the rotatory axis, resulting in inner ear stimulation. This appears to be the case for *Eremitalpa* and perhaps *Nannospalax*. In the Cape golden mole (*Chrysochloris asiatica*), there is evidence that the axis of rotation of the middle ear ossicles is frequency dependent. Moreover, low-frequency seismic stimuli result in rotation of the ossicles about the short process of the incus (roughly perpendicular to the long axis of the malleus), whereas high-frequency airborne sound causes a rotation about the long axis of the malleus. A middle ear in which the rotatory axis changes with acoustic modality may provide increased seismic acuity without compromising sensitivity to higher-frequency airborne sounds.

In addition to the enlarged ear bones, the dense fat within the foot pad of the elephant may facilitate a bone-conducted pathway and is similar to the 'acoustic fat' found in some marine mammals, particularly in the dolphin melon. This structure functions as an acoustic waveguide for the reception of acoustic communication signals ('jaw hearing'). An analogous structure, the mandibular fat body, may be used for the detection of vibrational signals by bone conduction in blind mole rats. For reception, the mandibular fat body provides a twofold increase in sound intensity by more efficiently coupling acoustic energy from the vibrating burrow to the bone and thus serving as an impedance-matching mechanism. Likewise, the elephant foot pad may perform an impedance-matching function across the air–ground interface for more-efficient seismic signal detection.

The Manatee's cartilaginous, fat-filled jaw lacunae and its skull's aerated sinuses and fatty deposits are thought to play a similar role in coupling sound to the manatee's ear. Analogously, the elephant's fatty deposits and aerated skull sinuses may facilitate low-frequency acoustic and seismic detection.

The circumference of the elephant foot just above the toenails increases by as much as 10% when the foot bears weight. The fatty digital cushion is much larger in the front than in the back foot, which may explain why elephants appear to lean forward on their front feet during periods of seismic detection, orienting their feet directly in line with the ear due to the unique graviportal structure of their forelimbs, thus facilitating efficient transmission of vibrations from foot to ear.

Anuran amphibians have in their inner ears two auditory organs sensitive to airborne stimulation: the amphibian papilla (AP), sensitive to low and middle frequencies, and the basilar papilla, sensitive to high frequencies. In addition, the sacculus responds to low-level vibrational stimuli and high-level airborne sounds. Recordings from single fibers in the eighth nerve of *L. albilabris* in response to controlled seismic stimuli revealed the greatest vibration sensitivity of any vertebrate. AP fibers exhibited clear phase-locking to a 130 Hz vibration with a peak acceleration of $0.002\ \mathrm{cm\,s^{-2}}$. In contrast, using firing rate increase as the threshold criterion, AP thresholds in both northern leopard frogs (*Rana pipiens pipiens*) and white-lipped frogs (*L. albilabris*) reached $0.01\ \mathrm{cm\,s^{-2}}$.

Seismic communication is not known definitively in any reptile, though chameleons probably possess some form of inter- or intraspecific signaling behavior via vegetation-borne vibrations. Crocodilians generate thoracic vibrations causing a showering of water at the surface prior to their high-amplitude, low-frequency vocalizations and appear to be likely candidates for further investigation of substrate-borne signal communication. In addition, dense pressure receptors located on the body and particularly around the snout of crocodilians are sensitive to water surface vibrations and are thought to be important in prey detection. These same receptors might also facilitate the detection of vibrations generated by conspecifics. Snakes are known to detect both airborne and substrate-borne vibrations through their body surface and can respond behaviorally to both airborne and substrate-borne stimuli. There is, however, no evidence of either airborne or substrate-borne acoustic communication in snakes.

One species of semifossorial snake (the Saharan sand viper, *Cerastes cerastes*) uses substrate-borne vibrations to detect its prey. The snake often strikes prey from a completely submerged position in the

loose sand of the Sahara desert. In the laboratory, *C. cerastes* can strike with accuracy even when its olfactory and vomeronasal organs are denervated. Occluding the eyes reduces striking accuracy somewhat, but the animals are still able to capture live mouse prey. Even with chemosensory-neutral, temperature-neutral targets, these snakes strike with a fair degree of accuracy, providing circumstantial evidence for the importance of vibration sensitivity. Sand vipers, with their sinuous bauplan, are suited to a fossorial lifestyle, and it might be expected that other snake species also utilize vibrational cues in prey location, and perhaps in communication as well. Further work is needed to elucidate the mechanism of seismic detection in snakes.

A second pathway for seismic detection that terrestrial species might employ in addition to or instead of bone conduction is somatosensory reception. Pacinian corpuscles, or pressure receptors, the largest cutaneous mechanoreceptors in mammals (0.5 mm in diameter) are deeply placed whereas Meissner's corpuscles, or touch receptors, are superficially located and smaller (40–60 μm in diameter). Pacinian corpuscles in humans respond over a frequency range of 65–400 Hz, with peak sensitivity at approximately 250 Hz, whereas Meissner's corpuscles exhibit best sensitivity between 10 and 65 Hz.

Many small and large mammals are equipped to detect seismic cues via somatosensory reception. One notable example is the star-nosed mole (*Condylura cristata*), with an elaborate snout surrounded by 22 fleshy, mobile appendages covered with thousands of mechanoreceptive Eimer's organs, which act like a 'tactile eye.' Pacinian corpuscles found in the paws and knees of cats, lamellated corpuscles in the legs of kangaroos, and vibrationally sensitive Herbst corpuscles in the legs of birds are all thought to facilitate prey detection and predator avoidance. Both Pacinian and Meissner's corpuscles can also be found around the tip of the Asian elephant trunk and are as sensitive as the lips of a primate.

Enhancing Signal Detection Range

Temporal summation can be responsible for significant auditory threshold reduction; thus repeated signals can facilitate signal detection. Moreover, longer signals can increase the signal-to-noise ratio, improving signal detection as well. Examples of this can be found in animals communicating in both the acoustic and the seismic realms.

Weddell seals (*Leptonychotes weddelli*) repeat calls to enhance signal detection over long distances and during times of high background noise, as do some whales. Killer whales increase call duration in high background noise from boats. It follows, therefore, that species that communicate seismically would also employ similar mechanisms to enhance the propagation and detection of signals in noisy environments or over long distances.

To this end, African elephant family groups vocalize within interactive bouts more often than while calling individually. These bouts create an enhanced signal that is effectively three times longer than one produced by a single individual, serving to increase the signal-to-noise ratio and facilitating signal detection and processing at great distances. Furthermore, during departure from a resource, calling bouts are repeated at a greater rate. Elephants listening at a distance might use multiple bouts of longer signals to adjust their physical position to optimize signal resolution. Observations suggest they do just this by freezing for long periods and shifting positions, aligning themselves in the direction of the acoustic or seismic signal source.

Seismic Frequency Discrimination

Elephants can discriminate very subtle frequency differences in the seismic environment. If the pathway for detecting these signals is via bone conduction to the ear, then the seismic frequency discrimination ability should be correlated with the airborne frequency discrimination ability of this species. The acoustic critical bandwidth for the elephant is calculated at 0.75–0.95 Hz across a range of 15–19 Hz, allowing them to detect very small changes in frequency modulation across their low-frequency vocalizations in both the acoustic and the seismic realms.

If the seismic detection pathway is via vibration-sensitive corpuscles, then elephants should still be able to discriminate fine frequency differences, assuming they are at least as sensitive as primates at this task. The tactile frequency discrimination difference limen of adult owl monkeys, for example, is 2 Hz in the region of 20 Hz, which is similar to that of macaques and humans. Since elephants often lay their trunks on the ground during seismic events, they may make use of vibration-sensitive corpuscles described from the trunk, as well as those in their feet, to distinguish frequency modulation between different calls.

Summary

Seismic stimuli are used to navigate within the environment, enhance localization, and detect predators or prey; for intraspecific communication; and possibly as a cue to initiate migration. For percussive signals, large size is often associated with greater source amplitudes, leading to a greater propagation range. Moreover, the use of low-frequency, high-amplitude signals favors more-efficient coupling of airborne

vocalizations to the substrate and increased propagation range.

White-lipped frogs, kangaroo rats, blind mole rats, Cape mole rats, and golden moles appear particularly adept at generating and detecting seismic signals in the face of high levels of background noise. Moreover, they respond to playbacks of seismic signals by changing their signaling behavior or by moving. The seismic components of the foot-drumming signals of the Cape mole rat (*Georychus*) are capable of propagating in the sandy soil between natural burrows of these solitary rodents with little attenuation, whereas their auditory components attenuate into the background noise within a meter of the source. Thus, seismic signaling is strongly implicated in this species as well.

Elephants appear to use long-distance seismic communication by producing low-frequency, high-amplitude vocalizations that efficiently couple to the substrate, where they propagate over long distances and attenuate slowly. Moreover, they are equipped to detect seismic signals. Since of all extant terrestrial animal species, Asian elephants have the largest volume of cerebral cortex available for cognitive processing, we suggest they are likely well-equipped to integrate multimodal signals.

In theory, if a seismic eavesdropper, such as a lion on the African plain, were able to identify a potential prey item such as an antelope or a zebra by its seismic signature, it could be more selective in its hunting forays for preferred food. Likewise, elephant eavesdroppers might learn of the availability of a resource at great distances, which would facilitate intergroup spacing.

The ability to tap into the seismic environment to discriminate biologically relevant information from background noise and to discriminate subtle frequency differences in signals indicates that vertebrates may be using the ground as a communication channel for obtaining much more subtle cues than previously imagined.

Self-Organizing Maps

R Martin and K Obermayer, Bernstein Center for Computational Neuroscience and Berlin University of Technology, Berlin, Germany

Introduction

Self-organization is found at various levels of the brain, ranging from global areal organization and modularization to regularities in the fine structure of neural layers. Equally variable are explanations for this organization. Genetic regulation, chemical markers, and cell death account for much of the larger-scale specialization of areas, for anatomical differences observed in different regions and layers, and for differential afferentiation.

One ubiquitous property of the brain not fully accounted for by these mechanisms is the organization into topologically ordered maps. Smooth representations of features processed by the brain range from representations of visual space (Figure 1) and orientation in early visual areas to representations of motor output and of semantic content in higher brain areas. Activity-driven self-organization appears to play a major role in their development. The attempt to understand this process has inspired a number of models, one of which is the self-organizing map (SOM; sometimes called the self-organizing feature map).

Based on Hebbian learning and lateral inhibition, the SOM organizes its units into topographically ordered maps. The original SOM provided an abstraction of a class of processes underlying neuronal pattern formation, where units represented local populations of neurons and the algorithm was inspired by, rather than derived from, an underlying neuronal dynamics. However, later models also implemented SOM-like algorithms with units explicitly representing cortical columns, and there are also models which implement the SOM algorithm based on spiking neurons that employ a temporal code. Independent of these neuroscience aspects providing insight into the workings of the brain, the SOM has also developed into an important machine learning method.

History

Biologically plausible candidate principles for activity-driven self-organization of brain areas were identified early on, both in experimental and in theoretical neuroscience: the principle of Hebbian learning and that of lateral inhibition. Early studies combining these principles in neural network models to explain the spatial organization of brain function include the spatially ordered line detectors of von der Malsburg and the neural field model of Amari. In these studies, lateral inhibition resulted in the creation of localized activity blobs, and Hebbian reinforcement led first to the localization of features in the output map and then to a dependence of the projection zone size on frequency of stimulation. Kohonen suggested considering network activity and the synaptic modifications as two separate processes. The lateral inhibition essentially implements a winner-takes-all (WTA) mechanism, which confines activity in response to a stimulus to one subregion; a plasticity-control system restricts Hebbian learning to the winner and its neighborhood. Maps developing according to these principles are referred to as SOMs.

Consider using these rules on a representation of input features (e.g., position and orientation) in a map of model neurons. The WTA principle results in the grouping of input properties because different feature combinations can be assigned to the same unit. On the other hand, Hebbian learning restricted to the region around the winning unit creates a smooth representation. Similar input patterns are represented by nearby units of the map. Thus, the SOM combines two complementary principles of unsupervised learning: clustering and smoothness. Therefore, it is similar to many of the biological maps found in the brain.

Alternative models suggested for development of feature maps include elastic nets, wire length minimization models, and correlation-based learning. These are not reviewed in detail in this article.

Method

Low-Dimensional SOMs

In its simplest form, the algorithm operates on input which already contains an abstract representation of the features to be encoded. The variant that uses a rich high-dimensional input is discussed later.

A system such as the primary visual cortex of cat can be described as a two-dimensional neural sheet. Disregarding cortical depth, which by virtue of columnar organization leaves some response properties invariant, each unit is assigned a vector of response properties, giving the vector field or map $\bar{w}(\bar{r})$, where $\bar{r}$ denotes cortical location and $\bar{w}$ quantifies the response properties of the unit (i.e., the neurons at this location or in this cortical column). Maps are not necessarily restricted to two dimensions in $\bar{r}$. For example, a description of the functional organization of cat lateral geniculate nucleus could be based

Figure 1 The retinotopic projections from the retina onto the visual cortex of macaque monkey. The top shows the image the animal was exposed to and the bottom the activity in visual cortex during exposure revealed by processing deoxyglucose uptake. Scale bars indicate 2° of visual angle (top) and 1 cm (bottom). Reproduced from Tootell RBH, Switkes E, Silverman MS, and Hamilton SL (1988) Functional anatomy of macaque striate cortex: II. Retinotopic organization. *Journal of Neuroscience* 8: 1531–1568. Copyright 1988 by the Society for Neuroscience.

Figure 2 A representation of the network layout of a SOM. (a) A low-dimensional SOM receiving feature vector input coding for position *x* and *y*, orientation specificity *q* and orientation preference φ, and ocular dominance *z*. Connections to just one of the network units $\bar{r}$ are shown as well as the neighborhood function for this unit. (b) A high-dimensional SOM input layer corresponding to the low-dimensional SOM on the left. Two image patches provide information about features (position, orientation, and, possibly, intensity) for each of the two eyes. Topographic representations for such input take longer to arise. The representations can be compared to the corresponding low-dimensional representation through analysis of the connectivity matrix (dominant eigenvectors of left and right eye image determine orientation preference, etc.).

on a three-dimensional map $\bar{w}(\bar{r})$, where visual space varies along two dimensions of $\bar{r}$ and ocular dominance along the third (Figure 2(a)).

The SOM is an iterative algorithm which operates on such a map. Each stimulus is described by a vector $\bar{x}$ of input patterns or features, where the elements of $\bar{x}$ correspond to elements of the vector $\bar{x}$ of response properties. If $\bar{w}(\bar{r})$ describes the localization of receptive fields in visual space, the vector $\bar{x}$ describes the retinotopic location of a stimulus. Given a set of input patterns occurring with probability $P(\bar{x})$, the following algorithm describes self-organized map formation:

- Present stimulus $\bar{x}$ with probability $P(\bar{x})$.
- Determine the location $\bar{r}_0$ in the map with response properties most similar to stimulus $\bar{x}$ (WTA rule). Often, the Euclidean distance is used – that is,

$$\bar{r}_0 = \text{argmin}_{\bar{r}}(\bar{x} - \bar{w}(\bar{r}))^2 \qquad [1]$$

- Change the vectors $\bar{w}(\bar{r})$ of response properties according to

$$\Delta\bar{w}(\bar{r}) = \eta h(\bar{r}, \bar{r}_0)(\bar{x} - \bar{w}(\bar{r})) \qquad [2]$$

where η is the learning step. A common choice for the neighborhood function is

$$h(\bar{r}, \bar{r}_0) = \left(\frac{1}{2\pi\sigma^2}\right)^{d/2} \exp\left(\frac{(\bar{r} - \bar{r}_0)^2}{2\sigma^2}\right) \qquad [3]$$

Both learning step η and width σ of the neighborhood function are normally changed during the iteration of the previous algorithm from initially large to small (for σ) or zero (for η) final values. This annealing procedure helps obtain good convergence in the face of the frequent local minima in the model space.

Convergence Behavior

The neighborhood function ensures that neighboring locations in the map perform similar learning steps, leading to a smooth progression of response properties across the final map. However, the precise functional organization of the resulting map depends on a number of parameters. The overall representation is determined by the probability distribution of input patterns and by the final width of the neighborhood function. The fine spatial structure depends more on

the initial and boundary conditions and on the precise change in η and σ during iterations.

The convergence of the SOM has not been demonstrated in general; however, results have been obtained for specific geometric configurations. If the Euclidean distance $(\bar{x} - \bar{w}(\bar{r}))^2$ in the assignment step (eqn [1]) is replaced by its local average, $\sum_{\bar{r}'} h(\bar{r}, \bar{r}')(\bar{x} - \bar{w}(\bar{r}'))^2$, one can demonstrate that the SOM algorithm exactly minimizes the weighted average squared distance

$$E = \frac{1}{2} \sum_{\bar{x}} \sum_{\bar{r}} h(\bar{r}, \bar{p}(\bar{x}))(\bar{x} - \bar{w}(\bar{r}))^2 \qquad [4]$$

between input patterns and the feature vectors. Here, $\bar{p}(\bar{x})$ is the nearest unit according to the WTA rule. Both the closest unit and its neighbors contribute to the average, but squared distances are weighted by the neighborhood function. Feature vectors converge to the center of mass of the data assigned to their unit as well as to neighboring units, all weighted by the neighborhood function.

In the limit of a zero-range neighborhood function, eqns [1]–[3] are identical to the K-means clustering algorithm, which minimizes the average squared distance between the input data and the feature vectors of the units to which the input data are assigned (vector quantization). Feature vectors converge to the center of mass of their own data cluster. However, in this limit, the organizing power of the algorithm is completely lost.

Other Variants

The algorithm described previously can be referred to as the low-dimensional SOM since it provides an abstract representation of the input in the form of a feature vector with intensities corresponding to the features to be encoded in the map. This requires advance insight into the problem to be modeled. The most suited parameterization is not always obvious; also, different parameterizations of the same problem may lead to different results.

The high-dimensional alternative has an input layer, which provides a rich representation of the features as would be received by the system to be modeled (e.g., images contain a rich representation of local features such as color, orientation, and spatial structure; **Figure 2(b)**). The winning region for particular inputs, as determined by the WTA rule, no longer lends itself to interpretation as easy as that for the low-dimensional variant. However, through an analysis of the connectivity matrix for the winning unit, one can determine which features in the input (e.g., which pixel combinations) are responsible for a high response. Naturally, given the higher dimensionality, the high-dimensional SOM converges more slowly and its convergence depends more critically on the annealing procedure.

The use and interpretation of the parameters can also vary in different SOM applications. In modeling, the learning step η sometimes retains nonzero values to reflect continued plasticity of the network. The remaining competition between the different stimulus classes can result in a reorganization of the map if the input statistics change.

Soft topographic vector quantization contains a probabilistic version of the SOM as a special case. It offers a soft nonlinearity using a temperature hyperparameter with a deterministic annealing scheme to control the convergence and avoid local minima. Thus, σ annealing is not necessary for controlling good convergence, and σ can be used solely to determine the desired neighborhood structure of the map.

Over time, a number of variants of the standard SOM have been developed to reflect different goals. Soundly based on information-theoretic principles yet biologically plausible, van Hulle introduced a self-organized map in which the area representing a part of feature space is proportional to the density of the data in that part of space, thus providing load balancing for local calculations to be carried out on the map. Other variants include a time-adaptive SOM with adaptive learning rates and neighborhood functions for individual neurons, a parameterless SOM that removes the problem of appropriate choice of local neighborhood and learning rate by proving an internal state variable to achieve stable convergence, a batch-learning version of the SOM that improves convergence properties and provides a tool for stochastic approximation, and kernel-based variants of the SOM. Thus, SOMs remain an area of active research, although much of the focus has shifted to the domain of machine learning problems.

Properties

Clustering

As explained previously, grouping is achieved according to similarity because stimuli are assigned to units (clusters) minimizing a distance measure (eqn [1]). Algorithms have been provided to achieve efficient clustering for similarity measures other than the standard Euclidean ones (general topographic proximity mapping).

Clustering behavior is also well documented in feature maps in the brain. Similar input features are clustered in similar regions of the map, and the size of these regions depends on the probability of encountering these features.

Mapping

If the neighborhood function (eqn [3]) has finite range, neighboring units in the map perform similar learning steps according to eqn [2]. Thus, weight vectors of neighboring units converge to similar values, resulting in a smooth or neighborhood-preserving map of input space. In contrast to the clustering property, however, where a quality measure for grouping is directly optimized by the SOM, the mapping property is an implicit result of the neighborhood function (eqn [3]). Measures for smoothness and for the degree of neighborhood preservation have been designed, and it has been shown that the SOM in general improves representations according to these measures, but there is no evidence that an optimum is actually achieved. One of the most surprising features of the SOM is that without actually explicitly minimizing any smoothness measure, such near-optimal maps are nonetheless achieved.

Many of the maps found in different brain model systems are also neighborhood preserving. This may apply on different scales for different features represented in the map, as will become clear in the discussion of dimension reducing mappings.

Topographic Maps

If the dimension of the input data and the dimension of the map are equal, the representation is called a topographic map. Utilizing a formal relationship between clustering methods and mixture models, it can be shown that SOMs tend to generate representations where the number of input data per cluster and the size (variance) of the clusters are constant. If certain classes of stimuli appear more often than others, however, the constraints are incompatible, and the algorithm converges to a compromise solution. Equal size requires the number of units with feature vectors close to the input feature to be proportional to the occurrence probability of this feature; equal variance requires the number of units to be independent of this probability. The compromise is a representation in which the number of units increases sublinearly with occurrence probability.

Many of the maps found in the brain can be called topographic. Most prominently, the maps of visual space in early visual areas are organized retinotopically (**Figure 1**). However, maps in other modalities (e.g., tonotopic and somatotopic maps), maps representing the exterior environment, and maps producing motor output are also topographic. Properties organized in topographical fashion locally (local orientation, spatial frequency, or ocular dominance in V1) are considered later.

Magnification Factors

If the dimensions of input data and map are equal, one can define magnification factors based on volume (the ratio between a certain volume on the map and the volume in input space mapped onto this target region) or length changes (the ratio between distance along one direction in the map and corresponding distance in input space). Magnification factors are larger for regions in data space with a higher input density, and they are influenced by boundary conditions. If there is a mismatch between the shape of the data region in input space and the shape of the map, anisotropic magnification factors emerge or, in extreme cases, there are discontinuities in the mapping.

Magnification factors are also encountered in brain maps. Well-known is the magnification of the fovea in retinotopic V1, where the V1 area representing the fovea is larger than the already high-resolution representations found in retina and lateral geniculate nucleus. This may well be a consequence of the fact that input received via the fovea tends to show higher variability due to eye movements directed to features with more complex local structure. Other examples of magnification factors are found in the representation of the body surface. Areas which receive much distinct input (fingers, lips, and genitals) or input with high behavioral relevance (the index finger of brail readers) have larger representations in somatosensory cortex. Similarly, in the natural environment, more frequent vertical and horizontal orientations are represented by a larger number of neurons in V1 than other orientations, and the frequency range used by bats for navigation has an enlarged representation in the tonotopic map of bat auditory cortex.

Dimension Reducing Mappings

If the dimension of the input data is larger than that of the map, the representation is dimension reducing; its structure depends on the variance of the data distribution in input space. For example, when mapping two-dimensional input data with one highly variable and one not so variable dimension onto a one-dimensional map, the small variance dimension is discarded and only the large one will be represented. This automatic selection of feature dimensions generalizes to higher dimensions and to curved data manifolds. The suppression of the less prominent dimensions occurs up to a critical level of variance. Above this value, a hierarchical representation emerges, in which the direction of largest variance determines the coarse structure of the map and less variable directions in input space are represented on a smaller scale. The critical value increases with increasing range of the neighborhood function.

As long as the neighborhood function has a finite range, dimension reducing maps are also smooth in the sense that response properties of neighboring neurons are similar. However, there is a trade-off between the rates of change along different input dimensions. Generally, if one response property changes rapidly, the other response property changes slowly.

The emergence of such hierarchical representations of multiple stimulus feature dimensions is best illustrated with the well-studied feature maps of primary visual cortex as found in cat and macaque. Superimposed on the retinotopic presentation of visual space, orientation of local stimuli is represented around pinwheel centers; ocular dominance and possibly also spatial frequency selectivity are represented in stripes along the cortical surface, and color information is represented mostly in the cytochrome oxidase blobs (Figure 3a). Of these features, orientation represents a noteworthy special case because its representation around pinwheels also demonstrates a topological defect: The cyclical property orientation is mapped onto a flat surface, resulting in the creation of a singularity at the pinwheel center.

Coverage and Continuity

It has been proposed that cortical maps in the brain are often organized according to the principles of coverage and continuity. Coverage requires all combinations of response properties to occur. For example, in macaque V1, there should be groups of cells responsive to stimuli for every combination (or small intervals) of spatial location, orientation, ocularity, and spatial frequency. If this requirement is not met, 'perceptual holes' emerge and cortex is less responsive to one sort of localized stimuli than to others. Continuity requires response properties to vary smoothly along most of the cortical surface and discontinuities to be rare.

The SOM model generates maps according to these principles, even though measures of coverage and continuity are not optimized directly. Coverage is achieved because of the clustering property. Continuity emerges from the fact that neighboring units in the map perform similar learning steps and, therefore, converge to similar feature vectors.

Analysis of optical recording data from visual cortical maps has shown that coverage and continuity are indeed better for the experimentally observed arrangements of response properties than for random superpositions of visual feature maps.

Applications

The previous section highlighted many formal similarities between properties of SOMs and maps found in brains. Modeling studies of SOMs actually go beyond this and produce explicit parallels between maps generated in computational models and maps encountered in various *in vivo* model systems.

Visual Feature Maps

The vertebrate visual system is arguably the system in which SOMs have had the greatest impact. Early qualitative studies of self-organization in this system as pioneered by von der Malsburg were taken to a new level through optical recoding. The maps that optical recording unveils and the richness in visual features represented in the areas of visual cortex have

Figure 3 Orientation and ocular dominance in visual cortex. Color and brightness code for orientation tuning and strength; superimposed white lines show the borders of ocular dominance stripes. (a) Experimental results from adult macaque. (b) Stationary result of a SOM simulation. (c) Spatial structure of the topographic projection. Reproduced with permission from Obermayer K, Blasdel GG, and Schulten K (1992) Statistical–mechanical analysis of self-organization and pattern formation during the development of visual maps. *Physical Review A* 45: 7568–7589. Copyright 1992 by the American Physical Society.

allowed the demonstration of quantitative matches between the maps observed *in vivo* and those generated in model studies. Obermayer and co-workers first applied Kohonen's principle of self-organization to primary visual cortex and demonstrated that it can account for co-development of retinotopic organization and orientation columns (Figure 3).

Subsequent successes include the extension of this to other feature maps, such as ocular dominance and spatial frequency selectivity. Indeed, SOMs account for the interaction between the different feature maps: The higher density of pinwheel formations in the center of ocular dominance columns and the linear change of orientation preference along the border of the ocular dominance slabs could be attributed to the development of hierarchical representations of the different features represented in the map combined with the tendency of the SOM to keep the variance within the clusters constant. In fact, Sur and co-workers demonstrated that *in vivo*, high-gradient changes of different features in maps tend to occur perpendicular to one another, as SOM models predict, and that *in vivo* reorganization of visual cortex following the removal of one of the input features is also well described by an SOM.

Detailed analysis of the conditions under which ocular dominance and orientation selectivity in retinotopic maps develop shows that for stable emergence of the columnar structure, the neighborhood function (*in vivo*, the lateral connectivity) needs to be below a critical value. The fact that lateral interaction cannot be completely absent, however, was demonstrated by Piepenbrock and co-workers. They provided a generalized framework of soft competition with varying degrees of interaction for the development of topographic maps. It contains SOMs as well as correlation-based learning as limit cases and establishes that at least for Gaussian-shaped input patterns, the model must have a certain degree of lateral interactions (and, thus, SOM-like makeup) in order to develop topographic receptive fields. Interestingly, there was a sharp phase transition to maps without topographic structure when lateral interaction was decreased too much.

Boundary Conditions

Further applications indicating similarities in the development of local structure in SOMs and brain areas derive from simulations using elongated target maps. The simulations predict that, in this case, island-like representations will appear, thus violating the overall topography of the map while maintaining a locally topographic representation. These results are in agreement with experimental data indicating that visual areas with elongated shape (as found in owl monkey, cat, and mouse) will display an island-like structure (Figure 4).

Experimental observations of feature map development in visual cortex also allow the assessment of the influence of initial conditions on map formation. Wolf and co-workers analytically studied map formation for general self-organized map models. Assuming translational, rotational, and orientation shift invariance of the orientation maps found in V1, they demonstrated that early during development, maps have a certain minimum pinwheel density. Experimental data for pinwheel densities show that in some species (e.g., cat, squirrel monkey, and tree shrew), this initial orientation map structure undergoes a process of further refinement, during which a number of pinwheels are annihilated by merging with nearby pinwheels with opposite chirality, thus decreasing pinwheel density. Maps with strong ocular dominance structure, however, are more resistant to such map reorganization, consequently showing a larger density of pinwheels (e.g., macaque).

The co-development of lateralized feature map representations has also been shown to be compatible with activity-dependent synaptic changes. Provided that a crude initial mirror symmetric map is present and that the distribution of the sensory afferents is sufficiently divergent, mirror symmetric maps as frequently observed in adjacent topographic maps can develop.

Plasticity

Both the structure of maps observed in the brain and also the changes these maps undergo depending on their input resemble those of maps created using SOMs. The representation in the map encodes the most variable directions in the manifold of feature space and is thus adjusted to the statistics of the stimuli the system has to analyze; a change in these statistics results in reorganization of model maps to a new equilibrium. Similar behavior can be observed in maps *in vivo* when altering the input to certain brain areas. Kittens with eyes sewn shut do not develop ocular dominance and orientation columns in primary visual cortex, whereas rearing kittens with just one eye shut results in the absence of corresponding ocular dominance stripes and rearing them in an environment containing only horizontal or vertical structures will result in an impairment of their ability to see other orientations.

These effects tend to be most pronounced or even restricted to a critical period in the early life of the animal, typically a few weeks. Kittens without visual input for a sufficiently long period will remain blind, despite normally organized eyes and lateral geniculate nucleus. However, there is also evidence for a certain degree of reorganizing capacity remaining

Figure 4 Islands in retinotopic representations. (a) Retinotopic organization of cat area 18. The figures in the middle and on the right show how the visual field on the left is mapped onto area 18 for two different individuals. Both show a discontinuity in the representation of the horizontal meridian at the outer boundary of area 18 and the one on the right shows an island representation of a part of the periphery in the lower visual field. (b) Result of self-organization simulation showing two islands and one field discontinuity. Reproduced from Wolf F, Bauer H-U, and Geisel T (1994) Formation of field discontinuities and islands in visual cortical maps. *Biological Cybernetics* 70: 525–531. Copyright 1994 Springer-Verlag Berlin-Heidelberg. With kind permission of Springer Science and Business Media.

beyond the critical period. Lesions that remove a section of visual input lead to changes in the network structure; loss of limbs results in a reorganization of somatosensory cortex, where the area representing the lost limb is taken over by nearby areas. Replacing lost or damaged afferent fibers from the sensory periphery to primary auditory cortex with electrical stimulation can result in a reorganization of mature brains that allows them to make use of this representation of the sensory environment.

A possible anatomical correlate of plasticity changes throughout development is the development of lateral

connections. It coincides with the development of orientation and ocular dominance columns in the early visual areas. Moreover, lateral connections are initially uniformly distributed, but long-range connections become patchy during development as a result of neural activity. These longer range lateral connections preferentially connect neurons encoding similar properties (e.g., orientation preference) and are thought to be important for functionality such as perceptual grouping. The short-range lateral connections, however, remain approximately uniformly distributed, irrespective of a neuron's position in the orientation map. This is similar to a decrease in the neighborhood parameter, which improves convergence of SOMs and assists the formation of hierarchical representations of multiple dimensions in one map.

Semantic Maps

Whereas sensory feature maps can be studied *in vivo* with relative ease, cortical representations of higher faculties such as language are not as readily accessible. However, the pervasiveness of the columnar design throughout neocortex suggests that the SOM principle may also be relevant for other faculties.

The SOM has been applied to phonemes of different languages. Providing a representation of the phoneme's waveform as input patterns, a map emerges that represents the phonemes grouped according to their similarity in sound.

Modeling studies of more abstract representations such as semantic meaning are only suggestive in character. However, they do demonstrate that topologically correct map representations can also be found for these abstract features. For instance, words can be organized into a map representing their semantic relatedness from semantic feature vectors describing their meaning or even providing only the context in which they occur as input (Figure 5). Further examples can also be found in the many nonneuroscience applications that employ SOMs for organizing complex data in an intuitive way, as exemplified by the WEBSOM application for text mining.

An argument supporting such topological organization of these more abstract concepts *in vivo* derives from the degradation pattern observed in human patients after strokes or brain lesions, where failures in the use of specific concepts or categories have been observed.

Functional Considerations

Besides the indications that SOM principles may aid the self-organization of the brain, one can also consider functional advantages they offer over other approaches. However, this area is still an open topic.

Figure 5 Semantic map. (Left) The word list is used to generate simple three-word sentences (noun–verb–adverb, such as 1–5–12, 1–8–2, or 2–10–3). Sentences which make sense and have the correct structure are produced at random and concatenated to generate a text. Words in the text are encoded as random high-dimensional vectors of unit length and are presented, together with their predecessors and successors, as sensory input for a SOM. (Right) Representation of the words on the network layer. Words are grouped according to their grammatical categories as well as their meaning. Adapted from Obermayer K (1995) Mathematical theories of neural development. *B.I.F. FUTURA* 10(2): 72–87.

It has been argued that coverage and continuity are desirable features for map representations since they ensure a gap-free representation of the feature space. Indeed, feature maps found in the brain appear to at least locally maximize coverage and continuity.

Furthermore, studies have suggested that SOM-like models minimize wiring length for local calculations. In general, one can argue that SOMs provide a trade-off: on the one hand, they reduce the communications overhead through clustering and near-optimal wiring; on the other hand, they also provide a certain load balancing through adjustment of the representation to the input distribution (but, unlike equiprobabilistic topographic maps, also to input variance). However, it is difficult to define the optimum for this trade-off.

Finally, the cost function (eqn [4]) also provides a clue to the advantages of the SOM algorithm. The squared error term ensures the map representation is effective for signals affected by Gaussian noise.

Discussion

The overwhelming body of evidence for activity-driven plastic reorganization of cortex leaves no doubt that self-organization of the network is important for its overall structure. In this context, the SOM has been a very useful model of the result of this self-organization and, to some extent, of the process

generating this result. The extent to which map structure is determined through self-organization, however, is still debated. In particular, the formation of topographic mappings between different areas remains contended. Kohonen argued that such maps tend to signal co-occurring events (e.g., the orientation occurring in neighboring image positions) and provide no overall 'winner,' as required by the SOM algorithm. The soft competition approach can defuse these arguments somewhat: the restricted range of the neighborhood function effectively limits the number of winner foci locally. Point-to-point maps can thus form from restricted activity (like retinal waves) early during development, when the neighborhood function may still be large. The lateral interaction becomes more localized later in order to restrict the range of competition. However, evidence suggests that this discussion may be futile since the point-to-point-like maps may be determined chemically to a larger extent than previously thought, thus requiring only the local ordering power provided by the traditional SOM.

A trend in the study of map formation is a greater emphasis on the importance of lateral connectivity, which at greater distances is patchier. Miikkulainen and co-workers argued that the applicability of the general SOM principles can be broadened if the lateral (longer range) connectivity is also modified according to Hebbian rules. They extensively explored how this class of models (LISSOM) can account in detail for a range of phenomena observed in visual cortex.

However, to what extent should the connectivity between different areas be predetermined using genetic tools? This is an example of the bias–variance dilemma: predetermination of map structure effectively introduces a bias into the representation a subsequent SOM process will build. It has the advantage that the feature representation can be learned from fewer examples and is thus more quickly available. However, a bias that is too strong will result in inferior feature representations if the bias does not reflect stimulus statistics. Thus, in order to empower feature representations to be efficient in a wide variety of environments, the bias needs to be kept sufficiently low and the training period sufficiently long. Based on this, one could argue that the unusual and, in comparison to other animals, seemingly excessive length of the maturation period in humans reflects our extraordinary capacity for adjusting to different (sensory and otherwise) environments.

It must be cautioned that although the simple nature of the SOM combined with its proven explanatory power for relatively simple feature map models is intriguing, it should not be regarded as the universal key to understanding the brain. First, for some features there may not actually be a need to achieve selectivity through some organizational principle since even haphazard wiring with some basic order in connectivity may suffice to explain the observed distribution of selectivities. Second, a simplistic view such as considering the brain as something akin to a stack of hierarchically organized SOMs which represent increasingly complex features disregards much of the highly complex pattern of interareal connectivity. Finally, examining the detailed mechanisms of how self-organization in the brain occurs demonstrates that mechanisms such as spike time-dependent synaptic plasticity add further complexity to the picture. Thus, SOMs in their simplicity will not be able to cover all behavior of the brain.

In summary, the SOM provides major insights into the organizational principles used in the brain. Particularly noteworthy is the fact that such a simple principle can quantitatively account for experimental results in so much detail. It remains an active area of research that has yet to achieve all its potential.

Semantic Memory

A Martin, National Institute of Mental Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

'Semantic memory' refers to a major division of long-term memory that includes knowledge of facts, events, ideas, and concepts. As such, it covers a vast terrain, ranging from information about historical and scientific facts, details of public events, and mathematical equations to the information that allows us to identify objects and understand the meaning of words. Semantic memory can be distinguished from episodic/autobiographical memory by an absence of temporal and spatial details about the context of learning. In relation to episodic memory, semantic memory is considered to be both a phylogenically and an ontologically older system. Although many animals, especially mammals and birds, acquire information about the world, they are assumed to lack the neural machinery to consciously recollect detailed episodes of their past. Finally, although retrieval of semantic memory often requires explicit, conscious mediation, the organization of semantic memory can also be revealed via implicit tasks such as semantic priming.

Semantic Memory and the Medial Temporal Lobe Memory System

Studies of patients with amnesia due to damage to the medial temporal lobes have established three broadly agreed on facts about the functional neuroanatomy of semantic memory. First, like episodic memory, acquisition of semantic memories is dependent on medial temporal lobe structures, including the hippocampal region (CA fields, dentate gyrus, and subiculum) and surrounding neocortex (parahippocampal, entorhinal, and perirhinal cortices). Damage to these structures results in deficient acquisition of new facts and public events and the extent of this deficit is roughly equivalent to the deficit for acquiring personal information about day-to-day occurrences. However, despite broad agreement that acquiring semantic memories requires medial temporal lobe structures, there is disagreement concerning the role of the hippocampal region. One position, championed by Larry Squire and colleagues, holds that the hippocampus is necessary for acquiring semantic information. In contrast, others have argued that acquisition of semantic memories can be accomplished by the surrounding neocortical structures alone; participation of the hippocampus is not necessary. Recent studies have favored the hippocampal position by showing that carefully selected patients with damage limited to the hippocampus are impaired in learning semantic information, and that the impairment is equivalent to their episodic memory deficit. One potentially important caveat to this claim comes from studies of individuals who have sustained damage to the hippocampus at birth or during early childhood. These cases of developmental amnesia have disproportionately better semantic than episodic memories, suggesting that the hippocampal region may not be necessary for acquiring semantic information. Reconciliation of this issue will depend on direct comparison of adult onset and developmental amnesias with regard to extent of medial temporal lobe damage and its behavioral consequences.

The second major finding established by studies of amnesic patients is that the medial temporal lobe structures have a time-limited role in the retrieval of semantic memories. Retrieval of information about public events shows a temporally graded pattern with increasing accuracy for events further in time from the onset of the amnesia. Conceptual information about the meaning of objects and words acquired many years prior to the amnesia onset remains intact as assessed by both explicit and implicit tasks. Third, semantic memories of all types are stored in the cerebral cortex. In amnesic patients, impairments in semantic memory for information acquired prior to amnesia onset are directly related to the extent of damage to cortex outside the medial temporal lobes.

Cortical Lesions and the Breakdown of Semantic Memory

Studies of semantic memory in amnesia have concentrated largely on measures of public event knowledge. The reason for this is that these tasks allow memory performance to be assessed for events known to have occurred either prior to, or after, amnesia onset. These measures also allow performance to be evaluated for events that occurred at different times prior to amnesia onset to determine if the memory impairment shows a temporal gradient – a critical issue for evaluating theories of memory consolidation. Because these patients have either no or, more commonly, limited damage to regions outside the medial temporal lobes, they are not informative about how semantic information is organized in the cerebral cortex. To address this issue, investigators have turned to patients with relatively focal lesions compromising

different cortical areas. In contrast to the studies of amnesic patients, these studies have focused predominantly on measures designed to probe knowledge of object concepts.

Object Concepts

An object concept refers to the representation (i.e., information stored in memory) of an object category (a class of objects in the external world). Concepts are central to all aspects of cognition; they are the glue that holds cognition together. The primary function of a concept is to allow us to quickly draw inferences about an object's properties. That is, identifying an object as, for example, a 'hammer' means that we know that this is an object used to pound nails, so that we do not have to rediscover this property each time the object is encountered. Object concepts are hierarchically organized, with the broadest knowledge represented at the superordinate level, more specific knowledge at an intermediary level referred to as the 'basic level,' and the most specific information at the subordinate level. For example, 'dog' is a basic-level category that belongs to the superordinate categories 'animals' and 'living things,' and has subordinate categories such as 'poodle' and 'collie.' As established by Eleanor Rosch and others in the 1970s and 1980s, the basic level has a privileged status. It is the level used nearly exclusively to name objects (e.g., 'dog' rather than 'poodle'). It is also the level at which we are fastest to verify category membership (i.e., we are faster to verify that a picture is a 'dog' rather than an 'animal' or a 'poodle'). It is also the level at which subordinate category members share the most properties (e.g., collies and poodles have similar shapes and patterns of movement). Finally, the basic level is the easiest level at which to form a mental image (you can easily imagine an elephant but not an 'animal'). Studies of patients with cortical damage have documented the neurobiological reality of this hierarchical scheme and the central role of the basic level for representing objects in the human brain.

Semantic Dementia and the General Disorders of Semantic Memory

Several neurological conditions can result in a relatively global or general disorder of conceptual knowledge. These disorders are considered general in the sense that they cut across multiple category boundaries; they are not category specific. Many of these patients suffer from a progressive neurological disorder of unknown etiology referred to as semantic dementia (SD). General disorders of semantic memory are also prominent in patients with Alzheimer's disease (who, compared to SD patients, typically have a greater episodic memory impairment), and can also occur following left hemisphere stroke, prominently involving the left temporal lobe. The defining characteristics of this disorder, initially described by Elizabeth Warrington and colleagues in the mid-1970s, are deficits on measures designed to probe knowledge of objects and their associated properties. These deficits include impaired object naming (with errors typically consisting of semantic errors – retrieving the name of another basic-level object from the same category, or retrieval of a superordinate category name), impaired generation of the names of objects within a superordinate category, and an inability to retrieve information about object properties – including sensory-based information (shape, color) and functional information (motor-based properties related to the object's customary use, but this may include other kinds of information not directly related to sensory or motor properties). The impairment is not limited to stimuli presented in a single modality, like vision, but rather extends to all tasks probing object knowledge regardless of stimulus presentation modality (visual, auditory, tactile) or format (words, pictures). The semantic deficit is hierarchical in the sense that broad levels of knowledge are often preserved, while specific information is impaired. Thus, these patients can sort objects into superordinate categories, having, for example, no difficulty indicating which are animals, which are tools, which are foods, and the like. The difficulty is manifest as a problem distinguishing among the basic-level objects as revealed by impaired performance on measures of naming and object property knowledge.

Recent studies have expanded our understanding of SD in two important ways: one is related to location of neuropathology, the other to functional characteristics of the disorder. The initial neuropathological and imaging studies of SD indicated prominent atrophy of the temporal lobes, especially to the anterolateral sector of the left temporal lobe, including the temporal polar cortex inferior and middle temporal gyri, and the most anterior extent of the fusiform gyrus. However, recent advances in neuroimaging that allow for direct and detailed comparison of brain morphology in SD patients relative to healthy controls have shown that the atrophy extends more posteriorally along the temporal lobe than previously appreciated. In fact, the amount of atrophy in ventral occipitotemporal cortex, including the posterior portion of the fusiform gyrus, has been reported to be as strongly related to the semantic impairment in SD as is atrophy in the most anterior regions of the temporal lobes.

The other major advance in our understanding of SD is that it is not as global a conceptual disorder as

initially thought. Rather, certain domains of knowledge may be preserved, and the pattern of impaired and preserved knowledge appears to be related to the locus of pathology. Specifically, left-sided atrophy seems to impair information about all object categories except person-specific knowledge (i.e., information about famous people), which, in turn, is associated with involvement of the right anterior temporal lobes. Also relatively spared is knowledge of number and mathematical concepts, and information about motor actions needed to use familiar tools. Both of these knowledge domains are associated with left posterior parietal cortex.

Category-Specific Disorders of Semantic Memory

Although reports of cases of relatively circumscribed knowledge disorders date back over 100 years, the modern era of the study of category-specific disorders began in the early 1980s with the seminal reports of Warrington and colleagues. Category-specific disorders have the same functional characteristics as does SD, except that the impairment is largely limited to members of a single superordinate object category. For example, a patient with a category-specific disorder for 'animals' will have greater difficulty naming and retrieving information about members of this superordinate category relative to members of other superordinate categories (e.g., tools, furniture, flowers). Similar to patients with SD, patients with category-specific disorders have difficulty distinguishing among basic-level objects (e.g., between dog, cat, horse), thereby suggesting a loss or degradation of information that uniquely distinguishes among members of the superordinate category (e.g., four-legged animals).

Although a variety of different types of category-specific disorders have been reported (e.g., for fruits and vegetables), most common have been reports of patients with relatively greater knowledge deficits for animate entities (especially animals) than for a variety of inanimate object categories. While less common, other patients show the opposite dissociation of a greater impairment for inanimate manmade objects (including common tools) than for animals and other living things.

Models of category-specific disorders Two major theoretical positions have been advanced to explain these disorders. Following the explanation posited by Warrington for her initial cases, most current investigators assume that category-specific deficits are a direct consequence of an object property-based organization of conceptual knowledge, an idea that was prominent in the writings of Karl Wernicke, Sigmund Freud, and other behavioral neurologists during the late nineteenth and early twentieth centuries. The central idea is that object knowledge is organized in the brain by sensory (e.g., form, motion, color, smell, taste) and motor properties associated with the object's use, and in some models, by other functional/verbally mediated properties, such as where an object is typically found. In this view, category-specific semantic disorders occur when a lesion disrupts information about a particular property or set of properties critical for defining, and for distinguishing among, category members. Thus damage to regions that store information about object form, and form-related properties like color and texture, will produce a disorder for animals. This is because visual appearance is assumed to be a critical property for defining animals, and because the distinction between different animals is assumed to be heavily dependent on knowing about subtle differences in their visual forms. A critical prediction of sensory/motor-based models is that the lesion should affect knowledge of all object categories with this characteristic, not only animals. In a similar fashion, damage to regions that store information about how an object is used should produce a category-specific disorder for tools, and all other categories of objects defined by how they are manipulated.

The alternative to these property-based theories is the domain-specific view championed most recently by Alfonso Caramazza and colleagues. On this account, our evolutionary history provides the major constraint on the organization of conceptual knowledge in the brain. Specifically, the theory proposes that selection pressures have resulted in dedicated neural machinery for solving, quickly and efficiently, computationally complex survival problems. Likely candidate domains offered are animals, conspecifics, plant life, and possibly tools. Property-based and category-based accounts are not mutually exclusive. For example, it is certainly possible that concepts are organized by domains of knowledge, implemented in the brain by large-scale property-based systems. Much of the functional neuroimaging evidence (to be discussed later) is consistent with this view.

Functional neuroanatomy of category-specific disorders There is considerable variability in the location of lesions associated with category-specific disorders for animate and inanimate entities. Nevertheless, some general tendencies can be observed. In particular, category-specific knowledge disorders for animals are disproportionately associated with damage to the temporal lobes. The most common etiology is herpes

simplex encephalitis, a viral condition with a predilection for attacking anteromedial and inferior (ventral) temporal cortices. Category-specific knowledge disorders for animals also have been reported following focal, ischemic lesions to the more posterior regions of ventral temporal cortex, including the fusiform gyrus. In contrast, category-specific knowledge disorders for tools and other manmade objects have been most commonly associated with focal damage to lateral frontal and parietal cortices of the left hemisphere. However, it is important to stress that the lesions in patients presenting with category-specific knowledge disorders are often large and show considerable variability in their location from one patient to another. As a result, these cases have been relatively uninformative for questions concerning the organization of object memories in cerebral cortex. In contrast, recent functional neuroimaging studies of the intact human brain have begun to shed some light on this thorny issue.

Organization of Conceptual Knowledge: Neuroimaging Evidence

The functional neuroanatomy of semantic memory has been explored using a wide variety of experimental approaches and paradigms. The overarching goal of these studies has been to identify brain regions that show a heightened response during a conceptual or semantic processing task (e.g., is the object a living thing?) versus performing a nonsemantic, but equally difficult, task (e.g., does the object's name contain the letter 'p'?) with the same set of stimuli. Assigning a particular brain region a role in semantic processing is further strengthened when the activity is associated with semantic task performance, regardless of physical differences in the stimuli used to denote the objects (i.e., visual or auditory, pictures or words). As a result, activity in these brain regions can be linked to conceptual processes and not features of stimulus input modality or format.

Studies based on this type of approach have consistently isolated two regions, the left ventrolateral prefrontal cortex (VLPFC) and the ventral and lateral regions of the temporal lobes (typically stronger in the left than in the right hemisphere). Detailed evaluations of left VLPFC have shown that this region is critically involved in the top-down control of semantic memory. Specifically, left VLPFC is responsible for guiding retrieval and postretrieval selection of conceptual information stored in posterior temporal and perhaps other cortical regions. This neuroimaging finding is consistent with studies of patients with left inferior frontal lesions that have word-retrieval difficulties, but retain concept knowledge of the words they have difficulty retrieving. In contrast, a large body of evidence has linked activity in posterior regions of the temporal lobes to memory representations, especially concerning conceptual representations of specific properties associated with concrete objects.

Object Knowledge Is Organized by Sensory and Motor-Based Properties

One source of evidence concerning the organization of object property information comes from property production tasks. In these tasks, individuals are presented with an object, denoted either by a picture or the object's name, and are required to generate a word denoting a specific property associated with that object. Several studies have shown that generating an action associate (e.g., saying 'pull' in response to a child's wagon) elicits heightened activity in premotor cortex as well as in a posterior region of the left lateral temporal cortex, centered on the middle temporal gyrus (pMTG) just anterior to primary visual motion-sensitive cortex. In contrast, relative to action word generation, color word generation (e.g., saying 'red' for the child's wagon) activates the fusiform gyrus, anterior to regions associated with passive perception of color. Subsequent studies have shown that tasks requiring finer perceptual discrimination of colors, or perceiving more complex patterns of object motion, elicit activity in the same temporal lobe regions active when color or action knowledge is retrieved. The findings from these and similar studies suggest two important points. First, that information about different types of object-associated properties (e.g., color, action) is represented in different anatomical regions. Second, these regions directly overlap with sites that mediate perception of these object properties. A number of studies have replicated these two basic points using property verification tasks requiring subjects to answer yes/no questions about the relation between a particular object and property. These studies have linked retrieval of information about visual, auditory, and tactile properties to regions associated with processing within each of these sensory modalities. Similarly, retrieval of object use-associated information has been linked to motor regions active when objects are actually manipulated. These studies suggest that the same neural systems are involved, at least in part, in perceiving, acting on, and knowing about specific object properties.

Neural Networks for Animate Entities and Tools

A large number of studies have addressed questions concerning how information about different object

categories is represented in the brain. Many of these studies were motivated by the neuropsychological evidence for category-specific disorders discussed in the preceding sections. As a result, these studies have concentrated on the neural systems for perceiving and knowing about two broad domains: animate agents (living things that move on their own), and tools (manmade objects with a close association between their function and motor movements associated with their use). These studies have provided evidence for four major points about the organization of conceptual knowledge. First, information about a specific object category is not represented in a single cortical region, but rather is represented by a network of discrete regions that may be widely distributed throughout the brain. Second, the informational contents of these regions are related to specific properties associated with the object. Third, some of these property-based regions are automatically active when objects are identified, thus suggesting that object perception is associated with the automatic retrieval of a limited set of associated properties that may be necessary and sufficient to identify that object. These properties prominently include information about what the object looks like, how it moves, and, for a tool, its use. Fourth, this object property-based information is stored in sensory and motor systems active when that information was acquired.

Conceptual representations of animate entities have been most strongly linked to two regions of temporal lobe cortex, the lateral region of the fusiform gyrus, located on the ventral surface of the temporal lobe (including the fusiform face area; FFA), and the posterior region of the superior temporal sulcus (pSTS), located on the lateral surface of the temporal lobe (Figure 1). Activation of these regions is typically stronger in the right, rather than in the left, hemisphere. In contrast, conceptual representations of tools have been linked to four regions. Included in this network are the medial portion of the fusiform gyrus, pMTG (as discussed previously in relation to generating action words), and posterior parietal and ventral premotor cortices. Activity in these regions is typically stronger in the left, rather than in the right, hemisphere (Figure 1).

Activity in these networks transcends stimulus features, thus strengthening the claim that these regions are involved in conceptual processing. For example, category-related activity in the lateral region of the fusiform gyrus has been shown not only in response to pictures of people and animals, but also to the written and heard names of animals, human voices, animal-associated sounds (like the moo of a cow), and when simply imagining faces. In addition, category-related activity in the lateral fusiform gyrus has been found in response to degraded and abstract visual

Figure 1 Schematic illustration of location of regions showing category-related activity for animate entities (red) and tools (blue). (a) Ventral view of the right hemisphere, showing relative location of regions assumed to represent visual form and form-related properties such as color and texture of animate entities (1, lateral region of the fusiform gyrus, including, but not limited to the fusiform face area) and tools (2, medial region of the fusiform gyrus). (b) Lateral view of the left hemisphere, showing relative location of regions assumed to represent biological motion (3, posterior region of the superior temporal sulcus) and rigid motion vectors typical of tools (4, posterior region of the middle temporal gyrus). Also shown are the relative locations of the posterior parietal (5, typically centered on the intraparietal sulcus) and ventral premotor (6) regions of the left hemisphere assumed to represent information about the motor movements associated with using tools.

stimuli such as humanlike stick figures, point light displays interpreted as human figures in motion, degraded pictures of objects when misinterpreted as faces, and when simple geometric shapes in motion are interpreted as depicting social interactions. Similarly, category-related activity in the more medial region of the fusiform gyrus has been shown not only in response to pictures of tools, but also to the written and heard names of tools and to tool-associated sounds (like the banging of a hammer). In addition, category-related activity in the medial fusiform gyrus has been observed in response to degraded and abstract visual stimuli such as point light displays interpreted as depicting tools in motion, and when simple geometric shapes in motion are interpreted as depicting mechanical interactions. Taken together, these findings indicate that the critical determinant of differential activity in these regions is the conceptual interpretation assigned to a stimulus (e.g., as a person, animal, or tool), not the physical characteristics of the stimulus, *per se*.

Linking Category-Related Representations to Sensory and Motor Properties

Neuroimaging studies also have provided evidence about the functional role of regions showing category-related activity. The two regions in the posterior region of the temporal lobe that show a stronger response to animate rather than inanimate objects – the lateral region of the fusiform gyrus and pSTS – have been linked to representing the visual form and the flexible, fully articulated, patterns of motion associated with animate objects, respectively. These findings are consistent with a large body of neurophysiological data from studies of monkeys showing that neurons in inferior temporal cortex and STS are differentially tuned to visual form and biological motion, respectively. In contrast, the two regions in the posterior region of the human temporal lobe that show a stronger response to tools than to animate objects – the medial region of the fusiform gyrus and pMTG – have been linked to representing the visual form and rigid, unarticulated patterns of motion typically associated with manipulable man-made objects.

Other studies have provided evidence linking the representation of tools to two regions of the dorsal action-processing stream – the left posterior parietal cortex and left ventral premotor cortex. These findings are consistent with data from monkey neurophysiology showing that neurons in ventral premotor and parietal cortices respond both when monkeys grasp objects and when they see objects that they have had experience manipulating. Along with pMTG, functional brain imaging studies in humans have shown that these dorsal regions are active when individuals retrieve information about the functional properties of objects, suggesting that information about how objects are used is stored in these regions. Support for this claim comes from recent neuropsychological investigations linking impaired knowledge of tools and their associated actions to damage to either left pMTG, posterior parietal, or premotor cortices.

Finally, recent studies have shown that the category-related, property-based neural systems discussed here are not only active when objects are encoded into memory, but also that this activity is reinstated prior to recalling that information at a later time. These findings underscore the central role that these systems play in memory encoding, storage, and retrieval.

Semaphorins

J Verhaagen, Netherlands Institute for Neuroscience, Amsterdam, The Netherlands

© 2009 Elsevier Ltd. All rights reserved.

In the nineteenth century, a 'semaphore line' was a signaling system composed of rods or flags that was widely used in the maritime world to navigate ships, in rail transportation, and to direct movements of army battalions. In the early 1990s, a family of proteins was discovered that functions as signals involved in growth cone guidance and navigation. The term 'semaphore' was adopted to refer to this family of proteins as semaphorins. The first semaphorin, fasciclin IV, was identified in the grasshopper and was later renamed semaphorin-1a. The first vertebrate semaphorin was originally designated collapsin-1, a name referring to its collapsing effect on growth cones of chick sensory ganglia. Collapsin-1 was later renamed semaphorin 3A. In 1999, the Semaphorin Nomenclature Committee published a unified nomenclature for the semaphorins/collapsins based on structural features and phylogenetic tree analysis. To date, more then 25 semaphorin genes have been identified that encode both membrane-associated and secreted molecules subdivided into eight classes. Most semaphorins contain approximately 750 amino acids and share a conserved 'sema' domain of approximately 500-amino-acid residues (Figure 1). This article reviews the current knowledge on how semaphorins function in neuronal network formation during development. In addition, it discusses progress in understanding the role of semaphorins during adulthood in synaptic transmission and plasticity, in neural trauma, and in certain neurological and psychiatric diseases. The article does not touch upon the role these proteins play in organogenesis, vascularization, the immune system, and cancer.

The Concept of Chemorepulsion

Approximately 20 years ago, it was recognized that developing axons bend away from or can be inhibited by (at that time) hypothetical molecular cues they encounter on their path of growth. The first molecules shown to be able to mediate such effects were subsequently identified in genetic or antibody perturbation screens or by combining biochemical purification with well-defined bioassays as read-out systems for chemorepulsive activity (Figure 2). To date, five families of cellular guidance molecules that can function as chemorepulsive proteins are known, including (in order of their discovery) netrins, ephrins, semaphorins, slits, and repulsive guidance molecule (RGM). Interestingly, some members of these protein families also influence axon guidance decisions by functioning as neurite attractants. A large body of work has shown that the ability of growth cones to respond to chemorepulsive proteins is critical for the formation of stereotypical neural pathways and maps. Chemorepulsion is therefore an essential element of the total arsenal of coordinated morphogenetic processes that shape the brain's circuitry.

In the mid-1980s, observations on the differential substrate properties of peripheral and central nervous system (CNS) tissue led to the hypothesis that central nervous system myelin contains inhibitory factors for regenerating nerve fibers. Myelin-associated proteins, including Nogo, myelin-associated glycoprotein (MAG), and oligodendrocyte myelin glycoprotein (OMgp), were subsequently identified as inhibitors of regenerative neurite outgrowth in the CNS. Thus, around 1985 two independent lines of thinking led to the notion that the inhibitory or repulsive regulation of neurite outgrowth during development and the inhibition of regenerative neurite outgrowth are regulated by distinct molecular entities. Recently, however, developmental chemorepulsive guidance cues, including semaphorins, ephrins, and RGMs, have also been linked to regenerative failure. Therefore, the concept of chemorepulsion appears to have implications for our understanding of the molecular mechanisms that underlie the failure of damaged nerve tracts to regenerate as well.

Semaphorins Signal through Multimeric Receptor Complexes

To detect semaphorins in the extracellular space, growth cones at the leading tip of extending axons express specialized receptor complexes. A unifying feature of the neuronal semaphorin receptor complexes identified to date is the presence of a member of the plexin family within each complex (Figure 1). The founding member of this homogeneous family of transmembrane proteins, plexinA1 (plexin), was found in a screen for antigens involved in axon guidance in the developing tadpole retinotectal system. Since the identification of plexinA1, ten more plexins have been discovered (two plexins can be found in invertebrates and nine in vertebrates) and categorized into four subclasses on the basis of sequence similarities (Figures 1(a)–1(d)). Like semaphorins, extracellular sema domains are characteristic of plexins and it

Figure 1 Semaphorins and their neuronal receptors. The semaphorin family is subdivided into eight classes. Classes 1 and 2 contain semaphorins found in invertebrate species, classes 3–7 vertebrate semaphorins, and class V viral semaphorins. Semaphorins exist as secreted (classes 2, 3, and V) and membrane-associated molecules (classes 1 and 4–7). All neuronal semaphorin receptors identified to date contain a member of the plexin family. Semaphorins can either bind directly to plexins (a; classes 1, 2, 4, V, and Sema3E) or require neuropilins as ligand binding subunits (b; class 3 semaphorins). β_1 subunit-containing integrins also serve as receptors for class 7 semaphorins in a plexin-independent fashion (c). Modulatory receptor subunits such as L1 and Off-track have also been identified.

is believed that an intramolecular interaction between the plexin sema domain and the rest of the plexin extracellular domain inhibits receptor activity in the absence of semaphorin ligand. The plexin intracellular region shares homology with the GAP domain of p120 RasGAP and is highly conserved between plexins. Dominant-negative forms of plexins lacking their cytoplasmic region fail to mediate semaphorin-mediated repulsion which shows that plexins function as signal-transducing receptor subunits.

Although most semaphorins exert their functions by directly interacting with plexins, class 3 semaphorins (Sema3s), except for Sema3E, fail to bind any of the known plexin family members. Instead, Sema3s require neuropilins as essential semaphorin-binding coreceptors to signal through class A plexins (plexinAs) (Figure 1). Neuropilins are transmembrane proteins with short intracellular domains that lack intrinsic enzymatic activity and that are indispensable for Sema3 function. The initial identification of neuropilin-1 (A5, neuropilin (Npn)) in the *Xenopus laevis* nervous system using hybridoma techniques was followed by the characterization of the only other neuropilin, neuropilin-2, in rodents. Cell culture studies suggest that all four plexinAs (plexinA1–A4) can form receptor complexes with both neuropilins. The specific responses of different classes of neurons to individual Sema3s can be explained in part by restricted and unique 'neuropilin' distribution patterns and by the preferential binding of individual Sema3s to Npn-1 and/or Npn-2. PlexinAs also contribute to the specificity of axonal responses to Sema3s. A large body of work supports the idea that *in vivo* Npn-1/plexinA4 complexes act as principal Sema3A receptors, whereas Npn-2/plexinA3 complexes mediate responses to Sema3F. The Npn/plexinA complexes that mediate the *in vivo* responses of other Sema3s remain to be identified. In addition to Sema3s, neuropilins serve as (co)receptors for structurally unrelated ligands such as VEGFs and PDGFs.

Although less well-characterized, semaphorin receptor (components) unrelated to plexins and neuropilins do exist in neurons: (1) off-track, a protein similar to receptor tyrosine kinases but with a catalytically inactive kinase domain, associates with the *Drosophila* PlexA receptor to mediate semaphorin repulsion; (2) cell adhesion molecules of the immunoglobulin superfamily, including L1 and NrCAM, play a role in

Figure 2 *In vitro* assays for studying the effects of chemorepellents on growth cone behavior and axon steering. (a) In the growth cone collapse assay, dissociated neurons are grown and a putative chemorepulsive protein is added to the tissue culture medium to assess whether it can cause growth cone collapse. (b) Similarly, in the growth cone steering assay, dissociated neurons are grown but now the chemorepulsive protein is supplied in a small gradient by a micropipette. Chemorepulsive proteins will cause the growth cone to steer away from the gradient. (c) In the repulsion assay, a neuronal explant is cultured next to an aggregate of nonneuronal cells that secretes control or chemorepulsive proteins in a collagen gel. The chemorepulsive gradient that emerges from the aggregate will cause the axons to grow away from the aggregate. (d) Whereas the first three assays (a–c) are normally used to study secreted chemorepellents, the stripe assay is used to study membrane-associated proteins. Alternating stripes of protein or cell membranes are generated and explants are grown on top. If the axons can choose between lanes of control and chemorepulsive proteins, they will grow preferentially on control lanes.

the responsiveness of axons to Sema3A and are thought to be part of the neuropilin–plexinA receptor complex; and (3) β_1 subunit-containing integrins act as Sema7A receptors, or components thereof (Figure 1). Whether nonneuronal semaphorin receptors such as CD72 or Tim2 identified in the immune and other organ systems also function in neuronal semaphorin signaling remains to be determined.

Intracellular Signaling

On activation by semaphorins, plexins induce a series of intracellular signaling events that regulate the (dis) assembly of the neuronal cytoskeleton to control growth cone morphology and motility. The signaling mechanisms that are utilized by repulsive Sema3s have been studied in most detail and are summarized here. One of the first cytosolic proteins shown to link Sema3 receptor complexes to the neuronal cytoskeleton is collapsin response mediator protein (CRMP)-2, a member of a small family of membrane-associated phosphoproteins. Five different CRMPs have been identified, which in addition to plexinAs bind a plethora of other intracellular proteins, including kinases and cytoskeleton-associated proteins. Interestingly, sequential phosphorylation of CRMPs by different kinases is essential for Sema3-induced growth cone collapse as well as for semaphorin-independent functions of CRMPs during axonogenesis. In addition to CRMPs, members of the Rho family of monomeric GTPases play a prominent role in repulsive Sema3 signaling. RhoGTPases are critical regulators of cytoskeletal dynamics. Both RhoGTPases and the proteins that regulate their activity (i.e., GEFs and GAPs) associate with the plexin cytoplasmic region. In addition, the plexin cytoplasmic domain contains a RasGAP domain which in the case of plexinAs and plexinBs acts to inactivate R-Ras. This is considered as one of several signaling events by which plexins slow down integrin signaling to reduce growth cone adhesion and allow for changes in growth cone morphology. Cytoplasmic kinases also play a prominent role in Sema3s repulsion. After the initial observation of tyrosine phosphorylation of plexins in culture, several cytoplasmic kinases have been implicated in Sema3-mediated growth cone collapse and steering (e.g., Fyn, Cdk5, and GSK-3). However, their functional roles have not been fully explored. This also

holds true for cyclic nucleotide signaling. cGMP and cAMP have strong modulatory effects on growth cone turning responses induced by semaphorins. However, our understanding of how cyclic nucleotide levels are regulated under physiological conditions by semaphorins is still rudimentary. In addition to the four classes of signaling molecules discussed previously (CRMPs, RhoGTPases, kinases, and cyclic nucleotides), an ever increasing number of intracellular proteins and signaling mechanisms are implicated in semaphorin function. For example, recent findings support roles for redox reactions, novel protein synthesis, and microdomain signaling in axon responses induced by semaphorins. In addition, a high degree of cross-talk between semaphorin and unrelated signaling cascades (e.g., those mediating integrin or neurotrophic factor functions) exists that integrates different cellular processes during neuronal network formation. Furthermore, signaling cascades downstream of semaphorins other than Sema3s are being unveiled at a rapid pace, revealing both shared and unique signaling mechanisms between different classes of semaphorins. This, together with evidence that different classes of plexins may interact and the possibility for reverse signaling (i.e., plexin acting as a ligand and semaphorins as receptors), indicates that we are just beginning to understand the complexity of the semaphorin signaling network.

Semaphorin Function during Neurodevelopment

Loss-of-function studies in mice and invertebrate species such as *Drosophila* and *Caenorhabditis elegans* have provided compelling insights into the role of semaphorins during development. Several general themes have emerged. First, deletion of semaphorin or semaphorin receptor genes often results in severe defasciculation of peripheral nerves. Second, the effects on CNS development are usually more subtle. For example, errors in CNS axon guidance as a result of semaphorin or semaphorin receptor deletion in mice are most pronounced in the olfactory system, hippocampus, anterior commissure, and thalamocortical projections. Third, many of the null mutant mouse lines display severe abnormalities in the development of nonneural tissues, particularly the cardiovascular system. This may be an important reason for the perinatal death of many of these mutants. Fourth, the phenotypes of a ligand mutant and its corresponding receptor mutant are usually very similar. For instance, the phenotype of Sema3A and Npn-1 knockouts and of Sema3F and Npn-2 are remarkably similar. This indicates that these two secreted semaphorins indeed signal through Npn-1 and Npn-2, respectively, *in vivo*. Knockouts for plexinA3 and plexinA4 also display phenotypes that suggest that these plexins function as receptor components for Sema3F and Sema3A, respectively. Similarly, the neural phenotypes observed in fruit flies lacking Sema-1a resemble those of PlexA-deficient flies. Studies on genetically modified mice have also revealed additional novel functions for semaphorins in the developing nervous system, including their involvement in pruning of axons, synapse development and maturation, and the migration of neural crest and cerebellar granual cells.

Semaphorins in the Adult Intact Nervous System

The expression of several secreted and transmembrane semaphorins persists in the adult nervous system. This intriguing observation indicates that these guidance molecules also have functions in the fully wired adult brain. Unlike their role in neural development, research on a function for semaphorins in the adult nervous system is only just beginning.

So far, biochemical and cell culture studies have shown that several class 4 semaphorins are localized at synapses and associate with PDZ domains in postsynaptic density protein-95 (PSD-95), suggesting a role in as yet unknown aspects of synaptic functioning. Two Sema3s, Sema3F and Sema3A, have been studied in the context of synaptic transmission. Sema3F modulates synaptic transmission in acute slices of the adult rat hippocampus and Sema3A application to fully differentiated cultured hippocampal neurons decreases the efficacy of synaptic transmission. The expression of some secreted and membrane-associated semaphorins is sensitive to electrical activity, as has been shown in temporal lobe epilepsy and kainate acid-induced status epilepticus. Downregulation of Sema3s in the entorhinal–hippocampal complex of epileptic rats has been associated with pathological mossy fiber sprouting into the molecular layer of the hippocampus. Sema3A induces clustering of PSD-95 and NP-1 at synaptic sites in cultured neurons. In the cortex of adult Sema3A knockout mice, spine density appears to be reduced.

Semaphorins and Neurodegenerative and Psychiatric Disorders

Traumatic Injury

Regenerating axons stop growing when they reach the border of the glial–fibrotic scar because they encounter a potent molecular barrier that inhibits growth cone motility. Semaphorins have been implicated as factors

that contribute to the failure of axon regeneration. Theories on semaphorin function in traumatic nervous system injury are based on the cellular context in which semaphorins, their receptors, and intracellular signaling molecules are (re)expressed after damage. Four possible functions have been postulated. First, semaphorins may act in concert with the classical myelin-associated inhibitors of regeneration: multiple membrane-associated semaphorins are expressed by oligodendrocytes and Sema4D is upregulated in oligodendrocytes located in the vicinity of CNS lesions. Second, Sema3s are expressed by fibroblasts in the neural scar and may act as repulsive signals for injured axons approaching the scar. Evidence has shown that semaphorins can bind to chondroitin sulfate proteoglycans; these molecules are prominent components of the extracellular matrix of the neural scar and influence the activity of axonal guidance cues such as semaphorins. Third, neovascularization of the scar may be affected by semaphorins: blood vessels in the scar express Npn-1 and are surrounded by meningeal fibroblasts that secrete Sema3s. Sema3s may also directly influence the formation of the scar by affecting the migration of cells in the scar. Finally, in the peripheral nervous system semaphorins are regulated following injury in motor neurons, in epineural fibroblasts, and in a subpopulation of terminal Schwann cells at neuromuscular junctions where they may be involved in limiting plasticity of motor axons. The first causal evidence for an inhibitory role of Sema3s in axon regeneration comes from a study in which application of a Sema3A-blocking agent isolated from *Penicillum* resulted in enhanced regeneration. Additional evidence for a role of Sema3A in injury-associated changes in neurite outgrowth comes from observations on viral vector-mediated expression of Sema3A in the spinal cord following a dorsal root lesion. Enhanced ectopic Sema3A expression counteracts the nerve growth factor-induced sprouting response of injured sensory neurons, thereby preventing neuropathic pain.

Neurodegenerative Disorders: Alzheimer's and Parkinson's Disease

Alzheimer's and Parkinson's disease have in common the fact that specific populations of neurons and synaptic contacts atrophy and are then gradually lost. Alterations in neuronal connectivity in the mature nervous system appear to depend on a delicate balance between growth-promoting and growth-inhibiting influences. When this balance is disturbed, neurons may lose synaptic contacts and could eventually degenerate. It has been postulated that Sema3A may be involved in the pathogenesis of Alzheimer's disease. The expression and distribution of Sema3A are altered in the subiculum and hippocampus during the early stages of Alzheimer's disease. As described previously, Sema3A can stimulate Cdk-5 and GSK-3beta, which can lead to (hyper)phosphorylation of CRMP-2 and microtubule-associated protein-1B (MAP1B). During the clinical stages of Alzheimer's disease, a protein complex is formed in neurons that are affected by the disease consisting of Sema3A, plexinA1, plexinA2, and hyperphosphorylated CRMP-2 and MAP1B. It is not known whether Sema3A contributes directly or indirectly to the pathogenesis of Alzheimer's disease, but it is important to note that Sema3A can act as an apoptotic factor and as an axon retraction inducer during development. Both processes are part of the neuropathological repertoire in Alzheimer's disease. The possible involvement of Sema3A in dopamine-induced oxidative stress (one possible mechanism responsible for dopaminergic (DA) neuron death in Parkinson's disease) is so far only based on *in vitro* evidence. Application of Sema3A to E14 murine ventral mesencephalic neurons induces apoptosis of DA neurons. Antibodies that block Sema3A function can protect neurons from DA-induced apoptosis.

Neurodevelopmental Disorder: Schizophrenia

Two observations have linked possible changes in semaphorin signaling to schizophrenia. First, the expression of Sema3A is increased in the cerebellum of schizophrenic patients and elevated expression of Sema3A correlates with a decline in expression of synaptophysin and reelin, proteins involved in synapse formation and synaptic transmission. Second, variants of plexinA2 have been associated with schizophrenia in a genomewide association study. These findings are in line with an early developmental origin of this psychiatric disorder and may point to a disturbed balance between trophic and chemorepulsive influences in this disease.

Neuromuscular Disease: Amyotrophic Lateral Sclerosis

In amyotrophic lateral sclerosis (ALS), selective synaptic weakening and denervation of muscle fibers starts long before the actual motor neuron degeneration occurs and takes place prior to the clinical manifestation of the disease. Furthermore, fast-fatiguable muscle fibers are selectively denervated during the earliest phases of the disease. The chemorepellent Sema3A is selectively upregulated in terminal Schwann cell that occupy the neuromuscular junctions of fast-fatiguable muscle fibers in a mouse model of ALS. This observation has led to the hypothesis that Sema3A may act as a motor axon retraction inducer at the neuromuscular synapse in ALS, thereby contributing to the neuropathology of ALS. Alternatively,

elevated levels of Sema3A at the neuromuscular junction may affect retrograde signaling in motor neurons, a process that is disturbed in ALS.

Future Challenges

The current literature underscores that a more rigorous dissection of the function(s) of semaphorins in the adult intact and dysfunctional nervous system is essential. The hypotheses that predict a role for these chemorepulsive proteins in the normal physiology and plasticity of the adult brain and in neuropathological processes are predominantly based on descriptive findings. Many of the null mutant mice that have been so useful to study the role of semaphorins during development die soon after birth. Mouse mutants that do survive into adulthood may not be good models to study semaphorin function during adulthood because compensatory changes may mask functionally relevant phenotypes. Therefore, mice with conditional and cell type-specific semaphorin or semaphorin receptor gene ablation or transgenic animals with targeted and conditional overexpression will have to be generated to study the role of semaphorins in adult neurons. Furthermore, other experimental strategies (genetic modification based on direct viral vector-mediated expression in adult rodent brain and pharmacological intervention) will be instrumental to advance our knowledge of the role of semaphorins in the normal intact adult nervous system and under neuropathological conditions.

During the past century, our view of the nervous system as a fixed and immutable structure has changed radically. Most neuroscientists will agree that the nervous system is a highly plastic organ in which the structure and function of connections and synapses are continually modified. Like the formation of neuronal connections during development, the ongoing plasticity in the mature nervous system is regulated by a myriad of molecular interactions. It will be fascinating to witness how future neurobiological research will define the precise function(s) of semaphorins in plasticity of the mature nervous system. Moreover, whether or not the chemorepulsive activity of these molecules contributes to the limited capacity of the nervous system to repair itself after damage is another pivotal issue that will be resolved in the future.

Sensation from the Face

B J Sessle, University of Toronto, Toronto, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

Orofacial Touch, Thermal, Pain, and Related Sensations

The face and mouth have special biological, emotional, and psychological meaning. Humans, for example, use the orofacial region for ingestion of foods and liquids vital for life and for communicating with others by verbal and emotional expressions; furthermore, facial appearance is very important for most humans, and dysfunction or pain in the face and mouth can severely affect quality of life. In addition, some tissues in the face and mouth are unique in the body (e.g., teeth, cornea), and a wide range of sensory functions occurs in the orofacial region. While this article is limited to the somatosensory functions of touch, warmth, cool, and pain, it should be noted that the special senses of taste and smell are unique to this region, and sensory information from the mouth provides us with information about the texture, hardness, brittleness, and viscosity of foodstuffs.

As a consequence of the dense and diverse innervation of the face and mouth, the orofacial perceptions of tactile, thermal, and nociceptive events are unsurpassed in detail. With the exception of sensitivity to high-frequency mechanical stimuli, the tactile sensitivity of some orofacial tissues is as high, or higher, than any other region of the body. The same applies to the thermal sensations of cool and warmth as well as to pain sensibility. Nerve signals from the orofacial region provide us with sensory information on the temperature of some foodstuffs or liquids that we consume, and thereby not only add to our enjoyment of what we eat and drink but also help protect us from ingesting food or fluids that are too hot or too cold. Furthermore, the face and mouth represent sites of some of the most common pains in the body. Although pain arising from orofacial tissues shares many features in common with the pain originating in other body regions, there are several pain conditions that are unique to this region, for example, toothache, trigeminal neuralgia, various types of headaches, and temporomandibular disorders (TMD).

The following sections provide an overview of the neural mechanisms underlying these somatosensory functions. Peripheral processes are considered first, and then attention is given to the mechanisms in the central nervous system (CNS) that underlie these functions.

Peripheral Mechanisms

Like peripheral tissues elsewhere in the body, those in the orofacial region are supplied by primary afferent nerve fibers that terminate in sense organs (receptors) that respond to peripheral stimulation of the tissues; nearly all these fibers are carried in the trigeminal (V) nerve, the fifth cranial nerve. Most of the small-diameter, slowly conducting primary afferents terminate as nonspecialized free nerve endings which are activated by noxious stimuli, and so function as nociceptors, although some terminate in endings sensitive to cooling or warming stimuli and some may respond to nonnoxious mechanical stimuli. The larger-diameter, faster-conducting primary afferents end as specialized low-threshold receptors (e.g., Ruffini-like; Pacinian-like) that respond to nonnoxious mechanical stimuli or movements. In most muscles, some of these large-diameter afferents are associated with muscle spindles and Golgi tendon organs that respond, as in comparable tissues in other parts of the body, to muscle stretch and contractile tension respectively. Nearly all the afferents that supply these specialized and nonspecialized receptors are less than 10 μm in diameter, and have conduction velocities in the A–β, A–δ, and C-fiber ranges. However, not all the properties of the peripheral components of the V sensory system are equivalent to analogous components of the spinal system. There are some notable differences, and unique features, as outlined in Table 1.

Mechanoreceptors

The orofacial region has a dense and diverse supply of mechanoreceptors that provide the CNS with sensory input that is used for fine tactile detection and discrimination and for the regulation of the many behaviors that characterize orofacial function. The mechanoreceptors in the facial skin and oral mucosa may also be activated during lip and jaw movements associated with chewing, swallowing, speech, etc., and so may also provide proprioceptive information of importance to the control of orofacial motor functions. Like those in other parts of the body, facial and intraoral mechanoreceptors include slowly adapting type I and type II receptors, rapidly adapting type I receptors, and hair follicle receptors. Mechanoreceptors also occur in the periodontal tissues that surround the root of the teeth. These periodontal mechanoreceptors can accurately encode information about which teeth are loaded and the intensity, velocity, or direction of forces applied to one or more teeth. Their input to the CNS is crucial for the detection and

Table 1 Trigeminal sensory systems: differences from spinal sensory systems

Peripheral tissues and innervation
1. Tissues unique to the craniofacial region (e.g., tooth pulp; cornea)
2. Higher innervation density in many craniofacial tissues than in most spinally innervated tissues
3. Shorter conduction distances of peripheral nerve pathways
4. Slower conduction velocities of peripheral nerve fibers
5. Higher ratio of myelinated: unmyelinated fibers
6. Lower proportion of sympathetic efferents
7. Certain craniofacial receptors (e.g., some periodontal mechanoreceptors; jaw muscle spindles) have their primary afferent cell bodies within CNS
Central nervous system
1. Face and mouth represented completely at most rostrocaudal levels of VBSNC, and a dual representation of some tissues occurs in Vc
2. Distinctive brain stem termination patterns of some nociceptive afferents
3. Transitional regions between Vc and Vi, and between Vc and CDH, with distinctive properties (e.g., bilateral afferent inputs to Vc/Vi)
4. 'Deep bundle' fiber system especially prominent in Vc (connects caudal and rostral levels of VBSNC), whereas Lissauer's tract absent
5. Significant ipsilateral as well as contralateral projections from VBSNC to thalamus
Pain conditions specific to craniofacial region
1. Headaches (e.g., migraine; cluster headache)
2. Toothaches (e.g., pulpitis pain)
3. Trigeminal neuralgia
4. Miscellaneous (e.g., atypical facial pain; burning mouth syndrome; atypical odontalgia)

VBSNC: Trigeminal brain stem sensory nuclear complex; CDH: upper cervical dorsal horn; Vc: subnucleus caudalis; Vi: subnucleus interpolaris.

Reproduced from Sessle BJ (2005) Orofacial pain. In: Merskey H, Loeser JD, and Dubner R (eds.) *The Paths of Pain 1975–2005*, pp. 131–150. Seattle: IASP Press, with permission from IASP Press.

discrimation of occlusal forces applied to the teeth, and are also used in the fine motor control of masticatory function associated with the intraoral manipulation of foodstuffs.

The temporomandibular joint (TMJ) is also supplied by low-threshold nonnociceptive afferents with either slowly adapting or rapidly adapting responses to joint movement or to a change in jaw position. These responses have been implicated in both mandibular movement and position sense (kinesthesia). Nonetheless, other nonarticular primary afferents may show activity during jaw movements; these include not only skin and intraoral afferents as noted above, but also afferents supplying the muscle spindles that occur in some masticatory muscles. By their movement-related activity, these nonarticular afferents may thereby contribute to kinesthetic sense and motor control. The contribution of joint receptors, relative to muscular and cutaneous receptors, to joint position sense has been the subject of considerable investigation and debate in both humans and experimental animals, and it is currently thought that their role is quite limited and only becomes significant at extreme joint positions.

Thermoreceptors

As for sensations evoked in other parts of the body, thermal sensations in the face and mouth are subserved by thermoreceptors that respond specifically to cold or warm stimulation. The nasal mucosa and anterior tongue are especially sensitive to small changes in temperature, and the exquisite sensitivity of cold or warm thermoreceptors in these regions have been well documented. These warm and cold thermoreceptors respond to the resting temperatures of the tissues as well as to changes in temperature and so underlie the human capacity to distinguish between thermal stimuli at very low to very high temperatures. Some slowly adapting mechanoreceptors may also respond to cooling stimuli, but their role in cold sensation seems to be minor.

Nociceptors

Like nociceptors elsewhere in the body, those in the orofacial region are associated with a diverse population of mechanical, thermal, and chemically responsive A–δ and C-fiber afferents that detect and encode intense physical, thermal, and chemical events associated with actual or near-tissue damage. As in other parts of the body, tissue damage or inflammation can produce an increased excitability of the nociceptors at the site of an orofacial injury. The increased excitability of the nociceptors (so-called peripheral sensitization) can be reflected in their spontaneous activity, lowered activation thresholds, and increased responsiveness to subsequent noxious stimuli which appear to contribute, respectively, to the spontaneous pain, allodynia (pain produced by a

stimulus that is normally nonnoxious), and hyperalgesia (increased sensitivity to noxious stimuli) that are features of many chronic or persistent orofacial pain conditions.

The properties of those nociceptive afferents supplying facial skin or oral mucosa appear to be generally much the same as those of spinal nociceptive afferents, and include high-threshold mechanosensitive afferents (that are mostly A–δ), mechanothermal nociceptive afferents (also A–δ), and A–δ or C-polymodal nociceptive afferents excited by intense mechanical, thermal, or chemical stimuli. The cornea is a unique tissue found only in the orofacial region and is supplied by A–δ and C-fibers that respond to a wide range of mechanical, thermal, and chemical stimuli. Despite their low activation thresholds, their input to the CNS can evoke pain. The masticatory muscles and TMJ also are supplied by A–δ and C-fiber afferents that may respond to a wide range of peripheral stimuli, including heavy pressure and algesic chemicals. Small-diameter afferents also supply the cerebrovasculature and dura. Many of these afferents can be activated by noxious stimuli, but their modulation by peripheral chemical mediators (e.g., serotonin (5-HT), calatonin gene-related peptide (CGRP)) appears to be important in the initiation and control of certain types of headaches (e.g., migraine).

The tooth pulp of course is a tissue unique to the orofacial region, and its nerve supply warrants some particular emphasis. It is richly innervated by A–δ and C-fiber afferents, but it also receives some A-beta afferents and sympathetic efferents. The A–β, A–δ afferents are sensitive to a wide range of dental stimuli that produce pain in humans. Since A–β afferents are not normally nociceptive elsewhere in the body, it is unclear if these intradental afferents represent a notable exception or, rather, that their sensitivity has been altered by the experimental procedures required for the recording of their activity. Recent electrophysiological recording studies have suggested that many A-fibers terminate in the tubules within dentine and are responsible for the sensitivity of dentine, probably through a hydrodynamic mechanism, whereas C-fibers predominate in the pulp and may be activated only if the dental stimulus reaches the pulp. Injury or inflammation of the pulp can lead to neurochemical changes and nerve-sprouting as well as induce peripheral sensitization of intradental afferents. Since inflammation of the pulp occurs in a noncompliant environment (it is encased by dentine) with a high extracellular tissue pressure, these features may account for the exquisite sensitivity of pulp afferents and explain why toothache is such an intense pain.

Neurochemical Features

In vivo and *in vitro* recordings and molecular and immunocytochemical approaches have shown that the V primary afferent cell bodies in the V ganglion (see below) synthesize the vast array of chemicals that help define the role that the primary afferent neurons play in orofacial sensation. These include CGRP, substance P, somatostatin, and nerve growth factor, and the afferents may express several different types of receptors or ion channels (e.g., cholinergic, purinergic, bradykinin, histamine, anandamide, prostaglandin, transient receptor potential vanilloid receptor (TRPV1)). Each may be involved in the activation, sensitization, or modulation of orofacial afferent inputs into the CNS. In addition, receptors also exist for chemical mediators long thought to be involved in nociceptive transmission or modulation within the CNS, for example, glutamate, opiate, and γ-aminobityric acid (GABA) receptors, and sex differences occur in the peripheral actions of glutamate and morphine suggesting that peripherally based physiological mechanisms may contribute to the sex differences documented in the prevalence of many chronic pain conditions.

Central Trigeminal Processes

Brain Stem Nociceptive and Nonnociceptive Transmission

In the spinal somatosensory system, all spinal afferents supplying deep as well as superficial tissues have their primary afferent cell bodies in the dorsal root ganglia. In the V system, nearly all the primary afferents supplying orofacial tissues have their peripheral cell bodies in the V (Gasserian or semilunar) ganglion. The central projections of these primary afferent cell bodies enter the brain stem and may ascend or descend in the V spinal tract from which they give off collaterals that terminate in one or more subdivisions of the V brain stem sensory nuclear complex (VBSNC). Notable differences from the spinal system are that muscle spindles occur only in some muscles (e.g., jaw-closing musculature) and that their afferents, and some mechanosensitive afferents supplying periodontal tissues, have their primary afferent cell bodies within the CNS, in the V mesencephalic nucleus. From here they project to the V motor nucleus, or to adjacent nuclei where they excite interneurons involved in orofacial reflex function. In addition to its predominant input from V nerve afferents, the VBSNC (especially its subnucleus caudalis) may also receive afferent inputs from other cranial nerves (e.g., VII, IX, X, and XII) as well as from upper cervical nerves.

The VBSNC consists of the main sensory nucleus and the spinal tract nucleus, and the latter is subdivided into three subnuclei: oralis, interpolaris, and caudalis. Subnucleus caudalis is a laminated structure with many morphological and functional similarities with the spinal dorsal horn (although see below) to the extent that caudalis is now often termed the medullary dorsal horn. The structure of the other three components of the VBSNC is more uniform, although subdivisions of each can be distinguished in some species. Each component contains neurons, glia, and numerous nerve fibers that are the collaterals of the incoming primary afferents, as well as fibers intrinsic to the VBSNC (e.g., the 'deep bundles') and fibers derived from other brain stem or central neural structures that contribute to the substrate for modulatory influences on VBSNC neurons (see below). The V spinal tract lateral to each nucleus or subnucleus is composed largely of nerve fibers, but islands of neuronal elements are present in or adjacent to the tract lateral to subnuclei caudalis and interpolaris (the so-called paratrigeminal nucleus or interstitial islands).

The low-threshold mechanosensitive primary afferents terminate mainly in the more rostral components of the VBSNC and in laminae III–VI of subnucleus caudalis. Subnucleus caudalis also receives thermosensitive afferent inputs. Some cutaneous nociceptive afferents and dental pulp afferents terminate in some of the rostral components but most of the small-diameter V nociceptive afferents terminate in laminae I, II, V, and VI of caudalis. Some of the small-diameter afferents stain positive for CGRP, substance P, and neurotrophins, whereas others stain negative for the neuropeptides but positive for the cell surface marker, isolectin B4. It is noteworthy that these IB4 afferents have a different distribution in caudalis compared with the spinal dorsal horn.

Many neurons in the four components of the VBSNC project to CNS regions involved in somatosensory function or modulation, such as ventrobasal thalamus, hypothalamus, pontine parabrachial area, periaqueductal gray, or brain stem reticular formation. Some of the connections to the reticular formation and other parts of the brain stem are utilized in autonomic reflex responses to orofacial stimuli. Some neurons in the VBSNC and adjacent to it (e.g., supratrigeminal nucleus and reticular formation) also serve as interneurons in orofacial and cervical muscle reflex pathways, and there are also intrinsic connections between neurons in the different components of the VBSNC. One example is the caudalis axonal projections via the deep bundles to subnucleus oralis that underlie modulatory influences between rostral and caudal VBSNC neurons. The lamina II of caudalis, the so-called substantia gelatinosa (SG), also represents an important interneuronal system contributing to segmental and descending modulation of somatosensory transmission in subnucleus caudalis and more rostral components of the VBSNC (see below).

The VBSNC is somatotopically organized: the neurons receiving ophthalmic afferent input occur in the ventral part and those with mandibular afferent input are located in the dorsal part of each nucleus or subnucleus. The maxillary region is represented in between, and oral and perioral structures are represented medially. This medially facing, inverted somatotopic pattern of the face and mouth may shift in subnucleus caudalis to an 'onion-skin'-like arrangement, with perioral regions represented in the rostral part of the subnucleus and more lateral regions of the face more caudally. Investigations specifically of the somatotopic pattern of the vibrissae (facial whiskers) in the rodent VBSNC have revealed that the brain stem projections of single vibrissal afferents are organized into columns or cylinders that run rostrocaudally and are somatotopically parcellated in the transverse plane in the main sensory nucleus and in subnuclei interpolaris and caudalis; however, subnucleus oralis does not have such a clear-cut spatial patterning. This patterning, so-called barreletes, reflects the pattern of vibrissae on the ipsilateral face, and the vibrissal afferents and most low-threshold mechanoreceptive (LTM) neurons associated with each barrelete are optimally responsive to tactile stimulation of a single vibrissa.

Structure–function relationships have been well-documented in the spinal cord and dorsal column nuclei but are usually less clear-cut and often variable between types of afferents in the four different components of VBSNC. Nonetheless, investigations combining anatomical intra-axonal labeling with electrophysiological identification of the functional properties of labeled single primary afferents have shown that the spatial distribution of an afferent's collateral endings is influenced by the location in the orofacial region of the afferent's mechanoreceptive field (RF), thus accounting for the somatotopic pattern mentioned above. As for the V primary afferent endings, the morphological and physiological features of neurons in the VBSNC reveal also some fundamental differences between V and spinal systems in the extent of structure–function correlations, for example, correlations have been shown to be a strong feature for vibrissa-sensitive neurons in some parts of the VBSNC but not in other parts.

Properties of LTM Neurons

The rostral components of the VBSNC have long been considered to be the essential brain stem regions that relay orofacial mechanosensory information related to so-called 'fine touch' and thereby to be analogous to the dorsal column nuclei of the spinal somatosensory system. Such a view has been reinforced by findings that the RF properties of some of the neurons that relay this mechanosensory information (LTM neurons) may allow for a precise coding of orofacial mechanical stimuli, for example, the single-vibrissa receptive field of most LTM neurons in the V main sensory nucleus versus the multi-vibrissa RF of the majority of more caudally located neurons in the rat. Nonetheless, LTM neurons are abundant in all four nuclei/subnuclei of the VBSNC, including subnucleus caudalis where they predominate in laminae III/IV. At least some LTM neurons at all levels of the VBSNC appear to be capable of receiving and faithfully transmitting detailed somatosensory information about light tactile stimuli delivered to localized regions of the face and mouth, in keeping with the evidence mentioned above that V low-threshold mechanosensitive afferents project to all levels of the VBSNC.

Like analogous neurons in the dorsal column nuclei and spinal dorsal horn, LTM neurons in the VBSNC are activated by light tactile stimuli applied to a localized RF, show graded responsiveness as stimulus intensity or area of RF stimulation is gradually increased, and receive low-threshold A-fiber afferent inputs that may release glutamate as the principal excitatory neurotransmitter. In general, as noted above, they have functional properties ensuring a secure transmission through the VBSNC of tactile information from orofacial mechanoreceptors. The LTM neurons thereby provide the higher levels of the CNS with detailed information of the modality and spatiotemporal features (e.g., location, intensity) of an orofacial tactile stimulus.

Properties of Other Nonnociceptive Somatosensory Neurons

A small proportion of neurons in the VBSNC can be excited by low-threshold afferent inputs other than those derived from orofacial mechanoreceptors in skin, mucosa, or periodontal tissues. Some neurons, especially in the rostral components, can be activated by jaw movements (in particular, jaw opening), presumably through inputs from low-threshold mechanoreceptors in the TMJ or stretch-sensitive receptors in masticatory muscles. These neurons may contribute to ascending sensory pathways (e.g., to thalamus and cortex) or to brain stem circuits underlying the reflex regulation of masticatory muscle activity.

Some LTM neurons also respond to cooling of their orofacial RF, but other neurons, especially in V subnucleus caudalis, respond exclusively and with much greater sensitivity to innocuous cooling or warming. These are specific thermosensitive neurons which receive their afferent input from the specific cold or warm thermoreceptors mentioned earlier, and relay detailed information about orofacial thermal stimuli (e.g., intensity, duration, location) to the higher brain centers.

Properties of Nociceptive Neurons

Several lines of evidence indicate that subnucleus caudalis is critical in V brain stem nociceptive processing. These include its nociceptive afferent inputs, its laminated morphology and cell types resembling those of the spinal dorsal horn, and findings that the disruption of caudalis interferes with many behavioral responses as well as higher center and reflex responses evoked by noxious stimuli. In addition, two classes of nociceptive neurons, based on their cutaneous RF and response properties, occur in the superficial and deep laminae of caudalis: high-threshold or nociceptive-specific (NS) neurons and wide dynamic range (WDR) neurons. Like their spinal dorsal horn counterparts, NS neurons receive small-diameter nociceptive afferent inputs and so respond only to noxious stimulation whereas WDR neurons receive both large- and small-diameter afferent inputs and respond to both tactile and noxious stimuli. Additional features of caudalis that are consistent with its nociceptive role include the several receptor types associated with nociceptive processing that are present in the afferent endings or neurons in caudalis (e.g., neurokinin, opiate, GABA, purinergic, TRPV1, estrogen, and *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors), and the presence of a SG which, like the SG of the spinal dorsal horn, has neurons with axons that terminate locally within the VBSNC and release neurochemical substances such as enkephalin or GABA that modulate somatosensory transmission in caudalis (also see below).

The caudalis NS and WDR neurons with a cutaneous RF have been shown to play an important role in our ability to localize, detect, and discriminate cutaneous noxious stimuli. The majority of the caudalis NS and WDR neurons can nonetheless be excited by afferents from deep tissues (e.g., tooth pulp, cerebrovasculature, TMJ, jaw muscle) as well as by cutaneous (or mucosal) afferent inputs, and some can be

even activated by other cranial nerve afferents or cervical afferents. Such features are thought to contribute to central sensitization (see below) and to the referred pain patterns that are common in many pain conditions in the head and neck, and also underscore the inadvisability of using 'convergent' neurons as an alternative term for WDR neurons, since NS neurons typically also reveal extensive afferent convergence.

The similarities between caudalis and spinal dorsal horn have led to the long-held concept that these two structures are homologous, but this useful homology may need some revision as recent evidence indicates that portions of caudalis are organized differently from the spinal system (also see Table 1). A unique feature of caudalis is its dual representation of several different orofacial tissues in its rostral border with subnucleus interpolaris as well as in the transitional region between the caudal part of caudalis and the upper cervical spinal cord. Immunohistochemical and electrophysiological studies have shown that the caudalis/interpolaris transition region has a ventral transition area, which is especially clear in rodents and includes bilateral orofacial afferent inputs, and a dorsomedial transition area. Each of these two areas of the rostral caudalis, plus the caudal transitional part of caudalis, has its own unique morphological and functional features that may be differentially involved in contributing to perceptual, autonomic, endocrine, and muscle reflex responses to orofacial stimuli.

In addition, subnucleus caudalis is not the only VBSNC component with a nociceptive role. Some orofacial nociceptive behaviors may persist after caudalis lesions, lesions of rostral components (e.g., oralis) of the VBSNC may disrupt some orofacial nociceptive responses, and the rostral components have substantial numbers of NS and WDR neurons with an intraoral or perioral nociceptive RF (including tooth pulp). Furthermore, the rostral components of the VBSNC may also contribute to ascending and reflex nociceptive pathways and manifest some neurochemical markers for nociceptive processes. Nonetheless, these rostral regions receive only sparse direct input from small-diameter primary afferents and have a limited neurochemical substrate and lack the modulatory SG circuitry that are characteristic of caudalis (and spinal dorsal horn). Indeed, their nociceptive functions may be dependent on the functional integrity of caudalis since recent investigations have documented that caudalis, especially via its SG, exerts a modulatory influence on oralis through processes that include NMDA, purinergic, and opioid receptor mechanisms within caudalis itself (see also below). These various findings collectively suggest that the cutaneous RF and response properties of rostral nociceptive neurons, particularly in subnucleus oralis, may be dependent on caudal regions such as subnucleus caudalis for the relay of nociceptive signals from primary afferents supplying superficial craniofacial tissues. However, the responses of some neurons in the rostral VBSNC to tooth pulp stimulation may be dependent on pulp afferent relays in both rostral and caudal components of the VBSNC.

Thalamocortical Processes

Neurons in the VBSNC project to higher levels of the CNS, in particular to the posterior thalamus, and from there to the cerebral cortex. The thalamus receives direct contralateral input from each component of the VBSNC: an ipsilateral projection also occurs from some components. Although, in general, the majority of the V-thalamic projection neurons occur in the trigeminal main sensory nucleus, and are primarily involved in tactile sensation, the major thalamic projection related to pain and temperature perception arise mainly from neurons in subnucleus caudalis; there are, however, species differences in some of these projections.

The posterior thalamic regions that are especially involved in receiving and relaying this orofacial sensory information are the ventrobasal complex (VB) (or ventroposterior nucleus in humans), the posterior group of nuclei (PO), and parts of the medial thalamus. Those VB neurons that receive and relay somatosensory information from the face and mouth are concentrated in the medial half of the VB (the nucleus ventralis posteromedialis, VPM), whereas neurons in the lateral portion of the VB relay somatosensory spinal information derived from the limbs, trunk, and neck. The VPM neurons are somatotopically organized, and most are LTM neurons with a localized RF and other properties that allow for retention of the functional specificity that is characteristic of the LTM primary afferents and second-order LTM neurons. Many nociceptive neurons also occur in the VPM and generally have properties similar to those described for NS and WDR neurons in the VBSNC. The most medial aspect of the VB contains neurons that relay orofacial thermosensitive or gustatory information. The neurons in the PO and medial thalamus in general are much less specific in the information they relay. Nociceptive neurons may also occur in other areas such as hypothalamus and basal ganglia.

The RF and response properties of the LTM and nociceptive (NS and WDR) neurons in VPM and their connections with the overlying somatosensory cerebral cortex indicate that most may be involved in the

spatiotemporal coding of touch and pain, respectively. The somatosensory cortex also contains neurons that receive thalamic relays of gustatory or thermosensitive information, but the latter, in particular, have not been extensively studied. The primary somatosensory cortex (SI) is critical for fine tactile discrimination and face SI contains many LTM neurons which in general retain the features of the primary afferents, VBSNC, and VPM neurons that provide for detection and discrimination of the spatiotemporal characteristics of an orofacial tactile stimulus. SI (and VPM) neurons responding to tactile stimulation of the vibrissae aggregate in a barrel-like arrangement and their properties have been extensively studied. In comparison, only a limited number of studies have tested for nociceptive neurons in face SI. Nonetheless, NS and WDR neurons do occur in the face SI and respond to noxious facial or tooth pulp stimuli in a manner suggesting a role in the sensory-discriminative dimension of pain. Neurons responding to orofacial tactile or noxious stimuli also occur in other cortical regions such as the anterior cingulate cortex, the function of which includes the affective or motivational dimension of pain.

Trigeminal Somatosensory Modulation

Orofacial somatosensory transmission in the brain stem, thalamus, and somatosensory cortex can be modulated at each of these levels, although the modulation in the thalamus and cortex in large part reflects modifications of the sensory signals occurring first in the VBSNC. The intricate organization of each subdivision of the VBSNC and the variety of inputs to each from peripheral orofacial tissues or from different parts of the CNS provide important substrates for numerous interactions between the various inputs. For example, the responses of brain stem LTM neurons to orofacial tactile stimuli can be modified by anesthesia, by behavioral state, and by segmental (afferent) influences and modulatory influences intrinsic to the CNS that are derived from structures within the VBSNC itself as well as from other parts of the brain stem and higher centers (e.g., periaqueductal gray and somatosensory cortex).

Inhibitory Influences

Some of the first studies detailing segmental (so-called afferent) inhibition of tactile-transmission neurons were demonstrated in LTM neurons at various levels of the VBSNC. Subsequent studies also documented such inhibitory influences on thalamic and cortical LTM neurons. As in the spinal somatosensory system, these modulatory effects are thought to represent mechanisms for 'sharpening' the coding properties of LTM neurons and so contribute to, for example, spatial acuity in orofacial touch sensation. Afferent influences have also been shown to modulate V nociceptive transmission, especially through the interneuronal circuitry and neurochemical substrate existing within caudalis. These influences include inputs into the CNS from nociceptive and nonnociceptive afferents as well as visceral afferents (e.g., baroreceptors). The modulation by nociceptive inputs underlies the powerful diffuse noxious inhibitory controls (DNIC) effects that can be exerted on V nociceptive neurons, for example, by noxious stimulation of spially innervated tissues. These effects of noxious and nonnoxious afferent inputs may contribute to the analgesia reported for acupuncture and transcutaneous electrical nerve stimulation.

Electrical or chemical stimulation of the periaqueductal gray matter or rostroventral medial medulla activates descending pathways that project to the VBSNC and can inhibit V brain stem neuronal and related reflex and behavioral responses to noxious as well as nonnoxious orofacial stimulation in experimental animals. Other powerful modulatory effects on V somatosensory transmission include pathways emanating from the locus coeruleus, reticular formation, pontine parabrachial area, anterior pretectal nucleus, amygdala, red nucleus, and thalamic nucleus submedius, as well as the cerebral cortex (e.g., somatosensory and motor areas). Some of these influences are also expressed on somatosensory transmission in the thalamus and cortex. The descending pathways to the VBSNC exert their effects by the release from their endings within the VBSNC of certain neurochemicals (e.g., 5-HT) or by their causing other chemicals (e.g., enkephalins, GABA) to be released from the endings of interneurons intrinsic to the VBSNC (e.g., in the SG of caudalis). These pathways and chemical processes are involved in the modulation of somatosensation that occurs in a diverse set of conditions that include different states of consciousness and attention, emotion, exaggerated pain states, and the analgesia associated with deep brain stimulation and placebo effects.

Facilitatory Influences

As in the spinal somatosensory system, afferent inputs and intrinsic CNS processes may produce a prolonged facilitation of somatosensory transmission in certain conditions. In the V system, extensive investigations of the organization and neuronal properties of the whisker barrelettes in the VBSNC and analogous structures in VB thalamus and somatosensory cortex have revealed the susceptibility of the LTM neuronal properties to peripheral manipulations such as deafferentation in neonatal animals and even in adults. The effects of such deafferentation include facilitatory influences that have been viewed as evidence

of the neuroplasticity of the vibrissal somatosensory system. Interestingly, studies of the effects of the neonatal depletion of C-fibers reveal that C-fiber afferents appear to play an important role in shaping the adult RF and response properties of the LTM neurons. Furthermore, deafferentation of other orofacial tissues such as the tooth pulp in adult animals can also lead to profound changes in the properties of LTM neurons at the different levels of the VBSNC.

Nociceptive transmission in the V system can also be facilitated by alterations to the peripheral afferent inputs to the CNS that may result from inflammation or trauma of peripheral tissues and nerves, thus emphasizing the plasticity of the neural circuitry underlying nociceptive transmission, that is, that it is not 'hard-wired.' Afferent inputs from deep musculoskeletal tissues (e.g., TMJ, masticatory muscle) and tooth pulp are especially effective in inducing spontaneous activity, lowering of activation threshold, RF expansion, and enhancement of peripherally evoked responses of caudalis NS and WDR neurons. These features reflect an increased neuronal excitability analogous to the 'central sensitization' documented in the spinal nociceptive system and implicated in allodynia, hyperalgesia, and pain spread and referral following tissue injury or inflammation. Maintenance of these changes is thought to underlie chronic pain states. Studies in the V system have also shown that purinergic as well as glutamatergic (NMDA and non-NMDA) receptor mechanisms are involved in this central sensitization process, and that central depressive influences (e.g., opioid-related) can normally be 'triggered' by noxious orofacial stimulation and may serve to modulate, even limit, the sensitization. It is also noteworthy that V central sensitization is not restricted to subnucleus caudalis. It has also been shown in nociceptive neurons in subnucleus oralis and in higher brain regions such as VPM thalamus, although caudalis is responsible for their expression of central sensitization by way of its projections to both structures.

In addition to central sensitization, several other factors have been implicated in acute and chronic orofacial pain mechanisms related to peripheral tissue trauma or inflammation. These include ectopic impulses generated in damaged afferent fibers; peripheral sensitization, enhanced sympathetic modulation, and central sprouting of afferent fibers; phenotypic changes in afferent fibers and central nociceptive neurons; and changes in segmental and descending inhibitory and facilitatory influences on nociceptive transmission. Recent findings suggest that nonneural cells (e.g., glia) may also play an important role in some of these processes.

Contact Events and Action Goals in Manipulation Tasks

Most natural object manipulation tasks involve a series of actions or phases that accomplish specific goals (or task subgoals) typically associated with mechanical contact events. For example, consider the task of lifting, holding, and replacing a box on a tabletop. This task involves a series of action phases separated by contact events involving either the making and breaking of contact (Figure 1(a)). Thus, the goal of the initial reach phase is marked by the digits contacting the box, and the goal of the subsequent load phase (during which increasing vertical load forces and horizontal grip forces are applied under isometric conditions) is marked by the breaking of contact between the object in hand and the support surface. These and subsequent contact events give rise to discrete sensory signals from one or more sensory modalities. For example, when the box is replaced on the table, the contact between the box and surface gives rise to discrete tactile and auditory signals and, if the box is in the field of view, visual signals as well. It is likely that such contact events also give rise to discrete signals in proprioceptive systems. Thus, in general, contact events can be associated with distinct signals in multiple sensory modalities, each providing a neural signature of the event. These signals provide information about not only the timing of the event but also the characteristics of the mechanical interaction (e.g., direction and amplitude of contact forces). Thus, a given object-manipulation task can be represented as a sensory plan wherein a sequence of sensory goals is specified. The implementation of such a plan requires the selection and execution of a corresponding sequence of basic actions, or action-phase controllers, to achieve the sensory goals. To be accurate, each of these controllers requires information about the initial configuration of the motor system and objects in the environment, as well as their mechanical properties. This state information (multimodal) is used for feed-forward or predictive adaptation of motor output of the controllers with reference to attainment of their sensory goals.

The implemented action-phase controllers also generate predictions about the sensory consequences of the motor output, which are compared with the actual sensory signals (Figure 1a)). Contact events, which denote completion of action goals, represent critical sensorimotor control points in this respect because they give rise to discrete and distinct sensory signals in one or more modalities. By comparing predicted and actual sensory feedback, the brain can monitor the progression of the task and, if a mismatch occurs because of misleading initial state information or a faulty action-phase controller, launch corrective actions (Figure 1(a)). This use of sensory information as well as the characteristics of the corrective actions are highly task- and phase-specific and are presumably learned with the learning of the underlying action-phase controller. Moreover, mismatches can lead to an updating of the memory representations of object properties that can be subsequently used for predictive control later in the task and in other tasks with the same object, thus reducing future prediction errors.

Although we have emphasized that manipulation tasks can be divided into a sequence of action phases, it is important to note that sensory predictions generated in one action phase are used in the next. Specifically, sensory predictions about the terminal state of the motor system and environment of one action phase also provide initial state information for the subsequent action-phase controller. This information can be used to parameterize the next action phase in advance, which allows a smooth transition between the component actions of the task. In the absence of such anticipatory control, delays between phases would occur because the brain would have to rely on peripheral afferent signals to obtain this state information. Such a process would be time consuming due to long time delays in sensorimotor control loops associated with receptor transduction and encoding, neural conduction, central processing, and muscle activation. For example, it takes approximately 100 ms before signals from tactile sensors in the digits can bring about a significant change in fingertip actions. Even longer delays, in excess of 200 ms, are usually required to transform visual events into purposeful fingertip actions. Because of these long time delays in sensorimotor control loops operating on the hand, anticipatory control policies govern the swift and smooth transitions characteristic of dexterous manipulation.

Vision provides critical information for predictive control of task kinematics. In addition to locating objects in the environment, vision is used for identifying contact sites that are both stable and advantageous for various actions that we want to perform with the grasped object. For example, when we pick

Figure 1 A person grasps and lifts an instrumented test object from a table, holds it in the air, and then replaces it, using the precision grip: (a) contact events and subgoals; (b) signals in the four types of tactile afferents from the glabrous skin of the human hand. In (a), the contact events shown at the top define the subgoals of the task (i.e., goals of each action phase). Sequentially implemented action-phase controllers generate motor commands that bring about the required action phases. After digits contact the object, the grip force increases in parallel with the tangential (load) force applied during isometric conditions to the object to overcome gravity. When the load force overcomes the force of gravity, the object lifts off. After the object is replaced such that it contacts the support surface, the load and grip forces decline in parallel until the object is released. In conjunction with generating motor command, the action-phase controllers predict internally the sensory consequences of these commands in one or more modalities (predicted sensory subgoal events), whereas the actual sensory consequences are signaled in one or more modalities (actual sensory subgoal events). For example, when the object is replaced on the surface, the contact event gives rise to tactile, visual, and auditory sensory events. By comparing predicted and actual sensory events, the sensorimotor system can monitor task progression and detect mismatches used to bring about corrective actions tailored to the action phase (see also **Figures 5, 6(b),** and **6(c)**). The predicted sensory events from each action phase can be used to provide initial state estimates for the next phase (not illustrated). In (b), signals in the four types of tactile afferents are recorded with the technique of microneurography during the lifting trial. At four points corresponding to subgoal events, tactile afferents show distinct burst discharges: (1) contact responses preferentially in FAI and SAI afferents when the object is first contacted, (2) burst responses in the FAII afferents related to the mechanical transients at lift-off and (3) when the object contacts the support surface, and (4) responses primarily in FAI afferents when the object is released. In addition to these event-related responses, SAII afferents and many SAI afferents show ongoing impulse activity when forces are applied to the object. Some spontaneously active SAII units are unloaded during the lift and cease firing. FA, fast-adapting; SA, slow-adapting. Data from Johansson RS and Westling G (1991) Afferent signals during manipulative tasks in man. In: Franzen O and Westman J (eds.) *Somatosensory Mechanisms*, pp. 25–48. London: Macmillan.

up a hammer to drive in a nail, we probably use different grasp sites than when we pick it up to give it to another person. Furthermore, visual cues about the identity, size, and shape of an object provide cues about its mechanical properties that are useful for predicting the forces required for successful manipulation. Visual cues related to object weight and mass distribution can be used to predict magnitudes of required fingertip forces and visual cues about the shape of grasp surfaces can be used to predict stable fingertip force directions. However, vision is of limited utility when objects are out of sight or partially occluded.

The use of vision in manipulation relies on learned associations between visual cues and their mechanical meaning. Such associations are grounded in movement–effect relationships evaluated through signals in sensors that transmit veridical information about mechanical interactions between the body and objects in the environment. The tactile modality directly provides information about mechanical interactions between our hands and objects and plays a pivotal role in the learning, planning, and control of dexterous object manipulation tasks. Relatively little is known about the contribution of proprioceptive signals in manipulation. Like vision, proprioception can provide only indirect information about mechanics. For example, signals related to muscle length, joint angle, and muscle force do not directly code the contact state between the hands and objects.

The importance of tactile afferent signals in manipulations is most apparent in people with impaired digital sensibility. Such individuals have great difficulty with routine tasks even under visual guidance. For example, they often drop objects, may easily crush fragile objects, and have tremendous difficulties with everyday activities such as buttoning a shirt or picking up a match. In humans, the density of tactile innervation is highest in body surface areas that typically contact objects including the palmar surfaces of the hands, the soles of the feet, and the tongue and lips. Approximately 2000 tactile afferents innervate each fingertip and some 10 000 afferent neurons innervate the remaining glabrous skin on the palmar surface of the hand. Microneurography studies in humans have shown that there are four types of tactile afferents that encode different aspects of the deformations of the soft tissues when the hands interact with objects (Figure 2). Overall, these sensors have evolved for extracting, rapidly and with high spatiotemporal fidelity, features of dynamic mechanical events that occur on top of the low-frequency and often large forces typically present when holding and transporting handheld objects. These dynamic tactile signals code the contact events that mark the attainment of subgoals in manipulation tasks (Figure 1(b)).

In the remainder of this article, we describe a series of experimental results from manipulation tasks that illustrate and further develop the general principles just described.

Predictions and Control Points in the Tactile Modality

The first action phase in most manipulation tasks is to bring the hand to the object in order to grasp it. The goal of this reach phase it to place the fingertips on the object in locations that will allow the development of a stable grasp in the context of the actions that will be performed with the object. In many manipulation tasks, it is important that the fingertips contact the object at around the same time and that the fingertip force vectors sum to zero. This is particularly important when grasping a light object that might otherwise be displaced or rotated when initially contacted. The contacts between the fingertips and object represent control points for goal completion of the reach phase. In some cases, these contact events may be visible and can be encoded visually. However, in many instances, the contact sites of at least some of the digits are out of view (as when digits contact the back side of an object). In contrast, tactile signals encode reliably and robustly all contact events (Figure 1(b)).

For each digit, contact responses in ensembles of afferents convey information about contact timing, the contact location on the digit, and the direction of contact force. Ensembles of tactile afferents also encode the frictional status of the contact and the shape of the contact surface, which are critical parameters in the control of object manipulation. All of these contact parameters are represented by signals in ensembles of tactile afferents that encode the patterns of stresses and strains distributed throughout the viscoelastic fingertip. Fast-adapting type I (FAI) afferents provide the most well-defined contact responses; however, slow-adapting type I (SAI) and fast-adapting type II (FAII) tactile afferents may also respond dynamically at the moment of contact. Tactile information associated with discrete mechanical fingertip events (including contact events) can lead to appropriate changes in motor output (i.e., fingertip forces) within 100 ms or less. Traditionally, it has been posited that tactile information is coded by the firing rates of tactile afferents. However, such a mechanism would be too slow to account for the rapid use of tactile information in manipulation. That is, to estimate firing rates at least two impulses in a given neuron are

Figure 2 Types of tactile (mechanoreceptive) sensors in the glabrous skin of the inside of the human hand: (a) functional properties; (b) nerve endings in the fingertip. In (a), the middle graphs schematically show the impulse discharge (lower traces) to perpendicular ramp indentations of the skin (upper traces) for each sensor type. Two types (FA) show fast adaptation to maintained tissue deformation (i.e., they only respond to deformation changes). Two types adapt slowly (SA); that is, in addition to being dynamically sensitive (particularly the SAIs) they show an ongoing response related to the strength of maintained tissue deformation. The type I sensors (FAI and SAI) have small and well-defined coetaneous receptive fields (typically 10 mm^2) when defined by light, pointed stimuli (patches in the left drawing of the hand represent the fields of 15 different sensors). The density of these sensors increase in the distal direction of the hand and is especially high in the very tips of the digits (see the right drawing of the hand; the numbers indicate the innervation density as the number of afferents per square centimeter of skin area for the fingertips, fingers, and palm). In contrast, the FAII and SAII sensors show lower and approximately uniform densities over the hand and their receptive fields are larger and less well defined (left drawing of the hand). The FAIIs are especially responsive to mechanical transients that propagate though the tissues, whereas the SAIIs sense strain in the dermal and subdermal fibrous tissues, often with a remote origin. Sensors with encoding properties akin to the type II sensors of the hand are found in virtually all fibrous tissue in the body. The relative frequency of occurrence in the glabrous skin and the probable morphological correlate are indicated for each type of sensor. In (b), the organized nerve terminals corresponding to the four types of tactile sensors are shown for the fingertip. FA, fast-adapting; SA, slow-adapting. Data from Johansson RS and Vallbo ÅB (1983) Tactile sensory coding in the glabrous skin of the human hand. *Trends in Neuroscience* 6: 27–31.

required and reliable estimates generally require that neural responses are averaged over a substantial time window and over several trials. Recently it has been proposed that the relative timing of first spikes in ensembles of tactile afferents (temporal codes) encode tactile information for use in manipulation tasks. Neural recordings in humans indicate that such a mechanism would provide information about tactile events more rapidly than rate coding and fast enough to account for the use of tactile signals in natural manipulation.

Sensory Predictions That Support Grasp Stability

After contact is established between the object and the hand, practically all manipulation tasks require the application of forces tangential to the contacted surfaces (load forces). For example, to lift an object with the digits at the side, vertical load forces must be applied to overcome the weight of the object (Figure 1(a)). In many cases, twist forces (torques) tangential to the grasped surfaces are also applied. For example, if we lift a bar from one end, in addition to the vertical load force we need to apply tangential torque to prevent the bar from rotating as we lift it. These tangential loads destabilize the grasp, and to prevent the object from slipping (either linearly or rotationally) we need to apply forces normal to the surface (grip forces) to create stabilizing frictional forces.

When manipulating objects, grip forces are controlled to increase and decrease in phase with increases and decreases in the tangential loads with no time delay (Figures 1(a) and 3). This anticipatory modulation of grip force with movement-dependent changes in load force generates grip forces that are greater than the minimum required to prevent slip while at the same time not excessive. This coordination of grip and load forces is not innate but develops during ontogeny and is gradually refined until approximately 8 years of age. The coupling between grip force and load force supports grasp stability in a wide variety of maneuvers that we perform with objects. For example, it is observed at the level of

Figure 3 Parametric adjustments of motor output: (a) to change in object weight; (b) to change in friction between the object and skin; (c) to change in shape of the contact surface during object lifting; (d) to change in shape of the contact surface during object tilting change in tilt. In (a–c), the subject lifts an instrumented test object from a table, holds it in the air, and then replaces it, using a precision grip. Upper graphs show the horizontally oriented grip force, the vertically oriented load force (lift force), and the object's vertical position as a function of time for superimposed trials, indicated by differently colored curves. The lower graphs show the grip force as a function of the load for the same trials. The dashed lines indicate the minimum grip force to prevent slips and the safety margin against slips is indicated by hatching. In (a), with weight variations, the parallel change in grip and lift forces coordinated by the action-phase controllers ensures grasp stability when lifting objects of different weights. In (b), the balance between grip force and load force is adjusted to deal with changes in friction. In (c), a similar scaling of the grip-to-load force ratio is observed when object shape is varied. In either instance, the coordination of grip and load force ensures an adequate safety margin against slips. In (d), an already lifted object is tilted by 65° around the grip axis, which causes tangential torques at the grasp surfaces. Three superimposed trials are shown, one for each of the following surface curvatures: spherically convex with a radius of 5 mm, flat, and spherically concave with a radius of 20 mm. The top traces show the grip force, tangential torque, and tilt angle against time. Note the parallel change in grip force and the tangential load and the higher grip force with the greater surface convexity. The bottom graph emphasizes this adjustment by plotting the grip force against tangential torque load for the corresponding data. The shading indicates a similar safety margin against rotational slips irrespective of curvature. individual digits when people use two or more digits of the same or both hands to manipulate objects, when grasping and moving objects held between the palms, and when load forces on a handheld object are generated by jumping up and down. Likewise, it applies to bimanual coordination when the hands have different and complementary roles, such as when we use one hand to add things into, or remove things from, a receptacle held by the other hand. Coupling between grip and load forces also operates when we move objects with different complex dynamics (combinations of inertial, elastic, and viscous loads), even though this involves altering the mapping between motor commands that generate load forces and those that generate grip forces.

The control of grasp stability requires that the balance between the grip and load forces be adapted to the properties of contacted surfaces. The friction between digit and object surface determines the minimum ratio between grip force and load force required to prevent slip, and people parametrically adapt the balance between grip and load forces for different frictional conditions, using greater grip forces with more slippery surfaces. This is achieved by varying the ratio between the grip force change and load force change (Figure 3(b)). In the same vein, people parametrically scale the balance between the grip and load forces to the shape of the contacted surface. For example, the greater the curvature of a spherically curved grasp surface, the larger the grip force required to generate a given tangential torque (Figure 3(d)). Similarly, when people lift tapered objects, a greater grip-to-load force ratio is required when the grip surfaces are tapered upward as compared to downward (Figure 3(c)). These parametric adaptations to contact surface friction and shape typically result in grip forces that exceed the minimum required to prevent slips by a safety margin of 10–40% of the applied grip force (gray areas in the force coordination plots of Figure 3).

When manipulating objects, people control their fingertip forces based on predictions of surface properties. Vision can, under favorable conditions, provide accurate information about object shape that can be used for predictive parameterization of fingertip forces. In contrast, it appears that vision is unhelpful in predicting the friction of an object, in part because friction depends not only on the object surface but also on sweating rate and the greasiness and wetness of the skin (Figure 4(a)). Instead, predictions of frictional conditions are based on the memory of previous haptic experiences with the same or similar objects, whereas a default prediction, perhaps based on some average, appears to be used in novel situations. The critical role of tactile afferents in the control of grasp stability is clearly illustrated by the fact that people with digital sensory impairments fail to adapt grip-to-load force ratios to object surface properties and, instead, consistently use large grip forces (cf. Figures 4(b) and 4(c)).

Information about surface friction and shape is rapidly extracted during initial contact between the fingertip and object surface by signals in ensembles of tactile afferents (Figure 4(d)). Thus, the initial contact event

Figure 4 Adjustment of hand grip force to frictional changes in everyday situations: (a) static grip force before and after washing the hand; (b) with changes in object surface structure with normal digital sensibility; (c) with changes in object surface structure with anesthetized fingertips; (d) with friction; (e) in response to accidental slippage. In (a), the static grip force when holding an object in air using a precision grip (diamonds) and the corresponding minimum grip forces to prevent slips (slip force (dots)) are shown before and after the subject's hand was washed (with soap and water) and dried (towel); there were 48 consecutive lifts with suede as surface structure (single subject, weight constant at 400 g). In (b–c), the corresponding grip force data is shown during frictional changes between lifts caused by changing the surface structure among fine-grain sandpaper, suede, and smooth rayon. In (d), the influence of friction on force output and initial contact responses in a fast-adapting type I (FAI) afferent are shown. Two trials are superimposed, one with less slippery sandpaper (black lines) and a subsequent trial with more slippery silk (blue lines). The sandpaper trial was preceded by a trial with sandpaper, and therefore the force coordination is initially set for the higher friction. The vertical line indicates initial touch. In (e), examples are shown of afferent slip responses and the upgrading of the grip-to-load force ratio elicited by small slip events occurring at only one of the digits engaged. Vertical dotted lines indicate the onset of the slips as revealed by vibrations in the object (acceleration signal); short vertical lines indicate the onset of the slip-triggered upgrading of the force ratio. The new higher and stable ratio restores the safety margin, preventing future slips. On the left, slip during the load phase is shown; the middle burst is the afferent slip response, whereas the third burst represents dynamic responses to the force changes following the slips. On the right, slip during the static phase is shown. (a) Based on data from Johansson RS and Westling G (1984) Influences of cutaneous sensory input on the motor coordination during precision manipulation. represents a critical control point in the manipulation task at which predicted and actual sensory feedback related to surface properties can be compared. Mismatches between predicted and actual contact responses – primarily provided by ensembles of FAI afferents – lead to an updating of the grip–load force coordination approximately 100 ms after contact. Figure 5 illustrates such updating when people repeatedly lift objects with tapered grasp surfaces without vision of the object. The tapering was changed between trials in a pseudorandom order. In all trials, the initial increase in grip force was determined by the tapering (and hence force requirements) in the previous trial. This indicates that knowledge about the status of the object, obtained in previous trials, specifies the force coordination. When the tapering was changed, the grip force output is modified approximately 100 ms after the digits contacted the object and tuned for the actual object properties (Figure 5(a)). By the second trial after the change, the force coordination is appropriately adapted right from the onset of force application. Thus, when a prediction error occurs, tactile information obtained at initial contact with the object rapidly initiates a corrective action accompanied with an updating of the representation of the object used to control forces in future interactions with the object. As previously indicated, people with digital sensory impairments fail to adapt grip-to-load force ratios to object surface properties (cf. Figure 4(c)).

Under favorable conditions, visual cues about object shape can influence the initial contact forces used in lifting in a feed-forward manner. For example, in sequential lifting trials with tapered contact surfaces, a change from upward to downward tapering results in a slower increase in grip force right from the beginning of the force application (Figure 5(b)). Similarly, with a change from downward to upward tapering surfaces, the grip force is adjusted from the very start of the lift in anticipation of the higher grip force required to lift the object. Hence, visual cues about object geometry can provide state information for anticipatory parametric adaptation of component actions of the manipulation task. Once the object is contacted, tactile signals also provides state information about object shape that can override visual predictions if necessary.

Occasionally, the updating of frictional and shape representations that typically occurs at initial contact is

Figure 5 Adaptation of fingertip forces to changes in object shape; vertical load force and horizontal grip force shown as a function of time for trials from a lift series in which surface angle was unpredictably varied between lifts: (a) without vision of the contacted surfaces; (b) with vision of the contacted surfaces. The blue curves refer to the last trial with the 30° object before the switch (T1; upward tapered grasp surfaces). (This trial was preceded by a trial with a 30° object.) The solid red curves show the next trial (T2) performed with the –30° object (downward tapered grasp surfaces). These curves thus illustrate adjustments to the smaller angle. The yellow dashed segment in the grip force curve in (a) indicates the epoch of the corrective action elicited by the new surface angle. The thin red dashed curves show the following trial, again with the –30° object. The top diagram represents the status of the sequentially implemented action-phase controllers. In T1, they are parameterized for the 30° object throughout. In T2, without vision of the contacted surfaces (a), a corrective action (Corr) is triggered approximately 100 ms after contact based on a mismatch between predicted and actual tactile information obtained at contact related to object shape. This action is interspersed during the loading phase and involves a change in the ratio between the grip force change and load force change, which, in turn, change the balance between grip and load forces to better suit the –30° object for the remainder of the trial (see also Figure 3(c)). In T3, the controllers remain updated to the –30° object. With vision of the contacted surfaces (b), visual cues about object geometry provide state information for anticipatory parametric adaptation of the motor output after the change in tapering (T2), and no corrective action is triggered. Data from Jenmalm P and Johansson RS (1997) Visual and somatosensory information about object shape control manipulative fingertip forces. *Journal of Neuroscience* 17: 4486–4499.

inadequate and may result in an accidental slip later in the task. For example, when an object is held in air after being lifted, such a slip usually results in a transitory and partial unloading at one digit, and this increases the loads on the other digits engaged (Figure 4(e)). These transient load shifts are signaled by tactile afferents and trigger a corrective action that increases the grip-to-load force ratio at all digits for the remainder of the task. The nature of the corrective action triggered by slips depends on the phase of the task. Slips during the load phase in lifting lead to a slowing down of the increase in load force, whereas slips during the hold phase lead to an increase in grip force. Hence, different action-phase controllers are associated with different smart reflexes that support grasp stability and help achieve the current subgoal of the task.

Figure 6 Adaptation of motor output to object weight: (a) fingertip forces and object movement during the initial part of adequately programmed lifts with three objects of different weights (data from 24 single trials superimposed; single subject); (b) single-unit tactile afferent responses and adjustments in force to unexpected decrease in object weight (trials between lifts from 800 to 200 g); (c) second experiment showing single-unit tactile afferent responses and adjustments in force to unexpected increase in object weight (trials from 400 to 800 g). In (b–c), the data from the single-lift trials are aligned on initial touch (vertical line). Gray circles and vertical lines indicate the moment of lift-off for each trial and the arrowheads point to the actual sensory events generated by the lift-off in a fast-adapting type II (FAII) afferent. The circles behind the nerve traces indicate the corresponding predicted sensory events. In (b), three successive trials (T1–T3) are shown in which the subject lifted an 800 g object (blue curves), a 200 g object (red solid curves), and then the 200 g object again (red dashed curves). The forces exerted in the first lift are adequately programmed because the subject had previously lifted the 800 g object. The forces are erroneously programmed in the first lift of the 200 g object (T2) because they are tailored for the heavier 800 g object lifted in the previous trial. The sensory information about the start of movement occurs earlier than expected for the erroneously programmed 200 g object trial (cf. the actual and predicted sensory events) and initiates a corrective action (yellow dashed red curves). The strong force drive of the ongoing load phase is terminated but still results in an overshoot in position due to the reflex delay, and corrective motor command is launched that brings the object back to the intended position. In (c), the participant performed an adequately programmed lift with a 400 g weight (T1, green curves), followed by a lift with an 800 g object erroneously programmed for the lighter 400 g weight lifted in the previous trial (T2, blue solid curves) and then a lift with the 800 g object again (T3, blue dashed curves). The absence of burst responses in FAII afferents at the predicted point for the erroneously programmed 800 g object trial (cf. the actual and predicted sensory events) elicits a corrective action (yellow dashed blue curves). This involves abortion of the lift-phase command followed by triggering of a second load-phase command that involves a slow, discontinuous, and parallel increase in grip and load forces until terminated by sensory input signaling lift-off. The top diagrams in (b) and (c) represent the status of the sequentially implemented action-phase controllers. In T1, they are parameterized for the 800 g (b) and 400 g (c) weight throughout. In T2, a corrective action (Corr) is triggered approximately 100 ms after the occurrence of the mismatch between predicted and actual sensory information related to object lift-off. This action involves abortion of the operation of the current action-phase controller and the implementation of action patterns that allow the task to continue. The corrective action is linked to an updating of the subsequently implemented controllers for the new weight. In T3, the controllers remain updated to this weight. Elements compiled from Johansson RS (1996) Sensory control of dexterous manipulation in humans. Sensory Predictions Related to Object Motion

The successful lifting of an object requires that the forces developed during the load phase be predictively tuned to the weight of the object. People tend to lift objects of varying weight in about the same amount of time. To accomplish this, they scale the rate of increase of vertical load force, prior to lift off, to the expected weight of the object – increasing load force more rapidly for objects they expect to be heavy (Figure 6(a)). In addition, people predict the load force required for lift-off and, when lifting an object just off the surface, reduce the increase in load force rate so that it approaches zero at the expected lift-off time. When people lift to different heights – requiring different amount of object acceleration – load forces are likewise scaled predictively to achieve the desired acceleration and lift height. This ensures a smooth and critically damped lifting motion. Because no sensory information is available about weight until lift-off, this tuning of force output relies on estimates of weight. Such estimates are based on sensorimotor memory of the object derived from previous interactions with the object. Familiar objects can be identified visually (or by haptic exploration) for retrieval of weight estimates. Moreover, memory representations of familiar objects are organized into families or categories of objects in which the objects within a family can vary in size (e.g., cups, books, and loafs of bread). In such situations, people exploit size–weight associations when predicting the motor commands required to lift objects.

The fact that people rely on predictions related to object properties is clearly illustrated when people make erroneous predictions that result in pronounced performance errors. For example, when we lift up an object that is lighter than we expect, we typically make a jerky movement and lift the object higher than intended. A jerky movement occurs because the load phase is programmed for a heavier weight such that lift-off happens earlier than predicted and excessive lifting force is generated (Figure 6(b), T2). Conversely, an unexpected increase in weight results in a slow and hesitant load phase because the force drive is targeted for a lighter weight and additional increases in force are required to bring the object aloft (Figure 6(c), T2).

The expected lift-off represents a control point related to the goal of the load phase. Ensembles of FAII afferents, supplied by Pacinian corpuscles located in subcutaneous tissues, most quickly and reliably signal the outcome of the load phase by encoding both the timing and the dynamics of the lift-off event. Such afferents, which are distributed throughout fibrous tissues of the body, are particularly sensitive to transient mechanical events that propagate through handheld objects into the hand and arm. The transient events take place when contacts between handheld objects and surfaces are formed or broken and effectively excite these highly sensitive afferents. When lifting an object that is lighter than expected, the sensory events elicited by the lift-off occur before the predicted events that are part of the sensory plan (cf. predicted and actual neural events in Figure 6(b)). The mismatch triggers a learned corrective action that involves termination of the load phase force followed by corrective motor commands that bring the object back to the intended position. However, due to delays in sensorimotor control loops, this corrective action pattern kicks in too late to avoid an overshoot in the lifting movement (see position signal in Figure 6(b)). When lifting an object that is heavier than expected, the sensory event elicited by lift-off occurs neither before nor at the point predicted by the sensory plan (cf. predicted and actual neural events in Figure 6(c)). Hence, again there is a mismatch between actual and predicted sensory events. In this case, the corrective action triggered by the mismatch results in slow, probing increases in finger forces until terminated reactively by sensory events signaling lift-off. Thus, the sensorimotor system reacts to both the presence of an unpredicted event and the absence of a predicted sensory event. Significantly, in addition to triggering corrective actions, these sensory mismatches lead to an updating of memory representations related to object weight, which in turn improves predictive control in subsequent action phases and tasks that engage the same object. In natural situations, this updating generally occurs in a single trial (see Figures 6(b) and 6(c)). However, in the presence of misleading or confounding visual and haptic cues, or when people deal with objects with unusual dynamics (relating applied force to motion), updating may require repeated lifts or movements of the object.

When people transport and hold an object, knowledge about object weight, mass distribution, and surface properties remains critical for controlling action and maintaining grasp stability. When people replace the object on a surface, the sensory goal is to produce an afferent signature signifying contact. This contact event, which represents a sensorimotor control point, is signaled by FAII afferents that encode the timing and nature of the event (Figure 1(b)). The contact event is followed by an unloading phase where grip and load forces decrease in parallel. The sensory events related to the digits breaking contact with the surface of the object represent the goal of this phase. The coupled decrease in the load and grip forces ensures the maintenance of a grip-to-load force ratio that provides grasp stability even in this phase. The outcome of the unloading phase is distinctly signaled by release

responses in ensembles of tactile afferents, especially FAI afferents (Figure 1(b)).

Predictions and Control Points in the Visual Modality

Because visual resolution is far better in and around the fovea, we use saccadic eye movements (fast jumps in the line of sight) to shift gaze to targets of interest. In addition to providing high-resolution visual information about target features, gaze fixations provide information about target location in space based on knowledge about the orientation of the eyes with reference to the head and to other body segments as well. Different types of visually supported tasks have characteristic patterns of eye movements that accompany them. In object manipulation, people direct their gaze to successive contact locations as they gain salience in the evolving task according to the demands of the implemented action plan. For example, when people pick up a bar, move the bar in hand to contact a target switch, and then replace the bar, gaze is successively directed to the grasp site on the bar, the target, and the landing surface where the bar is replaced (Figures 7(a) and 7(b)). Furthermore, people may direct fixations to points where contact must be avoided, including obstacles that must be circumnavigated with the hand (or object in hand). In familiar manipulation tasks, subjects almost never fixate their hand or objects being moved by the hand. An important role of foveal vision is to monitor contact events representing subgoals of the task.

The spatiotemporal coordination of gaze and hand movements emphasizes the segmentation of manipulation tasks into distinct action phases (Figure 7(c)). At the start of most action phases, congruent hand and eye movements are launched concurrently to the contact location representing the goal. Thus, both hand and eye movements are specified based on peripheral vision about the contact location (or on memorized landmark locations). Because eye movements are quick, gaze reaches the contact location well before the hand (or object in hand). This permits the use of foveal and parafoveal vision in monitoring the final approach of the hand to the contact location. Gaze typically remains at the contact location until around the time of goal completion (e.g., until the grasp is established, the target switch is released, or the bar is replaced in the target contact task) or remains at a location where a contact should be avoided until the time of the potential contact (e.g., when the tip of the bar passes closest to the obstacle in the target contact task). Thus, the gaze shift to the contact location associated with the next action phase occurs around

Figure 7 Predictions and control points in the visual modality, gaze, and hand movements for a target contact task: (a) a single trial in which the participant reached for and grasped a bar and moved it to press a target switch; (b) and then moved it from target contact and replaced it on the support surface; (c) spatiotemporal coordination of gaze and manipulatory actions shown as time-varying instantaneous probability of fixations within the landmark zones indicated in (a) and (b). In the task in (a–b), a triangular obstacle was located between the bar and target. Dashed black lines in (a–b) represent the path of the tip of the index finger during the reach for the bar and during the reset phase when the hand was transported away from the bar after it was replaced and released. The solid black lines represent the path of the tip of the bar. The red lines indicate the position of gaze; the thin segments with the arrowheads represent saccadic eye movements and the thick patches represent gaze fixations. The colored zones represent landmark zones that captured 90% of the fixations recorded during several trials by 10 participants; these zones are centered on the grasp site (green), tip of the bar (purple), protruding part of the obstacle (orange), target (blue), and support surface (pink). The plot in (c) is derived from data pooled across 10 participants, each performing four trials with the triangular obstacle. The red circles and vertical lines mark contact events demarcating phase transitions in the task, and the spatial locations of these events are schematically indicated by the location of the corresponding numbered circles in (a) and (b). The common time base has been normalized such that each phase of each trial has been scaled to the median duration of that phase. Data from Johansson RS, Westling G, Bäckström A, and Flanagan JR (2001) Eye-hand coordination during learning of a novel visuomotor task. *Journal of Neuroscience* 21: 6917–6932.

the predicted time of goal completion. In fact, in most cases, both gaze and hand movement commands are initiated in anticipation of goal completion and are not delayed until sensory feedback is obtained verifying goal completion. With the latter strategy, a smooth transition between successive phases of the manipulation task would not be possible because of the substantial time delays in sensorimotor control loops. In summary, contact events that demarcate action phases can be predicted and monitored in both the tactile modality and the visual modality.

Predictions in Action Observation

Although there is no question that tactile feedback related to control points is essential for skilled object manipulation, there are control points that do not give rise to tactile events. For example, when we drop a ball onto a surface, we typically direct our gaze to the predicted contact point between the ball and surface. Here, sensory feedback related to contact is available only through vision (and possibly audition). Thus, vision and the tactile system can play complementary roles in monitoring contact events. We have recently argued that, when observing an actor perform an object manipulation task, the observers – like the actor – predict and monitor contact events linked to the subgoals of the task. Although the observers cannot use tactile feedback to monitor contact events, they are free to move their gaze to monitor contact events via vision.

When people observe an actor performing a predictable block-stacking task, their gaze behavior is similar to the actor's gaze behavior. Specifically, the gaze of both the actor and observer predicts forthcoming contact sites (where blocks are grasped and replaced), and gaze is maintained at each contact site until around the time of goal completion (grasp contact and block landing). Even when observers do not know, in advance, which of two possible blocks the actor will grasp, they shift their gaze proactively to the correct target as soon as possible based on vision information. Taken together, these results indicate that observers implement a dynamic sensory representation of the task they are observing. Furthermore, these findings provide support for the hypothesis that observing and understanding the actions of another person involves a mechanism that maps the observed action on to sensorimotor representations in the observers' brain. In action observation, as in action, we argue that gaze is controlled, in part, for monitoring the consequences of action in central vision. By comparing actual and predicted visual feedback related to contact events, both observers and actors may be able to obtain valuable information about the outcomes of action and action plans that can be exploited by the sensorimotor system when learning, planning, and controlling future actions.

Sensory Control Policies during Learning

Although skilled behaviors involve learning to execute motor commands that fulfill sensory goals, little is known about possible changes in sensory control policies across learning stages. We have recently studied the learning of a novel visually guided object manipulation task in which participants had to discover how to move a cursor to successive targets presented on a screen by applying forces and torques to a rigid tool held between the two hands. As when people discover how to ride a bicycle, the learning proceeds in three stages. In the initial exploratory stage, participants attempt to discover the basic mapping rule relating motor and sensory signals by busily generating apparently uncontrolled cursor movements. In the skill acquisition stage that follows, control begins to emerge and performance improves rapidly. In the final skill refinement stage, performance continues to improve but gradually. During the exploratory stage, gaze reactively pursues the cursor via saccades directed to successive cursor locations, possibly allowing the learner to build a map between hand actions and gaze-related signals. As the learner starts to gain control over the cursor during the subsequent skill acquisition stage, gaze begins to predict forthcoming cursor positions. In the subsequent skill refinement phase, learners launch spatially and temporally congruent gaze and cursor movements directed to the target as in well-learned natural manipulations. These findings indicate that people adopt different sensorimotor schemas depending on the stage of learning and that learning to predict sensory consequences of motor commands precedes accurate control. It is not yet known how the use of other sensory modalities in manipulation may also depend on learning stage.

Conclusion

Dexterity in object manipulation depends on anticipatory control policies that rely on knowledge about movement–effect relationships when interacting with environmental objects. A sensory plan specifies the sequence of task subgoals in terms of sensory signals linked to contact events. This sensory representation of the task provides a scaffold for the selection and shaping of the action-phase controllers required for achieving sensory subgoals. Prediction of sensory states pertaining to the outcome of executed action phases

allows for smooth phase transitions, in contrast to the stuttering transitions that would result if the brain relied on peripheral afferent information to confirm subgoal completion and to update state information before launching the next action phase. Tactile sensors signal information about both the timing and the physical nature of the discrete mechanical events that represent the outcomes of the action phases. Contact events in manipulation are also represented in the visual and auditory modalities and, presumably, the proprioceptive modality. When the brain successfully predicts the actual sensory signals at a given contact event, no corrective action is required and the task runs in a feed-forward fashion. When a prediction error arises, a learned corrective action, the nature of which depends on the task and its action phase, is generated and representations of object properties are updated. We suggest that contact events that represent sensorimotor control points are encoded in multiple sensory modalities and serve at least two critical functions. First, by comparing actual and predicted sensory events in multiple sensory modalities, the sensorimotor system can simultaneously monitor multiple aspects of task performance and, if prediction errors arise, respond to the pattern of errors observed in different modalities. Second, because contact events give rise to salient sensory signals from multiple modalities that are linked in time and space, they provide an opportunity for sensorimotor integration and intermodal alignment helpful for learning and upholding multimodal sensorimotor correlations that support prediction of purposeful motor commands.

Sensorimotor Integration: Attention and the Premotor Theory

T Moore, B Noudoost, and K M Armstrong, Stanford University School of Medicine, Stanford, CA, USA

The Neural Basis of Attention before the Neuron Doctrine

Our ability to selectively process important sensory information at the expense of extraneous or potentially distracting information is afforded us by the process of attention. Without attention, as William James (*c*. 1890) stated, "experience is an utter chaos." In the visual domain, attention allows us to sequentially process individual items among the multitude stimulating the retina, thus permitting us to, for example, read this text. Much work, and indeed much progress, has been made in recent years in establishing a neurobiological basis of visual attention. However, a significant fraction of the experimental groundwork was laid during the late nineteenth century. In addition to William James, the American psychologist who fractionated attention into two types, voluntary and involuntary, other noteworthy thinkers and experimentalists set the stage for what has only recently been explored further. Having carried out an extensive set of cortical lesions studies, primarily in dogs and monkeys, David Ferrier (*c*. 1876) concluded that the faculty of attention was "intimately related to the volitional movements of the head and eyes." Ferrier had observed that large lesions of the prefrontal cortex of monkeys resulted not only in paralysis of head and eye movements but also in deficits that would today be best described as 'neglect' – that is, a tendency to ignore sensory events in the affected half of space. Although Ferrier understood that visual attention did not require eye or head movements, this fact was not clearly established experimentally until Hermann von Helmholtz demonstrated it in 1894. Helmholtz set up a screen on which letters were scattered systematically and fixated the center of the display. Although there were too many letters, and the display was too large to view without moving the eyes, Helmholtz found that he could nonetheless selectively perceive different portions of the display while fixating. Using an electric spark, Helmholtz could briefly illuminate the entirety of an otherwise darkened display while still holding his gaze at its center. He found that he could choose a portion of the display to attend to while still fixating centrally, and that by doing this he could identify letters in that portion during the brief period of illumination, whereas he could not identify letters in other portions. Helmholtz thus observed experimentally that attention can be deployed covertly – that is, in the absence of eye movements. Helmholtz concluded,

> Our attention is quite independent of the position and accommodation of the eyes, and of any known alteration in these organs; and free to direct itself by a conscious and voluntary effort upon any selected portion of a dark and undifferentiated field of view. This is one of the most important observations for a future theory of attention.

As discussed later, the ability of primates, most notably humans and monkeys, to covertly attend has facilitated the study of the neural basis of visual attention. However, Ferrier's view regarding independence of the focus of attention from the direction of gaze during covert attention was more complicated and suggested a possible mechanistic basis for Helmholtz's later observation: "During (attention) we suppress actual movements, but keep up in a state of greater or less tension the centres of the movement or movements with which the various sensory factors of ideation cohere."

Ferrier thus argued that the apparent independence of movements from the direction of visual attention resulted from an active suppressing of it. Interestingly, noted physiologist, psychologist, and color theory nemesis of Helmholtz, Ewald Hering (*c*. 1894), further suggested that

> whilst attending to the marginal object we must always attend at the same time to the object directly fixated. If even for a single instant we let the latter slip out of our mind, our eye moves towards the former.

Thus, even before the neuron doctrine was established in the late nineteenth century, testable hypotheses regarding one of the brain's most complex mental functions had already been posed. In the many years to follow, much of the progress in pinpointing the neural mechanism of visual attention and in understanding its relationship with motor control came from neuropsychological studies of human subjects and monkeys with brain damage.

Parietal and Frontal Neglect

Neglect, or the failure in spatially directing visual attention to a region of space, is typically found in patients with unilateral lesions of parietal or frontal cortical regions. Typically, human patients with neglect omit elements on their contralateral side when copying simple drawings. They also show a bias

toward the intact side when asked to bisect a horizontal line. It is generally believed that the more 'perceptual' deficits tend to be associated with parietal lesions, whereas the more 'motor' tasks tend to be associated with frontal lesions. However, lesions of parietal cortex also lead to impairments on motor tasks. Gross inaccuracy in reaching for objects and marked clumsiness in picking up objects are also common following posterior parietal damage in both human patients and monkeys. Parietal lobe lesions also disrupt oculomotor behavior in monkey and man. Monkeys with parietal lesions are unable to track quickly moving visual targets with eye movements. In addition, the slow phase of vertical optokinetic nystagmus is disrupted following bilateral parietal lesions. Cooling of parietal area 7 causes a slowing of eye movements toward the contralateral side. Indeed, there is clear involvement of both parietal and frontal cortices in both perceptual and motor tasks, and this suggests a strong coupling of attention and motor programming. In the framework of a 'premotor theory of attention,' neglect has been interpreted as an imbalance of spatial representations that control motor programs, thus producing an attentional deficit.

Consistent with the initial observations of David Ferrier, subsequent lesion studies involving monkeys carried out by numerous investigators during the past century have repeatedly implicated the frontal eye field (FEF) in the control of visual spatial attention. Modern neurophysiological studies have established that FEF neurons play a key role in the programming and triggering of saccadic eye movements. However, studies both new and old indicate that the FEF is crucial to attention as well. Similar to parietal lesions, lesions of the FEF in monkeys have long been known to result in marked neglect. Like Ferrier, Bianchi (*c.* 1895) observed clear perceptual defects after excision of the frontal lobe in monkeys and dogs. Later, Kennard (1939) found that visual impairments following restricted lesions of the frontal lobe were indistinguishable from a hemianopia following occipital lobectomy. Other frontal lesions did not result in neglect. Subsequently, Clark and Lashley (1947), Denny-Brown (1951), Welch and Stuteville (1958), and Brucher (1966) all observed contralateral neglect after unilateral FEF lesions. Mapping visual fields before and after FEF lesions, Latto and Cowey were the first to quantify visual field deficits by training monkeys to make manual responses in response to a flash of light presented at different locations throughout the visual field. They found that unilateral FEF removal transiently impaired performance in the contralateral visual field. The animals were not blind, however, because they could still respond correctly on a fraction of trials. Yet, monkeys were far more likely to fail to respond to stimuli presented in the affected hemifield than elsewhere. Latto and Cowey suggested that the FEF might normally modulate the visual system according to eye position, and that this could explain the fact that such small lesions were able to produce such pronounced deficits.

More recently, studies have used reversible pharmacological inactivation to temporarily disrupt neural activity in a number of structures with known roles in the control of saccades, including the FEF, the superior colliculus (SC), and the lateral interparietal area. Generally, inactivation of these structures increases the time it takes an animal to initiate saccades to visual targets appearing in the affected part of space. In addition, the inactivation also impairs performance on attention-demanding tasks in the affected part of space when other distracting stimuli are present. Attention performance on tasks with isolated stimuli is not affected. Thus, there is good evidence that brain structures involved in controlling visually guided saccades also play a causal role in directing visuospatial attention.

Neurophysiology of Covert and Overt Visual Attention

It is well established that the responses of visual cortical neurons to covertly attended stimuli are enhanced above that of unattended stimuli. In a typical experiment, a monkey is trained to attend to peripheral stimuli appearing at a particular location or to a particular stimulus, regardless of location, while maintaining central fixation. The responses of extrastriate cortex neurons to physically identical stimuli presented to their receptive fields (RFs) are then compared between the different conditions. During covert spatial attention, responses to attended RF stimuli are enhanced, and this enhancement has been found to result in changes in orientation tuning, direction of motion tuning, contrast sensitivity, color tuning, and the representations of multiple, competing RF stimuli. Thus, the perceptual benefits of covert attention appear to be supported by neuronal sensitivity changes within visual cortex. However, the mechanism driving these correlates of attention is unknown.

Before it had been established that covert attention effects were widespread within visual cortex, it had been demonstrated that visual-evoked neuronal responses in a number of structures are enhanced when an animal targets an RF stimulus with a saccadic eye movement. This effect was first observed by Wurtz and Goldberg among neurons within the superficial layers of the SC and subsequently by Mountcastle and colleagues in posterior parietal cortex. Later studies demonstrated that the presaccadic

visual enhancement is also observed among neurons in area V4 and in inferior temporal cortex. Although there is a striking parallel apparent between the presaccadic enhancement of visual responses throughout the visuo-oculomotor axis and the attention-related modulation in visual cortex, a causal connection between the two was difficult to draw for many years since attempts to find covert attention effects in the SC and in the FEF were unsuccessful. However, recent studies have indeed found modulation of SC and FEF neuronal activity during covert attention. Thus, there is now good evidence that visual responses, whether exhibited by neurons more closely related to saccades or more closely related to coding the parameters of visual stimuli, are modulated by both covert and overt attention.

Testing a 'Premotor Theory' of Attention

A number of psychophysical studies have found evidence linking covert attention and the preparation of saccades. Generally, this evidence suggests one or both of two possibilities: that visual spatial attention influences saccade preparation and that saccade preparation influences the deployment of visual spatial attention. The most classic demonstration of the influence of directed attention on saccades was provided by Rizzolatti and colleagues. In their study, the authors examined how covert attention perturbed saccade trajectories. Subjects were instructed to initiate saccades to a location in one half of the visual field according to cues presented in the other half. The cues could be presented in one of several locations in the cued half of the visual field. The authors found that saccade trajectories were systematically deviated according to the location of the covertly attended (i.e., cued) location. Thus, the deployment of covert attention can perturb saccade programming. The previous observation as well as similar findings from other investigators are frequently cited as evidence for what is commonly referred to as the premotor theory of attention, a more modern incarnation of the ideas of Ferrier and others.

To address the role of saccade preparation in the deployment of attention, Hoffman and Subramaniam had subjects make saccades to a location while also detecting visual targets presented prior to the eye movement. These authors found that target detection was typically best at the location of planned saccades, and that subjects were unable to completely dissociate the attended and saccade locations. These results suggest that the preparation of saccades to a location deploys attention to that location. Deubel and Schneider obtained similar results and concluded that a single mechanism must drive the selection of objects for perceptual processing and the information needed to drive the appropriate saccadic response.

Although these psychophysical studies provide a sound rationale for the hypothesis that oculomotor and attentional circuits have a common neural substrate, they cannot rule out the alternative view that these are two distinct and independent systems. In recent years, neurophysiological studies have taken a more direct approach to this problem by perturbing neural signals within oculomotor structures and examining the effects of those perturbations on spatial attention. These structures include the FEF and the SC, both having a known role in the programming and triggering of saccades. The approach of directly manipulating signals in these areas addresses the causal relationship between neural activity in oculomotor circuits and shifts of spatial attention.

The results from recording and lesions studies suggest that the locus of spatial attention is driven by neural activity from saccade-related structures. If this is the case, then it should be possible to direct attention by perturbing neural activity within these structures. Studies have used electrical microstimulation to test the hypothesis that saccade-related circuits play a causal role in driving attention to particular locations in the visual field. Although it had long been known that microstimulation of the FEF and the SC can elicit saccades, Moore and Fallah were the first to examine the effect of microstimulation on visual attention (Figure 1). They found that when they stimulated sites within the FEF using currents that were too low to evoke a saccade, they could nonetheless enhance monkeys' ability to detect changes in a visual target. Importantly, the improvements observed with microstimulation were dependent on the target of attention being positioned at the location to which suprathreshold microstimulation would shift the monkey's gaze. Thus, it appeared that by increasing the likelihood that the monkey would foveate a location in visual space, the experiments also enhanced the animal's ability to process visual events there. Subsequently, two other studies reported similar enhancements in visual spatial attention following subthreshold microstimulation of the SC. In both cases, the performance-enhancing effects of microstimulation were spatially dependent as in the FEF studies.

The effect of electrical microstimulation of the FEF and the SC on visual spatial attention performance in monkeys suggests that during stimulation, visual representations of particular stimuli are enhanced above those of others. As mentioned previously, a wealth of evidence has established that correlates of visual attention can be observed throughout much of macaque visual cortex; visual responses to RF stimuli are typically enhanced when a monkey is trained

Figure 1 Enhancement of covert spatial attention with microstimulation of the FEF. (a) Monkeys were trained to maintain central fixation and covertly attend to detect the transient dimming of a peripheral target while ignoring a flashing distracter. Before engaging in the attention task, the movement field of the FEF site was determined by mapping the saccades (red arrow) evoked by suprathreshold microstimulation of a site within the FEF. The attention target was then placed at the endpoint of the suprathreshold saccade vector (dotted circle) and the microstimulation was decreased to 50% of the threshold current (i.e., to a level that did not evoke a saccade). Next, the luminance change sensitivity of the monkey at the target location was determined during control trials or trials in which subthreshold microstimulation was delivered to the FEF site. (b) Microstimulation increased the monkey's sensitivity to the target change, relative to control trials. Average relative sensitivity values (microstimulation/control) are shown for each stimulation onset asynchrony tested (red circles), with red lines indicating the standard error of the mean. Monkeys were able to detect smaller changes in target luminance when the target was in the part of space represented at the microstimulation site. The increase in sensitivity with microstimulation was greatest when the target change and the stimulation occurred at the same time.

Figure 2 Modulation of visually driven responses of area V4 neurons with microstimulation of the FEF. Sites within the FEF were electrically stimulated while recording from neurons in area V4. (a) A side view of the macaque brain. (Top) The locations of the FEF in the anterior bank of the arcuate sulcus and of area V4 in the prelunate gyrus are shown (shaded). (Bottom left) The response of a V4 neuron when a visual stimulus (V stim) appears in its receptive field (RF) while the monkey maintains central fixation (dots at origin). (Bottom right) Eight saccades evoked to a location overlapping the V4 RF following microstimulation of an FEF site (E stim). (b) Subthreshold microstimulation of the FEF increases the visual activity ('Response') of V4 neurons with RFs (circles) that overlapped with the saccade represented at the stimulated FEF site (arrow from crosshairs), but it decreases visual activity when the receptive fields and the saccades did not overlap. Gray bars represent the visual stimulus used to drive the V4 response. Responses for control and stimulation conditions are shown in white and black, respectively. (c) The enhancement of V4 visual responses depends on the spatial alignment of the RF stimulus and the FEF saccade vector.

to covertly attend to them. Thus, one might expect that microstimulation of the FEF or the SC will likewise result in the enhancement of the responses of visual cortical neurons to RF stimuli. Indeed, this was the hypothesis posed by Moore and Armstrong, who paired FEF microstimulation with single-neuron recording in extrastriate area V4. Specifically, they studied the impact of subthreshold microstimulation of FEF sites on the visual responses of V4 neurons with RFs that were either overlapping or non-overlapping with the spatial location represented at the FEF site (Figure 2). They found that following very brief trains of FEF stimulation (20–50 ms), visual responses were enhanced at overlapping locations in the visual field, whereas they were suppressed at non-overlapping locations. Furthermore, this attention-like modulation was greatest when there was another 'distracter' stimulus presented outside of the V4 neuron's RF. A subsequent study also found that FEF microstimulation can alter the structure of V4 RFs and can bias V4 responses in favor of one of two RF stimuli. Importantly, these changes in V4 responses are very similar to what has been observed in the same area during voluntary attention. Together, the previous results suggest that microstimulation of oculomotor structures drives covert attention and its correlates in visual cortex, and that indeed, as speculated by Latto and Cowey, visual spatial attention seems to be the result of feedback from the oculomotor system onto visual cortical areas, and this feedback influence may exist in order to modulate processing according to eye movement plans.

Conclusion

Neurophysiological work has directly addressed and found much evidence of a role of saccade mechanisms in directing covert visual spatial attention. This evidence appears to support the conclusion that the neural mechanisms of covert and overt spatial attention are identical with respect to the influence of the saccade plan on visual representations. Although it should be assumed that a different set of mechanisms are in effect when attention is directed overtly (i.e., when planned movements are triggered and shifts in gaze are actually carried out) than when it is directed covertly, results suggest that these differences are less important than the similarities.

Sensorimotor Integration: Barrels, Vibrissae and Topographic Representations

Barrels

A barrel is a cylindrical group of neurons located in the middle cortical layer (layer IV) of the somatosensory cortex. Barrels receive segregated inputs from the thalamus that are related to spatially separate parts of the somatic sensory periphery. In this respect they are similar to ocular dominance columns in the primate visual cortex that receive segregated inputs related to each eye. Many rodents, rabbits, and other small mammals have barrels. Barrels are most clearly related to whiskers (some of which are termed 'vibrissae'), which are tactile organs located principally on the face (see Figure 1). Barrels are also related to other peripheral structures such as the toes and footpads of the paws. Rodent barrel cortex is planar, compact, and accessible. Barrels can be seen with the naked eye in unstained sections of the rat brain.

The Barrel Field

The barrel field is the architectonic field defined by the barrels. It is homomorphic (similar) to the whisker pattern on the face and on parts of the paws on the limbs. There is a precise topographic anatomical correlation between the sensory periphery and the barrel cortex, first understood by recording surface potentials evoked by stimulation of the contralateral face and body. Each whisker barrel has a unique position corresponding to the vibrissa projecting to it (Figure 1). This relationship has been detailed in numerous independent ways, including (1) via microelectrode recordings, because most cells in a particular barrel are activated by the appropriate contralateral whisker, (2) by metabolic markers, which measure short- and long-term changes in activity and are altered in corresponding barrels with stimulation of selected parts of the body, and (3) by selective surgical removal of different vibrissae or limbs in early postnatal life, after which the corresponding barrels are altered.

Vibrissae

A whisker or vibrissa is a large tactile hair in a mechanically isolated hair follicle. Each whisker on the face receives a substantial, segregated sensory innervation from the trigeminal (fifth) nerve. The facial vibrissae are arranged in species-specific, stereotypical, gridlike patterns. The arrangement of the barrels is also species specific, stereotypical, and gridlike. Each vibrissa has a unique position to which a barrel in the homologous grid position corresponds. Single afferent fibers are related to one of several receptor specializations in the hair follicle that collectively encode direction, velocity, frequency, magnitude, and duration of whisker movements. Sensory inputs to the vibrissae are modulated through coordinated motor activity. Striated muscles innervated by the facial (seventh) nerve are attached to and actively move or 'vibrate' the larger whiskers (vibrissae) back and forth during exploratory whisking behavior at frequencies averaging 7 Hz in rats and 15 Hz in mice. Each vibrissa follicle contains erectile tissue (sinus hair is the general name), under opponent autonomic control, to dynamically alter tactile thresholds.

Topographic Representations

A topographic representation is a coherent, if distorted, map in the brain. In rats, mice, and some other animals, histological markers outline this map in layer IV in single sections parallel to the cortical surface (Figure 2). This visible representation of the body – head, body, limbs, tail – in the somatosensory cortex is a concrete example of representation of sensory and motor functions in the brain deduced from clinical observations, electrophysiological recording, and experimental neuroanatomy. This illustrates a general principle: sensory inputs from the body (skin), eyes (retina), and ears (cochlea) and outputs for voluntary movements (muscle groups) have systematic representations in many central nervous system structures that are topographically similar to the order of the parts represented.

Barrel Components

The larger barrels in mice are ovoid, with a major diameter of about 300 μm; in rats they have a major diameter of about 600 μm. Cells are arranged around dense clusters of afferent endings from the thalamus (Figure 3). In mice, there are about 2500 neurons in the larger mouse barrels and approximately 10 000 neurons in a functional barrel column extending throughout the full cortical thickness. The number of neurons in a barrel is directly proportional to, but 17-fold greater than, the number of fibers innervating its contralateral whisker. Segregated thalamic projections for single whiskers from

Figure 1 Whisker barrels in rat somatic cortex. (a) Barrels stain intensely for activity of an enzyme (mitochondrial cytochrome oxidase) involved in metabolism to produce energy. Each barrel (arrowheads) in layer IV is part of a functional column that extends through the full cortical thickness from the pia to the white matter (50-μm perpendicular section). (b) A section in the plane of layer IV of the left somatic cortex shows a pattern that is similar to that of the whiskers. The white holes are penetrating vessels. The marker in the lower right-hand corner indicates anterior a and medial m orientations. (c) The C3 whisker is identified on the right face of a rat.

Figure 2 Barrels are demonstrable in the appropriate part of the physiologically defined cortical map of the contralateral body surface in histological sections from the flattened cortex. The distortions of the form of the animal in the map are directly related to peripheral innervation density (orientation: a, anterior; m, medial).

the ventroposterior medial (VPM) nucleus of the thalamus end largely on neurons in layer IV, and also in upper layer VI. The stellate neurons in layer IV are of two principal types: spiny and smooth, in a ratio of about 10:1. Most smooth cells are positive for glutamic acid decarboxylase (GAD) and are inhibitory interneurons. The axons and dendrites of layer IV neurons cells are largely confined in layer IV to the barrel in which their soma is located. About 93% of the synapses in a barrel are asymmetrical (excitatory) and of these about 20% of these are from the somatosensory thalamus. Both types of stellate cells receive thalamic synapses. Those on the smooth cells are distributed on the soma and proximal dendrites, while those on the spiny cells terminate on spines at regular intervals. Each barrel has a rich capillary plexus that is supplied by several penetrating arterioles.

Barrel Activation

Functional organization of the barrel cortex is predominantly vertical, or 'columnar.' Neurons in layer IV, and to a lesser extent those in layer VI, respond principally

Figure 3 Barrel components from tangential sections of mouse cortex. (a) Barrel neurons in a ring define a barrel with a cell body (Nissl) stain. Each barrel is separated from its neighbors by relatively cell sparse regions. (b) Several thalamocortical axons projecting to a barrel labeled with a brightly fluorescent dye. Throughout the whisker barrel pathway, whisker-related afferents have dense, segregated ramifications confined to the appropriate whisker patch (prepared by Dr. Stephen Senft). (c) Single neurons stained by a Golgi method with Nissl counterstain showing barrel neuron processes (dendrites and axons) that mainly arborize in the barrel where their cell bodies are located. (d) Radioactive 2-deoxy-D-glucose labels a single whisker barrel after stimulation of the homotypical single contralateral whisker (autoradiogram prepared by Dr. Tony Mosconi). (e) Dense capillaries (filled with a black marker) in a cytochrome oxidase-stained barrel. (f) Serotonin-containing axons from the brain stem raphe are confined to barrels in young animals and mediate aspects of the development of the anatomic and functional organization of the cerebral cortex (prepared by Dr. Carol Bennett-Clarke).

to deflections of a single vibrissa. They indicate direction of whisker movement, have sustained or transient discharges to whisker deflections, can code for amplitude and rate of displacement, and may follow sinusoidal stimuli to frequencies exceeding 50 Hz. In these respects, they closely resemble those of the primary whisker afferents. Metabolic (2 deoxy-D-glucose) uptake after stimulation of a single whisker labels a single column of cells and neuropil that coincides precisely in layer IV with the relevant barrel and extends throughout the full cortical thickness. Prompt, focal changes in blood flow to barrels accurately reflect the location, timing, and magnitude of whisker-evoked neuronal activity.

Cells in all layers of barrel cortex are activated by highly specific stimuli that vary by layer. With whisker stimulation they exhibit precise directional sensitivities, are often inhibited by certain forms of stimulation, and integrate information from several different neighboring vibrissae. Interactions are through asymmetrical patterns of intracortical connections within and between different whisker columns. For instance, cells in layer V are responsive to particular spatial and temporal sequences of movement of adjacent whiskers as if the neurons were detectors for objects of finite sizes touched by whisker hairs. Models suggest that convergence from different thalamocortical fibers and intracortical inhibition improve the signal-to-noise ratio during whisker activation.

Whisker-to-Barrel Pathways

Activity is conveyed from the whiskers to the barrel cortex over two direct, parallel pathways, each crossing three synapses (see Figure 4). Afferent cell bodies are in the trigeminal ganglion where, as a rule, one ganglion cell innervates only one whisker. Central processes of these neurons terminate mainly in two separate ipsilateral brain stem nuclei: the principal

Figure 4 Parallel rodent trigeminal pathways. Sharply somatotopic neuronal patterns and projections (lemniscal), identical to the pattern of the whiskers on the face, can be seen from standard histology of the brain stem, with the thalamus just as in layer IV barrels of the cortex. The hallmark of this system is the predominance of single whisker representations that are dominated by activation of the appropriate whisker. A parallel pathway (paralemniscal) is activated at slightly slower latencies by multiple whiskers. Primary afferents converge on neurons in brain stem trigeminal nuclei, which project mainly to the posterior nucleus of the thalamus and to the cortex between and above and below the barrels in the cortex. Rows of whiskers and barrels are labeled with letters (A–E), whiskers and barrels within the rows are numbered (e.g., A1–A4), and whiskers and barrels between the ends of the rows are labeled with Greek letters ($\alpha-\gamma$). PrV, principal sensory nucleus of the trigeminal nerve; SpV, spinal nucleus of the trigeminal nerve (SpVo, subnucleus oralis; SpVi, subnucleus interpolaris; SpVc, subnucleus caudalis); VPM, ventroposterior nucleus of the thalamus; Po, posterior nucleus of the thalamus. Lines and lower case letters indicate the principal orientations in the animal (d, dorsal; a, anterior; m, medial; c, caudal).

trigeminal nucleus (PrV) and the spinal trigeminal nucleus (SpV), which is subdivided into three subnuclei where whiskerlike patterns of afferents and neurons are termed 'barrelettes.' Cells from these two nuclei project to two contralateral somatosensory thalamic nuclei: the ventroposterior medial nucleus, where whiskerlike patterns of afferents and neurons are termed 'barreloids,' and the architecturally homogeneous posterior nucleus (Po). Neurons in the thalamus project to the somatosensory cortex of the same side.

The 'lemniscal' pathway is faster and is activated by single whiskers. Afferent terminals in each locus on this path are grouped in whiskerlike patterns and the target cells typically have processes confined to a whisker patch and are strongly activated by single whiskers. The PrV is the main brain stem relay and the main thalamic relay is the VPM nucleus. Thalamocortical axons from VPM nuclei end in clusters in barrels in layer IV and in upper layer VI. Representations can be demonstrated throughout the entire lemniscal pathway, in a single individual, in sections cut in specific planes, with simple, routine staining methods.

In contrast, a 'paralemniscal' pathway originates mainly from large cells in the SpVi (subnucleus interpolaris), on which afferents from many whiskers converge. These project to the Po in the thalamus, which then projects between the barrels in layer IV and also to layers III and V of the barrel cortex. This pathway is slower and its cells are activated by multiple adjacent whiskers (Figure 4). Information from the two systems is integrated to provide accurate information about spatial locations of objects encountered as the animal moves its whiskers back and fourth during exploration.

Development of the Whisker Barrel System

The whisker barrel system offers special advantages for studies of brain development. Rodents such as hamsters, mice, and rats are very immature (altricial) at birth. Although the neurons of somatosensory pathway are generated *in utero*, at birth, young neurons are still migrating into the cortex. Further, the segregation of the central axonal projections along the pathway is not yet complete, synapses are forming, and most of the target neurons in the brain have only begun to differentiate. The vibrissae are recognizable in the fetus a week before birth. Temporal gradients in the development of whisker representations follow the same sequences as found for earlier neurogenesis along the neuraxis and within a particular part of the brain. The pattern of central projections is evidently instructed from the periphery and transmitted from one central locus to the next. Cortical transplant experiments demonstrate that visual cortex placed in the somatosensory area can express barrels, and, conversely, putative barrel cortex transplanted to the visual area takes on visual cortical architecture. The size of representations in the whisker pattern is related to relative, rather than absolute, peripheral innervation density.

Developmental and Adult Plasticity

Surgical removal of whiskers changes the architecture and function of the central whisker system in predictable, time-dependent ways. Repeatedly cutting off whisker hairs in neonates or in adults reduces activity in the whisker pathway and deprives it of patterned input. Chronic whisker clipping changes a number of biochemical parameters related to energy metabolism and transmitter synthesis in appropriate whisker barrels in adults. Deprivation can be tested in the short term, or reversed in the longer term, by letting the whisker hairs grow back. Neurons in barrel columns deprived by whisker clipping from birth exhibit higher spontaneous activity and less specific spatial tuning, and are more strongly activated by adjacent unclipped whiskers than is seen in normal animals. Sensory deprivation or pharmacological blockade of neuronal activity or synaptic transmission in the postnatal period does not apparently alter the patterns of long axonal projections. These manipulations, however, change patterns of intracortical connections in ways that are consistent with a strong role for activity in establishing circuits for functional integration. Novel synapses form in the appropriate barrel of adults after only 16 h of continuous whisker stimulation.

Genetic Analyses

Mice are the mammalian species of choice for genetic analysis. Animals created through selective breeding and homologous recombination permit better understanding of the molecular basis of central nervous system development, peripheral pattern specification, and brain function. Numerous strains of mice with abnormalities of the central nervous system and vibrissal patterns have been well documented. For example, mice have been selectively bred without barrels (barrelless) and a gene uniquely expressed in somatosensory cortex has been described. The *N*-methyl-D-aspartate (NMDA) receptor expression is necessary for development of the whisker pattern in the trigeminal brain stem, but patterns are preserved in the thalamus and cortex. Pattern formation is not (NMDA) subunit specific. These and a host of other findings have opened the way to profound insights from the detailed genetic analysis of the mouse central nervous system. The whiskers, rather like fruit fly bristles, and the barrel pathway provide practical markers for interpreting genetic control of brain development, function, and pathology.

Behavior and Ethology

The large whisker barrels constitute 20% of the total somatic representation that constitutes 30% of the dorsolateral surface of the rat cerebral cortex. A neural system as prominent as the whisker-to-barrel system would seem to have considerable importance for the creatures that possess it. Rodents spend significant time in active exploration in the dark, in burrows or other close quarters, and in contact with other individuals. In these species, the whisker barrel system appears to have developed for analysis and recognition of objects which can be touched (this is how other species, such as carnivores, use their whiskers), and also for navigation (rather as the blind use canes to scan the environment as they walk). Rats can be trained to discriminate different tactile surfaces and they can detect textures that are at least as fine as those that can be distinguished by humans with their fingertips. Rats can be taught to use their whiskers to determine whether to jump across an abyss from one platform to another in the dark. Interestingly, it has been shown that animals can be guided remotely, via paired stimulation of indwelling electrodes in the barrel cortex and other structures, through complex three-dimensional environments. These studies add to classical work showing that rats use their whiskers to quickly traverse mazes for food. Simultaneous recording from different sites in the whisker pathway of active animals shows that the system monitors coordinated whisking and whisker inputs. The whisker barrel pathway is not used solely for tactile processing; mice establish social hierarchies by chewing off the whiskers of subordinates.

The whisker barrel pathway has many features – behavioral importance, accessibility, ease of stimulation, certainty of localization, and genetic and developmental modifiability – that make it a good model system for the study of the mammalian brain and brain disorders in common laboratory species.

Introduction

With the advent of robotics, scientists have become increasingly aware of the complex problems that the brain must solve to carry out even the common task of bringing a glass of water to one's mouth. In this respect, our nervous system is an expert in mechanics, far more competent than the most advanced physics student. Two approaches have been considered as a means to simplify the problems associated with movement control. One is based on reflexes and on the concept of feedback. The other is based on the idea of memory-based computation.

The study of reflexes, in combination with the engineering concept of feedback control, led to early models of voluntary movements. In a feedback control model, the nervous system generates forces that tend to eliminate the sensed error between desired and actual state of motion (position and velocity). This concept is attractive because it does not require any knowledge of dynamics. However, feedback control systems tend to exhibit severe instability problems in the presence of large delays.

An alternative approach to the control of movements was based on the computational idea of storing motor programs into memory and retrieving them when needed. This is analogous to the concept of a 'lookup table.' In a lookup table, the control signals that are needed to generate a movement are not computed explicitly from knowledge of the limb dynamics. Instead, patterns of neural activations are stored as they are produced, in conjunction with the movement that they cause, in an associative memory bank. Subsequently, when a movement is required, the desired movement is used as an address for retrieving the corresponding neural activations. David Marr and James Albus proposed this as a computational model of cerebellar motor control. Subsequently, Marr criticized this approach based on its inability to capture and express the wide variety of movements that characterize natural behaviors. The failure of lookup table models is due to a combinatorial explosion arising from the structure of multijoint kinematics: The number of movement patterns that need to be stored grows exponentially with the number of degrees of freedom.

This article discusses how the nervous system learns to control body-environment dynamics by representing and learning the transformations that relate movements and forces to the neural activities that drive the muscles. These transformations are maps that are accessed in different ways. For example, one way to access a motor map is by deriving a prediction of expected movement given the activities of the muscles. Conversely, another way to access the same map is by deriving the muscle activities that are needed to generate a desired movement. From a mathematical standpoint, the input and output entities are exchanged in these two situations. The transformation from muscle activities to movement is called a 'forward' model, and the transformation from desired movement to muscle activities is called an 'inverse' model. There is ample evidence suggesting that the brain represents both types of models.

The use of the term 'model' may engender some misunderstanding because we are used to thinking of mathematical models as representations involving symbolic operations, such as trigonometric functions, logarithms, integrals, and derivatives. Here, it is not suggested that the brain carries out these symbolic operations. The concept of internal model in motor neuroscience refers to the existence of transformations that are equivalent to the computation of dynamics' equations but are based on a radically different form of 'calculus.' This calculus is based on elementary units, or primitives, that execute simple operations and that can be combined to generate a broader repertoire of behaviors. This article reviews some of the experimental evidence and theoretical arguments supporting the existence of such primitives and their role in the learning and generation of motor behavior.

A Geometrical Framework

A variety of computations associated with the generation and control of movements can be formulated as coordinate transformations. Sensory information about the state of motion of the body comes from a variety of sources, each concerned with particular mechanical variables. For example, skeletal muscles are endowed with sensors that measure the muscle strain and its rate of change. Muscles are also endowed, at their junction with tendons, with Golgi tendon organs that sense variations in muscle force. Signals from other sensory modalities, such as the eyes and the vestibular organs, provide information about the position of the body and its parts with respect to the environment.

The quantitative description of motor and sensory signals implies the choice of a coordinate system,

which falls quite naturally into three classes: actuator coordinates, generalized coordinates, and endpoint coordinates.

Endpoint Coordinates

Endpoint coordinates reflect the properties of the environment in which we operate. Perhaps the most striking of these is the Euclidean symmetry: the invariance of distance between points under rotations and translations. The dimensionality of endpoint space is generally rather low. Since the position of a moving rigid body is completely described by six coordinates (three translations and three angles), the force applied to the body is a six-dimensional force/torque vector. Human hand movements tend to be spontaneously organized in endpoint coordinates: The kinematics of reaching is generally a smooth trajectory (i.e., a straight line with bell-shaped velocity profile) when described in the coordinates of the hand. This is remarkable because the kinematics of a multijointed limb defines a curved manifold that does not obey the symmetry of Euclidean space. For instance, a given angular excursion of the shoulder and elbow causes a net displacement of the hand that varies in amplitude and direction depending on its starting position; however, the length of a segment in Euclidean geometry does not depend on the location or the orientation of the segment. Similar observations have been made across species.

Actuator Coordinates

Information about the position of the arm in space can also be conveyed by specifying a collection of muscle lengths, $l = (l_1, l_2, \ldots, l_m)$. In this coordinate system, a force is a collection of muscle tensions, $f = (f_1, f_2, \ldots, f_m)$. Actuator coordinates afford the most direct representation for the motor output of the central nervous system. The final output stage (or 'final common path') of the motor system is provided by the motor neurons in the spinal cord, whose activities determine the state of contraction of the muscles. The latter is measured by the receptors in the muscle spindles, which deliver this information to the nervous system via the dorsal root ganglia.

Although each muscle is operated by a distinct set of neural signals, actuator coordinates do not constitute a system of mechanically independent variables: one cannot set arbitrary values to muscle lengths without eventually violating a kinematic constraint. Different approaches to the study of motor control may employ different levels of detail in the description of physiological processes, leading to actuator models with different dimensionality. For example, some approaches focus on simplified models in which a single joint is operated by a pair of muscles acting as reciprocal (agonist/antagonist) actuators. At the most detailed level of analysis, individual motor units may be considered as actuator elements. In this case, the dimensionality of the actuator space can reach hundreds of thousands.

Generalized Coordinates

A different description of body motions is afforded by the values of the joint angles that define the orientation of each skeletal segment either with respect to fixed axes in space or with respect to the neighboring segments. Joint angles are a particular instance of generalized coordinates. Generalized coordinates are independent variables suitable for describing the dynamics of a mechanical system. The term dynamics refers to a description of how the state of motion of a limb evolves under the influence of the muscle forces, of the passive mechanical properties of the moving limb, and of the forces generated by the environment with which the limb comes in contact. Mathematically, dynamics are expressed by differential equations that relate these forces and the current state of motion of a limb (its position and velocity) to the rate of change of velocity (i.e., the limb's acceleration). A typical problem in engineering is to find the forces that must be applied to the mechanical joints of a robotic arm so as to generate a desired trajectory. The solution to this problem – called 'inverse dynamics' – requires representing the dynamics equation of the arm and calculating the applied force from the desired position, velocity, and acceleration of each joint.

The concept of state is critically important in a dynamical formulation. The state of a mechanical system is the smallest set of variables that suffices to describe the future evolution of a system given its current value and the applied forces.

The idea that the state of a system is specified by its position and velocity is generally applicable to all mechanical systems, but specific applications require a careful definition of what is meant by 'position' and 'force.' This extension to generalized coordinates and generalized forces was introduced soon after Newton's early definition of force for simple point mass systems, and it involves the incorporation of constraints between the constituents of a composite system.

General Formulation of Limb Dynamics

In vector notation, the dynamics equations for a multijoint limb can be written as

$$I(q)\ddot{q} + G(q, \dot{q}) + E(q, \dot{q}, \ddot{q}, t) = C(q, \dot{q}, u(t)) \quad [1]$$

where $q = (q_1, q_2, \ldots, q_n)$ is the generalized coordinate description for the position – or 'configuration' – of the limb though its n joint angle coordinates; $\dot{q}$ and $\ddot{q}$ are respectively the first (velocity) and second (acceleration) time derivatives of q, I is an $n \times n$ matrix of inertia (that depends on the configuration); $G(q, \dot{q})$ is a vector of centripetal and Coriolis torques; and $E(q, \dot{q}, \ddot{q}, t)$ is a vector of external torques, which depends, in general, on the state of motion of the limb, its acceleration, and also, possibly, time. In a more compact notation, Coriolis and inertial forces are lumped in a single function $D(q, \dot{q}, \ddot{q})$ representing the passive dynamics of the limb, and eqn [1] becomes

$$D(q, \dot{q}, \ddot{q}) + E(q, \dot{q}, \ddot{q}, t) = C(q, \dot{q}, u(t)) \qquad [2]$$

The left side of eqns [1] and [2] represents the torque due to inertial properties and to the action of the environment (part of which may be considered as 'noise'). The term $C(\cdot)$ on the right side represents the net torque generated by the muscles. The time-dependent function $u(t)$ is a vector of control variables representing, for example, a set of neural signals directed to the motor neurons or the desired limb position at time t. An additional term, to be added to the right side of eqns [1] and [2], could represent the noise associated with $u(t)$.

Costs and Benefits of Motor Redundancy

A distinctive feature of biological control systems is what appears to be an overabundance of controlled components and of degrees of freedom. The term 'kinematic redundancy' describes this feature. Advanced robotics technologies have recognized the value of design that allows for 'extra' degrees of freedom in favor of greater versatility and dexterity. Ultimately, the term 'redundancy' could be considered as a misnomer because it does not acknowledge that the dimension associated with a task may well exceed the dimension of the kinematics space. For example, Hogan pointed out the important role played by what appear to be extra degrees of freedom that modulate the impedance of the endpoint of a limb in the face of an expected impact.

The computational problem associated with kinematic redundancy is illustrated in Figure 1, which represents the maps of force and position in a serial limb, such as the arm. On the right side of the figure are the representations of state and force variables in endpoint coordinates. These variables are observed at the interface with the environment – for example, the position of the fingertip and the contact force at this point. On the left side are descriptions in actuator coordinates. Note that the force generated by the muscular system results from a function that maps the state of motion of the muscles – collectively indicated by the two vectors $l, \dot{l}$ of muscle lengths and their rates of change – and the muscle control signals $u(t)$ into a vector f of muscle tensions. This map of muscle tensions is in general nonlinear and noninvertible. The generalized coordinates, typically joint angle variables, are an intermediate representation between actuator and endpoint coordinates. The directions of the arrows in Figure 1 correspond to the directions in which kinematic and force transformations are well posed. For example, joint angles map into endpoint position via a direct kinematics function L and into muscle length via a function M. Both functions are generally noninvertible, although for different reasons. The map L is noninvertible because a given endpoint position can be obtained through a large number of joint configurations that define a so-called 'null space.' The term null space refers to directions of variability in the space of generalized coordinates that result in no change of the endpoint location. In more formal terms, if A is a matrix acting on a vector space x, the null space of A is the set of all vectors x that satisfy $Ax = 0$. The map M is noninvertible because an arbitrary set of muscle lengths may not be realizable because it may have no corresponding image in configuration space. Although the kinematic maps L and M refer to coordinate transformations, forces transform in a dual, reciprocal way through the Jacobian derivatives ∂L and ∂M of the corresponding kinematic functions. Note the reversed direction of the corresponding arrows.

Figure 1 Coordinate systems and coordinate transformations for planning and control.

The Representation of Space in Motor Planning

The remarkable ability of the visual system to capture the Euclidean invariance of object size and shape with respect to rigid translations and rotations has been extensively studied. For example, it has been proposed that the Euclidean metric of object space is implicitly learned and represented internally. In contrast with the long-standing interest in the visual perception and representation of space, little is known about how the fundamental geometrical properties of space are represented in the motor system, in which

neither sensory nor muscle command signals are characterized by Euclidean invariance. Our ability to generate straight motions of our hand in different directions and from different starting points, without apparent effort, is a simple demonstration of our motor system's de facto ability to capture the Euclidean properties of the space in which we move.

Mosier et al. investigated how movement representations are reorganized by the central nervous system to capture the Euclidean properties of the space within which actions take place. In these experiments, subjects wore a data glove that allowed for the measurement of 22 signals related to hand and finger postures. A highly redundant linear mapping was used to transform these 22 signals into two coordinates defining the location of a cursor on a computer monitor (Figure 2). The results suggested that subjects not only learned to produce novel coordinated movements

Figure 2 Reorganization of hand movements. Subjects were asked to control movement of a cursor by changing the configuration of hand and fingers. The hand was instrumented with a data glove. Hand configuration controlled the position of a cursor on the screen via a smooth and linear map from the 22-dimensional vector of glove signals to the two coordinates of the monitor. Circular targets were presented and subjects were asked to make a rapid movement to the target, stop, and then correct. Movements were executed under one of two training protocols. In the no-vision (NV) protocol, the cursor was suppressed during the reaching movements. The cursor was only presented at the end of reaching to allow for a correction (not analyzed). In the vision (V) protocol, the cursor was always visible. Subjects in the P2 group were trained and tested under the NV protocol. Subjects in the P3 group were trained under the V protocol and tested under the NV protocol. Data analysis was carried out only for test trials allowing comparison of how subjects executed reaching movements without visual guidance after having trained without (P2) and with (P3) visual guidance. (a) The linear map from glove signals to screen coordinates was set up by asking the subjects to hold their hand in four 'standard gestures' corresponding to the corners of a rectangular region on the monitor. (b) Two sets of cursor trajectories obtained from a subject on day 1 and on day 4 of training. (c) Subjects in both P2 and P3 groups learned the reaching task with similar results. The two plots show the average reaching error measured in each of four sessions on consecutive days. The vertical bars are 99% confidence intervals. (d) Under both training conditions, subjects tend to produce straighter cursor motions as evidenced by the decreasing trend in 'aspect ratio,' the ratio of lateral deviation to movement extent. Subjects trained with vision generated significantly straighter trajectories than subjects trained without vision of cursor motion. Modified from Mosier KM, Sceidt RA, Acosta S, and Mussa-Ivaldi FA (2005) Remapping hand movements in a novel geometrical environment. *Journal of Neurophysiology* 94: 4362–4372, with permission.

to control the placement of the cursor but also developed a representation of the two-dimensional space (the plane of the monitor) onto which hand movements were mapped. The emergence of this representation is evidenced by the practice-induced tendency to generate controlled trajectories that were both shorter and less variable. The construction of this representation appears to involve the subjects' ability to partition the degrees of freedom of the hand into combinations that contributed to cursor movements and null space combinations that did not generate any cursor movement.

From Planning to Control

Although the transformation from a desired motion to a set of control signals $u(t)$ may be ill-defined, a plan of action may be implemented as an approximation of a desired force field by an appropriate tuning of viscoelastic actuators. The force field f generated by the combined viscoelastic behavior of the muscles under a pattern of control signals $u(t)$ is given by a function $f(l, \dot{l}, u(t))$. This force field can be expressed in terms of generalized coordinates through the Jacobian derivative of the map M, resulting in a computational structure that does not involve any ill-posed inverse mapping:

$$Q = \phi_f(q, \dot{q}, u(t)) = \partial M(q)^T f\Big(l(q), \dot{l}(q), u(t)\Big) \quad [3]$$

The planning of a desired behavior can in turn be expressed as a force field F that maps a state of the endpoint (e.g., a heading direction) into a corrective force $F(x, \dot{x}, t)$. This is a way to represent what some researchers would call a 'policy' – a prescribed action in response to an observed state. This policy can be represented as a force field in terms of generalized coordinates through the Jacobian derivative of the map L, resulting also in this case in a computational structure that does not involve any ill-posed inverse mapping:

$$Q = \psi_F(q, \dot{q}, t) = \partial L(q)^T F(x(q), \dot{x}(q), t) \quad [4]$$

Therefore, the biological implementation of a planned policy can be seen as the approximation

$$\varphi_f(q, \dot{q}, u(t)) \approx \psi_F(q, \dot{q}, t) \quad [5]$$

to be achieved through the appropriate choice of $u(t)$.

Motor Primitives and Field Approximation

In a series of experiments, the activity induced by chemical and electrical stimulation of the spinal interneurons of the frog was found to spread to several groups of motor neurons. This distribution of activity was not random but, rather, imposed a specific balance of muscle contractions. The activation of a group of muscles generated a force that was recorded by a sensor at the endpoint of the limb. This force vector changed in amplitude and direction depending on the position of the limb. The resulting force field converged toward a location in the reachable space of the limb – a stable equilibrium point.

Perhaps the most interesting aspect of these investigations was the discovery that the fields induced by the focal activation of the cord follow a principle of vectorial summation: when two separate sites in the spinal cord were simultaneously active, the resulting force field was the vector sum of the force fields induced by the separate activation of each site.

Consistent with the finding of vector summation, the net force field C induced by a pattern of K motor commands may be represented as a linear combination over the corresponding K primitive force fields, labeled by an index i running from 1 to K:

$$\sum_{i-=1}^{K} c_i \varphi_i(q, \dot{q}, t) \quad [6]$$

In this expression, each spinal force is a field that depends on the state of motion of the limb, $(q, \dot{q})$ and on time t. The descending commands $(c_1, c_2, \ldots, c_K)$ modulate the degree with which each spinal field $(\varphi_1, \varphi_2, \ldots, \varphi_K)$ participates in the combination. These commands select the modules by determining how much each one contributes to the net control policy. The linear combination of eqn [6] generates the torque, the generalized force that drives the limb inertia. Substituting it for the right-hand side of eqn [2] results in

$$D(q, \dot{q}, \ddot{q}) + E(q, \dot{q}, \ddot{q}, t) = \sum_{i=1}^{K} c_i \varphi_i(q, \dot{q}, t) \quad [7]$$

For simplicity, let us start by analyzing the implications of eqn [7] in the case in which the controlled limb is not affected by external forces – that is, $E = 0$. In this case, a least squares approximation (**Figure 3**) can efficiently determine the optimal set of coefficients $(c_1, c_2, \ldots, c_K)$ for a desired trajectory $q_D(t)$:

$$c_i = \sum_{i=1}^{K} [\Phi]_{i,j}^{-1} \Lambda_j \quad [8]$$

with

$$\begin{cases} \Phi_{l,m} = \int \varphi_l(q_D(t), \dot{q}_D(t), t) \bullet \varphi_m(q_D(t), \dot{q}_D(t), t)\, \mathrm{d}t \\ \Lambda_j = \int \varphi_j(q_D(t), \dot{q}_D(t), t) \bullet D(q_D(t), \dot{q}_D(t), \ddot{q}_D(t))\, \mathrm{d}t \end{cases} \quad [9]$$

where the symbol $\bullet$ indicates the ordinary inner product.

Figure 3 Control by field approximation. The desired trajectory is represented schematically in blue. The black arrows are the dynamic forces generated by D along the desired trajectory. The green vectors are the forces generated by a linear combination of force fields. The red bars are the errors to be minimized by least squares.

Although spinal force fields offer a practical way to generate movement, they also provide the central nervous system with a mechanism for movement representation. The possible movements of a limb can be considered as 'points' in an abstract geometrical space in which the fields $\{\varphi_i\}$ provide a basis such as that provided by Cartesian axes, and the selection parameters $\{c_i\}$ that generate a particular movement may be regarded as generalized projections of this movement along the $\{\varphi_i\}$ axes.

The Presence of Noise and Uncertainty Leads to a Segmentation of Motor Control

Primitive force field combinations do not have to be restricted to simultaneous activation, as in eqn [6]; they can be combined over time:

$$\sum_{i=1}^{N} c_i \varphi_{n_i}(q, \dot{q}, t - \Delta t_i)$$

where $n_i \in \{1, 2, \ldots, K\}$. Such a temporal summation of primitive force fields can arise when executing a preplanned complex movement or when the executed movement needs to be updated. Updating an ongoing movement may be required when the goal of the movement has changed during movement execution, or when the executed movement deviates from the planned one. Deviations between the planned and actual movement may be caused by inaccurate inverse/forward models or because of noise in the planning and execution stages of the movement. Indeed, many studies have demonstrated that rapid reaching movements of human and nonhuman primates are often characterized by irregular multipeaked velocity profiles, which can be interpreted as a temporal summation of movement primitives with bell-shaped velocity profiles. Many movement segmentation methods have been proposed, most of which assumed that all movement primitives share the same basic velocity profile but could be scaled in time and magnitude to best match the combined movement. It is important to note that demonstrating that a velocity trace can be represented by a linear superposition of a set of discrete primitives is not sufficient evidence for the existence of these primitives. Indeed, studies have suggested that a continuous control process can produce kinematic irregularities that do not reflect superposition of discrete movement primitives. However, Fishbach and collaborators have reported several experimental findings that are difficult to reconcile with a purely continuous controller. In their experiments, monkeys were trained to perform a one-dimensional reaching task, in which the target was occasionally perturbed at movement onset. Analysis of the movement corrections shows a wide distribution of the time of the first correction and a strong correlation between the correction timing and the amplitude of the initial portion of the movement. These results suggest a model for movement update in which a forward model is used to continuously estimate both the expected error of the ongoing movement and the variance of the predicted error. Once the probability distribution of the predicted endpoint is statistically different from the target's location, a discrete movement primitive is triggered to compensate for the discrepancy. This control strategy is similar to the sliding variable control which uses a threshold nonlinearity on the predicted error, except that the former uses a threshold nonlinearity on the predicted z score of the error. Fishbach and coworkers used their model to successfully predict the timing of the observed corrections. Whereas Fishbach et al.'s study provides strong support for the view of temporal superposition of discrete movement primitives, the interpretation of multipeaked velocity profiles of reaching movements remains a strongly debated subject.

Sensory Motor Adaptation

If the arm dynamics change while the modules remain unchanged, then the representation of the movement must change accordingly. Suppose that a desired trajectory $q_D(t)$ is represented by a selection vector $c = (c_1, c_2, \ldots, c_K)$ for a limb not affected by external forces (i.e., $E = 0$). If the limb dynamics are suddenly modified by an external force, $E(q, \dot{q}, \ddot{q}, t)$, then the full form of eqn [7] must be considered:

$$D(q, \dot{q}, \ddot{q}) + E(q, \dot{q}, \ddot{q}, t) = \sum_{i=1}^{K} c_i \varphi_i(q, \dot{q}, t)$$

The solution to this equation will be a trajectory $\tilde{q}(t)$, generally different from the original $q_D(t)$ for $E = 0$. To recover the desired trajectory, the selection vector needs to be changed from c to a new vector, $c' = c + e$, where the correction vector e satisfies

$$E(q_D(t),\dot{q}_D(t),\ddot{q}_D(t),t) = \sum_{i=1}^{K} e_i\varphi_i(q_D(t),\dot{q}_D(t),t) \quad [10]$$

The modified coefficients $c' = c + e$ offer a new representation of the desired trajectory $q_D(t)$; the change reflects an alteration of the dynamic conditions within which the trajectory is to be executed. This computational procedure for forming a new representation and for recovering the original trajectory is consistent with the empirical observation of aftereffects in force field adaptation. If the force field is removed after the new representation is formed, the dynamics becomes

$$D(q,\dot{q},\ddot{q}) = \sum_{i=1}^{K}(c_i + e_i)\varphi_i(q,\dot{q},t) \quad [11]$$

which can be rewritten as

$$D(q,\dot{q},\ddot{q}) - \sum_{i=1}^{K} e_i\varphi_i(q,\dot{q},t) = \sum_{i=1}^{K} c_i\varphi_i(q,\dot{q},t) \quad [12]$$

Therefore, removing the load while maintaining the new representation will result in a trajectory that corresponds approximately to applying the opposite load with the old representation, in agreement with observed aftereffects.

The modification of motion representation through the selection coefficients thus provides a useful mechanism for rapidly adjusting to changes in limb dynamics. It is of interest to ask whether these representations need to be recalculated in response to every dynamical change or whether previously existing representations can be restored. From a computational standpoint, whenever a dynamical change becomes permanent, such as when due to growth or damage, it would be convenient for the central nervous system to have the ability to restore the previously learned motor skills (i.e., the previously learned movement representations) without need to relearn them. It is possible for the adaptive system described here to do this by modifying the force fields expressed by the individual modules. A specific mechanism follows from expressing the coefficients $e = (e_1, e_2, \ldots, e_K)$ as a linear transformation of the original coefficients $c = (c_1, c_2, \ldots, c_K)$:

$$e = Wc \quad [13]$$

This is a simple coordinate transformation applied to the change e in selection vector; a linear associative network can implement it. A few steps of algebra lead to

$$\begin{aligned} D(q,\dot{q},\ddot{q}) + E(q,\dot{q},\ddot{q}) &= \sum_{i=1}^{K} c_i'\varphi_i(q,\dot{q},t) \\ &= \sum_{i=1}^{K}(c_i + e_i)\varphi_i(q,\dot{q},t) \\ &= \sum_{i=1}^{K} c_i\bar{\varphi}_i(q,\dot{q},t) \quad [14] \end{aligned}$$

where the old fields ϕ_i have been replaced by the new fields

$$\bar{\varphi}_i = \sum_{i=1}^{K}(\delta_{li} + W_{li})\varphi_l \qquad \delta_{li} = \begin{cases} 1 & \text{if } l = i \\ 0 & \text{otherwise} \end{cases} \quad [15]$$

This coordinate transformation is then made permanent through a change in the modules that represent individual force fields. By means of such coordinate transformation, one obtains the important result that the movement representation (i.e., the selection vector c) can be maintained invariant after a change in limb dynamics.

Forward and Inverse Models as Basis for Adaptive Control

The ability to generate a variety of complex behaviors cannot be attained by just storing the vector c of control signals for each action and recalling these selection coefficients when subsequently needed. Simple considerations about the geometrical space of meaningful behaviors are sufficient to establish that this approach would be inadequate. To achieve its typical competence, the motor system must take advantage of experience for going beyond experience by constructing internal representations of the controlled dynamics, such as the projections of D onto the fields φ_i, as in eqn [7] for $E = 0$. These representations need to allow the nervous system to generate new behaviors and to handle situations that have not yet been encountered. The term 'internal model,' used to indicate the collection of available internal representations, implies the ability to perform two distinct mathematical transformations: (1) the transformation from a motor command to the consequent behavior and (2) the transformation from a desired behavior to the corresponding motor command. A model of the first kind is called a 'forward model.' Forward models provide the controller with the means not only to predict the expected outcome of a command but also to estimate the current state of the limb in the presence of feedback delays. Conversely, a representation of the transformation from desired actions to motor commands (as in eqns [8] and [9])

is called an 'inverse model.' Studies by Kawato, Wolpert, and Miall have led to the proposal that neural structures within the cerebellum perform sensorimotor operations equivalent to a combination of multiple forward and inverse models. Strong evidence for the biological and behavioral relevance of internal models has been provided by numerous experiments. Some of these experiments involved the adaptation of arm movements to a perturbing force field generated by a manipulandum. The major findings of these studies are as follows (**Figure 4**):

1. When exposed to a complex but deterministic field of velocity-dependent forces, arm movements are at first distorted, but the initial kinematics are recovered after repeated practice.
2. If, after adaptation, the field is suddenly removed, aftereffects are clearly visible as mirror images of the initial perturbations, as described by eqn [12].

Figure 4 Force field adaptation experiment. (a) Subjects hold the end effector of a two-joint planar robot and execute reaching movements to a set of targets. (b) The robot can generate a force that depends on the measured velocity of the end effector. (c) Typical trajectories generated by a subject when the robot is not generating any force field. (d–g) Average ± standard deviation of hand trajectories during the training period in the force field (b). The four panels represent the performance during four consecutive sets of 250 targets. (h) Aftereffects of adaptation. These trajectories were obtained at the end of the training period by exposing the subject to random trials in which the field was unexpectedly removed. Note that the shape of these trajectories is approximately the mirror image of the trajectories in (d). Modified from Shadmehr R and Mussa-Ivaldi FA (1994) Adaptive representation of dynamics during learning of a motor task. *Journal of Neuroscience* 14(5): 3208–3224, with permission.

3. Adaptation is achieved by the central nervous system through the formation of a local map that associates the states (positions and velocities) visited during the training period with the corresponding forces.
4. This map, which is the internal model of the field, undergoes a process of consolidation after adaptation.

In order to generate the appropriate command for a desired movement of the arm, an inverse model must take into account that multijoint inertia depends on limb position and velocity. Therefore, an inverse model must be informed about the current state of motion of the limb. This information may come from (1) the input to the inverse model that specifies where the limb should be or (2) a prediction of the current state based on delayed sensory feedback and on the past history of motor commands. Bhushan and Shadmehr found compelling evidence for the second way. Their experimental results are consistent with the hypothesis that we learn to compensate changes in limb dynamics by a process that involves the combined adaptation of a forward and an inverse model of the limb.

State Space Models of Motor Learning

The process of learning requires practice. In this respect, the formation of an internal model can be described as the temporal evolution of a dynamical system. This is the point of view taken by Thoroughman and Shadmehr and others. Thoroughman and Shadmehr proposed to describe the adaptation to a force field as the temporal evolution of a system whose internal state is characterized by a hidden, unobservable variable z. The system produces an observable output to which a 'performance error' y can be associated. An input signal p describes the applied perturbation through binary values that indicate the presence ($p = -1$) or absence ($p = +1$) of the applied field. The proposed state space model is a quite simple because it involves only linear first-order dynamics over discrete time steps counted by the index n:

$$\begin{aligned} z_{n+1} &= az_n + bp_n \\ y_n &= z_n + dp_n \end{aligned} \qquad [16]$$

Despite its simplicity, the model proved adequate to capture a number of observed features of the learning process. One such feature is the time course of adaptation, as captured by the deviation of each movement from a straight line; this deviation was taken to be the observable error y. Thoroughman and Shadmehr noticed that following each 'catch trial' – a trial in which the force field is unexpectedly removed – the experimental data indicated a brief but distinguishable unlearning period. The time course of this effect was

Figure 5 Unlearning effects captured by a state-space model. The plot depicts the time course of error in subject reaches in a particular direction. The circles are the errors (maximum lateral deviations from straight line) measured in each movement during training in the field. The field was suppressed at random trials during this experiment. When the field was suppressed in a 'catch trial', there was an aftereffect, indicated by a large negative error spike. Following a catch trial, the error returned at a level higher than the level immediately preceding the catch trial. Thus, catch trials cause unlearning. This effect is captured by state-space models of learning both in a scalar (black line) and in a vector (red line) form. Reproduced from Thoroughman KA and Shadmehr R (2000) Learning of action through adaptive combination of motor primitives. *Nature* 407: 742–747.

adequately captured by the state space model (Figure 5). Another important feature of this model is expressed by the value of the parameter b, which represents the effect on the current state (and therefore on the current error) of having experienced a force in the previous state. By estimating from the empirical error data the dependence of b on the direction of the previous movement, Thoroughman and Shadmehr were able to derive 'tuning curves' which demonstrate a destructive interference from previously experienced forces when there is a major difference between the current and the previous direction of movement.

An intriguing feature of this state space model is its low order as a dynamical system. All that seems to matter is the experience that the learner has acquired in the previous repetition of the task. This conclusion is supported by the observations of Scheidt and collaborators, who exposed a group of subjects to randomly varying force fields. In each trial, subjects were exposed to velocity-dependent forces perpendicular to the direction of motion. The amplitude of the force was related to movement speed by a gain factor B. The actual value of this factor was randomly drawn on each trial from a Gaussian distribution. With practice, the best performance of the subjects (zero error) was achieved for the mean value of the perturbing gain factor (Figures 6(a) and 6(b)).

Figure 6 Adaptation to random force fields. Subjects were asked to move the hand against a velocity-dependent force field, whose gain varied randomly from trial to trial. For one group of subjects, the gain was drawn from a Gaussian probability distribution (a). The scatter plot of movement error versus field gain (b) exhibited a nearly linear relation ($r = 0.82$). Note that the zero crossing is near the mean value of field gain: subjects learned the mean field. A second group of subjects was exposed to a random perturbation that followed a bimodal distribution (c). The scatter plot of movement error versus field gain showed a linear trend ($r = 0.85$) and the zero crossing was again in the vicinity of the mean value of the gain (d). This is remarkable because subjects learned to compensate the mean perturbation, which in this case was never encountered during learning.

Remarkably, the same result was observed when the random gain factor was drawn from a bimodal distribution (Figures 6(c) and 6(d)). This is apparently paradoxical because in the bimodal case the mean value of the gain factor B is never experienced. The situation is reminiscent of the Buridan ass, which died of starvation because he could not chose between two identical stacks of hay placed in opposite directions. However, paradoxical as it may seem, a strategy based on the estimated mean value of the gain factor B is optimal in the sense of minimizing the mean square error.

These experimental observations indicate the existence of an underlying linear mechanism that guides the learning process. This suggests the possibility of using a simple linear time series – an autoregressive model with external input – to describe the learning behavior:

$$y_i = \sum_{j=1}^{L} a_j y_{i-j} + \sum_{k=0}^{M} b_k B_{i-k} \qquad [17]$$

In this model, y_n and B_n are, respectively, the error (deviation from linearity) and the input (field gain) at the nth trial. An estimation of the time windows L and M of the autoregressive process showed that the error at the current trial is only affected by the current input and by the immediately preceding input and error. The previous equation can then be rewritten as

$$y_i = a_1 y_{i-1} + b_0 B_i + b_1 B_{i-1} \qquad [18]$$

A simple transformation establishes the equivalence between this $L = M = 1$ model and the formulation of Thoroughman and Shadmehr shown in eqn [16].

Sensorimotor Plasticity and Control of Movement Following Spinal Cord Injury +D18

V R Edgerton and R R Roy, University of California at Los Angeles, Los Angeles, CA, USA

© 2009 Published by Elsevier Ltd.

Comparison of the Control of Movement in the Intact Neuromuscular System and after a Spinal Cord Injury with and without Sensory Input

Normally, movement is controlled with a high level of precision as a result of a combination of highly integrated input between the brain and the spinal cord and the peripheral sensory information associated with the movement. All these components are important elements in the control of normal movement. However, perhaps due to the extensive redundancy and the intrinsic plasticity within the neuromuscular system, some of these components can be lost and reasonably effective movements still can be performed.

It is clear that locomotor-like activity can be generated by the spinal cord in the absence of any input from the brain when the peripheral sensory information that is generated during the movement is available to the spinal cord. Just as impressive is the fact that the spinal cord can generate coordinated motor outputs that share many of the features of normal locomotion, even in the absence of supraspinal or peripheral sensory oscillatory input. The isolated spinal cord can generate repetitive steplike cycles for hours with an impressive level of coordination of the flexor and extensor muscles that normally control the hindlimb joints. This is particularly evident when the spinal circuitry is at a high tonic and excitable state, a state usually induced in the laboratory pharmacologically, by tonic brain stem stimulation, by tonic spinal cord stimulation, and/or by tonic peripheral nerve or dorsal root stimulation. This oscillatory and coordinated flexor–extensor output of the spinal cord in the absence of oscillatory supraspinal or peripheral input is referred to as fictive locomotion. It should be noted, however, that the functional capability of the spinal cord in the absence of supraspinal input is even greater when sensory input is present. For example, when the spinal cord has access to the sensory inflow associated with weight-bearing stepping, it can adjust to varying loads and speeds placed on the hindlimbs, can perform complicated motor responses to unpredictable events such as stepping over obstacles, and can learn to perform specific motor tasks when trained appropriately over a period of weeks.

With respect to spinal cord injury and the practical application of the ability of the spinal cord isolated from the brain to perform useful movements, the spinal cord must have access to the cutaneous and proprioceptive input that provides the information that enables the spinal cord to generate functionally useful weight-bearing stepping. The role of sensory input is emphasized because of its critical importance in rehabilitative strategies designed to recover motor function following a spinal cord injury. The spinal cord circuitry cannot generate effective locomotion in the absence of sensory input, and it cannot learn to step or to stand in response to training. Fortunately, the pathways for normal sensory input to the spinal cord are preserved following most spinal cord injuries. Equally fortunate is the fact that the spinal circuitry and neurons necessary to interpret and generate the appropriate motor patterns are located within the lumbosacral spinal cord, a region that is not usually damaged when a spinal cord injury occurs.

An exception to the preservation of the lumbosacral segments following a spinal cord injury is when there is direct damage to the dorsal and ventral roots, as can occur from an impact on the sacrum as in falling, often resulting in damage to the cauda equina. In this case, both the sensory and motor output to the muscles of the hindlimb usually can be critically damaged. The major barrier to motor recovery in these cases is the magnitude of the damage, that is, the number of motor neurons and sensory fibers damaged. The critical questions are: (1) are there enough intact motor neurons remaining to generate sufficient force to accomplish weight-bearing stepping or standing? and (2) is there a sufficient number of sensory fibers that can provide adequate information to contribute to the control of these movements? The functional prognosis when there is an injury to the cauda equina, in some cases, can be better than for injuries at a higher level because the supraspinal control of the remaining spinal circuitry can effectively compensate for a significant loss of neurons in the damaged sacral area. In contrast, the loss of function following injuries within the thoracic or cervical regions of the spinal cord is usually not due to the loss of neurons associated with motor output or with sensory input but, instead, is related to the lack of supraspinal control of those neurons persisting below the lesion that continue to have the potential to generate effective standing and stepping.

Why Is the Sensory Input to the Spinal Cord So Crucial When the Spinal Circuitry Alone Can Generate a Coordinated Output?

As noted previously, in order to be of practical significance in the rehabilitation setting, a critical feature of the spinal circuitry is its ability to receive and interpret online and very accurately the ensemble of sensory information that it is provided continuously. For example, the interneuronal components that are necessary to activate the flexor muscles at the appropriate level and time during a step cycle must recognize the sensory input that is associated with each phase of the step cycle. In this case, the initiation of extension of the plantarflexors of the foot and the sensory input associated with the first phase of foot contact during stance must know that the end of the swing phase has just occurred and, furthermore, must know which muscles to activate next. That is, those neurons associated with a given phase of a motor event recognize the ensemble of sensory input that is normally associated with that motor event (e.g., the specific phase of a step cycle). But it is important to recognize that these sensorimotor circuits are not acting as simple reflexes (i.e., stimulus-response during weight-bearing stepping). In essence, the sensory enables the spinal circuitry to interpret and anticipate the motor event that will be initiated next during a given phase of the step cycle.

In addition to being able to generate routine repetitive stepping, the spinal circuitry is highly capable of rapid adaptability. For example, it can adapt the stepping mechanics in spinal cats when there is an attempt to prevent the hindlimb from moving forward during the swing phase of a step. More specifically, when a stimulus is provided to the dorsum of the paw of the spinal cat during the flexion phase of a step cycle, ipsilateral flexion is enhanced, thus enabling the cat to step above an object in its path. In contrast, when the same stimulus is applied during the stance phase of a step cycle, the duration and magnitude of extension is enhanced. These experiments demonstrate that the motor output generated depends on the functional state of the spinal cord and, more specifically, on the phase of the step cycle. This is an obvious example of decision making or interpretation made by the spinal circuitry based on temporal sensory input, pointing out that the neural processing that occurs within the spinal circuitry reflects much more sophisticated circuitry than is typically associated with spinal reflexes. There are similar examples of the importance of sensory information derived from the limbs during stepping in human subjects. For example, the level of activation of extensor muscles during stepping is modulated directly with the level of loading. Even more interesting is the observation that this modulation of level of activation of extensor muscles with load changes is similar whether the subject is nondisabled (Figure 1(a)), has a severe spinal cord injury (Figure 1(b)), or even has a complete spinal cord injury (Figure 1(c)).

As already stated, it is apparent that the motor responses generated by the spinal cord are a function of the ensemble of sensory information and the physiological state of the spinal circuitry. The degree to which

Figure 1 The effects of changes in levels of loading on the lower limbs on the level of activation of an extensor muscle of the ankle (i.e., the soleus) when stepping on a treadmill: (a) nondisabled subject; (b) subject with a severe but incomplete spinal cord injury, classified as ASIA C; (c) subject with a complete spinal cord injury, classified as ASIA A. The loading is controlled through a suspension apparatus, with the subject wearing a vest similar to that used during mountain climbing. The amplitude of the EMG increases similarly with increasing loading for all subjects. EMG, electromyogram. Modified from Harkema SJ, Hurley SL, Patel UK, et al. (1997) Human lumbosacral spinal cord interprets loading during stepping. *Journal of Neurophysiology* 77: 797–811.

this response depends on an ensemble of information versus a specific response of a specific type of receptor, however, remains to be determined. Although there is increasing evidence that the spinal circuitry, as well as the brain circuitry, responds to profiles of sensory information rather than to a specific receptor inducing a specific response, the critical experiments that confirm this hypothesis have not been performed. An analogy to this ensemble concept might be that the individual letters within this paragraph have no meaning in themselves, but when the letters are combined in certain patterns (words, phrases, sentences, and paragraphs) complex meanings or states can be derived by the brain. A similar analogy can be conceptualized in processing visual information. For example, an individual pixel of a high-density photograph has little or no meaning, but when all the pixels are in their normal spatial positions complex meanings and responses are generated.

Physiological State of the Spinal Cord

Pharmacological Modulation

After a complete thoracic spinal cord injury in cats, rats, and mice, the spinal circuitry necessary for generating full weight-bearing stepping remains anatomically intact. For example, several months after a complete spinal cord transection in an adult cat that had not recovered any stepping ability, weight-bearing steps over a range of speeds on a treadmill could be generated within 30 min after the administration of strychnine, a glycinergic receptor blocker that results in less inhibition, and therefore a greater level of excitability, of the spinal circuitry. Although it is not entirely known which neurotransmitter receptors are actually affected by this pharmacological intervention, spinal inhibitory circuits are mediated by glycinergic and γ-aminobutyric acid (GABA)ergic neurotransmitters. These neurotransmitters usually are co-expressed at the same terminals and play an important role in the coordination of agonist–antagonist motor pools. Our interpretation of experiments in which spinal cats were administered strychnine is that it has a facilitatory effect on the sensorimotor pathways involved in stepping. In general, the hindlimbs were flaccid prior to the administration of the inhibitory antagonist. We suggest that the spinal circuitry needed to generate weight-bearing stepping was present but that this circuitry was unable to interpret the sensory input until its general level of excitability was elevated. The physiological state of the circuitry was modified significantly by this pharmacological treatment. Similar conclusions can be drawn with the administration of other pharmacological agents. For example, Goldberger and colleagues reported that bicuculline, an inhibitory antagonist for GABAergic neurotransmission, had an effect similar to strychnine in facilitating locomotion in spinal cats. More recently, similar effects were observed in complete spinal adult mice given the serotonergic agonist quipazine. The general concept illustrated by these observations is that the physiological state of the spinal cord circuitry can be readily modulated. A very important feature of this concept that evolved from the most recent experiments, however, is that these pharmacological interventions need not, and actually preferably do not, induce the locomotion themselves but, instead, facilitate locomotion by enabling the spinal circuitry to interpret the cutaneous and proprioceptive information associated with specific phases of stepping and standing. This enabling phenomenon potentially can allow an individual with a spinal cord injury, particularly paraplegia, to manipulate the position of the legs and hip joints for generating weight-bearing stepping and sensory input.

Modulation of the Physiological State of the Spinal Cord with Epidural Stimulation

The physiological state of the spinal cord also can be readily modulated by tonic stimulation of the lumbosacral spinal cord via epidurally located electrodes. As with pharmacological interventions, the stimulation itself can be administered at an intensity level and frequency that does not induce stepping unless sensory signals associated with weight-bearing stepping are provided, as occurs when the hindlimbs are placed on a treadmill belt. Thus, these experiments also demonstrate the changing of the physiological state of the spinal cord so that the sensory information can reach those spinal circuits that have the capability to accurately interpret the sensory ensemble associated with specific phases of the weight-bearing state of the hindlimbs and then generate the appropriate motor response. Based on the success of prior experiments using epidural stimulation over the lumbosacral spinal cord in mice, rats, and cats, this approach represents an exciting potential for enhancing the recovery of stepping and standing in human subjects following a complete spinal cord injury. We have recently demonstrated that epidural stimulation also has been successfully applied to facilitate rhythmic activity and improve the training effect in chronic spinal rats.

In humans, spinal cord electrical stimulation has been successfully used for the suppression of pain and spasticity. To control severe spasticity, an optimal location of the electrodes was reported to be between L1 and L3, with a stimulus frequency of 50–100 Hz. It appears that the optimal stimulation parameters for

the control of spasticity and for initiating steplike electromyography (EMG) differ. A nonpatterned tonic stimulation at a frequency of 25–50 Hz elicited rhythmic, alternating EMG patterns in individuals with chronic complete spinal cord injury. Recent studies have suggested improved overground ambulation following a combined treatment of body-weight-support treadmill therapy and epidural stimulation in a chronic incomplete spinal-cord-injury subject.

Changing the Physiological State of the Spinal Cord by Combining Pharmacological Agents, Epidural Stimulation, and Motor Training

Other, more long-term modulation techniques can be used to change the physiological state of the spinal cord. Step and stand training represent two examples in which the repetitive activation of specific sensorimotor pathways results in a reinforcement of the order of activation of these pathways, resulting in a higher probability of generating successful weight-bearing standing or stepping.

In developing more effective rehabilitative strategies following spinal cord injury, it appears that a productive direction will be to identify how we can modulate the physiological state of the spinal cord in a highly predictable manner using a combination of electrical stimulation techniques, which can be rather noninvasive, and modulation via pharmacological cocktails targeting specific inhibitory and excitatory pathways. Both electrical stimulation and pharmacological modulation have been shown to be effective ways to enhance concomitant rehabilitative procedures in achieving an improved ability to step. Similar procedures are likely to be effective in improving standing.

Improved Coordination Is an Important Component of Learning to Step as a Result of Step Training Following a Complete Spinal Cord Transection

After a complete mid-thoracic spinal cord transection in an adult animal, the motor pools projecting to the muscles of the hindlimb remain active although at a lower than normal level. In addition, the activation of these motor pools is not well coordinated. This is shown by the higher incidence of co-contractions of the motor pools that normally function as agonists and antagonists after a spinal cord injury. Experiments in animals and humans suggest that step training can improve the level of coordination of agonistic and antagonistic muscles to a level more typical of normal than when there is no training. Improved coordination between the two hindlimbs in spinal cats is an important component of successful stepping. For example, we observed that one of the primary factors contributing to an unsuccessful step (i.e., continuous stepping fails when the hindquarters can no longer be supported), was a gradual shift in the coordination of the two hindlimbs, resulting in a shorter duration of double-weight support to the point at which both legs were in a non-weight-supporting position and the hindquarters collapsed. The results of a number of other studies examining the coordination within and across limbs in spinal animals and in humans with a spinal cord injury are consistent with the interpretation that an important aspect of step training is the improved coordination of the motor pools that generate stepping. This lack of precise timing of the normal pattern of the activation of the motor pools after a spinal cord injury is manifested as limb movements that are highly variable and, therefore, less predictable (Figure 2). Step training has been shown to reduce this variability by improving the preciseness of the motor pool coordination.

The Role of Muscle Plasticity in the Recovery of Locomotion Following a Complete Spinal Cord Injury

After a complete spinal cord transection, the muscles below the level of the lesion atrophy and generally shift in their functional and metabolic properties toward those of a faster muscle. These adaptations are observed to some extent in most muscles below the lesion, but the magnitude of the changes appears to be greater in predominantly slow extensor muscles (vastus intermedius, adductor longus, and soleus) than in predominantly fast extensor muscles (vastus lateralis, gastrocnemius, and plantaris) and greater in the extensor (vastus lateralis, gastrocnemius, plantaris, and soleus) than in the flexor (semitendinosus and tibialis anterior) muscles.

Motor training has some beneficial effects in restoring these properties toward normal levels in some muscles, but full recovery of muscle size and function does not seem to be an essential factor for improved motor performance. For example, the relative muscle mass and maximum tetanic tension of the soleus muscle of complete adult spinal cats that were weight-supported step trained for approximately 5 months were greater than in nontrained spinal cats but still lower than in normal control cats. Furthermore, these properties for the medial gastrocnemius muscle were similar in step-trained and nontrained spinal cats and were similar to normal control values for the tibialis anterior in both groups. Because the step-trained cats showed markedly better locomotor ability than the nontrained cats, the combined results

Figure 2 Plots of several *x* trajectories (dashed lines) and their corresponding first principal component (PC; solid lines): (a) for a quipazine-treated nontrained spinal (mid-thoracic, complete) mouse; (b) for a quipazine-treated robotically trained spinal (mid-thoracic, complete) mouse. The first PC from a principal component analysis (PCA) identifies the most representative step pattern executed by a mouse. A mouse with a high PCA percentage for its first PC stepped with a more consistent step shape than a mouse with a lower PCA percentage score. The PCA percentages, 67.9% (a) and 97.6% (b), respectively, indicate that quipazine facilitated a greater improvement in spatial stepping consistency in the trained mouse than the nontrained mouse. Note also from the different scales of the *x*-displacement (ordinate) axis that the trained mouse generally took much longer steps than the nontrained mouse. From Fong AJ, Cai LL, Otoshi, et al. (2005) Spinal cord-transected mice learn to step in response to quipazine treatment and robotic training. *Journal of Neuroscience* 25: 11738–11747.

indicate that adaptations in muscle properties alone cannot account for the improved locomotor ability of step-trained spinal cats. This is particularly evident when we consider that a decrease in ankle flexion (foot drop) during the swing phase of the step cycle is considered to be a primary deficit in generating a successful step, yet the mass and maximum tension capability of the tibialis anterior, the primary ankle flexor, is unaffected by a complete spinal cord transection. Thus, it appears that a combination of a critical mass and functional capacity of the musculature and adequate excitability of the appropriate spinal circuitry can contribute to an improvement in motor performance in complete spinal animals.

The size, metabolic, and functional properties of a skeletal muscle are highly dependent on the amount and pattern of neuromuscular activity imposed on that muscle. The actual amount of activation and/or loading required to maintain normal muscle properties, however, is undefined. Recent evidence from our and other laboratories indicates that these requirements may be minimal. For example, we have shown that as little as 1 min of high-load contractions (30 contractions, 1 s duration, performed twice per day) is effective in maintaining the size and force-generating properties of the otherwise inactive rat medial gastrocnemius muscle.

Dramatic Differences in the Mechanisms of Recovery Following Complete versus Incomplete Spinal Cord Injuries

Improved posture and locomotion can occur in complete spinal animals following training, as noted previously. As many as 10–15 consecutive weight-bearing steps have been generated successfully when human subjects with a complete mid-thoracic spinal cord injury were trained to step on a treadmill with some body-weight support. In human subjects, however, the success of independently regaining stepping capability with full weight bearing has been insufficient in individuals with a complete spinal cord injury. Thus, to date some weight-bearing assistance has been necessary for the steps to be generated consecutively by individuals with a clinically complete injury. It also has been reported, however, that an individual with a complete spinal cord injury learned to take some steps using a walker, through which considerable weight-bearing assistance and balance was provided by the subject's upper body.

On the other hand, human subjects with incomplete, even severe, spinal cord injuries can dramatically improve their locomotor ability. In a recent clinical trial, 90% of the subjects with incomplete injuries, 95% of whom could not generate any steps approximately 6 weeks following their injury, were able to step at nearly normal speeds following rehabilitation interventions that included weight-bearing step training. Similar recovery levels were observed in individuals who were trained using only overground step training compared to those who were trained on a treadmill with weight-bearing assistance. The important point is that the probability of recovering effective posture and locomotor function following a very severe, but incomplete, spinal cord injury is extremely high, assuming that appropriate rehabilitative and postinjury procedures are followed.

The results on motor recovery following a complete mid-thoracic spinal cord transection in mice and rats are more similar to that observed in humans than in cats with complete spinal cord injuries; that is, there is a more modest level of motor recovery unless the interventions involve pharmacological facilitation in combination with training. In contrast, partial lesions of the spinal cord in mice, rats, cats, and nonhuman primates result in near-normal recovery of posture and locomotion without any extensive training and rehabilitation. Thus, the specific mechanisms by which recovery occurs following a complete versus an incomplete lesion are fundamentally different. If the injury is incomplete, there is a possibility of reorganization of the descending control from the brain and of the spinal circuitry. With even a small amount of supraspinal input, the reorganization of the spinal circuitry allows for the remarkable levels of recovery seen in humans and laboratory animals. This phenomenon probably reflects not only the redundancy in the sensorimotor system, as noted earlier, but it also appears that novel pathways for sensorimotor control evolve, particularly with training. The important point in terms of rehabilitative strategies and of strategies to achieve novel reconnectivity of the appropriate neural circuits for generating posture and locomotion is that as long as some continuity (even very indirect) remains, the reorganization of existing circuits can be the basis for the extensive motor recovery. Thus, with incomplete injuries, reorganization can occur and reconnectivity can be achieved indirectly around the lesion by the expansion of existing noninjured neural circuits. This is not possible with a complete lesion because no noninjured descending pathways remain. After a complete lesion, on the other hand, (so far) to achieve full weight-bearing stepping new pathways by previously injured axons must grow through a major physical and chemical barrier. After an incomplete lesion, the existing circuitries can be enhanced, and these circuits can go around rather than though the lesion site. The reorganization of connectivity after a complete injury must involve regeneration through the lesion site.

Therefore, although remarkable and impressive levels of recovery are being reported regularly as a result of various types of surgical and pharmacological interventions, almost all of these experimental models involve incomplete lesions. The real challenge is to achieve improved function in humans with complete spinal cord lesions. Furthermore, in individuals with severe incomplete lesions, the degree to which we can take advantage of the minimal connectivity remaining above and below the lesion by using activity-dependent interventions to promote reorganization of this functional connectivity needs to be studied carefully.

Potential Advances on the Horizon

An exciting and growing list of widely varying strategies are being tested experimentally for their efficacy in facilitating the recovery of sensorimotor function after a spinal cord injury. There is a general consensus among scientists working on spinal cord injury that greater improvement can be achieved with multiple interventions. Theoretically, multiple strategies could be additive, particularly if the mechanisms involved with each intervention are different. Some of the strategies that have been reported to have positive effects, although very modest in most cases, are (1) modifying the properties of endogenous cells (i.e., altered gene expression); (2) transplanting cells that will replace those that are lost or transplanting cells that can generate molecules that have growth-promoting properties of the remaining axons (e.g., adult olfactory ensheathing cells; embryonic or adult stem cells); (3) transplanting segments of peripheral nerves to bridge the gap across the lesion; (4) transplanting embryonic tissue; (5) modifying the concentration of cyclic adenosine monophosphate (cAMP); and (6) modifying the extracellular matrix of the neuronal networks.

One of the most consistent observations has been that supraspinal and spinal plasticity is highly activity-dependent. Consistent improvement in motor function has been observed in different models of spinal cord injury, and it is likely that the effectiveness of each of the other interventions noted here will depend, in part, on whether there is an optimal level of neuromotor activity for the tissues that are involved in that intervention.

It cannot, however, be assumed that any given combination of interventions when used in concert with training will have a favorable outcome. Each intervention, including the activity-based therapies, ideally will be optimized with respect to dosage, time of administration, route of administration, and so on. But it will be even more difficult to identify the optimal activity-related behaviors when there are interactive effects of multiple interventions being used concomitantly. The challenge remains, however, to learn to use every mechanism of recovery so that their actions are complementary rather than competitive.

With continuing progress toward a better understanding of the basic biology of neural repair and of the mechanisms of the spinal control of locomotion and how it can reorganize in concert with supraspinal descending systems, it is likely that at least modest success in facilitating axonal growth across a complete spinal cord lesion can be achieved eventually. Even when this has been demonstrated, however, we still will not understand whether the connections will be of a sufficient magnitude or whether they will be

beneficial or disruptive with respect to pain and the control of movement. Based on the results obtained from incomplete lesions, it appears that the brain and spinal cord have a rather remarkable ability to reorganize in a functionally advantageous manner. The remarkable level of locomotor recovery that occurs after a lateral hemisection in mice, rats, and monkeys is consistent with this interpretation.

Sensory Aging: Chemical Senses

R L Doty, University of Pennsylvania, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The senses of taste and smell are critical for esthetics, discerning the flavor of foods and beverages, and detecting environmental toxins, including spoiled foods, leaking natural gas, polluted air, and smoke. Although age-related losses are present in all sensory modalities, the chemical senses – particularly olfaction – seem to be unduly influenced by aging. While approximately 2% of the American population has demonstrable olfactory loss before the age of 65 years, this percentage rises to 50% for those between the ages of 65 and 80 years, and to 75% for those above this age range. This likely explains why a disproportionate number of the elderly die from accidental gas poisoning, and why many elderly report that their food lacks flavor. The latter problem can lead to decreased motivation to eat, nutritional deficiencies, depression, and, in rare instances, death.

The age-related declines in taste and smell function are influenced by a number of factors, including gender. For example, in the case of odor identification ability, men exhibit a greater age-related decline in function than do women, a sex difference that increases in magnitude in the later years of life. The reasons why women maintain better function than men into older age are poorly understood, although estrogen may be involved. If this is the case, estrogen's organization effects on the brain may be largely responsible, since some chemosensory-related sex differences are present before puberty.

Age-Related Alterations in Olfaction

The decline in olfactory function observed in the later years of life is, on average, quite large. This decrement is apparent on a wide variety of olfactory tests, including tests of odor detection, identification, discrimination, memory, and suprathreshold odor intensity perception. In addition, age-related declines have been noted in tests sensitive to chemically mediated somatosensory sensations derived from intranasal stimulation of the trigeminal cranial nerve (CN V), such as irritation, sharpness, coolness, warmth, and fullness. The changes in odor identification ability, as measured by the standardized University of Pennsylvania Smell Identification Test, and odor memory, as measured by a standardized Odor Memory Test, are shown in Figures 1 and 2, respectively. Such age-related changes are accompanied by alterations in brain activation, as indexed by functional magnetic resonance imaging (fMRI; Figure 3). The losses have been demonstrated in a number of different cultural groups, are much more pronounced than the influences of gender or smoking, and are present in the prepubescent period (Figure 4).

In general, the age-related decrease in sensitivity occurs for a spectrum of odorants, although some odors are more influenced than others, depending upon such factors as an individual's threshold to the odorant, whether multiple chemicals are involved in producing the odor, the number of receptor types activated by the odorant or odorant combination, and the nature of the psychophysical functions relating odorant concentration to perceived intensity. The tendency for threshold values of different odorants to be correlated suggests that a 'general olfactory acuity' factor exists, perhaps analogous to the general intelligence factor derived from items of intelligence tests. Interestingly, thresholds of a number of sensory modalities tend to be correlated with one another, as well as with several cognitive measures (e.g., verbal memory), implying that a 'general sensory acuity/cognitive factor' may also exist that subsumes intermodal correlations.

It is noteworthy that experience with odors can enhance olfactory sensitivity, suggesting the possibility that variation in age-related changes among people could reflect differences in prior experience with odorants. Improvement in olfactory function as a result of prior exposure is greater in women than in men, or in some cases may even be confined to women, implying that somehow the female brain is more plastic in this regard. The underlying physiological mechanisms regarding this phenomenon are poorly understood.

Age-Related Alterations in Taste

Commonly, persons who complain of taste loss have, in fact, altered olfactory function. This is because flavor sensations, such as chocolate, mint, pizza, apple, strawberry, and so on, are dependent upon stimulation of the olfactory receptors via the retronasal route. Blocking the nose while eating, for example, greatly decreases or eliminates such flavor sensations, since active movement of air into the nasal pharynx from the oral cavity is significantly impeded.

The sensations mediated by the taste system are largely limited to such qualities as sweet, sour, bitter, salty, and metallic. Unlike olfaction, which is mediated by a single cranial nerve (CN I), the taste system

Figure 1 Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of age in a large heterogeneous group of subjects. Numbers by data points indicate sample sizes. Figure 2 Scores on the Odor Memory Test (OMT) as a function of sex and age. Data averaged across 10, 30, and 60 s delay intervals. From Choudhury ES, Moberg P, and Doty RL (2003) Influences of age and sex on a microencapsulated odor memory test. *Chemical Senses* 28: 799–805. Copyright 2003, Oxford University Press.

is subserved by a number of cranial nerves: the facial nerve (CN VII), the glossopharyngeal nerve (CN IX), and the vagus nerve (CN X). Like olfaction, age-related decreases in gustatory function are well documented. However, when the whole mouth is evaluated (e.g., by "sip and spit" testing), the magnitude of the age-related loss is not as marked as that seen for the sense of smell. This is not true when small regions of the tongue are evaluated, where marked age-related declines are observed.

Decreases in taste threshold sensitivity have been reported for such tastants as caffeine, citric acid, hydrochloric acid, magnesium sulfate, propylthiourea, quinine, sodium chloride, sucrose, tartaric acid, and a large number of amino acids. As with odorants, not all taste qualities appear to exhibit the same degree of age-related loss. Thus, sweet taste sensation appears to be less ravaged by age than are salty, bitter, and sour sensations. Figure 5 shows the marked age-related decrement to NaCl seen in small regions of the tongue.

Changes in suprathreshold taste perception to chemicals as a result of aging have also been observed. For example, flatter functions relating tastant concentrations to perceived intensity have been reported in elderly persons relative to young adults, at least for some stimuli. However, the slope of such functions can be markedly altered by changes in intensity that occur at the extremes of the stimulus continuum, and may not reflect decreased sensitivity across the entire suprathreshold stimulus range. In a manner analogous to what occurs in olfaction, sex differences in taste function become more apparent in the later years.

Although the genetic influences on smell function are poorly established, a number for taste have been worked out. For example, the sensitivity to bitter-tasting agents is a heritable trait, presumably having

Figure 3 Odorant-induced fMRI activation of brain regions in a young (top) and an old (bottom) individual. In the image of the young person's brain, note the strong activation in both inferior frontal lobes (arrowheads), on the right more than left. Perisylvian activation inferiorly on the right (open arrows) is also noteworthy. In the bottom image(older person), note minimal activation in the left inferior frontal (straight arrows), right perisylvian (arrowheads), and right cingulate (curved arrow) areas. Figure 4 Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of gender across the prepubertal, adolescent, and young adult years. Note the consistently better performance of women than of men. From Doty RL (1986) Gender and endocrine-related influences on human olfactory perception. In: Meiselman HL and Rivlin RS (eds.) *Clinical Measurement of Taste and Smell*, pp. 377–413. New York: Macmillan Publishing Co. Copyright 1986, Macmillan Publishing Company.

evolved to protect against ingestion of poisonous toxins, such as a number of bitter-tasting plant-derived alkaloids and glycosides. The tastants that have received the most experimental attention in this regard are phenylthiocarbamide (PTC) and 6-*n*-propylthiouracil (PROP). About three times more Europeans and North Americans of European descent are PTC 'nontasters' than are Asians, Africans, and Native Americans. Tasters and nontasters exhibit different food preferences, as well as different preferences for hot spices. Research from the 1930s suggested that sensitivity to PTC followed a simple Mendelian pattern, with tasters being homozygous or heterozygous for the dominant gene, and nontasters having two recessive genes. In the 1980s, alternative genetic models proved to be a better fit to the data (e.g., a two-locus model in which one locus controls PTC taste perception and the other controls more general taste acuity). Recently, genes have been identified that account, to a large degree, for bitter taste perception.

Figure 5 Detection sensitivity to NaCl in two age groups for three stimulus concentrations at two tongue loci for three different sizes of tongue regions. Size 1 = 12.5 mm^2; size 2 = 25 mm^2; size 3 = 50 mm^2. Means reflect scores on a nonparametric signal detection measure of olfactory sensitivity. Error bars represent +1 SEM. From Matsuda T and Doty RL (1995) Regional taste sensitivity to NaCl: Relationship to subject age, tongue locus and area of stimulation. *Chemical Senses* 20: 283–290. Copyright 1995, Oxford University Press.

Despite evidence for strong heritability, sensitivity to PTC and PROP declines with age. In one study, for example, the percentage of a group of 378 women who perceived PROP as being strong dropped from over 70% between the ages of 18 and 29 years to approximately 50% between the ages of 60 and 70 years. Corresponding values for men in the same age ranges were 53% and 30%. The complexity of the inheritance of the PTC taster gene is illustrated by a community living in an isolated mountain region of Ecuador. In this group, PTC nontasters eat maize-derived bread which contains a goitrogen, and consistently develop large unsightly goiters. PTC tasters, on the other hand, avoid such bread and do not develop such goiters. However, the PTC nontasters exhibited greater resistance to malaria, providing an explanation as to why the nontasting genes remain in the gene pool.

Alterations in Olfactory and Gustatory Function in Alzheimer's Disease

A number of age-related neurodegenerative diseases, most notably Alzheimer's disease (AD), exhibit marked olfactory loss relative to age-matched controls. Taste loss, while found in some studies, is much less marked. As with the influences of age, the olfactory decrements of AD are observed on numerous types of tests, and can be seen in functional imaging studies (Figure 6). A recent meta-analysis of 11 studies examining olfaction in AD found effect sizes ranging from 0.98 to 12.15 (median = 2.17), suggesting this is a robust phenomenon.

It has been argued that olfactory test scores are inversely related to the severity of dementia. However, such associations are weak. Moreover, they are enigmatic, given the influences of dementia on nonolfactory components of the tests. The AD-related olfactory dysfunction may reflect, to some degree, physiological changes associated with normal aging, although very early stage AD patients with mild dementia consistently score more poorly on olfactory tests than do age-matched controls. Recent studies suggest that smell loss may be occurring in the so-called preclinical stage of the disease process, and that it is more likely to occur in relatives than in nonrelatives of AD patients. In one study of 1604 non-demented community-dwelling senior citizens 65 years of age or older, a test of odor identification was a better predictor of future cognitive decline than was a global cognitive test. Persons who were anosmic and possessed at least one $\varepsilon 4$ allele of apolipoprotein E, a genetic risk factor for AD, had 4.9 times the risk of exhibiting cognitive decline than did persons with normal smell not possessing this allele. This is in contrast to the 1.23 times greater risk for cognitive decline in persons with normal smell who possessed this allele.

Figure 6 Left: Whole brain subtraction of olfactory stimulation minus control stimulation in healthy elderly control participants, co-registered on a T1-weighted reference magnetic resonance image ($N=7$). Right and left are reversed. Regions of interest are as follows: (A) right frontotemporal junction (piriform area), (B) left piriform area, and (C) right anterior–ventral temporal lobe (Brodmann 20). Right: Same whole brain subtraction in patients with Alzheimer's disease. Regions of interest are as follows: (A) 7 mm anterior to the frontotemporal junction (piriform) region in the control participants' image and (B) left amygdala–uncus. Causes of Olfactory Deficits in Aging and Alzheimer's Disease

The most common cause of age-related alterations in the ability to smell appears to be damage to the olfactory neuroepithelium from environmental insults (e.g., from viruses, bacteria, toxins, and pollutants). The dendritic knobs and the olfactory receptor-laden cilia are exposed rather directly to the external milieu, thereby being susceptible to nosogenic attack. In general, the olfactory neuroepithelium undergoes cumulative damage throughout life, exhibiting increasing numbers of islands of respiratory-like metaplasia soon after birth, decreased epithelial thickness, and decreased numbers of olfactory receptor cells. Some environments, such as cities or workplace environments polluted with airborne toxins, accelerate such pathology. Older persons may be more susceptible to epithelial damage than are younger ones, having a less resilient olfactory membrane due to such factors as reduced protein synthesis (as in hypothyroidism), loss of neurotrophic factors, altered vascularity and decreased intramucosal blood flow, altered nasal mucus viscosity, atrophy of secretory glands and lymphatics, and decreases in enzymes that deactivate xenobiotics within the olfactory mucosa. Some age-related deficits reflect subclinical neuropathology of the development of plaques and neurofibrillary tangles (NFTs) related to AD. Additionally, the number and cross-sectional area of the foramina of the cribriform plate are decreased in the elderly as a result of appositional bone growth, in effect pinching off the bundles of olfactory nerve axons as they traverse the foramina. In one study of this phenomenon, the mean area of the foramina was 47.3% less in men over the age of 50 years compared to those under the age of 50 years. The corresponding figure for women was 28.8%.

Despite the fact that olfactory receptor cells have some capacity to reconstitute themselves, this plasticity is compromised by age-related processes. Animal studies suggest that the ratio of dead or dying cells to the number of receptor cells increases with age, implying age-related decreases in mitotic activity. In older animals, epithelial repair is slower or nonexistent after damage by chemical agents such as zinc sulfate or methyl-formimino-methylester, unmasking an altered neurogenic process. Damage to the olfactory receptors leads to degenerative changes within the glomerular and mitral cell layers of the olfactory bulb. The number of mitral cells and glomeruli decreases steadily with age at an approximate rate of 10% per decade. By the ninth and tenth decades of life, less than 30% of these structures are present. *In vivo* quantitative magnetic resonance imaging studies confirm that the volume of the human olfactory bulbs and tracts decreases with age. Higher order structures associated with olfactory processing, such as the piriform cortex, show much less age-related change than do the olfactory bulb and epithelium. For example, in one study of rats, no significant age-related volumetric changes were found within cortical laminae Ia and Ib. The numerical and surface densities of the synaptic apposition zones in layer Ia, which are formed largely by mitral cell axons, were also not altered by age, although the proportion of layer Ia occupied by dendrites and spines was modestly decreased. An increase in the proportion of glial processes, but not in the proportion of axons and terminals, was also present.

The basis of the olfactory loss of patients with AD is poorly understood. No one has found within the olfactory epithelia of AD patients marker proteins or messenger RNAs that are specific to the disease. Nevertheless, tau-reactive and partially ubiquitin-reactive dystrophic neurites have been found in the lamina propria of AD patients. Both tau and ubiquitin contribute to the aggregation events associated with AD pathogenesis (e.g., NFTs). Recent behavioral studies in transgenic mice reveal that those that overexpress tau develop olfactory dysfunction, whereas those that overexpress β-amyloid, the major aberrant protein associated with neuritic plaques, do not. Interestingly, the $\varepsilon 4$ allele of apolipoprotein E is more than threefold greater in AD than in control olfactory receptor cells, and heat-shock proteins – proteins that are highly conserved and upregulated in cells

after exposure to stressors – are markedly downregulated in the olfactory epithelia of AD patients. This conceivably increases the susceptibility of the receptor cells to damage from xenobiotic agents.

There is considerable evidence that the olfactory bulbs and tracts are damaged early in the AD process, although the most salient early signs of AD neuropathology appear within transentorhinal cortical regions. The pathology then seems to spread from these cortical areas to other brain regions. Postmortem studies report up to a 40% reduction in the cross-sectional area of the olfactory tracts of individuals with AD, as well as ~50% loss of myelinated axons in these tracts. The AD-related NFTs and neuropil treads and PD-related Lewy bodies have been found in all layers of the olfactory bulb, with the exception of the olfactory nerve cell axon layer. Interestingly, the olfactory bulbs of over 40% of nondemented persons 50 years of age and older exhibit NFTs, suggesting such individuals may be in the earliest stages of developing the ultimate disease phenotype. Central limbic structures that receive olfactory bulb projections preferentially exhibit relatively high numbers of NFTs and neuritic plaques, including the hippocampus, the periamygdaloid nucleus, the prepiriform and piriform cortices, and the entorhinal cortex.

Among the more interesting and controversial theories concerning the etiology of the olfactory dysfunction in AD and some other neurodegenerative disorders (e.g., Parkinson's disease), as well as the etiology of the diseases themselves, is the 'olfactory vector hypothesis.' One form of this hypothesis suggests that the olfactory loss results from a xenobiotic agent (e.g., virus, bacterium, prion, pesticide) that enters the brain from the nasal cavity via the olfactory fila. Since the time of Galen it was known that dyes can move from the nasal cavity into the cerebrospinal fluid (CSF), and as early as 1912 it was shown that the olfactory neuroepithelium is a major route of entry of the poliovirus into the brain. The latter observation led to the discovery that cauterizing the olfactory mucosa of monkeys with picric acid and other caustic chemicals protected them against contracting polio. This led, in the late 1930s, to public health initiatives to prophylactically spray the noses of Toronto school children with zinc sulfate during polio epidemics.

The central-to-peripheral direction of the development of the neuropathology of AD need not be in opposition to the olfactory vector hypothesis. Thus, a xenobiotic could be transported to brain regions that are more vulnerable to its effects and could initiate genetically determined pathology in the susceptible region. The possibility also exists that damage to the olfactory system, for whatever reason, leads to degenerative alterations in brain structures that ultimately produce the cognitive alterations associated with AD. Limited support for this understudied concept comes from the observation that older rats that have been anosmic for a period of time have considerable difficulty in learning an active avoidance learning task, unlike older rats of the same age whose anosmia is of recent origin.

Causes of Taste Deficits in Aging and Alzheimer's Disease

Relative to olfaction, comparatively little research has been done to explain age- or AD-related alterations in gustatory function. As with other sensory systems, a relationship between the number of functioning receptor elements and the system's sensitivity is present. Thus, the perceived intensity of tastants presented to localized regions of the anterior tongue is correlated with the number of fungiform papillae and, hence, the number of taste buds within the stimulated regions. Individuals with higher densities of taste buds and fungiform papillae rate the intensity of a number of tastants as being 'more strong' than do individuals with lower densities of such structures. Age-related loss of taste buds has been found for human circumvallate papillae, although recent studies of rodent, monkey, and human tongues suggest that taste bud numbers on the fungiform papillae may be little influenced by age. For example, the average percentage of fungiform papillae-containing taste buds in Fischer 344 rats aged 4 to 6 months, 20 to 24 months, and 30 to 37 months was found in one study to be 99.6%, 99.3%, and 94.7%, respectively. A human study found no statistically meaningful relationship between age and taste bud densities on either the tip or the midregion of tongues from young adults (22–36 years, $N = 5$), middle-aged adults (50–63 years, $N = 7$), and old adults (70–90 years, $N = 6$). This work, however, is limited by its small sample sizes and marked variability in the number of taste buds on the tongue at all ages.

Although taste bud numbers appear not to be markedly decreased in old rats, electrical responsiveness of the chorda tympani nerve, which innervates the anterior tongue, is decreased to a number of salts, acids, and sugars. Among the possible explanations of this phenomena are decreased intrinsic reactivity of taste buds to taste solutions, decreased multiple neural innervation of taste buds by some taste fibers, alterations in the general structure of the epithelium (which, e.g., might impair the movement of stimulus solution into the taste bud pore), and decreased taste nerve responsiveness, *per se*. It is also possible that some taste buds, although anatomically present, are

not fully functional because of altered receptor cell turnover or related metabolic events. Since taste buds function in a complex ionic milieu and are bathed with saliva and other secretory products, changes in such products may also undergo age-related changes. There is suggestion that heightened taste threshold values and flattened suprathreshold psychophysical functions observed in many elderly persons reflect background tastes noticeable at low, but not at moderate or high, stimulus concentrations. Changes in both the neural and oral chemical milieu (e.g., salivary constituents) could contribute to this noise. Evidence that improved oral hygiene improves taste sensitivity in some elderly persons is in accord with this hypothesis.

Relatively few studies have examined the structure of the gustatory system of patients with AD. In one study, the innervation of the foliate and circumvallate taste buds was examined in five AD (three men, two women) and two control (both women) study participants, using antisera to protein gene product 9.5 (PGP 9.5), neuron-specific enolase (NSE), tyrosine hydroxylase (TH), dopamine β-hydroxylase (Dβ-H), and calcitonin gene-related peptide (CGRP). The mean number of PGP 9.5-immunoreactive intragemmal nerve fibers in taste buds of the foliate and circumvallate papillae was lower in the AD patients. Although very provocative, this study is limited by the small sample of individuals evaluated.

Presbycusis

Causes

The term presbycusis, or presbyacusis, refers to age-related hearing loss. There are many causes of hearing loss in older people, including environmental factors such as exposure to noise and ototoxic drugs, genetic factors, and generalized effects of aging such as cell damage and neural degeneration. Many age-related hearing impairments are types of sensorineural hearing loss involving damage to the cochlea, or inner ear. The hallmark of this damage is the elevation of the thresholds of audibility for high-frequency pure tones.

Our knowledge of cochlear pathology, its effects on perception, and many issues pertaining to treatment and rehabilitation can be generalized across the adult age range. In addition to types of cochlear damage that are common to adults across the age range, the peripheral and central auditory systems of older adults may also be damaged in ways that are not typical in younger adults. Furthermore, older adults often exhibit perceptual deficits that are disproportionate to the problems observed in younger adults with similar hearing thresholds. Importantly, studies of several species of mammals have demonstrated that hearing declines as a function of chronological age, even when all genetic and potentially damaging environmental effects have been carefully controlled.

The classification of subtypes of presbycusis, defined according to the particular structures of the auditory system that are affected by age, has continued to be refined for over four decades. Unfortunately, there is not a straightforward correspondence between damage to particular structures and perceptual deficits. Damage at multiple sites likely contributes to the differences in auditory processing that are observed between younger and older adults with similar hearing thresholds. Although high-frequency pure-tone threshold elevation is very common in older adults, the more age-specific structural and perceptual aspects of presbycusis have been the focus of most research conducted in the past decade.

Prevalence

The prevalence of hearing loss increases with age and is greater in males than in females. The prevalence of presbycusis, based on audiometric pure-tone threshold data, ranges from almost 50% to over 80%, depending on the sample, age, and the definition of hearing loss. Some reports indicate that hearing loss is the third most common chronic disability in senior citizens. About three-quarters of those who have impaired hearing are over the age of 75 years.

Age-related hearing loss characterized by high-frequency threshold elevations can begin in the fourth decade of life. The degree of hearing loss and the range of frequencies affected continue to increase with age. The specific prevalence estimates based on pure-tone thresholds depend on the degree of loss and on which frequencies are used to determine the inclusion criteria. One explanation for the greater prevalence of hearing loss in males is that their cumulative exposure to noise, including industrial and military noise, is typically greater than that of females. Age cohorts may also differ in history of noise exposure associated with wars and changing industrial practices, as well as changes in longevity.

In industrialized countries, a century ago, fewer than 1 in 20 persons lived to age 65 years, but by 1980, there were 1 in 10, and by 2030, 1 in 5 persons will be over age 65 years. As the baby-boom generation enters retirement age and longevity increases, with the fastest growing age group now being those over the age of 85 years, because hearing loss increases with age, estimates of the prevalence of hearing loss increase for the coming decades.

In general, self-reported hearing loss yields prevalence estimates that are lower than those based on pure-tone thresholds measured objectively in the clinic. A typical finding is that by 65 years of age, over one-third of adults report hearing problems, and the prevalence of hearing loss has been reported to be as high as 80% for the frail elderly living in residential care facilities. The most obvious explanation for this apparent discrepancy in the estimates based on subjective and objective measures is that the effect of hearing loss on functioning in everyday life depends greatly on the individual's auditory ecology and not only on the degree of hearing impairment.

Research Issues

Most early research on presbycusis was confounded by the high degree of correlation between high-frequency hearing loss and age. More recent studies of the effects of age on auditory perception have

attempted to minimize this confound by matching younger and older adults as closely as possible for audiometric thresholds, by simulating the effects of hearing loss in younger listeners with normal hearing, or by amplifying sound so that it is equally audible to younger and older listeners. By controlling better for the effects of audibility it has been possible to isolate changes in auditory perception that are specific to aging.

Studies of nonhuman mammal species have enabled researchers to differentiate between the effects on the peripheral auditory system of genetic factors, environmental factors, and aging *per se*. A high degree of variability in hearing thresholds in quiet-reared gerbils and patterns of hearing loss in different strains of mice suggest that there is a strong genetic component in age-related hearing loss. A consistent finding is that heritability coefficients for age-related hearing loss in humans are strong (0.22–0.55), especially for mother/daughter and sister/sister relationships, with magnitudes similar to those reported for hypertension and hyperlipidemia. Whereas in studies of humans it is virtually impossible to eliminate the role of environmental factors that are known to cause hearing loss, it has been possible to rear animals in quiet and to control their diet and acoustical environment so that the effects of aging can be isolated.

Animal models have greatly advanced our understanding of age-related changes in peripheral auditory anatomy and physiology and how these changes relate to changes in pure-tone thresholds. Nevertheless, the auditory central nervous system, from the brain stem to the cortex, also undergoes significant age-related changes. It is more difficult to compare the nature and consequences of these changes across species, especially with regard to the perception of complex signals such as speech or music. Studies of the human central auditory system using electrophysiological techniques, such as evoked potentials and brain imaging, are beginning to address questions concerning age-related changes in the more cortical aspects of auditory perception.

Anatomy and Physiology

The main structures of the peripheral auditory system are the outer, middle, and inner ear. The effects of aging on auditory perception result mainly from changes in the inner ear and the auditory nervous system.

Outer Ear and Middle Ear

The outer ear, including the pinna, concha, and the ear canal to the ear drum, does not undergo any age-related change that significantly affects auditory perception in everyday life. Two outer ear conditions that may affect hearing testing are cerumen buildup and collapsing ear canals. Buildup of cerumen, or ear wax, may impede the perception of sound and possibly cause tinnitus, or ringing in the ears; however, cerumen can be safely removed by a qualified health professional. The cartilage of the outer ear loses rigidity, with the consequence that the ear canal may collapse if pressure is applied to the pinna. Collapsing canals occur in about a third of older adults. The occlusion produced when the ear canal collapses impedes the transmission of high-frequency sounds such that thresholds measured using circumaural earphones may over-estimate the degree of hearing loss. This testing artifact can be avoided by using insert earphones. A tester can easily identify a collapsing ear canal by pressing on the pinna with a finger and observing a change in the shape of the opening of the ear canal.

The middle ear cavity, from the ear drum to the inner ear, is normally air filled and contains a chain of three ossicles. The middle ear structures transduce the airborne acoustical sound vibrations arriving at the ear drum into mechanical vibrations that are relayed to the fluid-filled inner ear. Some older adults have hearing loss resulting from middle ear damage that developed earlier in their lifetime; however, the middle ear does not undergo any changes specifically related to age that significantly affect auditory perception in everyday life or during hearing testing.

Inner Ear

The high-frequency threshold elevations commonly observed in older adults may be partially the result of environmental factors such as exposure to noise or ototoxic drugs, rather than age *per se*. Losses due to such environmental factors are characterized by damage to and loss of the outer hair cells of the cochlea, or inner ear. In the normal cochlea, the outer hair cells have a gain-control function that enables low-intensity sounds to be heard. The outer hair cells are motile and under efferent control. Their status is evaluated clinically by testing otoacoustic emissions. Importantly, there is less change in otoacoustic emissions with age than would be expected if outer hair cell damage were the only pathology contributing to the high-frequency hearing loss typical of presbycusis.

In addition to outer hair cell damage resulting from environmental factors rather than to age *per se*, there are two subtypes of presbycusis in which cochlear pathology is attributable specifically to aging. One subtype of presbycusis, sensory loss, characterized by atrophy or degeneration of the sensory receptor

cells, the inner hair cells, and supporting cells, is now considered to be of only minor importance in the aged ear. A second subtype of presbycusis, metabolic loss, characterized by atrophy and degeneration of the lateral wall of the cochlea, especially the stria vascularis and spiral ligament, is now considered to be the predominant and most distinctive lesion of the aging ear.

The stria vascularis has a dense capillary network and an exceptionally high metabolic rate. There are significant losses of strial capillaries in aging animals. Age-related changes in the stria vascularis affect the basic mechanoelectric transduction process of the cochlea, the generation of electrochemical gradients, and the regulation of cochlear ionic homeostasis. Specifically, there is an age-related decrease in the endocochlear potential and in the gain of the cochlear amplifier. Importantly, metabolic presbycusis accounts for high-frequency threshold elevations, but is not observed in cases of noise-induced or ototoxic hearing loss. Furthermore, animal studies show that there can be at least temporary reversals of age-related threshold elevations on the order of 20–40 dB when the endocochlear potential is increased by the introduction of a direct current voltage into the scala media of the cochlea.

Auditory Nerve

A third subtype of presbycusis, neural loss, is characterized by loss of spiral ganglion neurons and pronounced degeneration of the auditory nerve. In quiet-reared gerbils and other species, spiral ganglion cell density decreases and the average volume of the surviving cells also decreases in older compared to younger ears. In aging gerbils, reduced slopes of the input–output functions are observed for the compound action potential of the auditory nerve and for the auditory brain stem response. Such reduced amplitudes of physiological responses in aging ears to moderate to high-level signals, in cases in which there are only small changes in auditory thresholds, are consistent with reduced synchronization of neural firing. Importantly, these changes have been observed in the presence of intact inner hair cells, consistent with age-related primary degeneration of the auditory nerve, as opposed to degeneration secondary to loss of sensory receptor cells, as is observed in cases of noise-induced or ototoxic hearing loss.

Perception

Auditory aging alters the perception of sound. The most commonly reported problem of older adults is difficulty understanding speech in noise. For the most part, the perceptual consequences of high-frequency hearing loss due to environmental factors are well known and will be the same for older adults as for younger adults. The perceptual consequences of the three subtypes of presbycusis are less well known, but seem to be distinctive. Importantly, older adults often find it more challenging than do their younger counterparts with similar audiograms when listening in complex acoustical environments, even though they have little or no problem listening in quiet situations. Furthermore, these problems can occur even if the audiometric thresholds of the older adults are within the normal range for speech or if sound is adequately amplified by hearing aids.

Psychoacoustic studies have documented changes in how older adults perceive the basic dimensions of sound. Studies have also documented age-related declines in speech perception and spoken language comprehension in more realistic, complex listening conditions. In humans, it has been difficult to distinguish the perceptual consequences of outer hair cell damage due to environmental factors from the perceptual consequences of the three subtypes of presbycusis, because most older adults have a combination of these pathologies. Insight into how the perceptual abilities of older adults resemble, or differ from, those of younger adults have been provided by studies in which the pure-tone thresholds of younger and older adults are matched as closely as possible, especially in the low-frequency range from 250 to 3000 Hz that is most important for speech perception.

Psychoacoustics

Absolute auditory thresholds Compared to a population of human adults with normal hearing, the perceptual decline that defines the degree of hearing loss is the increase in absolute thresholds. The absolute threshold of audibility is the lowest intensity at which a sound is detectable. Clinically, these thresholds are measured for pure-tone frequencies at octave intervals between 125 and 8000 Hz and they are plotted on an audiogram in decibels referenced to standards based on population hearing level (HL) norms, or dB HL. The typical hearing loss associated with presbycusis is characterized by normal thresholds, less than or equal to 25 dB HL, in the low-frequency range, and a sloping high-frequency hearing loss with thresholds increasing progressively with frequency. Figure 1 depicts the common progression of audiometric pure-tone threshold hearing loss with age for males and females.

An increase in high-frequency absolute thresholds, and thus a decline in sensitivity, can affect perception and function in everyday life; for example, some speech sounds, especially consonants, become inaudible. In addition, such hearing loss is usually

Figure 1 Median thresholds in decibel 'hearing level' (dB HL; i.e., relative to normal hearing in 18-year-olds) as a function of age for males (a) and females (b), based on population data from the International Standards Organization (ISO 7029).

associated with alterations in the perception of the physical dimensions of suprathreshold sounds. The main physical dimensions of suprathreshold sound are frequency, intensity, and duration. In general, variations in the frequency of sound are perceived as variations in pitch, while variations in the intensity of sound are perceived as loudness. Older adults often exhibit changes in suprathreshold perception that are not predictable from their audiometric thresholds.

Frequency selectivity and discrimination The cochlea is tonotopically arranged such that different regions respond maximally to different frequencies (i.e., there is place coding of frequency). The characteristic frequency, or the frequency that elicits the maximum response, is highest in the basal region of the cochlea (nearest to the middle ear) and it decreases more or less logarithmically with distance along the cochlea, with the most apical region having the lowest characteristic frequency. The tuning of the cochlear response to different frequencies has been examined using psychoacoustic experiments in humans and physiological measurements in mammals. The frequency tuning of the cochlea is often characterized in terms of auditory filter properties. The auditory filters of listeners with outer hair cell loss are broader than are those of listeners with normal hearing. The degree to which the auditory filters are broadened is correlated with degree of audiometric hearing loss.

A perceptual consequence of broadened auditory filters, or decreased frequency selectivity, is an increased susceptibility to masking of one signal by a simultaneous competing signal, especially masking signals lower in frequency than the target signal. Listeners with outer hair cell loss often have difficulty understanding speech in noise because of their increased susceptibility to masking. The deleterious effects of the upward spread of masking continue to undermine speech perception in noise, especially when the noise is the speech of other talkers, even when hearing aids amplify sound sufficiently to restore the audibility, because both the target and any competing signals are amplified.

The effect of outer hair cell loss on ability to discriminate sequentially presented tones differing in frequency is less clear. While frequency discrimination is usually adversely affected, there is significant variability among individuals, and the size of the just-noticeable frequency difference is generally not well correlated with the degree of threshold hearing loss.

In general, older adults with normal audiograms for low-frequencies do not discriminate sequentially presented tones of different frequencies as well as younger adults do. Importantly, these age-related differences in frequency discrimination do not appear to vary with presentation level and they are larger for low-frequency pure tones than for high-frequency tones. The place coding of frequency is dominant for high frequencies while temporal coding is dominant at low frequencies. Temporal coding of low frequencies is possible because the timing of the firing of primary auditory neurons is phase-locked to the signal which causes the movement of the cochlear structures. Thus, the synchronized timing of the firing of auditory neurons provides a cue that can be used to code low frequencies. At higher frequencies, the speed of firing needed for this type of coding exceeds the limits of the neural response. The pattern of age-related declines in frequency discrimination is

consistent with disruptions in temporal coding, rather than with the disruptions in place coding associated with outer hair cell damage that results in high-frequency threshold elevations.

Loudness and intensity discrimination Loudness recruitment is a phenomenon that is observed with almost all cases of outer hair cell loss. This phenomenon refers to an increased rate of growth in perceived loudness as the intensity level of a signal is increased. Consider an individual with a unilateral hearing loss – that is, one ear with normal thresholds and abnormally elevated thresholds in the other ear. While the range of audible sound levels will be different for both ears, the full range of perceived loudness will be the same (i.e., from barely audible to painfully loud). In the case of complete recruitment, once a tone becomes audible in the ear with elevated thresholds, the perceived loudness of that tone will grow faster there than in the normal ear as the level of the tone is increased, until the sound level is sufficiently high to produce the same perceived loudness in both ears. Overrecruitment or underrecruitment can also occur in some cases of cochlear hearing loss; respectively, these refer to the perceived loudness of a sound presented at a high level as being either greater or less in the impaired ear compared to the normal ear.

Typically, when tested at low intensity levels relative to their absolute thresholds, listeners with cochlear hearing loss who have recruitment discriminate smaller intensity differences compared to listeners with normal absolute thresholds. This is the basis of the behavioral tests sometimes used in the clinical evaluation of cochlear hearing loss characterized by recruitment. However, when tested at high intensity levels relative to their absolute thresholds, listeners with recruitment discriminate intensity differences that are similar, or sometimes larger, compared to young adults with normal audiograms.

Older adults with normal audiograms in the low-frequency range often exhibit larger intensity discrimination thresholds than do younger adults, with the largest age-related differences in intensity discrimination occurring for low-frequency tones. For high-frequency tones, loudness is mostly coded by the spread of activation along the length of the cochlea; that is, the overall rate of neural firing increases because activation occurs at more places in the cochlea. However, coding of loudness for low-frequency tones is influenced by temporal cues based on the number of neurons firing synchronously. The pattern of larger age-related threshold differences for low-frequency tones than for high-frequency tones is not consistent with the disruptions in place coding associated with outer hair cell damage resulting in high-frequency threshold elevations, but it is consistent with an age-related decline in neural synchrony.

Temporal processing The pattern of age-related differences in frequency and intensity discrimination for low frequencies is consistent with declines in auditory temporal processing. Age-related declines in temporal processing undermine the coding of the durational and transitional time-varying properties of the input signal and the extraction of signals from noise.

The gap detection threshold, the smallest gap between two sound markers that a listener can detect, is the most common measure of temporal resolution. Many older adults do not detect gaps until the gaps are significantly longer than those that can be detected by younger adults. Notably, age-related differences in gap detection thresholds are not associated with absolute threshold elevations. The effect of age on gap detection threshold is more pronounced when the markers surrounding the gap are shorter than 10 ms, when the gap is nearer to the onset or offset of the signal, and when the markers differ in frequency composition.

Older adults are also significantly worse than younger adults in discriminating the duration of two tones. The effect of age on duration discrimination is more pronounced when the target tone is embedded in a sequence of tones. There are also significant age-related declines in the discrimination and recall of the temporal order of short sequences of sounds, especially when the sounds are presented at fast rates.

Synchrony or periodicity coding is another aspect of auditory temporal processing that declines with age. Loss of neural synchrony is implicated by the pattern of age-related differences in frequency and intensity discrimination, as well as by the pattern of age-related differences in masking-level differences. Other evidence pointing to loss of periodicity coding in older adults is that they have more difficulty than do younger adults in detecting mistuned harmonics in complex sounds and in segregating concurrently presented sounds.

Speech Processing

Like listeners of any age who have outer hair cell loss, audiometric thresholds explain nearly all of the problems encountered by older adults when they listen to speech in relatively quiet environments. However, specifically age-related deficits seem to be most apparent in difficult or complex auditory perception tasks, such as when speech is presented rapidly or in noisy or reverberant conditions, particularly in a background of interrupted or modulated noise, or when there is competing speech, even from a single talker.

Importantly, age-related deficits are much larger for temporally complex conditions compared to spectrally complex conditions. There is growing evidence that age-related declines in auditory temporal processing account for the disproportionate difficulties in understanding speech in noise that are experienced by older adults, including those for whom the audibility of speech is not a problem because they have normal audiometric thresholds throughout the speech frequency range up to 3000 Hz.

Declines in auditory temporal processing affect the ability of older adults to use different types of speech cues. At the sentence level, prosodic cues, such as syllable stress and rhythmic patterning, impart syntactic and affective information. At the word level, gaps and durations serve phonemic contrasts that enable word recognition (e.g., the stop consonant gap of [p] distinguishes the words split and slit). At the subphonemic level, periodicity cues derived from the voice fundamental frequency and harmonic structure contribute to voice quality and talker identification. Older adults exhibit deficits at all levels of speech processing that can be related to declines in auditory temporal processing.

Interactions between Auditory and Cognitive Processing

There is a strong correlation between sensory and cognitive aging. The difficulties of older adults in understanding spoken language in complex listening conditions may be exacerbated by the effect of age on cognitive processing, including declines in working memory and attention. As the listening condition becomes more adverse, it becomes more cognitively demanding for listeners of any age to process heard information. However, older adults demonstrate preserved knowledge and better ability, compared younger adults, to use contextual cues to compensate for difficulty hearing in challenging listening conditions.

Rehabilitation

In quiet, older adults with outer hair cell loss exhibit perceptual deficits resembling those of younger adults with comparable loss. Beyond the difficulties in speech perception explained by loss of audibility, many older adults also have problems attributable to subtypes of presbycusis involving declines in temporal processing. Currently, hearing aids are unable to correct for these declines; however, other assistive listening technology which enables the segregation of sound sources can reduce the challenge of listening in complex acoustical environments. Other forms of rehabilitation focus on training the older person and their communication partners to use strategies to avoid and cope with everyday listening challenges.

Introduction

Aging of the eye affects all structures, and changes in visual function accompany the aging process. The elderly often exhibit a decrease in visual acuity, ocular accommodation, and dark adaptation. Diseases can interfere with the aging process and cause blindness. Blindness among white and black persons in the US was caused by age-related macular degeneration (AMD; 46% and 4% of (cases); cataract (9% and 37%); glaucoma (6% and 26%); and diabetic retinopathy (5% and 7%). Vision loss is currently a major public health problem in the United States.

Approximately 3.3 million Americans age 40 years and older are blind or have low vision. With aging of the US population, the number of Americans with eye disease will increase such that by 2020 the number of people who are blind or have low vision is projected to increase substantially, to 5.5 million. Advanced age is the strongest risk factor for AMD, which is currently estimated to affect 20–25 million people in the industrialized world, causing severe vision loss in 8 million. With the aging of society, the number of people with AMD will triple in the next 40 years. This article discusses the normal pattern of aging in the choroid, retinal pigment epithelium (RPE), retina, vitreous humor, lens, and cornea (Figure 1). Diseases of aging associated with these structures are also covered.

Outer Retina

The retina is divided into the light-detecting outer retina and the visual-processing inner retina (Figure 2). The outermost layer of the retina, composed entirely of rod and cone photoreceptors, is physiologically and functionally dependent on the neuroectoderm-derived RPE that covers the photoreceptors, and the choriocapillaris that delivers vitamin A, nutrients, and all oxygen utilized by the photoreceptors. The choriocapillaris is separated from the RPE and photoreceptors by Bruch's membrane, a thick avascular area of extracellular matrix (Figure 3). Gradual age-related changes in the RPE, Bruch's membrane, and choriocapillaris become quite marked at advanced age, and influence photoreceptor life and function.

It has been suggested that it would be productive to consider age-related degenerative diseases as a cluster of problems associated with poor aging, rather than as problems arising from disease-specific pathologies. AMD may well be an archetypical condition for exploration of this view. As the following discussion illustrates, reduced photoreceptor function in older eyes can derive from age-related changes in any or all of these functionally intertwined layers. Moreover, age-related changes observed in the RPE are known to induce pathology.

Photoreceptors

Aging Changes in Photoreceptors

Decline in visual acuity is especially prominent in low light. Human rods are lost more rapidly with age, declining ~3% per decade, than are cones, which decline in number by 1.8% per decade. With increasing age, the diameter of rod outer segments and the optical density of rhodopsin increase, whereas the scotopic sensitivity of the rods, and the time needed to recover visual sensitivity following a bleach, both decline. Accumulated oxidative damage contributes to photoreceptor loss.

Photoreceptor outer segments contain photosensitive visual pigments (e.g., rhodopsin), which mediate light damage to the photoreceptors, and a high concentration of readily oxidized polyunsaturated fatty acids. This structure and the component environment (high concentration of oxygen and constant light exposure) result in a high rate of photooxidation in outer segment membranes. Photoreceptor function is maintained by rapid turnover of outer segments: new materials are added proximally, and the RPE ingests and digests the distal oxidized tips daily (Figure 4). Photoreceptor degeneration occurs if the RPE is unable to ingest or digest the photoreceptor tips – age-related changes in the RPE affect both processes.

Photoreceptors and the RPE are protected from damaging blue light by accumulation of the carotenoids lutein and zeaxanthin in photoreceptor axons and outer segments, and in axons in the inner plexiform layer of the central retina. The high carotenoid concentration in the retina creates a visible yellow region known as macular pigment.

AMD-Related Changes in Photoreceptors

Soft drusen, a clinical hallmark of AMD, cause photoreceptor distortions (Figure 5). Large areas of soft drusen are associated with disturbances in photoreceptor physiology, including decreased sensitivity of rods and short-wavelength cones, delayed dark adaptation of rods, and, with longer duration of AMD,

Figure 1 Diagram of a human eye, illustrating the structures discussed in the text. Data from the National Eye Institute, National Institutes of Health (NEI/NIH) website, http://www.nei.nih.gov.

Figure 2 Histological section of a retina. The inner retina is composed of neural cells and their processes, including the inner limiting membrane (ILM), ganglion cell layer (GCL), inner plexiform layer (IPL), and inner nuclear layer (INL). The outer retina contains only photoreceptor nuclei in the outer nuclear layer (ONL) and photoreceptor inner and outer segments (IS, OS) in the subretinal space. The photoreceptors are covered and maintained by the retinal pigment epithelium (RPE) and the vascular supply (choriocapillaris; CC). Modified from Kolb H, Fernandez E, and Nelson R, *WebVision: The Organization of the Retina and Visual System*, available online at http://webvision.med.utah.edu/.

deficiencies in color vision. Rod photoreceptors are lost preferentially and at an accelerated rate, leading to measurable loss of extrafoveal acuity, while retention of cones leaves central visual acuity unaffected.

Figure 3 Histological section of retina stained to reveal nuclei (red) in the inner nuclear layer (INL) and outer nuclear layer (ONL), and choriocapillaris (CC, yellow-green). Autofluorescence from retinal pigment epithelium (RPE) lipofuscin and Bruch's membrane (BM) are also shown in red. Choriocapillaris (CC) profiles contact BM; outer segments (OS) are not stained. Adapted from Yang Z, Alvarez BV, Chakarova C, et al. (2005) Mutant carbonic anhydrase 4 impairs pH regulation and causes retinal photoreceptor degeneration. *Human Molecular Genetics* 14: 255–265, with permission from Investigative Ophthalmology Visual Science.

Eventually in 'dry AMD,' visual field defects occur in macular areas of geographic atrophy, where both photoreceptors and RPE are missing. 'Wet AMD' – characterized by growth of choroidal neovascularization into Bruch's membrane and/or the photoreceptor layer – also causes marked loss of visual acuity. Both types can ultimately cause blindness.

Retinal Pigment Epithelium

The RPE is a single layer of nondividing cells that extend processes across the subretinal space toward the photoreceptors. The basal surface of the RPE rests on the innermost layer of Bruch's membrane (see Figure 2). Age-related changes dramatically alter both structure and function of the RPE, impact photoreceptor function, and may contribute to the pathogenesis of AMD.

RPE Functions Essential for Survival and Function of Photoreceptors

Visual cycle Photoreceptor function is dependent on constant delivery of vitamin A in the proper form. Retinol in the choriocapillaris is transported through Bruch's membrane to the basal RPE, transported into the RPE, isomerized to the required retinol isomer, and transported to the photoreceptors; after light absorption, it cycles back to the RPE.

Absorption of short-wavelength light The apical RPE contains numerous eumelanin granules. Melanin absorption of ultraviolet (UV) and blue light serves

Figure 4 Illustration of retinal pigment epithelium phagocytosis of damaged rod outer segment tips. In panel (e), lysosomal enzymes will enter the phagosome to digest the tip, leaving fluorescent residue. Adapted from Matsumoto B, Defoe DM, and Besharse JC (1987) Membrane turnover in rod photoreceptors: Ensheathment and phagocytosis of outer segment distal tips by pseudopodia of the retinal pigment epithelium. *Proceedings of the Royal Society of London, Series B: Biological Sciences* 230: 339–354, with permission from The Royal Society.

two purposes: reduced scatter of light back onto the photoreceptors improves visual acuity whereas reduced exposure to blue light reduces generation of singlet oxygen by A2E, an endogenous photosensitizer (see later).

Blood–retinal barrier The RPE serves as the interface between the photoreceptors and the rest of the body. Its tight junctions form the outer blood–retinal barrier, regulating movement of molecules and cells into the retina. Factors expressed by RPE cells modulate the activities of inflammatory cells that enter Bruch's membrane, and control their access to the retina. Risk for inflammatory damage to the retina is reduced by RPE inhibition of T cell proliferation and activation, and inhibition of complement cascades. However, when exposed to inflammatory cytokines, the RPE produces factors chemotactic for neutrophils and monocytes and expresses cellular adhesion molecules that facilitate migration of leukocytes across the RPE barrier.

Age-Related Changes in the RPE

Age-related cell loss The RPE population declines about 3% per decade, losing 30% of RPE cells over a lifetime. As in aging neurons, RPE cells experience age-related loss in number and area of mitochondria, and loss of cristae. These losses occur earlier and are exaggerated in AMD. Taken together, these findings indicate that the ability of the RPE to execute its phagocytic, transport, and visual cycle functions will decline with age.

Increased oxidative damage A major change with advancing age of the RPE is decreasing ability to face oxidant challenge. Expression of antioxidant enzymes and levels of blue-light-absorbing melanin both decline. At the same time, the RPE accumulates a blue-light-absorbing photosensitizer. Increasing oxidative stress may contribute to the age-related increase in DNA mutations, and is strongly linked to the progression of AMD; a multicenter prospective

clinical trial has demonstrated that high doses of antioxidants (vitamin C, vitamin E, β-carotene, and zinc) slow progression of AMD.

Ingestion of oxidized outer segments probably impairs RPE digestion, since lysosomal enzyme activity declines in RPE fed oxidized lipid, and in other cell types fed oxidized protein. Moreover, exposure to oxidized membranes may help switch the RPE to a proinflammatory state: ingestion of oxidized outer segments triples RPE production of monocyte chemotactic protein-1, which would increase macrophages along Bruch's membrane.

Lipofuscin accumulation With advancing age, RPE lysosomes become engorged with lipofuscin (Figure 6), autofluorescent residue from the daily ingestion of oxidatively damaged tips of photoreceptor outer segments. The prominent fluorophore (A2E) is of particular interest, for it can be cytotoxic. The number of lipofuscin granules increases with age: by the ninth decade they occupy almost 20% of the free cytoplasmic space in the macular RPE cell. Lipofuscin levels are low in the fovea, increase across the macula, and decrease in the periphery. Regions with higher fundus autofluorescence (of RPE lipofuscin) exhibit delayed dark adaptation and decreased scotopic sensitivity, and are regions of preferential loss of rod photoreceptors in AMD.

A2E: Fluorophore by-product of the visual cycle A2E is a prominent lipofuscin fluorophore, composed of two molecules of vitamin A (retinol) and one molecule of ethanolamine. Upon absorption of a photon, visual pigments release highly reactive retinaldehyde. Under normal conditions, the photoreceptor-specific ATP binding cassette transporter (ABCA4) rapidly transports retinaldehyde across the disk membrane to the cytoplasm for reduction. When the retinaldehyde levels are sufficiently high to permit two retinaldehydes to sequentially interact with one phosphatidylethanolamine, an A2E precursor is formed. RPE digestion releases A2E. A2E formation is accelerated under conditions of high light irradiance, low antioxidant capacity in the photoreceptor, or when the ABAC4 activity is impaired by oxidative damage or inherited polymorphisms. A2E accumulates rapidly in Stargardt's retinal dystrophy (juvenile macular degeneration), caused by polymorphisms in ABCA4. The role of A2E is strongly implicated by evidence that mice lacking this enzyme accumulate high levels of A2E before photoreceptor atrophy.

Toxicity of A2E A2E may contribute to pathogenesis of AMD. RPE cells loaded with A2E *in vitro* have impaired lysosomal acidification and, consequently, inhibited lysosomal enzymes and impaired digestion of outer segments. Noxious A2E is also a photosensitizer in blue light, generating reactive singlet oxygen and lysing lysosomes. Released into the cytoplasm, A2E targets mitochondria, releases apoptosis-inducing proteins, and causes RPE apoptosis. The blue light hazard for RPE is increased by higher A2E levels and is decreased by absorption of blue light by lens brunescence, macular pigment optical density (determined by dietary lutein and zeaxanthin), and RPE melanin (which declines with age). Higher dietary, plasma, and retinal levels of lutein and zeaxanthin are associated with decreased risk for AMD; higher retinal zeaxanthin prevents light-induced photoreceptor death in quail.

The RPE in AMD

The functionally impaired RPE is unable to support the visual cycle – consequently, patients exhibit impaired dark adaptation. RPE changes contribute to the pathology seen in Bruch's membrane and the choriocapillaris. Foci of high lipofuscin (fundus hyperfluorescence) surrounding geographic atrophy (Figure 7) identify areas of subsequent photoreceptor and RPE apoptosis. The RPE in AMD has reduced ability to suppress inflammation, as described in the following sections.

Bruch's Membrane and Choriocapillaris

The choriocapillaris is a bed of interconnected, highly fenestrated capillaries lying on the outer surface of Bruch's membrane (Figure 8). All peptide factors and waste products from the RPE and all nutrients from the choriocapillaris must pass through Bruch's membrane. Unfortunately, the aging Bruch's membrane accumulates debris that interferes with transport and induces inflammatory reactions. The RPE and choriocapillaris are functionally intertwined – death of either layer will ultimately cause attenuation or death of the other. The RPE produces angiogenic vascular endothelial growth factor (VEGF) and anti-angiogenic factors (e.g., pigment epithelial growth factor and endostatin) that maintain and regulate growth and status of the choriocapillaris.

Age-Related Changes in the Choriocapillaris

The choriocapillaris volume declines with advancing age. By age 90 years, almost half of the capillary

Figure 7 Clinical images of fundus fluorescence from retinal pigment epithelium lipofuscin taken at yearly intervals (a–d). The dark areas are geographic atrophy, where both retinal pigment epithelium and photoreceptors have died. Atrophy expands in areas of higher lipofuscin; the bright area in b (arrow) became an atrophic area 1 year later (arrow in c). Reproduced from Holz FG, Bellman C, Staudt S, et al. Figure 9 Drusen in clinical photographs of the human macula. Scattered hard drusen deposits with distinct boundaries are seen in most older eyes (a), whereas the presence of soft indistinct drusen (b) is associated with decline in photoreceptor function, and high risk for age-related macular degeneration. (a) Reproduced from Galan A and Tavolato M (2004) Cataract surgery as risk factor for AMD progression. *Oculista Italiano* 138, with permission from La Oculista Italiano.; (b) Reproduced from Charles Retina Institute, http://www.charles-retina.com, with permission from Dr. Charles.

profiles have been lost and their diameter has decreased by 30%. Consequent RPE hypoxia induces production of factors that can cause choroidal neovascularization in AMD. RPE production of antiangiogenic factors declines with aging and oxidative stress. At advanced age, the balance of angiogenic and antiangiogenic factors is tipped toward angiogenesis, increasing risk for choroidal neovascularization and visual loss due to retinal edema or scarring.

Aging changes in Bruch's membrane Age-related changes can be characterized as deposits which thicken Bruch's membrane and/or change in its biophysical properties. Deposits of amorphous material and long spacing collagen accrue above and below the RPE basal lamina, whereas vesicular and fibrillar deposits accumulate within Bruch's membrane. Focal exaggeration of these deposits under the basal lamina form a small lump that elevates RPE and is visible clinically as hard drusen in virtually all older eyes (Figure 9(a)). The thickening of Bruch's membrane is linearly correlated with lipofuscin accumulation. Lipids, cholesterol, phospholipids, triglycerides, and apolipoproteins accumulate throughout life. The hydraulic conductivity of Bruch's membrane declines rapidly, losing 70% by age 30 years; permeability to macromolecules declines 10% per decade. Reduced permeability to RPE factors could contribute to loss of the choriocapillaris.

Some eyes also develop larger soft drusen with indistinct borders; this feature is used to identify eyes at risk for AMD. Bruch's membrane in these eyes is thickened by ubiquitous layers of membranous debris and proteins; localized areas of thicker deposits form soft drusen where RPE displacement narrows the subretinal space, and distorts the regular array of the photoreceptors. Photoreceptors over drusen exhibit altered distribution of opsin, shortened outer segments, and altered synaptic terminals. Patients with maculopathy exhibit reduced color contrast sensitivity and decreased light sensitivity. Large numbers of confluent soft drusen deposits increase risk of progression to geographic atrophy or choroidal neovascularization.

The known components of hard and soft drusen are not different. Deposits include oxidatively

damaged proteins, and serum and RPE proteins that regularly traverse Bruch's membrane. It is noteworthy that complement C5 and the membrane attack complex (MAC) (C5–C9) are found in all types of drusen.

Inflammation in Drusen and AMD

Advanced glycation endproducts (AGEs) are cross-linked complexes of oxidized sugars, lipids, and proteins; they are considered a universal phenomenon of aging. Continuous deposits of AGEs are found in Bruch's membrane in AMD (Figure 10). Cellular responses to AGEs are mediated by cell surface receptors for advanced glycation endproducts (RAGEs) (Figure 11). Photoactivation of A2E induces RAGE expression in cultured RPE. RAGEs are expressed in the RPE over drusen, but not in RPE associated with normal extracellular matrix. RAGEs have been strongly implicated in the pathogenesis of complications of diabetes, atherosclerosis, and arthritis. Activation of RAGEs is associated with release of reactive oxygen species and increased expression of RAGEs, nuclear factor-kappa B (NF-κB)-regulated inflammatory cytokines, chemotactic factors for inflammatory cells, adhesion molecules, and members of the complement cascade.

Complement Activation

Activation of the complement cascade on cell surfaces can result in damage by the MAC, a membrane-piercing aggregate of the final five complement components (C5–C9). Activated complement components, including MAC, are routinely found in both hard and soft drusen (Figure 12). Cell responses to MAC include shedding of damaged membrane and/or production of regulators (such as fibronectin or clusterin) that impede formation of MAC. Vitronectin and clusterin are present in drusen and are produced by RPE cells (Figure 12(c)).

Despite evidence that complement activation occurs in drusen, only a fraction of people with drusen develop AMD. When complement C3b is deposited on cell surfaces, factor H prevents cell damage by binding and inactivating C3b. Recently, single polymorphisms in factor H were found in ~50% of patients with AMD; adding significant variants in other complement factors (component C2 regulator factor B) predicts up to 75% of AMD outcomes. Thus

inability to prevent complement-mediated cell damage may be a key factor determining whether the inflammation observed in aging eyes will lead to macular degeneration.

Normal Aging of the Inner Retina

Age-Related Changes of the Inner Retina

While there is a paucity of studies analyzing changes in interneurons (bipolar, horizontal, and amacrine cells) in the retina with age, a number of histological studies show an inherent loss of retinal ganglion cells (RGCs) with age. RGCs, located in the innermost layer of the retina (adjacent to the inner limiting membrane and the vitreous humor; Figure 13) have large somas with dendritic processes that project into the inner synaptic layer, where they synapse with amacrine cells and bipolar cells. A single axon projects from each RGC and runs centripetally along the vitreous surface in the nerve fiber layer (NFL). These axons (approximately 1 million in total) produce the first action potentials in the visual system and carry information already processed by the retina to targets in the brain (primarily the lateral geniculate nucleus of the thalamus) for further processing. Although a larger percentage of RGCs is lost with age in the peripheral retina than in the central retina, the number of RGCs actually lost is similar, because of the higher density of RGCs in the central region. Therefore, a relatively constant number of RGCs die with age in different retinal locations. The

Figure 13 Schematic illustrating the synaptic connections between the photoreceptors and horizontal and bipolar cells of the inner retina, and between bipolar cells and ganglion cells and amacrine cells. Note that the retinal pigment epithelium is at the top. From Kolb H, Fernandez E, and Nelson R, *WebVision: The Organization of the Retina and Visual System*, available online at http://webvision.med.utah.edu.

naturally occurring RGC loss with age means that about 5000 RGC axons (about 0.5%) die per year per eye. Noninvasive imaging techniques that measure the topography of the optic nerve head and the thickness of the NFL show at least a 20% thinning of the NFL with age. This thinning appears to be more pronounced in the superior quadrant. The reduction in the number of visual cells (photoreceptor cells and/or RGCs) in the retina and in higher visual centers is thought to be associated with the reduced visual acuity, decreased contrast sensitivity, and higher thresholds for light detection in visual field measurements that occur with age.

Diseases of Aging Inner Retina

RGC loss may also play a role in visual dysfunction observed in neurodegenerative diseases. Parkinson's disease (PD) is characterized by a progressive loss of dopamine-containing neurons in the substantia nigra. There is also a progressive loss of dopaminergic cells in the retina and possibly within other areas of the visual system in PD. Selective spatial–temporal abnormalities in RGC function (arising from altered receptive field organization) may be due to the retinal dopamine deficiency.

Many patients with Alzheimer's disease (AD) also exhibit impairments of visual perception and eye movements. These defects can include anomalies in color vision, spatial contrast sensitivity, susceptibility to visual masks, electroretinographic and visual evoked potential abnormalities, and saccadic and eye tracking dysfunction. The precise basis for these deficits is unknown, but senile plaques, neurofibrillary tangles, and amyloid protein deposits are found in multiple regions of the brain that mediate vision, excluding the retina. Some of these visual impairments may also be due to retinal lesions, since RGC loss, reduction in the number of RGC axons in the optic nerve, and electroretinographic abnormalities have been reported in AD patients.

Glaucoma

Glaucoma is an eye disease in which the normal fluid pressure inside the eye slowly rises, leading to vision loss or blindness. The disease is characterized by changes in the morphology of the optic disk, the pattern of visual field loss, and the progressive death of RGCs. RGC damage is usually not uniformly distributed throughout the eye. The uneven regional death of RGC axons in the NFL is clearly demonstrated in stained specimens of retinal whole mounts from glaucomatous animals (Figure 14). The principal treatment for glaucoma involved lowering the intraocular pressure (IOP). Increased IOP is directly related to the flow of aqueous fluid. Aqueous fluid is produced by the ciliary body and passes through the pupil into the anterior chamber of the eye (Figure 15). Aqueous fluid nourishes the lens and cornea and generally drains through the trabecular meshwork, a complicated arrangement of cells and extracellular 'beams' found at the junction of the iris, cornea, and sclera. This

Figure 14 Comparison of ganglion cell axons entering the optic disks of normal (A1; higher power views B1, C1) and glaucomatous (A2; higher power views B2, C2) retinas. More fibers are present in the central retina (C1, C2) than in the periphery (B1, B2) but numbers in both areas are diminished in glaucoma. (Higher power views of insets D1, D2, E1, and E2 not shown.) Reproduced from Jakobs TC, Libby RT, Ben Y, et al. (2005) Retinal ganglion cell degeneration is topological but not cell type specific in DBA/2J mice. *Journal of Cell Biology* 171: 313–325, with permission from Rockefeller University Press.

Figure 15 Illustration of fluid formation in the ciliary body and movement around the iris to the anterior chamber, where fluid exits through the canal of Schlemm (seen in **Figure 1**). Impaired drainage raises intraocular pressure, causing glaucoma. Courtsey: National Eye Institute, National Institutes of Health.

outflow pathway maintains normal levels of aqueous humor outflow. When aqueous production exceeds outflow, the pressure within the eye rises.

The most common form of glaucoma is primary open angle glaucoma (POAG). It is a late-onset disease usually accompanied by elevated IOP resulting from pathology in the aqueous outflow pathway (the trabecular meshwork and Schlemm's canal). A combination of genetic and environmental factors is likely involved in the pathology of the outflow pathway. Oxidative stress may play an important role in the pathophysiology of POAG, since the cells of the trabecular meshwork are constantly exposed to an oxidative environment. Decreased antioxidant potential, increased expression of oxidative stress markers, and increased oxidative DNA damage have all been reported in glaucoma patients.

One or more of the following events may lead to the apoptosis of RGCs observed in POAG: elevated IOP, mechanical compression, ischemic changes, glutamate neurotoxicity, astrocytic reaction, autoimmune attack, neurotrophic deprivation, intracellular calcium toxicity, changes due to reactive oxygen species, and/or nitric oxide production. Several studies suggest that the region where the axons exit the eye, the lamina cribrosa, is the primary site of mechanical damage leading to RGC death. Most likely the compromised blood flow in the optic nerve noted in glaucoma patients would cause ischemic injury to RGCs. Therefore, it is possible that excitotoxic injury (routinely seen in ischemic injury) may play a major role in the pathogenesis of glaucoma.

Figure 16 Erosion of fibers in glaucoma causes the pale area around the optic disk (yellow) and cupping, where vessels curve downward toward the optic disk. Reproduced from the Southwestern Medical Center; image available online at http://www.swmed.edu/home_pages/ophth/images/dlc-fun8.jpg, with permission from UT Southwestern Medical Center.

Clinically, the loss of RGCs is monitored by University of Texas by biomicroscopy and is seen as a progressive loss of tissue in the optic nerve head. The optic nerve head in POAG has an unusual appearance on examination with an indirect ophthalmoscope – it appears to have a halo around the rim of the optic disk due to the massive loss of optic nerve fibers (Figure 16). Visual field testing is important in documenting the location and progression of RGC loss during the progression of the disease. A scotoma is an area of relative or complete blindness in an area of the visual field. Glaucoma invariably causes isolated scotomas in the visual field, such that the patient loses the ability to see one or more peripheral regions, while vision is completely normal in other areas of the eye. As the disease progresses, the field of vision gradually narrows and blindness can result.

Risk Factors for Primary Open Angle Glaucoma

Advanced age and increased IOP are fundamental risk factors for POAG. Other predisposing factors include mutations in specific genes, toxic effects, and mechanical damage due to elevated IOP. There is broad consensus that genetic risk factors play an important role this disease. The trabecular meshwork-induced glucocorticoid response (TIGR) gene, *MYOC*, for juvenile glaucoma (J-POAG) was identified by mapping and mutational analysis. This gene codes for myocillin, a protein which plays an important role in maintaining the structural integrity of the trabecular meshwork. A mutation in this gene is a high risk factor for the onset of POAG. Other strong risk factors include positive family history of glaucoma in a first-degree relative, higher incidence in African-Americans, and central corneal thickness less than 0.5 mm.

A possible diagnostic indicator for glaucoma may be the presence of the endothelial leukocyte adhesion molecule-1 (ELAM-1). ELAM-1, a member of the cell-adhesion family of molecules (CAMs), is present in trabecular meshwork cells from glaucomatous donor eyes, compared to normal eyes. This finding suggests that the activation of a tissue-specific stress response in the aqueous outflow pathway of the eye defines the glaucoma disease phenotype.

Treatments for Glaucoma

Current therapeutic strategies for glaucoma are aimed at reducing IOP by pharmacologically decreasing aqueous humor production or by microsurgically increasing the outflow capacity. However, lowering the IOP in glaucoma may not prevent further damage.

Neuroprotection or Rescue of RGCs

Knowledge of mechanisms of neuronal death of RGCs, and prevention, delay, or reversal of the processes, are now sufficient that glaucoma therapy may be designed to preserve RGCs and their axons. Neuroprotection is a therapeutic strategy to keep RGCs alive and functional. Neuroprotective strategies proven successful in animal models of glaucoma have included blocking retinal excitotoxicity mediated by glutamate and administration of neurotrophic factors (such as brain-derived neurotrophic factor) which maintain RGC survival. To date, none of the these strategies has worked in randomized controlled clinical trails in patients with glaucoma, but the use of neuroprotective agents to treat glaucoma still remains promising.

Vitreous Humor

Eighty percent of the interior volume of the eye is made up of the vitreous humor. The primary structure of the vitreous is collagen and hyaluronic acid. In the vitreous, the predominant proteoglycans are chrondroitin and heparan sulfate.

Age-Related Changes

The vitreous is primarily a collagen gel at 2 or 3 years of age, but the gel portion decreases and the liquid portion increases steadily throughout life. The continual increase in the liquid fraction of the vitreous suggests that there is a gradual change in the vitreous collagen. Data suggest that bundles of collagen form in the vitreous with aging.

The vitreous is attached to the posterior retina, but detaches with aging in 25–30% of the population. The process of posterior vitreal detachment occurs early in

the second to third decades of life in people with high myopia, but typically occurs anywhere along the inner margin of the retina between the fourth and ninth decades of life. Detachment occurs suddenly, when fluid trapped in the middle of the vitreous humor floods into the interface between the vitreous base and the inner limiting membrane (Figure 17). Because the attachment over the macula is much firmer, the floating vitreous gel tugs on the retina. The process can cause the individual to see 'sparkles' or 'flashes' of light. When the vitreous base is firmly attached, the tugging on the retina can cause a tear in the retina, or a macular hole.

Lens

Normal Aging of the Lens

The lens is the optically clear structure located behind the iris and in front of the vitreous humor and retina (see Figure 1). The lens functions to focus light onto the retina. In order to form an image on the retina, the lens must maintain its shape, transparency, and refractive index. The lens has only one cell type, and these cells are precisely aligned to lead to the transparency of the lens. Young lens cells have organelles, but the organelles are destroyed during early development. What remains are cells made up of a dense solution of large proteins termed crystallins, specifically the α-, β-, and λ-crystallins. The α-crystallins act as molecular chaperones as well as structural proteins. As stated by Bloemendal and colleagues, "The absence of protein turnover in the lens and the ability of the lens to retain life-long transparency means that the crystallins must meet not only the requirement of solubility associated with high cellular concentration but that of longevity as well. Longevity, as it relates to proteins, is commonly assumed to be correlated with long-term retention of native structure, which in turn can be due to inherent thermodynamic stability, efficient capture and refolding of non-native protein by chaperones, or a combination of both."

The complexes formed by crystallin proteins make the cytoplasm optically homogeneous – that is, the refractive index does not change inside the cell or

Figure 17 Liquefaction of the vitreous during aging can cause complete or partial vitreous detachment and is a risk factor for retinal detachment and macular holes. Reproduced from Bishop PN (2000) Structural macromolecules and supramolecular organisation of the vitreous gel. *Progress in Retinal & Eye Research* 19: 323–344, with permission from Elsevier Science & Technology.

Figure 18 The regularly arrayed fiber cells in a young lens (a; Cp, capsule) result in a transparent lens (inset, a). As the fiber cells become more disorganized with damage (b, c), there is a corresponding increase in the opacity of the lens, ultimately forming a full cataract (inset, d). Reproduced from Merriman-Smith BR, Krushinsky A, Kistler J, and Donaldson PJ (2003) Expression patterns for glucose transporters GLUT1 and GLUT3 in the normal rat lens and in models of diabetic cataract. *Investigative Ophthalmology & Visual Science* 44: 3458–3466, with permission form Investigative Ophthalmology & Visual Science.

from one cell to another. As the lens ages, new layers of fibers are added to the cortex, causing the lens nucleus to become compressed, harder, and more compact. Yellowing of the lens also occurs with age. The lens increases in bulk and mass, gaining weight steadily until about age 50 years. Some lenses remain clear with advancing age; but significant protein oxidation at the center of the lens causes cataracts. The key factor in preventing oxidation in the nucleus of the lens seems to be the concentration of nuclear glutathione (L-γ-glutamyl-L-cysteinylglycine; GSH). Nuclear sclerosis progresses slowly over the years, causing only a slight change in refraction, but these changes may not significantly affect vision. Further progression of nuclear sclerosis can lead to loss of color discrimination and also loss of distance vision.

Diseases of Aging Lens

Any opacity of the lens or its capsule is called a cataract. Age-related cataracts are divided into nuclear, cortical, and posterior subcapsular types, depending on their location and clinical appearance. Lens crystallins accumulate damage with age (from ultraviolet light, oxidation, dehydration, or elevated blood sugar from diabetes), and may collapse into misfolded fibers. The misfolded fibers aggregate, producing heterogeneity in the protein concentration within the lens. This protein aggregation can lead to light scattering and to cataract formation (Figure 18). The most common treatment for cataracts is surgical removal.

It should be noted that oxidation is the hallmark of age-related nuclear (ARN) cataracts. Loss of protein sulfhydryl groups and the oxidation of methionine residues are progressive and increase as the cataract worsens. Therefore, the ARN cataract is associated with a loss of GSH in the center of the lens, and extensive modifications to the nuclear proteins, including coloration, oxidation, insolubilization, and cross-linkng.

Risk Factors and Prevention

Cataracts are the most common cause of reversible vision loss worldwide. Age is by far the major risk factor for cataract formation. Ethnic variation has been reported with different cataract types. Genetic factors may account for as much as 50% of the severity of nuclear cataracts and may also be important in the development of cortical cataracts. Many reports suggest that women are at slightly higher risk than are men to develop cataracts. Other risk factors are

of much less importance to cataractogenesis, but are ones that we may be able to control: cigarette smoking, exposure to sunlight, alcohol use, and low dietary levels of carotenoids or antioxidants. Epidemiological studies also suggest that exposure to ultraviolet B causes cortical cataract changes.

Presbyopia

Presbyopia is the loss of accommodative amplitude which occurs with age. Around age 45 years, most people are unable to hold a book at the normal reading distance and still see the text clearly (i.e., the near point of accommodation is farther away than the normal reading or working distance). Presbyopia is largely thought to be associated with age-related changes in the lens. The many changes in the lens from birth onward (increase in diameter and thickness, volume, and mass; addition of new cells; changes in curvature) occur during the decline of accommodation that occurs with age. The link between lenticular changes and presbyopia is thought to be due to the increase in bulk and mass of the lens, such that the elastic forces are less effective in changing the curvature of the lens.

Cornea

Normal Aging of the Cornea

Research in aging of the cornea has focused on the inability of the corneal endothelium to replace cells that die with age. The corneal endothelium is a single layer of metabolically active cells that lines the entire posterior surface of the cornea. The aqueous humor in the anterior chamber of the eye is in direct contact with the corneal endothelium. The loss of the corneal endothelium during a life span is substantial: about half of the endothelium is lost. As endothelial cells die, neighboring endothelial cells expand and migrate in order to maintain a confluent layer of cells. Age-related changes in the tear film that bathes the cornea cause dry eye, a condition of irritating, burning, or itching eyes found in over 10 million people in the US.

In contrast to the endothelium, the corneal epithelium heals quickly and completely. The corneal epithelium replaces itself about every 10 days. It is believed that stem cells for the corneal epithelium are located in the limbus of the eye (the region between the transparent cornea and the sclera). If the limbal epithelium is damaged, then the epithelium is unable to repair itself. Corneal transplants were developed to replace damaged tissue with healthy limbal tissue.

Sensory Ganglia

R E Papka, Northeastern Ohio Universities College of Medicine, Rootstown, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Ganglia are enlargements along bundles of nerve cell processes derived from collections of nerve cell bodies. Several categories of ganglia are identified: motor ganglia of the autonomic nervous system, special sensory ganglia of the auditory–vestibular nerves, and general sensory ganglia associated with spinal nerves (e.g., dorsal root ganglia) and cranial nerves (e.g., nodose ganglion of cranial nerve X and trigeminal ganglion of cranial nerve V) (Figure 1). The focus of this article is general sensory ganglia.

Types and Locations of Sensory Ganglia

General sensory ganglia are the spinal (dorsal root) ganglia (DRG) and cranial nerve ganglia(CG). DRG are located along dorsal roots of the cervical, thoracic, lumbar, and sacral spinal nerves near their entry to the spinal cord (Figure 1(a)). The CG are located along the roots of cranial nerves V (trigeminal), VII (facial), IX (glossopharyngeal), and X (vagus) as they enter the brain stem. Sensory neurons (though not necessarily distinct sensory ganglia) are described in the walls of some tubular organs, particularly the gastrointestinal tract, where they function in reflexes, responses to distention, and sampling local and luminal environments. Each neuron cell body (soma) (Figures 2 and 3) has a single process (Figures 3 and 4) that divides into two: a peripherally directed process and a centrally directed process. Peripheral processes (neurites, or more specifically dendrites) respond to stimuli which are conducted toward the DRG and CG, and are relayed by the central process into the spinal cord or brain stem (Figure 1(a)). Sensory information is derived from somatic structures (e.g., cutaneous areas) and visceral structures (e.g., organs and body cavities). Sensory neurons have a spatial organization in ganglia; in general, proprioceptive neurons are located mainly in the ventral half of a ganglion whereas cutaneous neurons are broadly distributed throughout the ganglion.

Development and Neurotrophin Dependence

Sensory neurons develop embryologically from neural crest cells. Crest cells migrate from the developing neural tube to form ganglia near the future spinal cord and brain stem. The developing neurons are initially unipolar; however, this single process bifurcates with one branch growing peripherally, to reach a target structure, and one growing centrally, for connection with the central nervous system (CNS) (Figures 1). The migration, differentiation, and survival of ganglionic neurons are dependent on factors produced by the neuron and on protein growth/trophic factors produced by target tissues. Growth-associated protein of 43 kDa (GAP-43) (Figure 5) is an integral membrane protein that is such a factor and is expressed at elevated levels by developing or regenerating neurons during axon growth. Neurotrophins (NTFs) are a family of trophic factors that are survival substances essential during development of the neurons, though these factors continue to exert influences throughout the life span of neurons. Actions of NTFs are mediated through receptors expressed on sensory neurons – three high-affinity receptor tyrosine kinases (TrkA, TrkB, and TrkC) and low-affinity $p75^{NTR}$ receptors. Among the NTFs are nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF) (Figure 6), and neurotrophin-3 and neurotrophin-4/5 (NT-3 and NT-4/5). NGF utilizes TrkA; BDNF and NT-4/5 utilize TrkB; NT-3 primarily activates TrkC. All NTFs may bind $p75^{NTR}$ receptors. Another family of trophic factors is glial-derived neurotrophic factor (GDNF); GDNF utilizes a receptor complex for signaling. Many other growth factors influence sensory neurons, such as transforming growth factor-β (TGF-β), fibroblast growth factors (FGFs), insulin-like growth factors (IGFs), leukemia inhibitory factor (LIF), and ciliary neurotrophic factor (CNTF). Trophic factor requirements correlate with specific sensory neuron populations (e.g., neuron size) and transmission of specific modalities (e.g., nociception, thermal information, or mechanoreception). For example, NGF supports small-sized and nociceptive neurons; though approximately one-half of nociceptors are dependent on NGF, the other half are sensitive to other NTFs such as GDNF. BDNF supports mechanoreceptive populations and NT-3 supports large proprioceptive neurons.

Interactions between trophic factors and neurons are complex and new information is emerging from gene-deficient animals. For example, lack of NGF, BDNF, and NT-3 genes results in severe neuronal deficits and early postnatal death. In BDNF knockout mice, sensory ganglion cells forming slowly adapting mechanoreceptors are less sensitive, there is a reduction in number of cells in trigeminal ganglia, and the defects are worse when NT-4 is also deficient. In NT-3 knockouts, there is loss of large ganglion cells and absence of muscle spindles and Golgi tendon organs.

Figure 1 (a) Diagram illustrating a sensory neuron cell body in a dorsal root ganglion (DRG) and its peripheral and central processes (blue). The peripheral process (functionally a dendrite) ends as primary sensory nerve endings in tissue near an epithelium (left), and the central process (functionally an axon) terminates in the spinal cord (right). The branching of the peripheral process illustrates the basis for axon reflexes; such reflexes are the basis for neurogenic inflammatory reactions. Also shown are examples of neurotransmitters (e.g., substance P and calcitonin gene-related peptide (CGRP)) that are released from peripheral sensory nerve endings and a number of substances that can influence activity of the nerve ending. Some of the latter substances are the main components of the acidic inflammatory soup during inflammation, including peptides (bradykinin), lipids (prostaglandins), neurotransmitters (serotonin (5-HT) and ATP), and neurotrophins (nerve growth factor (NGF)). Each of these factors sensitizes (lowers the threshold) or excites the terminals of the C-fiber that acts as a nociceptor by interacting with cell surface receptors expressed by these neurons. Examples of these stimuli and representative molecular receptor targets are indicated. Activation of the nociceptor not only transmits afferent messages to the spinal cord dorsal horn (and from there to the brain), but also initiates the process of neurogenic inflammation. This is an efferent function of the nociceptor whereby release of neurotransmitters, notably substance P and CGRP, from the peripheral terminal induces vasodilation and plasma extravasation (leakage of proteins and fluid from postcapillary venules), as well as activation of many nonneuronal cells, including mast cells and neutrophils. These cells in turn contribute additional elements to the inflammatory soup. Inset: Whole mount of a dorsal root ganglion, illustrating its enlargement along the sensory dorsal root fibers (red arrows) of a spinal nerve (blue cells are the result of herpes virus-mediated gene transfer of β-galactosidase). Double-headed black arrows indicate corresponding parts of the dorsal roots and ganglion in the sensory neuron diagram

Figure 2 Medium-magnification view of a dorsal root ganglion, showing the numerous neuron cell bodies (somas; large arrows) that exhibit variations in sizes and staining. Many small nonneuronal cells are evident between neurons (small arrows). Scale bar = 25 μm.

In TrkC knockout mice, spinal proprioceptive afferents are absent in limb skeletal muscles; however, in the same animals, proprioceptive afferents from the trigeminal nerve innervate head muscles and form muscle spindle sensory endings. This implies that spinal and trigeminal proprioceptive afferents have different neurotrophin-supporting systems during differentiation and survival. In $p75^{NTR}$ receptor knockouts, most types of sensory axons are reduced by 50%. On the other hand, some neurons exhibit a switch in trophic factor dependence during development; for example, IB4-binding (isolectin from *Griffonia simplicifolia*) sensory neurons switch from NGF to GDNF dependence in early postnatal life.

Structure

Cellular Constituents

Each DRG and CG contains several thousand neurons (Figures 3 and 4); numbers vary at different levels of the spinal cord and brain stem. For example, neurons are most numerous in cervical and lumbar DRG that serve the upper and lower extremities. The trigeminal ganglia are the largest sensory ganglia

Figure 3 Higher magnification view of a dorsal root ganglion, illustrating neurons and nonneuronal cells. Neurons are classified into three size categories, large (L), medium (M), and small (S within dark brown cell). Within the neurons a centrally located nucleus (N) and nucleolus (No) are visible. Surrounding and enwrapping each neuron is a collection of nonneuronal satellite cells (S adjacent to arrow). Such cells isolate the neurons from the connective tissue extracellular space as well as contribute to the metabolism of the neuron. The granularity of the neurons results from the content of Nissl bodies (cisternae of rough endoplasmic reticulum). The lightly stained area (top horizontal arrow) of a large neuron is the axonal hillock, and is the site of origin of the single process that emanates from the cell body. Scale bar = 25 μm.

and in the adjacent dorsal root sensory ganglion micrograph (see (b)). Diagram adapted from Julius D and Basbaum AI (2001) Molecular mechanisms of nociception. *Nature* 413: 203–210. Inset reproduced courtesy of Dr. Steven P Wilson, Department of Pharmacology, Physiology and Neurobiology, University of South Carolina School of Medicine. (b) Low-magnification micrograph of a dorsal root sensory ganglion (also called spinal ganglion). The ganglion (G) is located along the nerve roots (NR) that will connect to the spinal cord and project to peripheral targets. Scale bar = 500 μm.

Figure 4 Dorsal root ganglion, immunostained for calretinin. There are subclassifications of sensory neurons based on size, neurochemistry, and other characteristics. In this view, a ganglion is specially immunostained by an antibody against the calcium-binding protein calretinin. A subclass of predominately large neurons (L) is stained, and the intensity of staining varies from moderate to intense, which may indicate a further subclass of neurons. A number of neurites coursing through the ganglion are also immunoreactive for calretinin (arrows). Such neurites appear to be large myelinated processes that likely originate from large neurons. Scale bar = 25 μm.

Figure 5 Dorsal root ganglion, immunostained with an antibody against the growth-associated protein GAP43. A subpopulation of mainly small and medium-sized neurons (arrows) is revealed by the immunostaining. Scale bar = 25 μm.

and innervate the face and head. Ganglionic neurons are organized as clusters (Figures 2, 7, and 8) among bundles of neurites (axons and dendrites) (Figures 2–4 and 7–10). Their somas are rounded and contain a centrally located nucleus and prominent nucleolus (Figure 3). They contain abundant Golgi complexes (Figures 10–13) and cisternae of rough endoplasmic reticulum (Figure 3) that are essential for synthesis of proteins (e.g., neuropeptide transmitters, structural

Figure 6 Dorsal root ganglion, immunostained with an antibody against brain-derived neurotrophic factor. A subpopulation of mainly small and medium-sized neurons (arrows) is revealed by the immunostaining. Scale bar = 25 μm.

Figure 7 Dorsal root ganglion, immunostained with an antibody against the neurofilament protein peripherin. This antibody immunostains only the small C-type neurons (S) of the ganglia. In addition, it is evident that some neurites extending from these small neurons are immunopositive for peripherin (arrows). Such processes are classified as small unmyelinated C-fibers that are slow conducting and transmit nociceptive and thermal information. Note that clusters of neurons are separated by bundles of nerve fibers. Scale bar = 25 μm.

Figure 8 Dorsal root ganglion, illustrating a subpopulation of neurons; these neurons fluoresce yellow (arrows) due to their content of the retrograde tracer Fluorogold. The tracer was injected into the wall of the uterine cervix, endocytosed by the peripheral sensory nerve terminals in the cervix, and retrogradely transported by axoplasmic flow to the cell bodies of neurons in the dorsal root ganglia which innervate the cervix. This is one method to 'mark' or 'identity subgroups of neurons that innervate a specific target. Note that neurons tend to be clustered and separated by bundles of nerve fibers (NF). Scale bar = 25 μm.

proteins, and cytoplasmic enzymes). Such features reflect that sensory neurons with large somas and extensive neurites have considerable volumes of protein-rich cytoplasm to maintain. The rough endoplasmic reticulum is organized into aggregates called Nissl bodies, giving the cytoplasm a fine granular appearance (Figure 3). Additionally, the soma may stain lightly, moderately, or intensely with general histologic stains (Figures 2 and 3), depending on their organellar and cytoplasmic content.

Sensory neurons are described as pseudounipolar because a single process (neurite) emanates from the soma (Figures 3, 4, 7, 9 and 10), but then bifurcates, sending one process (axon) to the CNS where it associates synaptically with a CNS neuron (Figure 1(a)). The other process (dendrite) innervates a peripheral target, such as the skin, muscle, or visceral organ, where it terminates as a receptor ending. This ending can be a specialized (morphologically) receptor (e.g., Meissner's corpuscle) or an unspecialized free ending (Figure 8). Special membrane-associated receptor molecules are inserted in the membranes of these terminals and provide responsiveness to specific stimuli (e.g., ions, cytokines, neurotransmitters). Stimuli are transduced at terminals of sensory neurons and this information is conveyed toward the ganglia.

Since sensory neurons and their processes are excitable, they must be protected by supporting cells equivalent to neuroglia in the CNS. The somas are encapsulated by satellite cells that are small and closely apposed to the neuron somas (Figure 3). They isolate neurons from the connective tissues and extracellular milieu, and influence their metabolism. Schwann cells are similar to satellite cells except that they are associated with axons and dendrites. They produce a lipoprotein layer called myelin around neurites of large and medium-sized neurons (basically, myelin insulates the neurites and increases the conduction velocity of action potentials). Additionally,

Figure 9 Higher magnification view of peripherin-immunoreactive C-fibers (arrows) in the ganglion. Scale bar = 25 μm.

Schwann cells are important in guiding and enhancing regeneration of damaged peripheral processes. Moreover, supporting cells appear to be metabolically and functionally involved with neurons in terms of transmitter metabolism and signaling.

Normally there are not synaptic structures in sensory ganglia. However, there are suggestions that neuropeptide transmitters are released in ganglia to influence adjacent sensory neurons. On the other hand, sympathetic innervation of sensory neurons is described in traumatic pathological conditions (discussed later). However, the peripheral processes of sensory neurons make contact with and influence peripheral autonomic neurons (e.g., in the pelvic and enteric ganglia).

Connections to the CNS

Activation of the peripheral nerve ending generates an action potential which conveys the sensory stimulus toward the cell body in the ganglia, and then to the CNS via the axon. Information is processed within the spinal cord dorsal horn or brain stem nuclei and then relayed to higher centers of the CNS and interpreted or perceived.

Central terminations of sensory axons enter into a complex neuronal circuitry. There is a differential pattern of distribution and termination of the centrally

Figure 10 Dorsal root ganglion, labeled with the biotinylated-lectin IB4 (isolectin from *Griffonia simplicifolia*). This lectin reportedly binds to peptide-poor, glial-derived neurotrophic factor-responsive small neurons. There is a subpopulation of small neurons (arrows) which are IB4-positive and others that are IB4-negative (arrowheads). Many neurites (NF) are also evident and bundled, separating groups of neurons. Scale bar = 25 μm.

directed processes in the laminae of the spinal cord. Larger heavily myelinated processes emanating from larger neurons enter the cord most medially and terminate in deeper laminae. Smaller unmyelinated fibers of smaller neurons enter more laterally and terminate in more superficial laminae.

Neuron Variability

Size, Conduction Velocity, and Sensory Modality Conducted

Neurons of sensory ganglia form heterogeneous groups of cells varying in size, response to sensory modalities, signal conduction velocity, neurochemistry (neurotransmitters and receptors), development and survival dependence on neurotrophins, and tissue/organ innervated.

Sensory neurons are classified into three subgroups based on diameter: small (<20 μm), medium (21–40 μm), and large (>40 μm) (Figures 2–4, 7, 10, 12, and 13). Functional differences exist among these groups. Small neurons have thin processes (0.3–1.3 μm in diameter) that lack myelin (referred to as unmyelinated C-fibers) and contain the neurofilament protein peripherin (Figures 7 and 9). Such fibers conduct signals (e.g., nociception, temperature) relatively slowly (0.7–2.3 m s^{-1}). Medium-sized neurons have lightly to moderately myelinated processes (called A-δ fibers) and conduct signals faster (1.7–7 μm in diameter, conduct at 3–15 m s^{-1}). Such fibers are mechanoreceptive. Large neurons have moderately to heavily myelinated processes (A-β and A-α fibers) and are the fastest conducting (for A-β and A-α fibers, respectively: 7–15 μm in diameter, conduct at 20–80 m s^{-1}; 13–19 μm in diameter, conduct at 75–120 m s^{-1}). The latter fibers conduct proprioceptive information.

Small C-type neurons are receiving considerable attention due to their involvement in nociception and inflammation. Such C-neurons are subtyped into groups based on neurotrophic factor dependence, cytochemical markers (such as expression of the neurofilament protein peripherin (Figures 7 and 9), and pattern of termination in the spinal dorsal horn:

- Group I: Classified as peptide rich; express pro-inflammatory neuropeptides (substance P (SP), and calcitonin gene-related peptide (CGRP)); function in neurogenic inflammation, respond to NGF and the sensory neurotoxin capsaicin, express the TRPV1 (VR1) receptor, and terminate in the spinal laminae I and II_{outer}.
- Group II: Neuropeptide poor; respond to GDNF, bind lectin IB4, and project to spinal lamina II_{inner}.

Groups I and II most likely are not exclusive and distinct classes of neurons because there is overlap of characteristics of both groups in certain subpopulations of cells. Furthermore, adding electrophysiological current signatures of acutely dissociated DRG neurons as another characteristic allows further subtyping of small neurons to nine types.

Neurochemistry

Transmitters Sensory neurons express peptide and nonpeptide neurotransmitters – for example, the peptides CGRP (Figures 11–13), SP, neurokinin-A (NK-A), secretoneurin (SN), galanin (GAL), somatostatin (SOM), vasoactive intestinal peptide (VIP), cholecystokinin , angiotensin II, bombesin, prolactin, oxytocin, and pituitary adenylate cyclase-activating peptide (PACAP). Moreover, neurons exhibit calcium-binding proteins (e.g., calretinin) (Figure 4), the gas messenger nitric oxide, and the excitatory amino acids glutamate and aspartate. Expressions of these substances in sensory neurons have variability based on species, neuron size, target organ innervated, and

Figure 11 Low-magnification view of a dorsal root sensory ganglion, immunostained for the neuropeptide calcitonin gene-related peptide (CGRP). The sensory neurons of the ganglion are concentrated at the periphery of the ganglion (bottom of the figure) and many neurites (NF) populate the interior of the ganglion and are mixed with neurons. There are subclasses, small (S), medium (M), and large (L), of neurons that are immunoreactive to CGRP; also many neurons are not immunoreactive for CGRP. CGRP-immunoreactive neurites are also evident in the central part of the ganglion (arrows). Scale bar = 25 μm.

Figure 12 Higher magnification view of a dorsal root ganglion, illustrating neurons immunoreactive for calcitonin gene-related peptide (CGRP). Only a subpopulation of neurons is CGRP-positive, and some neurons are large (L) and medium (M) in size; many neurons are negative for CGRP. Scale bar = 25 μm.

Figure 13 Subpopulations of neurons in the dorsal root ganglion are immunopositive for calcitonin gene-related peptide (CGRP). In some medium-sized neurons, multiple Golgi complexes appear immunopositive (arrow), and in small neurons (arrowhead) an immunostaining Golgi complex is evident. This staining pattern may indicate that a propeptide is staining. Note that nonneuronal satellite cells enwrapping the sensory neurons are not immunoreactive for CGRP. Scale bar = 25 μm.

pathophysiological state. Most, if not all, sensory neurons contain more than one neurotransmitter. However, even though most primary afferent neurons use glutamate as a neurotransmitter, recent evidence suggests that glutamate may not be co-expressed in peptidergic neurons.

Receptors Further classification of ganglionic-sensory neurons stems from their response to certain agents and receptor expression. For example, small C-type neurons are sensitive to capsaicin (pungent ingredient of peppers). Capsaicin-sensitive neurons are destroyed by treatment of neonates with capsaicin, whereas treatment during adulthood causes depletion of neuropeptide transmitters. Receptor types fall into two general classes: ligand-gated channels

and G-protein-linked receptors. Examples of substances operating through ligand-gated channels are capsaicin, serotonin (5-hydroxytryptamine; 5-HT), adenosine triphosphate (ATP), protons, and glutamate. Substances operating through G-protein-linked receptors are opiates, bradykinin, SOM, neuropeptide Y, adenosine, and prostaglandin E_2 (PGE_2). As indicated previously, tyrosine kinase-linked receptors respond to NTFs.

Some sensory neurons express temperature-sensitive transient receptor potential vanilloid ($TRPV_{1-6}$) receptors (e.g., receptors responding to various temperatures and to nonthermal stimuli such as acid, the vanilloid compound capsaicin, anandamide, and certain lipooxygenase products, and hypotonicity). TRPV1 acts as a polymodal transducer for nociceptive stimuli in primary sensory neurons. Purinergic receptors (P2; responsive to ATP) (Figure 14) are expressed as P2X ionotropic receptors and P2Y G-protein-linked receptors. P2X receptors are localized predominantly to small and medium-sized neurons and may have a role in pain. P2Y receptors are located mainly in large neurons and may play a role in touch sensation. Other receptors include NK-1 receptor for substance P (Figure 15), CGRP receptor, steroid hormone receptors for estrogen and androgens (Figures 15–18), opioid receptors

Figure 14 Low-magnification view of a dorsal root sensory ganglion, immunostained with an antibody against the purinergic receptor $P2X_3$. Note that a subpopulation of neurons is immunopositive and most are of the small size (arrows). Numerous neurites are also $P2X_3$ immunoreactive (arrowhead). Scale bar = 25 μm.

Figure 15 Dorsal root ganglion, double immunostained for estrogen receptor-α (red nuclear localization) and the neurokinin-1 receptor (green cytoplasmic and membrane associated). Subsets of neurons contain estrogen receptor-α (arrowheads) whereas others contain both estrogen receptor-α and neurokinin-1 receptor (arrow). Scale bar = 25 μm.

involved in pain modulation, 5-HT receptors (especially in the gastrointestinal tract, where they influence nausea and reflexes, and on cutaneous afferents, where they modulate inflammation), and D_2 dopamine receptors.

Steroid Influences

Estrogen (E_2) and androgens bind to nuclear estrogen receptors (ERs) and androgen receptor (ARs), respectively, in DRG neurons (Figures 15–18) and initiate changes in gene expression and alterations in cellular functions. Some, but not all, of these neurons innervate reproductive organs. Sex steroids modulate neurochemical features at many sites in the CNS that involve both reproductive and nonreproductive processes. Recent data indicate that rising serum E_2 over pregnancy alters the neurochemistry of DRG neurons during gestation. E_2 stimulates synthesis of SP, CGRP, SN and, PACAP and modulates expression of $P2X_3$ receptors of sensory nerves. Since sensory nerves are influenced by E_2, they in turn could have afferent and efferent roles in normal pregnancy and parturition. Finally, sensory neurons transmit information such as pain and neuroendocrine reflexes from their target organs, and, importantly, the presence of estrogen receptors makes them a likely target of estrogen action.

Functions

Conduction of Modalities

Signal detection Peripheral sensory nerve terminals have multiple functions: reporting normal and abnormal sensations, releasing transmitter substances in response to local factors, and releasing trophic factors to maintain the structure and function of cells in their local environment (e.g., epithelial cells). Signal detection by nerve terminals varies based on location, morphology or type of ending (e.g., encapsulated vs. free nerve endings), and molecular receptor properties. Sensory terminals are populated with specialized receptors that transduce stimuli (e.g., thermal, mechanical, and chemical) into electrical potentials which generate action potentials in their parent axons. Action potentials are propagated through neurites to communicate the modality and intensity of stimuli toward neuron somas and to the CNS. The physiology of these endings is usually dependent on intracellular [Ca^{2+}]. Generally, nociceptors are free nerve endings; mechanoreceptors or touch receptors show some type of encapsulation and are located in cutaneous and subcutaneous regions, and receptors located in muscle, joints, and deep structures monitor mechanical forces as proprioceptors.

Depolarization of nociceptors (mainly polymodal C-fibers) elicits pain and inflammation. In addition to transmitting signals to the CNS, nociceptors release peptides (SP and CGRP) peripherally to produce vascular leakage and vasodilation, leading to inflammation and tenderness at the site of irritant application

(see later and Figure 1(a)). Noxious chemicals (e.g., capsaicin) mediate these effects by activating a TRPV1 receptor belonging to a family of transient receptor potential (TRP) channels that are key components of signal transduction pathways in sensory systems. TRP channels respond to temperature, touch, pain, osmolarity, and other stimuli and are activated by stimulation of G-protein-coupled receptors (GPCRs) and receptor tyrosine kinases. For example, TRPV1 is activated by ligands, including the vanilloid capsaicin, and anandamide (endogenous ligand for cannabinoid receptor 1), as well as by moderate temperatures (>42 °C) and decreased pH. TRPV1 also participates in purinergic signaling from the urinary bladder epithelium. TRPV2 may mediate high-threshold noxious heat sensation (>52 °C), perhaps through lightly myelinated A nociceptors. Increased temperature also activates TRPV3 (>31 °C) and TRPV4 (>25 °C).

Touch or mechanoreceptors are distributed in various tissues (e.g., skin and hair follicles). A variety of mechanoreceptor neurons respond to touch; most show some degree of encapsulation, which determines the nature of the stimulus to which they respond. All of these receptors work in fundamentally the same way: touch produces deformation or changes the nerve ending, which alters the ionic permeability of the receptor membrane generating a depolarizing current, ultimately triggering an action potential. The peripheral endings of such neurons use touch-transducing molecules to generate the depolarizing current. A channel superfamily – epithelial amiloride-sensitive sodium channel (ENaC) – is expressed nearly exclusively in touch receptor neurons. Mammalian members of the ENaC superfamily fall into two subfamilies that are expressed in either epithelia (ENaCs) or neurons (acid-sensing ion channels activated by extracellular protons; ASICs).

Efferent Function of Sensory Nerves

DRG neurons not only relay information centrally, they also have peripheral neuroeffector functions by releasing mediators from their peripheral terminals. As early as 1901, the physiologist Bayliss demonstrated that stimulation of dorsal root sensory nerves induced peripheral vasodilation (Figure 1(a)). This phenomenon was eliminated by destruction of the DRG or peripherally directed processes of DRG neurons, suggesting that the vasodilation was caused by antidromic impulses in sensory nerves. Subsequent experiments demonstrated that cutaneous axon reflexes occur without connections to the CNS. Such phenomena utilize primarily polymodal C-fibers, but also A-δ fibers.

Axon reflexes involve activation of a C-fiber, which conducts information to the CNS as well as to other branches of the stimulated afferent nerve ending (Figure 1(a)). In this way, action potentials spread into branches of the activated terminal and mediators are released from all activated branches. Through this mechanism, stimulation of nociceptors releases neuropeptides resulting in vasodilation (flare), release of histamine from mast cells (leading to venular permeability and edema – protein extravasation), and influx of immune cells. Taken together, these actions constitute neurogenic inflammation. Neurogenic inflammation has roles in inflammatory responses, repair, and tissue remodeling. Substances that stimulate nerve endings can originate in local tissues and cells or from external sources and include ATP, PGE_2, bradykinin, 5-HT, protons, and histamine. The C-fibers release SP, CGRP, GAL, PACAP, SN, and other tachykinins from their peripheral ends. This expanded view of the sensory neuron stems from studies of the expression and function of their neuropeptides. It is emphasized here that many (if not all) sensory peptidergic nerves contain more than one transmitter, so peripheral stimulation and axon reflexes may produce multiple and complex effects. Such functions of sensory nerves play important roles in cutaneous blood flow, renal excretory function, protection during gut inflammation, release of proinflammatory agents, rheumatoid arthritis, and airway disease.

Pathophysiology

Plasticity in Sensory Neurons

Following injury to peripheral sensory endings, long-lasting changes can occur in the somas; for example, such changes may be in soma neurochemistry, including alterations of expression of neuropeptide neuro transmitters, receptors, immediate-early genes (e.g., c-*jun*), and gene-products such as growth-associated protein 43 (GAP43; associated with reparative events) (Figure 5). Injury to small and medium-sized neurons causes, in general, downregulation of excitatory peptides SP and CGRP and upregulation of inhibitory neuropeptide tyrosine (NPY) and GAL.Such changes result in decreased neurotransmission in the spinal dorsal horn and are thought to represent adaptive responses to protect the individual and to promote survival of the sensory neuron. Moreover, GAP43 increases along with upregulation of c-*jun*, both of which are thought to have roles in reparative processes.

Levels of neuropeptides are influenced by multiple regulatory factors, including E_2, electrical activity, substances derived from the environment of the terminals, and inflammation. After tissue injury, NGF is produced by inflammatory cells and is critical for maintenance of NGF-responsive peripheral nerves.

NGF binds to TrkA and $p75^{NTR}$ receptors, and TrkA mediates NGF internalization, retrograde transport, and subsequent cellular responses. E_2 can regulate NGF influence on DRG neurons via regulation of NGF receptors (NGF receptors are increased by 17-β-estradiol). As indicated previously, many DRG neurons contain estrogen receptors and express SP, CGRP, SN, and PACAP; rising serum E_2 levels in late pregnancy promotes expression of these neuropeptides. Thus, a linkage may exist between injury, inflammation, immune cells, NGF, rising E_2, and increase of neuropeptides in DRG neurons. Consequently, E_2 positively influences the plasticity of small C-type neurons.

Diabetes Mellitus

Patients with diabetes mellitus (DM) frequently suffer polyneuropathy with nerve conduction abnormalities. Decreases in sensory amplitudes and slowing of the nerve conduction velocities indicate axonal destruction and demyelination. Factors important in the pathogenesis of diabetic neuropathy are hyperglycemia, reduced Na^+/K^+-ATPase activity in nerves, and microvascular abnormalities.

In DM, peripheral nerves suffer deficient neurotrophic support – a situation which resembles axotomy. In animal models of diabetes, NGF is depleted in nerves; along this line, experimentally induced NGF deprivation results in decreased sensation and hypoalgesia. Early in DM, depletion of NGF leads to dysfunction of small-diameter sensory fibers and loss of SP. There may be a correlation between NGF depletion and decreased organ (particularly in skin) axon reflex vasodilation (promoted by the efferent function small sensory fibers releasing SP). Decreases in endogenous target-derived NGF may influence the onset of diabetic polyneuropathy, whereas metabolic or vascular abnormalities may underlie a full neuropathy. Loss of nociception and axon reflex vasodilation contributes to diabetic foot ulceration in patients. Exogenous NGF can reverse some pathological changes in diabetic nerves; thus, early and prolonged NGF treatment may provide a rational approach to maintenance of sensory nerve function in diabetes.

Other NTFs may be affected in DM. For example, NT-3 is a neurotrophic factor for large-diameter sensory nerves and helps maintain proprioceptive and mechanoreceptive fibers. Neuropathy involving large sensory fibers is frequent in DM. In DM animal models, decreased NT-3 gene expression occurs in hind limb muscle, and treatment with insulin prevents the decrease. Decreases in axonal transport of NTFs are also reported. Moreover, expression of the NT-3 receptor, TrkC, is also downregulated in lumbar DRG. Decreases in NT-3 production and axonal transport may indicate that large sensory neurons expressing TrkC may experience suboptimal neurotrophic support in DM.

It is interesting that expression of genes that are responsive to axotomy (i.e., increase after axotomy) – genes that code for GAP43, GAL, NPY, VIP, neuronal nitric oxide synthase (nNOS), TrkA, TrkB, and TrkC– seem to be unaffected in ganglia from diabetic rats. This suggests that damages caused by DM do not necessarily replicate axonal damage by trauma.

Viral Invasion

Sensory nerves are avenues for neurotropic viruses to enter the nervous system and cause neuropathy, skin lesions, and pain. Following infection, neurotropic viruses replicate in the epithelium, invade sensory nerve endings, and are transported retrogradely to the somas in sensory ganglia (Figure 19). Viruses become latent in the somas, with the possibility of later reactivation, often triggered by a stressful stimulus. Viruses that commonly invade sensory nerves are herpes simplex virus (HSV; types 1 and 2) and herpes zoster (varicella), which produce common clinical syndromes (e.g., chicken pox, shingles, and blisters). Viral presence in an epithelium (e.g., oral cavity or genital region) provides opportunity for invasion of mucous membranes and uptake by sensory nerve endings. A short period of viral replication within sensory ganglia is concomitant with establishment of a nonproductive latent infection. Neurotropic viruses may reemerge from the nervous system, spread to cutaneous areas by anterograde transport of the virus through sensory nerves, and cause disease within the same dermatome at a location distal from the initial site of infection. Spread of the virus requires an intact nerve supply. Both larger A-δ and smaller C-fibers take up and transport neurotropic viruses, thus pain and proprioceptive pathways can be infected.

Figure 19 Sensory neurons can take up viruses in their cutaneous terminals and transport them to the cell soma in ganglia. This micrograph shows a whole dorsal root ganglion, illustrating herpes virus-mediated gene transfer of β-galactosidase (shown as blue cells). Reproduced courtesy of Dr. Steven P. Wilson, Department of Pharmacology, Physiology and Neurobiology, University of South Carolina School of Medicine.

Sympathetically Maintained Pain

There are numerous pain conditions involving sensory nerves directly or indirectly, and these have been reviewed extensively. One condition involves sensory and autonomic nerve interaction.

In humans, trauma to a peripheral nerve may be followed by chronic pain which is only relieved by blockade of sympathetic nerve activity. This has been referred to as sympathetic maintained pain (SMP). SMP is a symptom occurring in neuropathic pain syndromes of different etiologies. However, there is controversy regarding use of the term SMP in clinical practice. A movement is under way to use the phrase 'complex regional pain syndrome' (CRPS) (older terms for CRPS are 'reflex sympathetic dystrophy syndrome' and 'causalgia') to describe several types of chronic pain conditions believed to result from dysfunction in the central or peripheral nervous system. Typical features of CRPS include changes in color and temperature of the skin over affected body parts, intense burning, skin sensitivity, sweating, and swelling. Since some of the symptoms could involve sympathetic activity, abnormal activity in the sympathetic nerves may be involved in the pathogenesis of such chronic pain syndromes. For example, fibromyalgia (FM) may be a type of SMP, because patients with FM display signs of relentless sympathetic hyperactivity, and pain is modulated by sympathetic blockade and is exacerbated by noradrenalin (norepinephrine) injections. Along this line, a recent theory suggests that pain receptors in the affected parts of the body become responsive to noradrenalin released from sympathetic nerves after tissue or nerve injury, and animal experiments have shown that nociceptive afferents, after partial nerve lesions, develop adrenergic sensitivity at the site of the injury.

A sympathetic–afferent coupling reportedly takes place in the DRG, but its exact nature has been enigmatic. However, animal experiments reveal that peripheral nerve injury often induces sympathetic nerve fiber sprouting into nearby DRG. It is presumed that, after the lesion, noradrenalin released from sympathetic axons excites primary afferent neurons by activating α-adrenoceptors and generating signals that enter the pain pathways of the CNS. Such connections provide a possible explanation for sympathetic–afferent coupling and SMP.

Introduction

Peripheral nerve injuries still represent some of the most challenging and difficult surgical reconstructive problems. Although evolving scientific concepts during the past decades have resulted in an enormous amount of new laboratory data, this has had little impact on the treatment of such injuries. The majority of nerve injuries occurs in the upper extremity of young males, varying in severity and level from clear-cut nerve transection to severe nerve lacerations and from digital nerve injuries to brachial plexus lesions. A simple transection of a median nerve at wrist level may have disastrous consequences for hand and upper extremity function. The probability of work loss is very high and there is a substantial economic impact on the patient as well as society. Nerve injuries may substantially impair the life quality for patients and may result in lifelong hand-function impairment, pain, cold intolerance, and dysesthesia.

Following nerve repair at distal forearm level the fingers will be without sensibility up to 6 months before any reinnervation at distal finger level occurs, and 5 years following surgery there still is a substantial disability in adults.

Nerve injuries are usually surgically repaired so that both ends of the cut nerve are anastomosed by use of microsurgical techniques. However, in spite of optimal technical refinement of the repair techniques, the outcome in adult patients is often disappointing with remaining deficits in terms of impaired sensory and motor function and discomfort based on pain and cold intolerance. A crucial factor is the great extent of axonal misdirection which always takes place after nerve repair regardless of how sophisticated technique is used. A result, and a major reason for bad functional outcome, is the profound cortical functional reorganizations, which takes place as a result of the peripheral axonal misdirection. The problem is even greater when a nerve injury is treated at a later stage when a reconstruction with a nerve graft may be required. Several factors influence the outcome from nerve repair such as timing of the repair, type of nerve, level of injury, and type of injury. In adult patients it has been demonstrated that specific cognitive capacities such as verbal learning capacity and visuospatial logic capacity help to explain variations in the recovery of functional sensibility. However, among all influencing factors, the age of the patient has turned out to be the most important. Although functional restitution after nerve repair in adults is usually far from satisfactory, the situation is quite different in children, who consistently show superior functional results as compared to adults.

The Cortical Response to Nerve Injury and Repair

It was demonstrated 70 years ago by Penfield and Boldrey that the hand is projected in a large area in the cortical body map. A nerve transection represents an acute deafferentiation with immediate and long-standing influence on the corresponding representational areas in brain cortex as well as in adjacent cortical territories. In early primate experiments it was shown by the Merzenich group that transection of a median nerve at wrist level results in a silent area in the somatosensory brain cortex corresponding to the projectional areas of the fingers that had been deprived of their central connections. The result was an expansion of adjacent cortical areas that gradually occupied a substantial area of the former median nerve territory. Such changes probably occur very fast after nerve transection, within minutes, as a result of unmasking of normally occurring but inhibited synaptic connections.

Later, when reinnervation of the hand occurs there is a new phase of cortical reorganization. Regardless of how refined surgical technique is used, there is a great deal of axonal misorientation at the repair site. Schwann cell tubes in the distal nerve segment may be reinnervated by sprouts from a large number of various axons, and axons in the proximal segment may hereby reinnervate incorrect distal pathways. As a result, distal skin areas will not, to a large extent, be reinnervated by the original axons but may instead be reinnervated by axons originally meant to innervate other parts of the hand. It is known from primate experiments that the original well-organized cortical representation hereby is transformed into a mosaic like pattern and that the nerve does not recapture all of its original territory. The former well-defined individual cortical representation of separate fingers disappears and changes into disbursed discontinuous islands. Skin surfaces, which previously had well-defined cortical representations such as a finger, a segment of a finger, or a palmar pad, become instead represented across multiple small, sometimes overlapping cortical patchlike areas. Cortical regions that receive tactile signals from reinnervated skin regions will now contain multiple recording sites

with abnormally located or multiple cutaneous receptive fields. In monkeys, such representational changes after nerve transection and repair occur both immediately and progressively at the cortical as well as the subcortical level. In humans, fuctional magnetic resonance imaging (fMRI) investigation has shown that tactile stimulation of the nerve-injured hand activates larger areas in the somatosensory cortex compared with the noninjured hand. This enlarged area has been regarded as a result of a cortical reorganization, and it is believed that larger cortical areas are involved in the discriminatory tasks after the supposed derangement of the peripheral input. From a clinical perspective, the result is an incomplete sensory restitution of the hand with impaired discriminative capacity – the hand speaks a new language to the brain. The capacity to detect touch may be restored so that an adult person can regain some protective sensibility. However, the prerequisites for a discriminatory capacity to identify textures, structures, and shapes in the act of touch are very limited and a sensory relearning process is required.

The Sense of Touch

Our senses are the windows through which we perceive our environment. Hearing, vision, taste, smell, and the sense of touch together provide our mind with an inner picture of the outer world. For the sense of touch, the hand is a key organ with huge cortical representation, and the sensation has therefore a vital role in hand function. Lost or impaired hand sensation after nerve injury is a major problem, causing not only considerable body function impairment but also substantial disability and reduction in life quality.

Four major modalities of somatic sensibility can initially be defined: the pure and discriminative touch, proprioception, nociception, and temperature sense. For clinical examination of hand sensibility, a hierarchy of sensory functions can be identified: if detection of touch is present, the next level is to examine if the patient can discriminate the touch – the most basic tactile gnosis. Two-point discrimination test is the classic test here – although the validity and reliability is disputed. Localization of touch is as well an aspect of discriminative touch. Identification by active touching is the third level – a more refined tactile gnosis. Functional sensibility – or what some name haptics – is the endpoint where tactile gnosis acts in concert with muscles and joints for a useful grip function.

In the interplay between the senses, the eye remains at the surface, while hearing and the touch of the hand obtain information on the inner of an object, the microstructure, thereby playing a great role in developing a belief in the reality of the external world. More than a 100 years ago, von Frey and Weber paid attention to clinical methods to describe the capacity to detect touch and spatial acuity, respectively. Spatial acuity is the smallest discriminated distance between two points of contact. Moberg paid further attention to the importance of tactile discrimination, and established the term 'tactile gnosis.' Tactile gnosis enables recognition of qualities and characters of objects without using vision, which is of utmost importance for functional sensibility – a prerequisite for what the hand can do. Napier described the hand as "an organ of touch which feels around corners and sees in the dark." The sense of touch can provide us with information not only about shape and texture but also about temperature, consistency, elasticity, density, dryness, wetness, stickiness, and oiliness. The discriminative touch, the basis for tactile gnosis, is based on various types of sensory receptors found in the glabrous and hairy skin which are sensitive to mechanical stimulation, transducing mechanical stimuli such as pressure, vibration, and stretching. Afferent signals from cutaneous mechanoreceptors of the hand reach the somatosensory brain cortex after passing the dorsal root ganglia, the dorsal column of the spinal cord via the medial lemniscuses pathway, and intermediate relay stations situated in the cuneate nucleus in the brain stem and the ventroposterior nucleus in thalamus. Signals elicited by touch primarily reach the contralateral hemisphere, but to a lesser extent also the ipsilateral somatosensory cortex. The somatosensory cortex has a complex multidimensional functional architecture with three major divisions: the primary (S-I) and secondary (S-II) somatosensory cortices and the posterior parietal cortex. In the primary sensory cortex there are four distinct somatotopic maps corresponding to the four areas of S-I that have been identified by Brodman named 1, 2, 3a, and 3b; each map represents one subquality of sensation. Information from the skin, important for touch, is primarily represented in area 3b.

Sensory Relearning and Sensory Re-Education

In the adult, the original neural program for understanding tactile information, which was generated in early childhood, is lost after nerve injury and repair as a result of cortical reorganization and distortion of the original cortical hand map. A relearning process is required. The capacity to recover tactile gnosis after nerve repair, as related to age, has much in common with learning to speak a second language

(Figures 1 and 2). In hand rehabilitation following nerve injury and repair, such sensory relearning is based on the use of sensory re-education protocols (Figure 3). Normally, such a relearning process may in parts be gained in daily activities by conscious use of the hand in common manual tasks, using vision as a guide and a code for impaired hand sensibility. The concept is to reprogram the brain to understand the new 'language' from the hand. Specific programs for sensory re-education have been suggested and are routinely used clinically in adult patients, subjected to nerve repair in the hand forearm, for regaining tactile gnosis. Protocols for sensory re-education have been presented in numerous books and articles. First, the perception of different touch modalities and the capacity to localize touch is trained, followed by touching and exploration of items, presenting shapes and textures of varying and increasing difficulty with the eyes open or closed. In this way, an alternate sense (vision) trains and improves the deficient sense (sensation).

The training is integrated in the overall rehabilitation program. Specific simple and repetitive sensory relearning exercises of increasing complexity and difficulty are supposed to be performed at home by the patient on a regular basis in frequent and short training sessions. Training in a quiet location for high attention is recommended.

Several factors may influence the results from the sensory re-educational programs in a positive or negative way. For instance, active and conscious use of the hand in daily activities and attention during training combined with high motivation by the patient are extremely important. From primate experiments, it is obvious that a behavioral state and the strength of reward and punishment in behavioral training have strong influence on the remodeling of cortical representations. When animals are stimulated on a routine stimulus schedule with the stimulation unattended cortical remodeling does not occur, and nonassociated meaningless inputs can drive negative representational changes. It is important that individuals are well rewarded in the training program since successful performance generates the most rapid representational changes. The molding of the brain is influenced in a positive direction in a stimulating environment with meaningful activities and much encouragement.

How Is Brain Organization Influenced by Sensory Re-Education?

Little is known about the effects of sensory re-education on brain organization. One possibility is that sensory training can reverse the disturbed cortical organization toward a normalized pattern. Another possibility is that the cortical hand map is permanently distorted and that the key is an improved processing and perceptual capacity in the sensory networks at a higher order of cortical level, facilitating interpretation of the distorted hand map. Although young individuals may have a greater capacity for normalization of the cortical hand map

Figure 3 Basic principles for sensory re-education and underlying physiologic mechanisms. By touching items of increasing difficulty with the eyes open or closed, a relearning process is initiated in which vision is the guiding sensation to understand 'the new language spoken by the hand.' The pathophysiologic events behind the altered sensibility in the hand, induced by the injury, are illustrated to the left ('before training'). The cortical hand map is changed (top) as a result of misdirected axons at the suture site (middle). The cortical receptive fields in the fingertips are becoming large and overlapping as reflected in an impaired tactile discrimination capacity (bottom). The 'sensory relearning process' passes through several steps. The cortical representation of a ball, schematically illustrated by (A), has been changed by the nerve injury into a dispersed, nonorganized cortical pattern (B). By touching items of increasing difficulty, with alternately closed and open eyes (C, D), vision guides sensation toward a better understanding of shapes and textures. Possible physiologic changes explaining effects of sensory re-education are illustrated to the right ('effects of training'). The distorted cortical hand map is modified toward a more normal pattern (top). The misdirection of axons at the suture site is not significantly changed, although some pruning of misdirected axons has occurred (middle). The receptive fields in fingertips shift toward a normalized pattern showing a finer grain in resolution (bottom). Reproduced from Lundborg G (2004) *Nerve Injury and Repair. Regeneration, Reconstruction and Cortical Re-Modelling*, 2nd edn. Philadelphia: Elsevier, with permission from Elsevier.

following nerve section and repair compared to adults, such capacity for normalization of the cortical hand map by training probably does not exist in the mature brain. The topic was studied by Florence, who investigated the effects of enriched environmental sensory experience on cortical organization on monkeys that had previously undergone nerve section and repair of the median nerve. One group was subjected to an enriched environmental sensory experience involving presentation of food treats on an artificial grass surface and toys, while the control group was allowed only restricted mobility with no such enriched sensory experience. Using direct cortical recording techniques, it was demonstrated that the enriched sensory environment had a significant effect on receptor field size with smaller, normalized, and better-located receptive fields likely to provide better resolution. In addition, the cortical hand maps in area 3b were less distorted in the sensory-enriched animals compared with the sensory-restricted animals. Thus, also in humans, sensory relearning programs, including an enriched environment, may hypothetically explain functional improvement after rehabilitation.

Evolving Strategies for Enhanced Sensory Relearning

The sensory re-education programs that are used today have not changed much during the last decades, in spite of the amount of increased knowledge and evolving concepts in neuroscience, cognitive science, and brain imaging techniques that have been presented over recent years together with our increased understanding of mechanisms underlying brain plasticity with a focus on learning. For instance, the timing of the sensory relearning has been little considered. Routine sensory re-education starts with beginning reinnervation of the hand that is 3–5 months after a median nerve lesion at wrist level. At this point, the

reorganizing cortex presents a random pattern which can be very difficult for the patient to control and utilize for regaining functional sensibility. It may be that the timing of onset of sensory relearning is a crucial factor, since functional reorganization changes of the cortex occur early after changes in peripheral input. For instance, following amputation of the hand, touching the face – the face being close to the hand in the cortical body map – gives rise to referred sensations in the phantom as early as 24 h after the injury. Analogous phenomena have been demonstrated, also after local anesthetic blocks, that temporarily induce shifts in neuronal receptive fields with cortical reorganization.

When discussing onset and principles for sensory re-education in the future, two postoperative time windows should be defined: phase one, covering the early postoperative phase when the hand is still without sensation, and when the original cortical projectional area of the denervated body part is being occupied by expanding adjacent cortical areas, and phase two, when reinnervation of the hand is beginning and when the original cortical projection is changed into a disbursed, mosaiclike pattern.

Phase One

In phase one, maintenance of the cortical hand projection, which otherwise will be occupied by adjacent cortical areas, may be a way to facilitate the course of sensory recovery when the hand is reinnervated. In uninjured individuals premotor areas, can be activated by solely using motor imagery exercises (imaging hand movements), observing movements of hands belonging to others by activating mirror neurons in frontal cortex, or reading or listening to action words, related to hand movements. In tactile imagery, the somatosensory cortex is activated by mental imagery and tactile stimulation of the hand. Alternative ways to activate somatosensory cortex are less documented, but somatosensory neural substrates have been activated by watching touch of legs or hands. Another principle is to use another sense – hearing – to substitute for sensibility. This method allows early sensory relearning, long before any reinnervation of the hand can be identified, in order to feed the sensory cortex with 'relevant' information. The ambition here is to maintain the cortical map from the affected hand until 'real' sensibility is present. Cortical audiotactile interaction has recently, with fMRI technique, been demonstrated in persons trained with such a system.

Phase Two

In phase two, when reinnervation of the hand is beginning and when the original cortical projection is changed, sensory re-education programs focus on detection and discrimination of touch in combination with identification of specific objects. A very conscious perceptive behavior when using the hand in daily activities is also of importance. New training strategies have been suggested in the literature recently. Examples of such strategies are cutaneous anesthesia of the forearm of the nerve-injured hand and continuous tactile stimulation to enhance the sensory relearning. Such strategies, based on new knowledge in brain plasticity and mechanisms in the brain's capacity for rapid redistribution of cortical resources, may have potential for improving sensory functions in the hand after nerve injuries.

Sensory System Specializations

E C Henry and K C Catania, Vanderbilt University, Nashville, TN, USA

© 2009 Published by Elsevier Ltd.

Introduction

Studies of specialized species often reveal general principles of brain organization and function and also help guide theories of brain evolution by revealing the neuronal traits that are correlated with specific sensory abilities. Although there is great diversity in the organization of visual, auditory, and olfactory systems across mammals, in some ways specializations of the somatosensory system are most easily appreciated because this system is so closely tied to the morphology of the body. Every different mammal has a differently organized somatosensory system reflecting the unique configurations of the skin receptors, joints, and muscles. Species with prominent mechanoreceptors usually have predictably large corresponding areas of the central nervous system for processing touch information.

Mice and rats, with their large facial whiskers, are well-known examples. In 1970, Woolsey and Van der Loos made a landmark discovery in the mammalian neocortex by identifying a series of cortical modules (barrels) in somatosensory cortex (S1) that correspond to the pattern of whiskers on the contralateral side of the face in mice (Figure 1). This visible reflection of peripheral mechanoreceptors in the central cortical representation, or map, was best revealed by cutting the cortical tissue tangent to the surface so that large areas of the map in cortical layer 4 could be viewed in a single section of tissue.

Refinements to the flattened cortical preparation and new histological techniques, in conjunction with electrophysiological recordings of cortical neurons, have provided increasingly detailed understanding of brain organization in a range of different species. In the case of somatosensation, it is particularly informative to examine species that depend most heavily on touch to navigate their environments. Subterranean mammals must 'feel' their way through their underground burrows, using tactile cues for orientation and prey identification, and they have correspondingly enlarged and specialized somatosensory systems. Two different subterranean species, the star-nosed mole and the naked mole rat, are specialized for life underground, but their somatosensory systems are very different.

Star-Nosed Moles (*Condylura cristata*)

Mechanoreceptor Specializations

There are about 30 different species of moles (family Talpidae) that exhibit a variety of different specializations for touch. However, a common theme among all these species is the use of the tip of the nose, rather than long whiskers, to collect the most detailed tactile information from their environment. For this purpose, nearly every mole species has a series of domed mechanosensory organs covering the distal surface of the snout. These are called Eimer's organs (Figure 2), and each contains a series of free nerve endings that run through an epidermal cell in the center of the organ. At the base of the organ, one or more merkel cells is contacted by a neurite, and just below this, a lamellated corpuscle is situated in the underlying dermis, just below the central cell column. In addition, recent investigations have identified a second, smaller set of free nerve endings that ring the periphery of the dome and are positive for substance P – a marker for nociceptive afferents. This subset of nociceptive afferents is well positioned to detect damage to the delicate organs.

An array of these complicated sensory organs generally covers the skin surface of a mole's nose. However, the snout of the star-nosed mole is by far the most elaborate and complex. The entire star is essentially composed of Eimer's organs that cover all the 22 appendages that form the star. Despite its small size (about 1 cm diameter), the star is innervated by more than 100 000 primary afferents that serve 25 000 Eimer's organs. Using this array of mechanosensory organs, the star-nosed mole can make very rapid sensory discrimination of small objects.

The star stands out as one of the more unusual mechanosensory specializations among mammals, and the organization of this touch organ shares similarities with the organization of visual systems in other species. For example, the star is divided into a high-resolution central area (the paired 11th appendages in the center) and a larger, low-resolution area consisting of the other 20 appendages of the star. When moles explore their environment, the star is moved like an eye, with the large surface area of appendages 1–10 used to scan the environment through touch, and the central pair used as the tactile fovea for detailed investigations of objects of interest. The sudden, jerky movements of the star that shift the tactile fovea to different areas of the environment are very similar to saccadic eye movements that position

Figure 1 Cortical barrels. (a) The face of a laboratory mouse, including the prominent whiskers or 'vibrissae.' (b) A section of flattened right cortex processed for the metabolic enzyme cytochrome oxidase to reveal the prominent cortical barrels in layer IV. Rostral is to the right and medial is up. The large facial vibrissae correspond to the barrels visible in the lower left quadrant whereas the smaller facial whiskers are represented by the smaller, more rostral barrels.

Figure 2 Schematic representations of the structural components of Eimer's organ of the mole. Eimer's organ contains a central column of large diameter intraepidermal free nerve endings (CC-FNE) that course directly to the stratum corneum (SC). A ring of smaller satellite free nerve endings surrounds the central column free nerve endings (S-FNE). The satellite fibers take a circuitous route to the skin surface, tracing the boundaries between epithelial cells one or two cell diameters removed from the central column fibers. There are Merkel cell–neurite complexes (MC) located at the base of the epidermal papilla. There are also lamellated corpuscles in the dermis below the papilla of each Eimer's organ (LC).

images on the retinal fovea in primates. This elaborate sensory system allows star-nosed moles to discriminate and consume small prey in only 200 ms.

Central Nervous System

The complexity of the star and associated behaviors suggest that star-nosed moles should have enlarged and specialized somatosensory areas in the central nervous system. This turns out to be true (Figure 3) and is most easily appreciated at the cortical level by examining flattened cortical sections from the somatosensory region – as previously described in mice and rats. Figure 3(b) shows a single section of layer 4 cortex, where touch information from half the star projects to primary somatosensory cortex (S1). As in many rodents, the distribution of mechanoreceptors on the mole's snout projects to a modular region of the cortex that reflects the morphology of the face. Simply put, the map of the star is visible in the brain.

Closer examination of the relationship between the star and the cortical map reveals a disproportionate expansion of the region representing appendage 11 (only the contralateral half of the star is represented in each cortical hemisphere; hence only 11 stripes are visible on each side of the brain). Although the 11th appendage is relatively small on the star, it has a disproportionately large representation in the brain, reflecting the behavioral importance of this region of the sensory surface. This is also true for the cortical representation of the retinal fovea in primary visual cortex of more-visual species.

Examining a larger region of the cortex reveals additional maps of the star in more lateral cortex (Figure 3(c)). These maps are densely interconnected with one another to form a network that most likely processes different aspects of touch information in each different area. Star-nosed moles have three maps

Figure 3 The unusual mechanosensory star, its corresponding cortical representation, and the organization of the superior colliculus in the star-nosed mole (*Condylura cristata*). (a) A star-nosed mole emerging from an underground tunnel shows its large forelimbs and the 22 fleshy appendages that surround each nostril. The 11th appendages on each side act as the somatosensory fovea and are used for detailed tactile investigations. (b) The pattern of cortical modules in S1 visible in flattened cortical sections processed for the metabolic enzyme cytochrome oxidase. Note the greatly expanded representation of the somatosensory fovea (appendage 11). (c) A section of flattened cortex revealing all three cortical representations of the star, visible as a series of modules, each representing an appendage from the contralateral star. (d) Schematized representation of the star-nosed mole's body proportions in the superior colliculus. The star has a greatly magnified representation and takes up approximately half of the somatosensory map.

of the star in cortex, whereas other mole species have only two maps. Star-nosed moles appear to have added a new cortical area to the processing network to handle the large volumes of somatosensory information from the star, and this may be one way they have achieved such rapid discriminatory abilities.

Finally, it is interesting to consider how the superior colliculus is organized in star-nosed moles. The superior colliculus in most mammals is dominated by visual inputs and plays a critical role in guiding orientation movements of the eyes. In star-nosed moles, the superior colliculus receives only minimal input from the eyes. Instead, somatosensory inputs dominate, and much like the organization of the somatosensory cortex, a map of the body surface in the colliculus is dominated by the representation of the star (Figure 3(c)). These findings suggest the superior colliculus in star-nosed moles plays a role in guiding the saccadic orientation movements of the nose.

Naked Mole Rats (*Heterocephalus glaber*)

The naked mole rat is a remarkable rodent with many unusual traits. Mole rats live in large subterranean colonies of 80 or more individuals but only a single reproductively active female. This eusocial colony structure includes separate castes – a queen, many workers, and occasional disperser morphs – thus closely resembling the organization of social insect colonies such as ants and termites. Naked mole rats also have extraordinarily long lives compared with other rodents, with captive animals living more than 20 years.

Mole Rat Mechanoreceptor Specializations

Naked mole rats also have a number of sensory specializations that allow them to navigate dark, underground tunnels. Much like star-nosed moles, naked mole rats have reduced eyes and sparse visual projections to the superior colliculus. They have few retinal ganglion cells compared with sighted rodents, and the architecture of their retina is disorganized such that form vision is impossible.

Not surprisingly, mole rats depend heavily on touch to navigate their environment. Although virtually hairless, they have unique 'body vibrissae' in rows along the trunk that act as touch sensors for navigation within their tunnels. These body vibrissae have follicle diameters and innervation that more closely resemble those of facial vibrissae than fur. These hairs guide orientation movements of the mole rat's head in the direction of novel stimuli. Mole rats also have facial whiskers more typical of other rodents, which they use for tactile perception (Figure 4).

However, the most obvious feature of mole rats' external anatomy is the large incisors that protrude beyond the oral cavity. The mole rat's mandibles connect at their anterior extent by a flexible mandibular symphysis, allowing the lower incisors to move independently. Mole rats use these teeth for digging extensive tunnel networks, carrying objects and young, chewing, and investigating their surroundings (by tapping their incisors against objects of interest). The teeth are also important for social interactions between colony members – 'incisor fencing' is often observed in struggles for dominance. From these observations, one might predict that the front teeth, rather than the snout, have the most important role in gathering sensory information from the environment. Investigation of mole rat cortex suggests this is the case.

Figure 4 The unusual anatomy of the naked mole rat (*Heterocephalus glaber*). (a) Photo of an adult mole rat, demonstrating the lack of fur and general proportions of the body. (b) The sensory hairs covering the tail are used for navigation while the mole rat is traveling backward through tunnels. (c) Front view of a naked mole rat, showing the enlarged incisors that are located permanently exterior to the oral cavity. Note also the sensory whiskers covering the front part of the face and mouth region. (d) A mole rat moves a small piece of earth with its teeth. (e) Summary schematic of the somatotopic organization, location, and relative size of areas S1, S2, and a region presumed to be the parietal ventral area (PV; dotted line). The large representations of the upper and lower incisors and the rostral tongue area are all part of S1. The 'mixed Incisors' region is composed of neurons responsive to the upper incisor, lower incisor, or both. (f) A single section of cortical tissue corresponding to layer IV in the naked mole rat. The section was flattened and cut parallel to the surface before processing for the enzymatic marker for oxidative metabolism, cytochrome oxidase (Wong-Riley et al., 1978; Wong-Riley and Welt, 1980). Cytochrome oxidase processing revealed dense modules corresponding to the predicted locations of S1 body areas and orofacial structures. (g) Comparison of the overall proportion of neocortex taken up by S1 in the naked mole rat (NMR) and Long Evans laboratory rat (Rat). S1 is approximately 50% larger, as a proportion of total neocortex, in the naked mole rat (right side of graph). A second comparison is the proportion of sensory cortex taken up by S1 in the two species (left side). Total sensory cortex here is defined as cortex caudal to the rostral border of S1.

Central Nervous System

As might be expected, the sensory specializations described above are reflected in an expanded somatosensory cortex. Somatosensory cortex (S1) in naked mole rats has been found to represent 31% of total neocortical territory and at least 47% of sensory cortex. This is a much larger area of the cortex than is typically taken up by somatosensory inputs. For example, S1 in laboratory rats takes up approximately 21% of neocortex and only 27% of all possible sensory cortex. Within mole rat somatosensory cortex, S1 is dominated by an expanded representation of the behaviorally important front teeth (Figure 4). This representation is dramatically magnified compared with the size of the dentition representation in rats, which takes up only about 7% of S1.

The S1 representation of the body can be visualized by reacting sectioned cortical tissue for CO. Although the subdivisions in mole rat cortex are less distinct that those in mouse cortex (Figure 1), this procedure nevertheless provides an indication of the relative position the various body-part representations in the cortex. It also reveals a series of modules within the S1 dentition representation located in rostrolateral cortex. These modules are similar to CO modules identified in primate area 3b (the homologous cortical area to S1 in other mammals), corresponding to the oral structures. One hypothesis for this modular representation of the dentition is that different modules process different kinds of touch information from the teeth.

Conclusions

Both star-nosed moles and naked mole rats have specialized somatosensory systems, yet each has different mechanoreceptor arrays and different areas of the body magnified in the neocortex. Star-nosed moles depend most heavily on the skin of the snout to explore their environment and have developed a tactile fovea on the star. This region of the body is greatly magnified in the cortical representation, which contains a series of modules representing the appendages of the star. The superior colliculus in star-nosed moles is dominated by somatosensation rather than vision, and this structure likely plays an important role in guiding saccadic head movements. In mole rats, a series of body whiskers is used for orienting in underground tunnels. In addition, the unusually large front teeth are used for collecting tactile information, and their representations are greatly magnified in the cortical map of the body. More than 30% of somatosensory cortex is devoted to the front teeth. Both species have been useful in understanding the organization and evolution of different somatosensory specializations in mammals.

Sentence Comprehension

Introduction

When people talk to each other, they translate their ideas into a series of sounds (or in the case of signed languages, gestures), and the recipient of the message must take this string of essentially arbitrary sounds or movements and interpret it as a discrete, abstract message. As such, processes of language comprehension run the gamut, from the earliest stages of perception of a speech sound or gesture to high-level inferences concerning the implications of the messages that have been comprehended. Sentence comprehension forms a middle ground in this sequence and concerns the processes by which a language perceiver transforms a linear string of words into an understanding of the essential sentence meaning.

The meaning of a sentence can be thought of as a hierarchically organized structure connecting and relating the meanings of individual elements to create propositional meaning. For example, in the sentences in example 1, a comprehender must understand that Silvia is the one doing the giving (that is, that Silvia has the thematic role of Agent in the sentence), that Mom is receiving something (Mom has the Recipient role), and the flowers are the thing being given (the Theme role). Although the three sentences in 1 have quite different word orders, these basic role assignments remain the same.

1a. Silvia gave some flowers to Mom.
1b. Silvia gave Mom some flowers.
1c. Mom was given some flowers by Silvia.

As this example illustrates, the role that any individual element will play in the event that is being described is determined by the sort of sentence structure it occurs in, as well as the position it occupies within that structure. Moreover, words and phrases toward the ends of utterances may have an effect on how the beginning of a sentence must be interpreted. Consider example 2:

2. I saw her fly . . .
   a. the fighter jet.
   b. was open.

Before listeners have heard the end of the utterance, they cannot be sure whether the phrase 'her fly' is the beginning of an embedded clause describing the actions of a pilot or a noun phrase denoting the front closure of a woman's pants. Sentence comprehension has the property of immediacy of interpretation: people begin interpreting language as soon as they hear it; listeners do not wait to find out how an utterance will end before they assign at least a tentative interpretation to its beginning. Immediacy of interpretation is an essential feature of the comprehension process because the acoustic speech signal is fleeting, and memory for unanalyzed acoustic information is strictly limited. Thus the memory of the input signal will be lost if it is not rapidly converted to a meaningful representation. The same is essentially true in reading, despite the fact that words on a page, unlike a speech signal, are available for reprocessing. If comprehenders did not advance beyond a visual or phonological (sound-based) representation of the written input for the early part of a sentence, then processing later parts of a sentence would simply create interference in the representation of the initial sequence. Thus, sentence comprehension proceeds through the rapid development of an initial interpretation of a sentence, with enrichment and adjustment of this interpretation as the sentence unfolds. The key research questions have concerned the nature of that preliminary interpretation and the mechanisms for its enrichment and revision. These issues have typically been addressed in investigations of sentence comprehension processes by adult native speakers of a language, but the work has clear overlap with studies of child language acquisition, comprehension processes in second language acquisition, and the nature of impairments in these processes following brain injury.

The first attempt to develop a theory of the processes executed during sentence comprehension emerged in the 1960s through a collaboration between linguist Noam Chomsky and psychologist George Miller, who tried to integrate the rapidly developing field of generative linguistics with studies of cognitive processes. The derivational theory of complexity (DTC) was built on Chomsky's transformational grammar, which posited that the structure of a sentence (the surface structure) was related to a meaning-based representation (a deep structure) through a series of transformations. The DTC posited that during the process of sentence comprehension, people mentally worked through the various sentence transformations to convert a perceived sentence to its deep structure, from which sentence meaning could then be extracted. The more transformations that had to be undone to arrive at the deep structure, the longer the sentence comprehension process should take. For example,

the passive sentence above 1c was hypothesized to need at least one more transformation than the active sentence 1a, yielding the prediction that passive sentences should take longer to comprehend than their active counterparts. Whereas early studies found good support for these predictions, later work suggested that the number of posited transformations had essentially no value in predicting comprehension difficulty. As a result, not only did the DTC fall out of favor as an account of sentence comprehension processes, but many psychologists became disillusioned with the idea that formal linguistic theories of the structure of language could offer insight into accounts of language comprehension.

More currently, research in sentence comprehension has addressed the cognitive processes, assumptions, and information that underlie the mechanisms and strategies of understanding everyday language in real time. This focus on the precise timing of comprehension processes emerges from a general interest in modularity claims within language research. Applied to sentence comprehension, the key modularity question concerns whether the many levels of language representation (sound, word, sentence, discourse, etc.) interact to derive sentence meaning or whether processes operate autonomously on different levels, saving any cross-level integration for the final stage of processing. Sentence comprehension research, situated between research on lexical (word) processing and the interpretation of entire conversations or texts, can be viewed as spanning three subfields – syntactic ambiguity resolution, syntactically complex utterances, and the relating of sentences to the broader discourse or text, including the interpretation of referentially dependent expressions such as pronouns.

Ambiguity Resolution

Language is rife with ambiguities at all levels of representation, and sentence comprehension research addresses the challenges presented by lexical ambiguity and syntactic ambiguity. Lexical ambiguities arise when a word has more than one meaning, as in example 3. Because the word 'glasses' can denote either eyewear or kitchenware, the intended meaning of the sentence is not obvious. Syntactic ambiguities, on the other hand, arise when a sequence of words is at least temporarily compatible with more than one sentence structure and more than one set of thematic roles and relations among the participants of the action. In example 4 below, the prepositional phrase 'with a lollipop' could be interpreted as modifying either the main verb of the sentence, as in 4a, such that the lollipop is the instrument used to tease the boy, or as modifying the object of the sentence, as in 4b. Lexical ambiguity and syntactic ambiguity frequently interact, as in example 2, in which the lexical ambiguity of the words 'her' and 'fly' created a syntactic ambiguity.

3. Phil wiped off the glasses.
4. The surly teenager teased the boy with the lollipop.
   a. The surly teenager teased the boy by using a lollipop (as bait).
   b. The surly teenager teased the boy who was holding the lollipop.

The modularity debate in syntactic ambiguity resolution has concerned the time course over which information is brought to bear on an ambiguity. Listeners must attach at least a partial interpretation to each word of an utterance as soon as it is encountered. The question then is, given that they have not yet heard the end of the utterance, on what information are they basing their interpretations? When do they integrate the information into their understanding of the unfolding utterance? Are certain types of information more useful (or used) than others?

One approach to these questions is exemplified by Lyn Frazier and colleagues' Garden Path model. 'Garden path' refers to an initial misinterpretation of a sentence, followed by a moment of surprise when later information in the sentence reveals that the initial interpretation was incorrect. The Garden Path model is a modular, two-stage approach in which the first-stage parser (the syntactic interpretation component of the comprehension system) develops an initial syntactic structure for the input, guided by only the lexical categories of the input words (noun, verb, etc.), the syntactic rules of the language, and structure-based heuristics that direct structure building when the given lexical categories can combine in more than one way within the syntax of the language. The structure-building heuristics typically favor syntactically simpler interpretations over more-complex ones. At some later point, a second stage integrates semantic and contextual information into the representation, and if this information conflicts with the initial interpretation built by the parser, the conflict may trigger a revision and reanalysis of the input. The guiding assumption of this and other 'syntax-first' models was that the demands of immediacy of interpretation could not be satisfied if all information were used in developing the initial interpretation, because probabilistic information, such as the implications of the prior context or the likelihood of the speaker's conveying a particular meaning, was too complex and would take too long to compute to be applied rapidly. The first-stage parser, with access to minimal and rapidly available information, was

therefore seen as serving the function of getting a syntactic interpretation started, leaving additional time for the second-stage system to finish computations.

The preeminent role accorded to the syntactic parser in the Garden Path model and other syntax-first models is accompanied by a prediction for sentence comprehension behavior during the interpretation of ambiguous sentences: namely that all nonsyntactic factors such as the context in which a sentence is produced, the actual words used, the relative frequency of its constructions with respect to the words involved, the prosodic features of the utterance, and so on, will affect the course of sentence comprehension only secondarily, in the second stage of processing. The alternative, constraint-based approach argues that the preference for one interpretation over another during comprehension of an ambiguous sentence emerges from the rapid combination of many probabilistic constraints, with no privileged role for syntactic information. Proponents of this approach explicitly reject the notion that nonsyntactic information is somehow harder to compute. A key observation of this approach is that different types of information tend to be correlated. For example, a verb's meaning is strongly related to the kinds of nouns and prepositional phrases (such as 'with a lollipop') it tends to appear with in sentences. As a result, even weak cues can combine with other correlated cues and have a strong effect on interpretation preferences.

Both the constraint-based and modular accounts have primarily been assessed with online measures, that is, precise, time-locked measures of comprehension processes as the sentence progresses, in order to look for behavioral evidence consistent with either early interaction or two modular subprocesses. A significant body of work in the 1980s and 1990s used measures of reading time during comprehension of written ambiguous sentences. Some early work using eye movement monitoring (eye tracking) during reading claimed to find evidence of a modular, two-stage interpretation system, with the earliest eye fixations on a region of text guided by operations of the first-stage parser, and later fixations on the text and rereading were driven by second-stage semantic integration processes. This view was motivated in part by studies in which manipulations of semantic information in syntactically ambiguous sentences were found to affect late eye fixations but not early ones. Subsequent studies suggested that at least some delayed effects of nonsyntactic information in eye fixation patterns were attributable to weak or infelicitous contexts or other biases in the ambiguous stimuli. More-robust manipulations of context have shown clear evidence of use of nonsyntactic information very early. These results challenged the modular claims for isolated subprocesses during sentence comprehension. Additional evidence for the constraint-based approach comes from studies of comprehenders' eye fixations on visual scenes while listening to spoken language related to the scene. Patterns of eye fixations suggest that information in the visual scene affects the early stages of interpreting ambiguous sentences. These results offer a powerful challenge to claims for modularity in sentence comprehension: not only does nonsyntactic information in the linguistic signal appear to constrain early syntactic ambiguity resolution, but even nonlinguistic information (such as from the visual scene) has a powerful early effect.

Complex Sentence Interpretation

A second area of investigation in sentence comprehension is syntactically complex sentences. The sentences in example 5 show two different types of relative clause. The example in 5a is known as a subject relative because the head of the relative clause (the element modified by the relative clause, here 'the reporter') is the subject of the attacking action in the relative clause. The object relative clause (also known as a center embedded clause) in 5b has a similar word order, but here the head of the relative clause ('the reporter') is the direct object of 'attacked' rather than the one doing the attacking.

5a. Subject relative: The reporter that attacked the senator admitted the error.
5b. Object relative: The reporter that the senator attacked admitted the error.

Despite the clauses' identical words and highly similar word order, sentences containing object relatives are typically much more difficult to comprehend than those with subject relatives. The added comprehension difficulty is not thought to reflect ambiguity resolution processes. The explanation of processing difficulty for object relatives varies, but the dominant view is that comprehenders encounter two unintegrated nouns (e.g., 'The reporter that the senator') before a verb, thus creating a working memory load in which two nouns must be held in memory while waiting for verb information that relates them. By contrast, in subject relatives such as 5a, the alternating pattern of nouns and verbs permits rapid integration of these sentence elements, reducing the memory burden. A minority view holds that object relative clauses are more difficult than the subject relatives because the object relative structure is unlike other sentence structures in the language, effectively leading to ambiguity in how to interpret them. If so, then relative clause interpretation may be a form of

ambiguity resolution, similar to that in the more widely recognized syntactic ambiguities discussed above.

Because of their syntactic complexity and their presumed dependence on working memory processes, relative clause structures have been a popular choice in investigations of sentence comprehension in atypical populations, including patients with aphasia, Alzheimer's disease, or other forms of dementia. The relationship between memory processes and relative clause comprehension has also been investigated in children, for whom both the ability to interpret relative clauses and the ability to perform well on working memory tasks develops fairly late.

Referentially Dependent Expressions and Links to Discourse Representations

Referentially dependent expressions are those which do not directly refer to something in the world but typically refer instead to some previously mentioned entity. For example, in 6a, we know that 'John' refers to a person, and we can interpret 'John' in this way even if we don't know him personally. By contrast, the pronoun 'he' does not refer directly to someone in this way but instead acquires its meaning indirectly, by being linked to the expression 'John.' This linking process is a form of ambiguity resolution, as the referent of a pronoun is not always clear. For example in 6b, 'he' might refer to either 'John' or 'Javier.' Research on pronoun comprehension spans both the ambiguity resolution processes that identify the correct referent of a pronoun and the consequences of pronominal reference – that is, how the comprehender's representation of the sentence changes as a result of having identified the referent of a pronoun.

6a. John went to the store after he got off work.
6b. John called Javier after he got off work.

The processes of pronoun reference resolution have a character similar to that of the processes of syntactic ambiguity resolution in that comprehenders appear to integrate a variety of probabilistic constraints to converge on the correct referent of a pronoun, including order of mention (earlier mentioned referents are more likely to be pronoun referents than later ones, at least within a sentence), grammatical role of referents (subjects of sentences are more likely to be referents than are other roles), and parallelism in grammatical role (nouns with the same grammatical role as the pronoun – e.g., both are subjects or both are objects – are more likely to be referents). These three constraints all serve to promote 'John' rather than 'Javier' as the referent of 'he' in example 6b.

In addition, the syntactic structure surrounding a referentially dependent expression may constrain the choice of referent. In 7a, the reflexive 'himself' must refer to John, while in 7b, the pronoun 'him' must not.

7a. John likes himself.
7b. John likes him.

These patterns of permissible co-reference have led to the hypothesis that syntactic structures define possible domains of reference, that is, the regions in which a referentially dependent expression may find a referent or may be blocked from finding a referent. Specifically, reflexives must find a referent within their own syntactically defined domain; pronouns must find a referent outside that domain. In examples 7a and 7b, this domain is the complete sentence. Thus, in 7a, 'himself' refers to the only possible referent within the relevant syntactic domain: 'John.' In 7b, 'him' can refer to any male entity except John. Extensive work within the field of linguistics has been devoted to defining these syntactic domains of reference, and modular accounts of pronoun resolution have suggested that these syntactic constraints have a privileged, early effect on pronominal reference resolution. However, recent work within both linguistics and sentence comprehension suggests that the syntactic domains are not so clear as originally thought, nor do they have a privileged status in referent resolution during comprehension. Online behavioral measures of referential interpretation (e.g., using eye tracking to monitor looks to displays of possible referents) confirm this intuition. These results suggest that while syntactic structure is certainly a factor in defining the preferred referents of pronouns and reflexives, other factors – such as point-of-view information or the specific lexical biases of other words in the construction – may also influence early stages of interpretation.

When someone identifies the referent of a pronoun, the mental representation of the sentence appears to be updated to reflect the re-mention (via pronoun) of a previously mentioned entity in the discourse. For example, when a comprehender has determined that 'he' must refer to 'John' in the examples above, the representation of 'John' appears to become more prominent in the discourse representation, as evidenced by shorter reaction times to the word 'John' compared with control conditions just after the pronoun has been comprehended. Moreover, other previously mentioned entities in the discourse (such as 'Javier' in 6b) appear to be inhibited and yield slower reaction times, as the pronoun indicates a shift toward focus on the referent in the ongoing linguistic input. The work

provides time-locked data concerning the processes of memory updating during the comprehension process.

Sentence Comprehension Methodologies

Research in sentence comprehension employs both online behavioral and brain imaging methodologies. Behavioral measures in sentence comprehension typically assess processing difficulty, as indexed by assessments of response time, errors, or both. The most common behavioral method has been reading times of particular words or regions within a sentence as a measure of processing difficulty. The focus on reading rather than comprehension of spoken sentences emerged out of the necessity to have a continuous measure of comprehension processes as the linguistic signal unfolds over time. Because reading proceeds at the comprehender's own pace, continuous measures of processing difficulty can be obtained from assessments of reading time, whereas there is no listening-time equivalent for spoken sentence comprehension.

In reading comprehension studies, the immediacy assumption holds that the reader is building an interpretation of the sentence as each new word or phrase is read. When the reader encounters a word or words that do not fit with this interpretation, this new material should take longer to read than in cases in which the material easily fits into the ongoing sentence interpretation. Comparing reading times of critical regions across different constructions yields a measure of the relative difficulty of integration of new material into the comprehender's interpretation of the sentence so far, which in turn sheds light on the interpretations that must have been developed by the reader in order for this difficulty to arise. The two primary reading measures are self-paced reading, in which the comprehender reads text on a computer screen and is allowed to see only a small portion of a sentence at a time, pressing a key to see each new word or region, and eye tracking, in which the entire sentence can be viewed while a device records the location and duration of eye fixations. Both measures yield data concerning the overall length of time spent reading a region, but eye tracking also yields data concerning the patterns of eye movements through a sentence, including patterns of rereading previously read text. Some researchers have interpreted different sorts of fixations within this sequence (e.g., the first fixation to a region vs. the second fixation or looks back to a region after reading later regions) as corresponding to the integration of different sources of information (syntactic, semantic, pragmatic, etc.) into the reader's interpretation of the sentence.

Eye movements have also been used to provide a time-locked measure of spoken sentence comprehension in the visual world paradigm, in which comprehenders view an array of objects or a scene on a computer and listen to speech referring to the scene, such as instructions to act on certain objects in view. Eye fixations on elements of the scene reflect their current state of understanding of the spoken material and its relationship to the visual environment. For instance, listeners who hear a sentence containing the verb 'eat' are more likely to look at edible items in a visual display than are listeners who heard a sentence that featured the verb 'take.' By manipulating both the visual display and the language accompanying it, researchers can investigate how context and language interact during spoken sentence comprehension.

Measures of brain activity as rendered by positron-emission tomography, functional magnetic resonance imaging (fMRI), magnetoencephalography, and event-related potentials (ERPs) have also been used to assess online sentence comprehension, often accompanied by an explicit task to encourage attention to the stimuli, such as to judge the sensibility of sentences. As with studies using behavioral measures, researchers typically compare materials that are similar save for one critical manipulation, such as contrasts between sensible sentences and scrambled words or between subject and object relative clauses.

Various fMRI studies of sentence comprehension have revealed a large number of areas that appear to be crucial to the comprehension process, beyond those that are important in interpretation of isolated words. These sentence-specific areas are believed to be important for interpreting the syntax of the sentence, identifying the thematic roles, and linking the sentence representation to prior knowledge. Whereas studies of patients with brain injury have named the left hemisphere as the site of virtually all language processes in most individuals, imaging studies have tended to find bilateral activation of a number of frontal and temporal brain regions during sentence comprehension, often with somewhat greater levels of activation in the left hemisphere than in the homologous area on the right. The fMRI studies of sentence comprehension have not factored heavily into the research issues addressing the time course of processing described above, which have been the focus of many behavioral studies in sentence comprehension. The temporal resolution of the blood oxygen level-dependent (BOLD) signal in fMRI, with about a 5 s latency, is not an appropriate instrument to address the precise time course of processes which behavioral data suggest operate on the order of a few dozen milliseconds.

The shorter latency of ERPs makes them more applicable to issues concerning the time course of comprehension, and some measures are thought to map onto specific comprehension processes. For instance, an early left anterior negativity is thought to be associated with syntactic difficulty, while negativity approximately 400 ms after stimulus onset is hypothesized to be an indicator of semantic discord. A more generalized process of information integration has been tentatively linked to a positivity 600 ms after stimulus onset. It should be emphasized, however, that these connections between activation patterns and specific comprehension processes are by no means uncontroversial and are at best only loosely understood.

Sentence Production

V S Ferreira, University of California at San Diego, La Jolla, CA, USA

Introduction

Sentence production refers to the ability of speakers of natural language to assemble known words into larger structured phrases or sentences. These phrases and sentences have two critical and related properties: They are grammatically well formed, as speakers generally do not produce 'the cat were happy' or 'cat happy the were,' and they convey the relational meaning of a sentence, or 'who did what to whom,' that the words by themselves cannot. For example, there is no single word (or, more precisely, morpheme – the smallest meaningful unit of language) that conveys 'the cat was happy'; one must assemble a sentence to relate one lexically denoted meaning, happiness, to another, the cat.

This article reviews different issues in sentence production research, roughly following a historical sequence. It begins with the first insights into sentence production from speech error evidence, followed by empirical and theoretical issues that have emerged from laboratory study, and moves on to more recent investigations of naturalistic issues. The article closes with a brief discussion of the neuroscience of sentence production.

Initial Insights: Evidence from Speech Errors

Compared with its sibling fields of language acquisition and language comprehension, research on language production in its current form began later and more slowly. This is likely due primarily to methodological challenges. In language comprehension at least, it is obvious how to precisely control the input to the system. For language production, however, it was not obvious how to get speakers to produce the sentences that were necessary for theory development and testing.

This methodological roadblock was overcome in the 1970s, through the pioneering work of Vicki Fromkin and Merrill Garrett. They sidestepped this input problem by amassing and exploring relatively large corpora of naturally occurring speech errors or slips of the tongue. These researchers made two critical discoveries that allowed speech error evidence to reveal the workings of sentence production mechanisms. First, they recognized that speech errors were often the (bungled) products of cognitive mechanisms involved in core language processing. At least for a relatively large class of errors, an utterance like 'that log could use another fire' is not a 'slip of the mind,' because speakers know when they make such errors, so they are not the result of bad conceptual knowledge. It is also (ironically) not a 'slip of the tongue,' because speech errors are unaffected by very peripheral articulatory or acoustic properties of speech. Instead, such errors are 'slips of the sentence production mechanism,' revealing the basic processing and representations speakers use to put sentences together. Second, Fromkin and Garrett discovered that when analyzed *en masse*, speakers slipped into consistent patterns, and these hinted at how sentence production mechanisms encoded nonlinguistic thought into phrases and sentences.

In a series of analyses published from the mid-1970s onward, Merrill Garrett used speech error evidence to lay a foundation for a theory of sentence production, the general outline of which can be recognized in most theories to this day. Garrett's initial investigations looked primarily at movement errors – slips in which one or more elements that a speaker intends are positioned in the wrong place. 'That log could use another fire' is a movement error because though the speaker intended to use 'log' and 'fire,' each word was produced in the place of the other and so were 'moved' with respect to the speaker's original intention. The same is true of 'I met someone who had a spet pider,' but with respect to the positioning of the sound 's.' Garrett first noticed that such movement errors clustered into two types. One typically involved words, like the log/fire error above, though larger units like phrases can be involved. In these errors, the words moved about as far as speakers could plan and nearly always came from the same part of speech (so that nouns traded places with nouns, verbs with verbs, and so forth). Such errors were also largely insensitive to the properties of the sounds of words. The other type of movement error typically involved individual speech sounds, like 'spet pider,' though again larger units like morphemes can be involved. In these, sounds rarely moved more than two or three words and exchanged between words of any part of speech. Also, the movement patterns in these errors were highly sensitive to the properties of the sounds of words, such as stress level or whether they were consonants or vowels.

These and related patterns of errors led Garrett to posit that sentence production proceeds through two distinct stages, sketched in Figure 1. The first type of

Figure 1 Sketch of the architecture of sentence production, as proposed by Garrett. Processing flow begins with the preverbal message (top), proceeds through functional processing and then positional processing, and concludes with articulation (bottom). V, verb; N, noun.

error reflects the organization of the first stage of sentence production, called functional processing, in which speakers assign words on the basis of their part of speech (noun, verb) to grammatical functions such as 'subject of the sentence.' These words are not phonologically defined, which is the reason why errors involving words are not sensitive to how they sound. According to Garrett, the processing dynamics at the functional level are independent of the spoken order of words. This explains why misplaced words can move large distances: what determines whether two units are processed at about the same time, and so might exchange, is unrelated to whether those units are adjacent in the eventual utterance. The second type of error reflects the organization of the next stage of sentence production, termed positional processing, at which speakers configure words into hierarchical constituent structures that determine their order in the spoken utterance. At positional processing, segmental content (individual speech sounds)

is specified, whereas functional information is not represented.

Though basic outlines of Garrett's proposal are still current, certain details of Garrett's proposals have been scrutinized. One prominent effort was a series of empirical and theoretical speech error studies carried out by Gary Dell. Dell first identified patterns of speech errors that revealed mutual influence or interactions among representations at different stages of processing. In particular, Dell showed that when one word replaces another that is similar in meaning, the words are more likely than chance to be similar also in sound. He also showed that when speakers erred in producing the individual sounds of words, the outcomes were more likely to constitute a known word than chance would predict. These patterns can be accommodated by assuming that processing at one level of sentence production is influenced by processing at other levels. So the phonological similarity of semantically related substituting words can be explained if representations at the analog of Garrett's positional level – phonologically defined words – are able to influence selection at the analog of Garrett's functional level – semantically selected and syntactically defined words. The tendency for sound errors to result in real words can be explained if the representations of words other than the one a speaker intends to say can influence the ongoing selection of individual sounds that a speaker does intend to say. Later, Dell developed a comprehensive connectionist model of the sentence production process that explained these observations and more. In connectionist models, knowledge structures are represented as units that become activated as a function of degree of evidence supporting those knowledge structures and are interconnected to represent the relationships among the knowledge structures. Dell's model could explain not only the speech error patterns already described but other, even less intuitive effects, such as the fact that sound errors are more likely to result in known words more as speech rate slows (because representations at different levels have more time to influence one another).

The Move to the Laboratory

The theory developed by Garrett proved seminal. Garrett's theory was important not only for investigations of speech errors; it succeeded in bootstrapping a laboratory sentence production enterprise as well. Recall that the primary impediment to developing a science of sentence production was the search for a valid way to elicit controlled, theoretically informative sentences. With Garrett's model, based as it was on face-valid evidence from speech errors, laboratory techniques further removed from natural production could confirm their own validity. This allowed laboratory investigations of sentence production to flourish until today, when diverse laboratory techniques are used to explore diverse theoretical issues. These issues are discussed next.

Scope of Planning

One of the first laboratory investigations of sentence production explored a simple question that has proven to have a rather complex answer: When speakers produce sentences, how far do they plan in advance, and what are the linguistic units they plan with? If freely speaking participants are asked to press buttons on hearing randomly presented tones, their responses are slowest at the ends of linguistic units called basic clauses, provided that they are about to produce more sentence material. A basic clause is a part of a sentence that includes a verb and all its directly associated arguments; thus, speakers evidently plan speech one basic clause at a time (fitting well with Garrett's claims regarding functional processing). Analyses of patterns of pausing in natural speech later verified this conclusion.

Subsequent work has revealed, however, that these original conclusions were likely too simple. Two factors complicate the story. First, the scope of planning seems different for different levels of sentence production. Early, during semantic and functional processing, the scope of planning is likely broader than later, during phonological and positional processing. Second, the scope of planning appears to be highly sensitive to task circumstances and speaker strategies. It is interesting that as production becomes more constrained and formulaic, speakers seem to plan ahead less. The idea is that speakers plan as little as they can get away with; when production is highly constrained and formulaic, speakers can be confident that they can come up with linguistic material to produce 'on the fly' and so can plan ahead less. With free-form production, speakers are less confident that they will be able to formulate on the fly, and so they plan ahead more. Relatedly, speakers are able to plan the same basic utterance about twice as fast (presumably because they plan ahead less) when given tight deadlines to begin speaking as they are if allowed to begin speaking whenever they like.

Accessibility Effects

Recall that Garrett assumed that functional processing is not affected by the order of words in the eventual utterance. A heavily investigated set of effects that revisits this assumption is termed accessibility effects. When speakers produce sentences, they tend

to mention easily retrieved or highly accessible material sooner, leaving harder-to-retrieve or less accessible material to be mentioned later. For example, Kay Bock discovered that speakers choose different syntactic structures to allow semantically primed words to be mentioned as the subjects of their sentences. Thus, speakers tend to say, 'The lightning struck the church' if semantically primed by 'thunder,' but 'The church was struck by lightning' when semantically primed by 'worship' – first retrieved, first spoken. This seems inconsistent with Garrett's assumption that functional processing is insensitive to the eventual orders of words in sentences.

Yet with reasonable assumptions, the core of Garrett's claim can be preserved. Specifically, one can claim that words that are accessible (e.g., because they are semantically primed) are selected sooner during functional processing (see the left box in Figure 1) and so are assigned to 'higher' grammatical functions (where 'subject' is higher than 'object,' for example). Across languages, higher grammatical functions tend to be mentioned earlier in sentences, and so these assumptions can accommodate accessibility effects without requiring that functional processing directly reference the eventual positions of words in sentences. Further support for this assumption comes from demonstrations that accessibility manipulations that are more meaning-based (e.g., differences in semantic priming or the imageability of words) more readily influence function assignment (e.g., whether something is produced as a subject or object); in contrast, manipulations that are more form-based (e.g., the lengths of words) influence word order independent of function assignment (e.g., the order of words in a conjunction like 'salt and pepper'). This fits with Garrett's original division of production into a meaning-based functional system and a form-based positional system.

Within models of sentence production, accessibility effects are generally motivated by incrementality – that sentences are produced piecemeal from beginning to end. Incrementality implies that if one part of a sentence becomes accessible before another, production is most efficient if the part that is accessible sooner is mentioned sooner and the part that is accessible later is mentioned later.

Grammatical Agreement

Another topic that can be couched within Garrett's framework is agreement, referring to when the form of one element in a sentence depends on some property of another element. In English, this arises with subject–verb agreement: One says, 'the cat was happy' and 'the cats were happy,' such that the form of the verb ('was' or 'were') depends on the plurality of the subject ('cat' or 'cats').

The core agreement-related object of study is attraction, in which some irrelevant part of a sentence influences agreement. For example, when given a subject noun phrase like 'The key to the cabinets' and asked to complete it, subjects are likely to say 'The key to the cabinets were lost,' with the verb ('were') agreeing with the local noun 'cabinets' rather than the subject noun 'key.' The empirical enterprise has primarily been to assess the properties of local nouns that do and do not cause such attraction. One factor that powerfully causes attraction is grammatical plurality: Local nouns that are grammatically plural (like 'cabinets') cause plural-agreeing verbs to be produced rather than singular-agreeing verbs. Curiously, this effect is asymmetrical, such that grammatically singular local nouns do not cause attraction (in utterances like 'The keys to the cabinet was/were . . .'). This has led to the proposal that in English, plurality is marked – it is an explicit feature that is associated with a noun argument; the singular, in contrast, is unmarked, such that nouns default to being singular when not otherwise specified.

Given the robust effect of plurality on attraction, the question arises whether properties that are correlated with plurality, such as plurals' meaning (they are usually more numerous than the singular, like 'keys' vs. 'key') or sound (the '-s' at the ends of words), cause attraction errors. Generally, such properties are much less potent (if influential at all) compared with true grammatical plurality. For example, local nouns that denote collectives but are not grammatically plural ('The general of the army . . .') do not cause attraction, nor do local nouns that sound like plurals but are not ('The petal on the rose . . .'). In contrast, local nouns that denote single entities but are grammatically plural ('The ad for the scissors . . .') cause attraction, as do nouns that are plural but do not sound that way ('The trap for the mice . . .').

Comprehensive theories of agreement are currently the subject of active debate, the details of which are beyond the scope of this article. The weight of evidence suggests that within Garrett's model, agreement processing should arise within positional processing. Some properties of attraction fit in with this, including the above-noted insensitivity to semantic correlates of plurality and the sensitivity to the hierarchical structure of sentences. However, given that positional processing has a phonological character, additional assumptions may be needed to explain why attraction is insensitive to phonological factors.

Syntactic Priming

A heavily investigated phenomenon in sentence production that does not fit as neatly into Garrett's framework is termed syntactic priming (sometimes

called structural or syntactic persistence). When a speaker produces or comprehends a sentence with a particular syntactic structure, the speaker is then more likely to use that structure rather than a reasonable alternative. For example, after hearing a prepositional dative structure ('The doctor gave the hat to the sailor'), speakers are likely to use another prepositional dative ('The ballerina showed the cake to the boxer') rather than a double-object structure ('The ballerina showed the boxer the cake').

Evidence has shown that at core, syntactic priming reflects the repetition of the syntactic structures of sentences. Properties correlated with syntactic structure either do not affect priming or affect priming independent of syntactic repetition. Such inconsequential properties include aspects of meaning (e.g., the order of agents and themes and recipients), sounds (e.g., rhythm or auditory structure), or words (especially syntactically relevant words like 'to') of sentences. Syntactic priming is enhanced by repeating meaningful words (especially verbs) in sentences but is reliable even without such repetition.
