The locations of the spinothalamic and relevant spinoreticular fibers in the human spinal cord are shown in Figure 1. During the past century, this pathway was commonly transected to alleviate pain. Patients were unable to feel pain of a pathological condition on the opposite side of the body and could not feel pain or warmth or cold when suitable stimuli were applied. However, although the sensations one would expect to be evoked by such stimuli do not occur, there is evidence that other spinal pathways are conveying impulses to higher centers. For instance, repetitive stimulation with noxious hot or cold stimuli to the parts of the body rendered analgesic by a cordotomy can cause sweating and nausea, which suggests that impulses are activating autonomic centers via pathways other than those located in the ALQ.

When the ALQ is transected, spontaneous pain can occur. This type of pain is usually called neuropathic pain. It occurs in the part of the body that is no longer connected to ascending fibers of the ALQ. It rarely appears soon after section of the ALQ but may occur spontaneously weeks, months, or years after this lesion has been made. Thus, it is apparent that pathways other than the tracts of the ALQ can be involved in the transmission of impulses that can give rise to some sort of pain. Nevertheless, these sensations are often described as 'not pain but worse than pain.' This is a sensation not previously experienced, and the patients find no words with which to describe it.

Figure 1 The anterolateral quadrant (ALQ) and pain. Distribution of ascending axons in the spinal cords of patients based on correlations of sensory losses with the location of transections. (Left) Diagram showing the somatotopic distribution of axons from sacral (S), lumbar (L), thoracic (T), and cervical (C) dermatomes in the ALQ. A considerable overlap of fibers is observed in its ventromedial portion. (Right) Diagram showing the location of ascending axons at the C3 level following transections that produced long-lasting contralateral analgesia in humans.

It is often referred to as dysaesthesiae or painful dysaesthesiae. It is poorly localized and may extend over half of the body. If it follows the operation of anterolateral cordotomy carried out for painful malignant disease, the sensations are felt in the area of the malignant lesion.

Another kind of pain that may occur following sectioning of the ALQ involves the sensation being referred. One of the features of this phenomenon is that the patient reports that a noxious stimulus applied at the analgesic part of the body is felt elsewhere. A pinprick applied to the analgesic skin is felt as touch and the referred pain is felt in normally innervated parts of the body as if it comes from within and goes outwards to the skin – a totally new type of sensation.

Following the operation of anterolateral cordotomy, there is usually a return of pain and thermal sensibility. It occurs within months or years, even though the entire tract has been divided. It is probable that this return of sensibility is due to conduction in the ALQ and not to other pathways becoming available since these sensations have their normal characteristics. It has been reported that performing a second cordotomy on the same side as the first 14 years later due to the return of the original pain removed all pain.

Some conclusions may be drawn from these facts. First, to have normal pain, one has to have an intact pathway running in the ALQ. Second, the sensation of 'not pain but worse than pain' does not occur when the pathways previously mentioned are intact; conduction in this system normally inhibits conduction in the other pathways used by impulses, giving rise to these abnormal sensations. If a cordotomy has rendered only part of the body analgesic, then these dysaesthesiae occur only in the analgesic part of the body and never in the part that is still connected to the tracts of the ALQ.

The Dorsolateral Funiculi

Some authors have reported that in various species, a large number of ascending axons from lamina I neurons are located in the dorsolateral white matter. In fact, it has been claimed that in the rat, some of the axons from lamina I neurons ascend in the most dorsal part of the lateral funiculus, an area that does not have to be transected to produce relief of pain in humans. Indeed, electrophysiological and behavioral data in animals show that dorsolateral lesions produce an increase in nociceptive reactions, probably by disrupting tonically active descending antinociceptive pathways. Moreover, dorsal spinothalamic axons lie at the level of the denticulate ligament and terminate preferentially in caudal ventral thalamic areas once referred to as the suprageniculate/posterior complex and now termed the ventromedial posterior nucleus. On the other hand, spinothalamic axons ventral to the denticulate ligament terminate predominantly in the main portion of the ventral posterolateral thalamus. The question of whether a 'dorsolateral' ascending nociceptive pathway exists may be merely a semantic problem since anatomical studies in monkeys have shown that lamina I spinothalamic axons are located more laterally than those arising from deep dorsal horn neurons. These axons are located in an area ventral to the region occupied by the pyramidal tract and are still within the ALQ.

The Dorsal Columns

Experimental Findings in Animals

The vast majority of fibers in the dorsal columns (DCs) are branches of myelinated primary afferent fibers. These fibers run medially and bifurcate in a Y-shaped manner to send one branch rostrally and another caudally that provide collaterals to the

Figure 2 The dorsal columns. (a) The putative visceral nociceptive pathway in the dorsal columns. It has been proposed that nociceptive inputs from viscera are relayed in laminae VII and X neurons, whose ascending axons are confined near the midline of the dorsal columns. These axons terminate in the medullary nucleus gracilis (Gr), which conveys these inputs to the thalamic ventrobasal (VPL) nucleus. (b) The location of centripetal fibers subserving micturition and sensations of temperature and pain from the lower end of the ureter, the bladder, and the urethra in man. (c) The location of centripetal fibers subserving defecation (dots) and the sensation of pain (red area on the lateral surface of the cord) from the rectum and anus. It is probable that the efferent fibers for voluntary control lie in the dotted region and the efferent fibers for autonomic control lie in the more central red area. Sensations that micturition is impending, that it is progressing, and that it has ceased and also sensations of touch and stretch in the anal region are retained following a bilateral anterolateral cordotomy. Such impulses probably travel via the dorsal columns.

dorsal horn. Only some of these fibers reach the dorsal column nuclei (DCN), and a minority of the fibers in the DCs originate from dorsal horn laminae III–V. Most of these neurons are activated by low-threshold mechanoreceptors and some of them from nociceptors activated by mechanical stimuli of the skin or deep structures.

Several studies in rats have shown a visceral nociceptive pathway that activates gracile neurons. As illustrated in Figure 2(a), the ascending axons that activate these neurons following either stimulation of reproductive pelvic viscera or colorectal distension are confined to the fasciculus gracilis. In addition, the suppression of ventrobasal (VPL) thalamic responses to colorectal distension following dorsal column lesions led to the hypothesis that this pathway is more important than the ALQ for transmitting visceral nociceptive signals to the VPL, whereas the ALQ may be more important for transmitting cutaneous nociceptive information. It was concluded that the visceral inputs traveling in the DCs could either cooperate with direct spinal pathways to produce the perceptions of touch and pain or serve as an alternative nociceptive pathway to the spinothalamic tract.

Clinical Findings

Patients with lesions including the DCs have impaired vibratory and postural sensibility, diminished ability to distinguish two points, poor tactile localization, and ataxia. Thus, in the mid-eighteenth century the concept of a dorsal column syndrome was proposed on the basis that the DCs conveyed only tactile and proprioceptive sensations. However, both animal and clinical studies indicate that the role of the dorsal columns–lemniscal system is more complex.

If there are two nociceptive pathways conducting impulses causing visceral pain, then the removal of

one should either have no effect or have some effect in reducing the pain. This effect should be present immediately after one of the pathways has been cut. The first cordotomies were usually designed to remove visceral pain, and the success of this operation has been amply confirmed throughout the past century. This operation has been done far more frequently for pain arising in the viscera than for pain of somatic origin. Although in some cases the pain arose from the spread of carcinoma to the posterior thoracic or abdominal wall and the pleura or peritoneum, in the vast majority of cases the operation was performed to eliminate pain from the kidneys, ureter, bladder, urethra, testes, ovaries, uterus, vagina, stomach, duodenum, pancreas, small and large intestines, as well as from the malignancy invading bone, the sacral and brachial plexuses, and various peripheral afferent nerves.

Indeed, the DCs interact in a complex manner with the pain system. The pain of distorted posture that can occur as a phantom sensation after amputation is relieved by cutting the DCs. In fact, the DCs not only convey ascending inputs to the brain but also contain direct descending spinal projections originating from the DCN and terminating in dorsal horn laminae I and V. In addition, the ventral DCN region, where the majority of spinally projecting cells are located, is an important target for corticobulbar projections. Thus, the spinal output could be modulated not only directly by the DCN–spinally projecting neurons but also indirectly through cortico-DCN influences. The possibility that the information traveling in the DCN could be under the influence of inputs from several levels, including the cerebral cortex, suggests that DCN neurons integrate information from several ascending and descending systems.

It may well be that transections confined to the DCs not only disrupt an ascending pathway but also interfere with descending modulatory mechanisms. Perhaps improved knowledge of these influences might help us understand the complex modifications of sensory perception that have been reported to follow lesions confined to the DCs in humans, including changes in tactile sensations, tactile and postural hallucinations, and increases in sensations of pain, tickling, warmth, and cold. Thus, the clinical effects of lesions of the DCs are much more complicated than those of lesions of the ALQ.

The Primary Somatosensory Cortex (S1) as a Key Link between Ascending and Descending Somatosensory Pathways

Although there are species differences in the anatomical organization of somatosensory pathways in terms of density of inputs and topography, the ventrobasal thalamic targets that receive tactile and noxious inputs exhibit in all species a widespread convergence of inputs and encode precisely the intensities of different kinds of stimuli.

However, the fine encoding properties or the fact that thalamic neurons receive somatotopically organized spinal inputs cannot account for a role in a specific aspect of somatosensory processing. The encoding of the intensity of peripheral inputs shown by single unit recordings demonstrates the fine-tuning functions of the neurons, but it does not resolve neural coding functions in the context of normal information processing. Indeed, the brain processes information in real time; that is, it normally accomplishes its task without the need for multiple repetitions to provide statistical resolution of the data.

To address this issue, it is important to take into account the fact that the brain encodes information through the concurrent activity of neuronal populations rather than from activity in single neurons repeated over time. It also has many ways and strategies for modifying the incoming information it receives. The idea of specialized chains of neurons from the periphery to the cortex, or of separated unidirectional pathways which convey the information that inevitably produces the somatosensory experience, is as obsolete as the concept of the homunculus. Perhaps the most important reason lies in the fact that the brain is an active, selective recognition system that has different means and strategies for modifying afferent information, and thus the specificity of a sensation results from *a posteriori* selection. Moreover, the existence of an homunculus supposes the existence of 'something able to read it' which results in an infinite series of processing mechanisms encased for reading the resulting messages. The fact that when considered separately some ascending pathways act as labeled lines does not imply that a sensation is merely a facsimile in consciousness of every stimulus to the central nervous system. Selection is the main mechanism that generates a sensation, and thus by means of modulation the brain modifies the efficacy of certain inputs to the nervous system.

Cortical activity must be highly dependent on reciprocal interactions with thalamic relays since there are nearly 10 times as many fibers projecting back from the cortex to the thalamus as there are in the forward direction from thalamus to cortex. The function of this massive feedback network in the processing of somatosensory information has not been fully elucidated, but attempts to address this question showed that after several months of chronic delivery of an NMDA antagonist into the monkey primary somatosensory cortex, at the site where the hand is represented, the tactile receptive fields of ventrobasal thalamic cells dramatically increased but only in the

hand region. As in other sensory systems, corticothalamic controls seem to excite relay cells directly by reducing the strength of the intrinsic inhibitory mechanisms affecting these cells (i.e., by disinhibiting them). Overall, these studies suggest that the primary sensory cortices, via their corticofugal projections, provide positive feedback for the 'correct' input while at the same time suppressing irrelevant information (the 'egocentric selection').

The rat ventrobasal thalamus contains only excitatory neurons that project mainly to layer 4 of the primary somatosensory cortex. Descending projections in the thalamocortical loop originate primarily in layer 6 of the S1 cortex. The distal dendrites of ventrobasal neurons are densely innervated by these projections, which activate both ionotropic and metabotropic glutamate receptors. These corticothalamic neurons exert both excitatory and inhibitory influences on relay neurons, and the resultant balance of excitation and inhibition is thought to influence the activity patterns and sensory response properties of relay neurons. Moreover, top-down influences from the S1 cortex are required to specifically discriminate between innocuous and noxious cutaneous inputs in the spinothalamic system. Corticothalamic feedback from S1 to VPL is stimulus driven and modality specific, consisting of either an enhancement of innocuous- or a reduction of noxious-evoked cutaneous responses. Thus, S1 produces a selective modulation of VPL responses to somatosensory inputs by engaging specific, GABAergic, and glutamaergic-mediated excitatory and inhibitory mechanisms in the thalamus.

On their way to the thalamus, corticothalamic projections also send branches to reticular thalamic neurons (RTs) that are exclusively inhibitory and that project locally in the RT or to ventrobasal thalamus. It was suggested on the basis of the similar organization for the visual system that the primary sensory cortices and their thalamic targets do not form a strong, reciprocal loop. The reason for this (the 'no-strong-loop hypothesis') is that a reciprocal excitatory loop would be strong enough to throw the cortex into uncontrolled oscillations, as in epilepsy. Thus, it would be difficult for such a network to constrain its effects, probably because thalamic neurons are near the edge of excitation by the highly specific positive feedback loop circuitry. However, since epilepsy or phenomena related to cortical spreading depression do occur, it is tempting to propose that disturbances in normal sensory processing within these loops could lead to modifications in perception and thus to sensations produced in the absence of peripheral, somatosensory stimulation.

The precise somatotopic organization of S1 and the well-circumscribed anatomical and functional organization of thalamocortical reciprocal modulation lead to small focal activations within S1 that can only be detected with high-resolution approaches. Studies have shown that discrepancies in the interpretation of brain imaging studies were due mostly to the fact that S1 activation by either tactile or painful stimuli is strongly modulated by cognitive factors, including attention, that modify somatosensory perception. Moreover, hypnotic suggestion specifically directed toward changing the perceived intensity but not the unpleasantness of pain evoked by a noxious stimulus significantly modulated activity in S1. Interestingly, modulation of S1 activity seems to occur only with the concurrent presence of somatosensory activation, and thus part of the modulation may be subserved by corticofugal mechanisms driven by peripheral stimuli that are modality specific, such as those described previously. Consistent with this possibility is the observation that nociceptive input to S1 can modulate tactile perception, as shown by the observation that noxious heat is able to reduce the intrinsic optical imaging signal in S1 evoked by innocuous mechanical stimulation of the skin. Furthermore, psychophysical studies have shown that the presence of pain reduces tactile perception of stimuli in the vicinity of the noxious stimulus. This phenomenon was described as a 'touch gate' and could not be attributed to nonspecific changes elicited by generalized arousal or attentional reactions. These mechanisms may also explain earlier clinical observations showing that chronic pain relief resulted in sharpening of tactile perception.

Taken together, human and animal studies indicate that stimulus-evoked responses of S1 corticofugal neurons can contribute to somatosensory discrimination by selecting thalamic responses to preferred versus nonpreferred inputs in a modality-specific manner. In conjunction with mechanisms underlying topographic response sharpening, heightened activity in corticofugal S1 neurons may create a circumscribed zone of enhanced activity within the thalamocortical loop that mediates discrimination between tactile and painful sensations.

The central nervous system networks that integrate somatosensory information do not consist of only a bottom-up process that involves progressively different relays. As summarized in Figure 3, the most important and most widespread source of top-down modulation arises from the cortex. Several cortical regions mediate subtle forms of plasticity by adjusting both thalamic and prethalamic maps and consequently altering all the modulatory mechanisms downstream as a result of sensory experience. Accordingly, psychophysical, behavioral, and clinical evidence show that somatosensory perception is an active process.

Figure 3 Diagram of the main corticofugal mechanisms of somatosensory modulation from the primary somatosensory cortex. Innocuous and noxious stimuli activate spinal and medullary relays. The most important, widespread source of top-down modulation arises from the cortex since both thalamic and prethalamic relays are under corticofugal modulation.

Introduction

An important factor in developing an understanding of mechanoreception has been the close relationship between psychophysical and neurophysiological measurements. A number of studies have carried out psychophysical measurements with human participants and, using the same stimulus conditions, neurophysiological recordings with monkeys. Even when such measurements have not been carried out in the same study, the psychophysical and neurophysiological measures often use similar stimuli and techniques that facilitate comparisons between measures. Many of the measures of tactile sensitivity discussed in the following sections have been part of corresponding neural measures.

In this article various measures of tactile sensitivity to mechanical stimulation and the results of those measures are described first. In two subsequent sections the effects of aging on tactile sensitivity and the use of tactile stimulation in sensory aids for the blind and deaf are examined. Aging is, of course, a topic of increasing importance as our population ages. Work on sensory aids is an important topic on its own and has been the impetus for a number of studies of tactile sensitivity.

Measures of Spatial Sensitivity

The classic measure of spatial sensitivity is the two-point limen. This is typically defined as the minimum distance between two contact points – presented simultaneously to the skin of the arm, for example – that study participant reports feeling as two points of contact, rather than one point. As a reliable measure of spatial sensitivity, the two-point threshold has been shown to have a number of problems. A major problem with its use is that individuals have difficulty in adopting a stable criterion for responding 'two,' a problem that contributes to the unreliability of the measure. Studies in which individuals were given extensive training with the two-point threshold task showed dramatic changes in sensitivity with repeated testing. At the end of repeated testing, an individual's threshold might drop to one-tenth the size it was at the start of testing. Because the threshold on the arm not tested also declined, the changes in performance are very likely to be the result of instability in the individuals' criteria rather than neural changes associated with the site of stimulation. The use of the two-point threshold as a measure of spatial sensitivity has been likened to a clinical screening procedure in which a patient is asked whether they see one or two fingers.

Another measure of spatial sensitivity, grating orientation, avoids the criterion problem. With this measure individuals are touched with a square-wave grating having equal-width grooves and ridges (Figure 1). The gratings are presented in one of two orthogonal orientations. When testing on the finger pad, for example, the grooves are presented in either the proximal–distal orientation or the lateral–medial orientation. The individual's task is to indicate the orientation. Spatial sensitivity is measured by varying the width of grooves, larger grooves leading to higher levels of performance. In effect, the judgment becomes a two-alternative, forced-choice task, and the problem of the individual's criterion is avoided.

One would expect that a valid measure of spatial sensitivity should correlate well with the density of innervation at particular locations, and indeed grating orientation does. At the distal end of the finger where the spacing between the receptors responsible for fine spatial acuity is approximately 1 mm, the grating orientation threshold is also approximately 1 mm. The threshold at the base of the finger is more than 4 mm and on the palm is nearly 6 mm, reflecting the decline in density of innervation at more proximal locations. A second measure of spatial sensitivity, gap detection, has been found to be a useful measure of spatial sensitivity. In this measure, individuals are presented with one of two stimuli, a solid edge or an edge with a gap in it (Figure 2). The individual's task is to indicate which of the two stimuli was presented. The results with this gap task correlate well with the results from the grating orientation task. The gap task has the advantage that it can be used on less sensitive areas of the body, such as the arms and torso, where the grating orientation task is not feasible: the large groove widths needed to achieve threshold performance in the grating orientation task make the size of the contactors unwieldy.

Sensitivity and Site of Stimulation

The surface area of the skin is extensive, approximately 1.8 m^2 for adult males, and sensitivity varies considerably from one area to another. People's intuitions about which areas are most sensitive are generally correct: the most sensitive areas are the glabrous skin of the fingers, lips, and tongue. Some regional differences in sensitivity are shown in Figure 3. Two

Figure 1 Drawings of two of the gratings used in the grating orientation task. The ability to discriminate the orientation of the gratings depends upon the widths of the ridges and grooves.

Figure 2 Drawings of the types of stimuli used in the gap detection task. The ability to detect whether the edge (left) or gap (right) was presented depends upon the width of the gap.

measures of sensitivity are shown, absolute sensitivity, as measured with a 50 Hz vibratory stimulus, and spatial sensitivity, as measured with the gap detection task. From these measures it can be seen that some areas of the body are much more sensitive than other areas. With higher frequencies of vibration, 200 Hz, the differences across regions of the body are even larger: the fingertip is 200 times more sensitive than the thigh. The gap detection task shows a reasonable correlation with the vibratory thresholds.

A traditional measure of force sensitivity involves the use of a von Frey hair as a stimulator. To produce a set of von Frey hairs, different lengths and thicknesses of hairs, often nylon bristles, are mounted at the end of a small holder. A hair is brought in contact with a scale until the hair bends, and the force exerted on the scale for that particular hair is recorded. With a set of such calibrated stimulators, the sensitivity of the body to force stimulation can be determined. What is somewhat surprising is that when measuring sensitivity with a von Frey hair, regional differences are much less pronounced and show less correlation with measures of spatial sensitivity. Sites on the hand have thresholds as high as those on the chest and thigh. The fact that vibratory stimuli produce more pronounced regional differences as compared to measures with von Frey hairs, and higher correlations with spatial measures, is likely due to the surface area of the vibratory contactor resulting in spatial summation and to the durative nature of the stimulus resulting in temporal summation. Also, vibratory stimuli may be more effective in eliciting neural activity, compared to the kind of 'step' produced by von Frey hairs.

Figure 3 Thresholds for vibratory stimuli (solid bars) and for gap detection (open bars) at selected body sites. The vibratory thresholds are for a 50 Hz stimulus and are measured in micrometers. The gap detection thresholds are measured in millimeters. Based on vibratory data adapted from Wilska A (1954) On the vibrational sensitivity in different regions of the body surface. *Acta Physiologica Scandinavia* 31: 285–289, with permission; and on gap detection data adapted from Stevens JC and Choo KK (1996) Spatial acuity of the body surface over the life span. *Somatosensory Motor Research* 13: 153–166.

Measures of Vibratory Sensitivity

Similar to the measures that have been made with auditory stimuli, vibratory threshold sensitivity has been determined as a function of frequency. There is agreement that sensitivity, measured as a function of the amplitude of the displacement of the vibratory stimulus, is best around 200–300 Hz. Two typical threshold curves are shown in Figure 4. The shape of the threshold curve depends upon a number of variables, including the size of the contactor, the duration of the signal, and physical factors relating to the way in which the contactor touches the skin. Some studies have found considerably more spatial summation with higher vibratory frequencies as compared with lower vibratory frequencies, a result that has been attributed to engaging Pacinian corpuscles (encapsulated receptors in subcutaneous tissue).

Measuring sensitivity to vibratory stimuli extends to discriminating vibratory frequency changes. In making such measurements it is important to understand the basis on which the discrimination is being made. Changing the frequency of vibration produces changes not only in perceived 'rate,' but also in perceived intensity. Several strategies have been used to try and ensure that the discrimination is based on changes in perceived rate, akin to changes in auditory pitch, rather than changes in perceived intensity, or 'loudness.' To avoid this problem investigators have matched different vibratory frequencies for equal perceived intensity prior to the start of the frequency discrimination measurements. Estimates of the Weber fraction from different studies vary somewhat. Weber fractions in the range of 5–10% have been reported for low-frequency vibration, whereas larger Weber fractions are often found at higher frequencies: 20–25% in the range of 200–300 Hz. Difference thresholds of this size are significant not only for what they indicate about how frequency and changes in frequency might be encoded, but also what they indicate about the skin's capabilities in processing speech information (see the section titled 'Tactile aids for the blind and deaf').

Figure 4 Thresholds for vibratory stimuli as a function of frequency. Two threshold functions are shown. A major difference in the two studies is the area of contact of the vibratory stimulus with the skin. In the study by Gescheider et al. (●) a contactor of 0.2 cm^2 was used. In the study by Brisben et al. (○) the area of contact was much larger. The study participants actively gripped the contactor, a tube, and the area of contact was a large area on the palm and fingers. Data adapted from Gescheider GA, Capraro AJ, Frisina RD, et al. (1978) The effects of a surround on vibrotactile thresholds. *Sensory Processes* 2: 99–115; and from Brisben AJ, Hsiao SS, and Johnson KO (1999) Detection of vibration transmitted through an object grasped in the hand. *Journal of Neurophysiology* 81: 1548–1558.

Measures of Temporal Sensitivity

Temporal Summation

Temporal summation for vibratory stimuli parallels the findings with spatial stimuli; that is, temporal summation is evident with stimulus conditions that favor stimulating Pacinian corpuscles. Higher temporal frequencies and larger contact surfaces yield the greatest amount of temporal summation. With these vibratory stimuli, threshold declines as the duration of stimulation increases out to 500 ms. Based on these and other results, it has been suggested that the Pacinian system (Pacinian receptors and their peripheral and central connections) is, in contrast to the other mechanoreceptor systems, capable of both spatial and temporal summation.

Although not as widely studied as temporal summation for vibratory stimuli, impulse stimuli also demonstrate temporal summation. Increasing the duration of a pulse from 0.35 ms out to 10 ms results in a more than threefold drop in threshold (amplitude of the pulse). Beyond 5 ms, the threshold remains nearly constant.

Temporal Masking

In studies of temporal masking, individuals are typically presented a target stimulus either preceded or followed by a nontarget stimulus, the 'masker.' In detection masking studies, the threshold for detecting the target is measured as a function of the time between the target and masker. Typically the masker is presented at a greater intensity than is the target stimulus. The general result is as one would expect: as the time between the target and masker increases, the amount of masking decreases. Two such masking functions for a tactile pulse are shown in Figure 5. One function shows the amount of masking when the target and masker are presented to the same location,

the right index finger. The overall amount of masking declines if the target and masker are presented to separate locations on the same hand, but as Figure 5 shows, masking is still seen even when the target is presented to one hand and the masker is presented to the opposite hand. This latter finding strongly suggests that the interaction between target and masker is not exclusively a peripheral event but has a central component as well. Detection masking studies with vibratory stimuli show similar functions, masking extending out several hundred milliseconds, and generally more forward than backward masking.

Masking studies with vibratory stimuli are useful for what they may reveal about processing by different types of receptors and their associated neural connections. When target and masking stimuli are presented at different frequencies, the amount of masking may be reduced or eliminated. For example, the threshold for a target stimulus at 15 Hz is unaffected by a masker of 250 Hz until the amplitude of the masker is quite high. Results such as these have been interpreted to suggest that there is no cross-channel masking, that is, when a target stimulus is confined to one mechanoreceptive channel, a stimulus that primarily activates another channel will not interfere with the detection of the target.

In addition to detection, target recognition is also subject to interference by masking stimuli. Spatial patterns such as those generated on the tactile display of the Optacon (see later section titled 'Tactile aids for the blind and deaf') are subject to both forward and backward masking. Using letterlike patterns, it has been shown that the interference in recognizing a target takes several forms. When the target is a spatial pattern presented in close temporal proximity to another spatial pattern (the potential masker), performance in identifying the target may be interfered with because of temporal integration: the study participants perceive the target as having additional features. In some cases individuals may perceive a composite of the target and masking patterns, and on other trials may respond with the masker rather than the target, an apparent difficulty in determining the temporal order of the two patterns.

There are several differences between the studies of recognition masking and detection masking. One is that in the former the masking stimulus does not have to be presented at an intensity greater than that of the target pattern: even when the target pattern is 'masked' it may remain detectable, but not identifiable. A second difference between recognition and detection masking is that there tends to be more backward than forward recognition masking, particularly at briefer temporal separations.

Figure 5 Amount of masking as a function of the interstimulus interval between the target and the masker. Negative time intervals refer to the condition in which the masker precedes the target (forward masking). Positive time intervals refer to the condition in which the masker trails the target pattern (backward masking). Masking is measured by the difference in amplitude (measured in decibels) required to detect the target stimulus in the presence of the masker and in the absence of the masker. Effects of Aging

Given the large number of studies that have shown changes in visual and auditory sensitivity with age, it should come as no surprise that various measures of sensitivity differ between old and young persons. Spatial sensitivity declines with age: spatial gap detection thresholds are about twice as large on the finger pad for individuals in their 70s as compared to those in their 20s. Absolute sensitivity also declines with age. The threshold, for example, for vibration at 250 Hz may be elevated by a factor of 10 for elders. Some studies report that sensitivity for lower frequency vibration remains virtually unchanged with age, whereas other studies show declines in sensitivity at both low- and high-frequency vibrations. The question (unresolved) of whether the loss in sensitivity is restricted to higher frequencies is important for determining the cause(s) for the age-related change: if the loss in sensitivity is restricted to higher frequencies, it suggests that changes in the Pacinian system may be responsible. A more uniform loss in sensitivity across frequencies would indicate changes in other receptor systems as well, or more central changes.

Temporal processing may also show changes with age. The effects of aging are revealed particularly in measures in which effects are seen when the representation of a stimulus persists beyond its offset. For

example, elders show more temporal masking than younger persons do in a forward masking paradigm – that is, when a vibratory masking stimulus precedes the target stimulus. Elders also have greater difficulty in detecting a temporal gap in vibratory noise. The effects of age appear to be greater with higher frequency vibratory stimuli, again suggesting that it is the Pacinian system that is showing more pronounced effects with age.

Spatial sensitivity has been measured at a number of locations on the body for younger and for older individuals. The decline in sensitivity with age was not uniform across locations: more peripheral locations tended to show greater declines in sensitivity. The largest decline in spatial sensitivity was on the great toe, with the elder persons' thresholds nearly five times the younger persons' thresholds. It has been speculated that the decline in sensitivity may be the result of a reduction in the number of receptors, which in turn might be due to decreases in peripheral blood flow. A discussion of possible mechanisms raises the issue of exactly what is meant when changes in sensitivity are attributed to age: older persons may have been exposed to more diseases, are more likely to be taking prescription drugs, have suffered more mechanical and thermal assaults to the skin, and so forth. It has also been observed that thresholds for older persons tend to be more variable than those for younger people – that is, same-age elders may show a greater range of sensitivities compared to same-age younger persons. Thus, age *per se* may not be the sole explanation for the well-documented declines in sensitivity seen in older persons.

Tactile Aids for the Blind and Deaf

The sense of touch has long been considered as a possible channel to aid blind and deaf individuals. Studies designed to examine the skin's capabilities as a communication channel have increased our knowledge of tactile sensitivity. Also, such systems can serve as proofs of the skin's ability to process information.

Tactile Aids for the Blind

Reading by means of braille provides an example that stimuli presented through a single finger pad are capable of being processed at relatively high rates. With braille, the reader is feeling individual cells containing from one to six raised dots. The dots are configured in a two-column by three-row matrix. Measured from the center of the dots, a cell is about 2.3 mm wide and 4.6 mm high. The spacing between dots is greater than the limits of spatial resolution for the finger pad. Proficient braille readers can read at rates up to 100 words per minute. In grade 1 braille, each cell stands for a single character, whereas grade 2 braille makes use of contractions and has cells that stand for short words, thus reducing the number of cells scanned per minute. A useful figure to keep in mind is that in reading grade 1 braille at 60 words per minute, the reader is processing a cell each 180 ms.

A second example demonstrating the rapidity with which stimuli presented through a single fingerpad can be processed is provided by the Optacon (so named for its optical to tactile conversion), a device developed as a reading aid for the blind. This device consists of a tactile display, a 6×24 array of tactors, measuring approximately 1.1×2.2 cm. Connected to the display is a camera which, when moved over printed material, provides an analog signal to the tactile display. If the camera is moved across the letter 'O,' it generates a corresponding circular pattern of vibration that moves across the tactile display. The blind user places his or her finger on the tactile display and moves the camera across the text. Some users of this device can read at rates exceeding 50 to 60 words per minute. Similar to reading grade 1 braille, a reading rate of 60 words per minute corresponds to the user processing the letters at rates of approximately 180 ms per letter. One of the advantages of the Optacon is that it provides the user direct access to printed material and does not require transcription, as does braille.

One potential limitation in reading with the Optacon, and indeed in reading braille, is the field of view, one letter at a time. One can get some sense of this by cutting a small slit, the width and height of a single letter, and then reading a paragraph. The reading rate will be slowed considerably, even though each individual letter is clearly perceived. This observation raises a question, both applied and theoretical, 'Can the tactile field of view be extended to two or more finger pads?' Attempts to alter the tactile array of the Optacon to accommodate two fingers and to allow two letters to be displayed simultaneously did not result in any improvement in reading speed.

Neurophysiological recordings from monkeys reveal that the tactile stimulation produced by the Optacon display does not stimulate Merkel (SA1) fibers; rather, both Meissner (RA1) fibers and Pacinian corpuscle (PC) fibers are stimulated. Because of the inability of PC fibers to transduce spatial patterns, it is likely that it is RA1 fibers that convey Optacon patterns. In light of the SA1 fibers' ability to resolve finer spatial patterns, as compared to RA1 fibers, one would expect that to be identified, letters displayed on the Optacon have to be larger relative to raised letters which activate SA1 fibers; and such is the case.

One of the recurrent questions about the blind and touch concerns whether blind people are more sensitive to tactile stimuli than sighted people are. Recent

interest in this question has been spurred by studies of brain functions that show activity in the visual cortex of blind persons as a result of tactile stimulation and that show that transcranial magnetic stimulation (TMS) directed at primary visual cortex can disrupt processing of spatial stimuli in sighted and in blind individuals. The question of improved tactile sensitivity for blind people appears straightforward, but, like many such questions, the answer is not straightforward. Some studies have found no difference in tactile sensitivity between sighted and blind persons; others have found differences favoring the blind, and still others have found that sighted individuals show better sensitivity. Three recent studies illustrate the complexity. All three of these studies tested spatial acuity with blind and sighted persons, all tested sensitivity on the fingers, and all used the grating orientation task. The fact that the grating orientation task was used is significant: First, as noted, it is a reliable measure. Second, of the various measures of sensitivity, spatial sensitivity might be expected to be affected by loss of sight. Two of the studies found blind persons to show significantly greater sensitivity compared to sighted controls. The third study found no difference in threshold between blind and sighted persons. Indeed, in this study the trend was slightly in the opposite direction. There is no obvious reason for the differences in results among these studies.

Tactile Aids for the Deaf

A variety of tactile aids have been developed for the profoundly deaf. The devices provide information about environmental sounds and aid in speech perception. The tactile information is typically vibratory. In some early attempts to use vibratory information, speech signals were amplified and imposed directly on the skin. The idea was that, with training, individuals would learn to associate particular patterns of vibration with the speech sounds that generated them. These attempts had limited success for several reasons. First, as noted, the skin is maximally sensitive to vibratory stimuli in the range of 200–300 Hz, and becomes relatively insensitive to vibrations above 500–700 Hz, well below the ear's sensitivity and below the range of much of speech information. Second, the auditory system is very sensitive to changes in frequency. At 1000 Hz changing the frequency by as little at 1 Hz is detectable. As noted, for touch the Weber fraction for frequency is about 25% at 300 Hz; an increment of 75 Hz is needed to detect a difference. The skin simply lacks the frequency-resolving power to understand speech directly imposed on it.

Various devices have attempted to circumvent these limitations. Often multichannel tactile aids are used and these employ a variety of ways to analyze the acoustic signals, particularly speech signals. Some analyze speech signals into various frequency bands, and, in a rough approximation of the analysis of frequency by the basilar membrane, the energies in the different bands of frequency are displayed at different sites of stimulation. Other tactile vocoders extract certain features of speech, such as the fundamental frequency and the first formant, and display analogs of the features through multiple sites on the skin. The Tickle-Talker is a device of this sort that generates the tactile signal by electrocutaneous stimulation.

When used as aids to speech perception, tactile aids are primarily used in conjunction with lipreading. The various devices have shown some success in this regard, generally producing significant but modest improvements in speech perception and being judged useful in responding to environmental sounds.

Somatosensory Plasticity

C Darian-Smith, Stanford University School of Medicine, Stanford, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

This chapter focuses on somatosensory pathway reorganization following peripheral injury and injuries of the cord that affect primary afferent pathways. Particular emphasis is given to primate studies, as these have greatest clinical relevance. However, a great deal has been accomplished in nonprimate mammals, particularly in the field of cellular mechanisms, and the reader is encouraged to read related chapters (see end of article) for a broader perspective.

Somatosensory Pathway Organization and the Hand

The primary somatosensory pathway comprises the afferent projections of the sensorimotor system, from peripheral receptors (mechanoceptors, thermoreceptors, nociceptors, etc.) to the cortex. Information received by the receptors of the skin, muscles, tendons, and joints of, for example, the left hand, is transmitted via the dorsal roots to the dorsal horn of the spinal cord. The dorsal column projection relays in the left cuneate nucleus of the brain stem, and crosses the midline in the medial lemniscus to terminate within the contralateral ventral posterolateral nucleus (VPLc) of the thalamus. The spinothalamic neurons have their cell bodies in the cervical dorsal horn and cross the midline within 1–2 spinal segments before terminating in the same thalamic VPLc nucleus. Spinothalamic fibers also terminate more caudally in the anterior nucleus of the pulvinar (Pulo) of the thalamus, and more rostrally in VLp, the posterior nucleus of the ventral lateral complex. Thalamocortical projections from the thalamic VPLc nucleus then terminate within the primary somatosensory cortex (S1) (Brodmann's areas 3a, 3b, 1, and 2). Projections from the Pulo also terminate within these regions, the posterior parietal cortex, and even the caudal primary motor cortex. Figure 1 shows these pathways at their simplest level of organization. In reality, additional afferent projections transmit sensory information to higher levels (e.g., spinoreticular, spinocerebellar, spinocervical), and feedback loops from higher levels of the pathway can be found at every step (Figure 1). For example, the somatosensory cortex (hand region) projects directly to the cuneate nucleus, and to the dorsal horn of the cervical spinal cord, as part of the corticospinal tract. In the execution of fine manipulative tasks that involve continuous tactile and proprioceptive feedback from the hand, many of these pathways and feedback loops are continuously involved. Somatosensory and motor systems are also intrinsically linked with the somatosensory pathways, since the effective execution of directed exploratory movements of the digits, for example, will depend on continuous sensory feedback from the hand.

As with the retina of the visual pathway, and cochlea of the auditory system, the skin and fascia of the body surface are represented at each level of the somatosensory pathway. These representations are ordered or somatotopic, such that inputs from adjacent parts of the body surface are always located adjacent to each other at subsequent levels of the pathway (e.g., within the cuneate nucleus, the VPLc nucleus, and the S1). The primate hand is like the retinal fovea, in providing the sharpest somatosensory image of the world within reach. As such, the digits of the primate hand have a greater mechanoreceptor density than elsewhere, and the glabrous skin of the digit pads is represented disproportionately within S1, and subcortical nuclei. Representations can be mapped at any level of the pathway by recording from neurons, and by determining their receptive fields by stimulating the skin surface. It is these maps that have been used extensively over the last two decades to explore the mutability of the adult brain following injury, disease, and other manipulations (e.g., learning paradigms).

In adult mammals under normal conditions, these maps are stable over time. However, when the activity of the constituent neuron populations alters significantly, following, for example, a repeated learned behavior, or an injury that blocks normal input from peripheral receptors, then these central maps reorganize to adjust to the new circumstances. Since the early demonstration of cortical remodeling following a median nerve cut or digit amputation, there have been countless demonstrations of this phenomenon in all sensory and motor systems and in a broad range of mammalian species. Though first observed in the 1960s in the spinal dorsal horn, the finding that reorganization also occurs at subcortical levels has only fully been appreciated in the last decade. There may be clear reasons for this. Earlier studies generally focused on the cortical map because it represents the last port of call for the primary pathway, and is easily accessed for electophysiological recordings. Another reason may reflect differences in the organization of visual and somatosensory pathways, and a certain

Figure 1 The primary somatosensory pathway showing the major afferent projections, and the different levels at which reorganization can occur following injury. a, b, and c indicate the three levels at which primary afferent neuronal populations can be severed following a peripheral nerve (a), dorsal root (b), or central dorsal column (c) injury. Inset shows terminal distributions for the different primary afferent subpopulations. In the macaque monkey and human, the primary somatosensory cortex (S1) comprises four regions, 3a, 3b, 1, and 2, each named according to Brodmann (1908). Adapted from Darian-Smith and Darian-Smith (2004).

inertia to fully appreciate the differences in these systems. In the visual pathway, there is a small receptor sheet (i.e., the retina) and tight afferent projection to the lateral geniculate nucleus (of the thalamus) and cortex. This means that following a retinal lesion, the most dramatic plastic changes have been shown to occur at the level of the cortex. In contrast, the receptor sheet for the somatosensory pathway is comparatively vast and multilayered (skin, muscles, and joints), and there is a spinal cord with its complex distributed parallel circuitry. This provides a greater opportunity for significant circuit reorganization at multiple subcortical levels. The central nervous system (CNS) appears to be opportunistic, in the sense

that neuronal reorganization can and will occur along a sensory pathway wherever the circumstances permit, so appreciating the underlying anatomy is critical for understanding where changes can occur.

How the somatosensory system responds depends on where the injury occurs, the extent to which fibers are spared by the lesion (the size of the injury), and the postlesion time period at which changes are examined.

With respect to the postlesion time period, there are several stages to the process of postinjury reorganization. These are generally divided into an acute phase (minutes to hours), a chronic phase (days, weeks, and early months), and an extended chronic phase (years). For example, immediately following a digit amputation or median nerve cut, there will be a 'silent region' within the corresponding contralateral cortical hand map, and a rapid expansion of the representation of parts of the hand lying adjacent to the silenced or deafferented region. This expansion can occur within minutes to hours, and may persist for weeks to months. During the chronic second stage (weeks to months), there is opportunity for the establishment of new connections from spared inputs and the consolidation of the cortical and subcortical body maps. A final stage (years) involves the eventual atrophy of chronically deafferented neuronal populations. This was evident more than a decade after monkeys received a dorsal rhizotomy that deafferented the forelimb. The cuneate nucleus of the brain stem and the VPLc nucleus of the thalamus reduced substantially in volume over this period, and an expanded face representation was observed within the somatosensory cortex. This suggests that when the deafferentation is complete and extensive, consolidation involving cell shrinkage and death can occur slowly over many years, and even decades.

Lesions of the Primary Afferent Neuron

The patterns of deafferentation that result from injuries to primary afferent neuron populations relaying sensory information from the hand to the cortex have been studied extensively. They include investigations into peripheral nerve injury, amputations, dorsal rhizotomies, and more central injuries to the spinal cord and dorsal column.

Whether the primary afferent neuron is injured peripherally, or centrally to the dorsal root ganglion, or centrally within the CNS (e.g., in the dorsal column), does make a difference to the postinjury changes that take place (Figure 1). The following sections briefly summarize what happens when injuries involve different components of the primary afferent, as shown in a–c (Figure 1). In the somatosensory pathway, subcortical structures have been shown to play a critical role in the postinjury responses, and this multilevel involvement is now generally accepted. For this reason, multilevel changes are discussed throughout the text and are not addressed separately.

Peripheral Nerve Injuries and Amputations

Peripheral nerves retain the capacity to regrow following injury, and will do so unless blocked by a physical or chemical barrier, so the central map changes that result following nerve cut are often relatively minor. Even so, studies in the macaque monkey have shown that if a nerve is cut and the cut ends sutured to enable nerve regeneration, the cortical somatotopic map may never completely recover. Many neurons in the reorganized cortex develop abnormal multiple receptive fields on nonadjacent skin regions, and the map becomes disorganized. Such mislocalization does not occur following nerve crush, where fibers regenerate to innervate their original peripheral target.

When nerves are unable to regenerate to their original target (e.g., following nerve ligation), reorganization is far more substantial. Following nerve transection, a 'silent zone' is initially observed within the corresponding cortical map where the digits and/or skin surface have been deafferented. Within minutes to hours, the 'silent zone' is surrounded by an expanded representation of the adjacent body parts, and over a period of weeks and months, there is a gradual 'filling in' or expansion of the representation of the adjacent skin surface until the new organization stabilizes. A specific example of this is seen in the squirrel monkey, where a median and ulnar nerve section results in a corresponding deprived region of cortex, that comes to respond over many months to inputs originating from the back of the hand.

Following the amputation of the hand or digits, where afferent and efferent nerves are both cut, the pattern of cortical reorganization mimics that seen following the permanent section of both sensory and motor nerves supplying the hand. Thus, following digit amputation, the representation of the stump region (or adjacent hand) expands into the deprived region of the cortical map. This can take weeks to months to occur, and parts of the cortex may remain silent during the postinjury period.

Similarities between amputation and nerve ligation diverge, most noticeably, when the amputation is large. For example, when the whole of the forelimb is amputated, there is some expansion of the face representation (which lies adjacent to hand representation) into the hand cortex. Imaging studies in humans with hand or forearm amputations have similarly reported face responses within the deprived

hand cortex many months to years following the amputation. Though the neural substrate for these observations remains unclear, the longer time frame suggests that local neuronal growth, synapse formation and modification, and perhaps even some transneuronal atrophy (where years have elapsed since the injury), may contribute.

In studies of nerve section or amputation, changes observed within the cortex reflect subcortical reorganization. Cutting nerves supplying the hand in the squirrel monkey, for example, results in the reorganization of the 'hand' map in both the brain stem cuneate nucleus and the thalamic ventroposterior lateral nucleus. Reorganization within the brain stem and thalamus was found to be similar in extent to that observed in the cortex of these monkeys.

Dorsal Rhizotomy – Root Cut

More than a century ago, Mott and Sherrington showed that cutting dorsal roots C4-T2 causes an extensive deafferentation of the macaque's hand and forearm, and a profound and lasting impairment of voluntary manipulative movements. In humans, the loss of sensory feedback from the hand (e.g., following brachial plexus injury), also typically results in a severe impairment in dexterity.

Recent investigations in our lab provide insight into a number of acute, chronic, and long-term changes (>8 months) that accompany experimentally induced dorsal root lesions. When dorsal roots that innervate the digits of the hand are sectioned, the central axons of the primary afferents that are cut, degenerate (while their cell bodies within the dorsal root ganglion and peripheral axons remain alive). In our experiments, only dorsal rootlets innervating the first two to three digits of one hand were cut (**Figures 2 and 3**). Immediately following one of these lesions, there is no detectable input from the experimentally 'deafferented' digits, and a 'silent region' is present in the corresponding spinal dermatomal map (**Figure 2(a)**), and in somatotopic maps at the level of the brain stem (**Figure 4**), and somatosensory cortex. These silent zones persist for many weeks at all levels of the pathway and correspond to an initially severe behavioral deficit (see below; **Figures 2 and 3**). Gradually, over the course of many weeks, and with constant hand use, there is some recovery of digit use (see 'Behavioral consequences of somatosensory plasticity'), and as this occurs there is a corresponding reorganization within the cuneate nucleus of the brain stem and cortex. Within dorsal root fascicles immediately adjacent to the lesion, cutaneous responses can also be elicited where this was not previously possible.

To investigate the neural basis of these changes, we conducted a series of anatomical experiments in monkeys with a similar lesion. It was shown that a small population of afferent fibers was spared by the lesion that continued to innervate the 'deafferented' digits. These entered the cord adjacent to the lesion site, and for many weeks following the lesion, they were apparently too few in number or too weak in their response to drive the somatotopic map at any level of the pathway. We showed that these primary afferent fibers sprout locally within the spinal dorsal horn and cuneate nucleus over the postlesion period. These 'sprouts' are likely to form additional connections with input-deprived postsynaptic target neurons (**Figure 5**) and play a role in driving reorganization at the spinal and higher levels of the pathway.

Our studies also demonstrate a limit to the amount of reorganization and recovery that can occur. Quite extensive postlesion reorganization can occur in the spinal dorsal horn (and at higher levels) as long as a small number (<5%) of uninjured primary afferents remain intact, that continue to transmit information from the periphery. For example, in monkeys with lesions that removed most input from the thumb and index finger, there was a complete re-emergence of the cortical map over the first 3–4 postlesion months (**Figure 2(b)**). However, in macaques with a slightly larger lesion (two to three segments; **Figure 3(a)**), the hand map never completely returned. This was true for the cuneate nucleus (**Figure 4**) and cortex (**Figures 2(a) and 3(a)**).

Earlier studies that provided insight into dorsal root injury in nonhuman primates focused on a group of macaque monkeys that received a massive dorsal root section (C2-T4) some 12–20 years earlier. These lesions completely deafferented the forelimb and, in some cases, part of the trunk, and the arm was rendered completely nonfunctional. These studies demonstrated several things. First, that chronic deafferentations of such a large magnitude result in significant transneuronal degeneration over many years. As might be expected, there was an extensive reorganization of the body map within the thalamic nucleus VPLc, and within the somatosensory cortex. In the cortex, no unresponsive zones were detected, but the face was represented over a larger region and abutted the trunk representation in the absence of any input from the deafferented limb. There was also significant atrophy within the cuneate fasciculus of the spinal cord, the cuneate nucleus of the brain stem (37–48% shrinkage by volume), the thalamic VPLc nucleus, and possibly even the somatosensory cortex, though the latter was not determined. Some atrophy in the cortex within the original forelimb

Figure 2 (a) A laminectomy showing a dorsal rootlet lesion in which tactile input was selectively removed from the thumb and index fingers. Cartoons of the hand show the distribution of cutaneous receptive fields on the palmar and dorsal surface of the hand in rootlets along the borders of the lesion zone, before the rootlets were cut. White line indicates which rootlets were sectioned and gray shaded rootlets identify fascicles that were left intact following the lesion. Afferent fibers within these rootlets altered in their response over several postinjury months such that cutaneous RFs could be mapped on the deafferented digits where this was not previously possible. See text. (b) The corresponding cortical 'hand map' for this monkey, 20 weeks following the lesion. By this time, a complete hand map had 're-emerged' and a silent region was not observed. Black dots indicate recording sites, and white dot identifies a site where no response could be elicited. (c) The accompanying recovery of performance of a reach–retrieval task in the same monkey over the course of 20 postinjury weeks. The opposition of the pads of the index finger and thumb was the preferred stratagem used by the monkey before the lesion, and in the control hand (open circles). The use of this stratagem was lost immediately after the lesion (filled circles) but was gradually recovered over 20 postlesion weeks. The time of the dorsal rootlet section is indicated with the gray line. The 1.0 N resistive force refers to the clamp force holding the target object. Adapted from Darian-Smith C and Ciferri M (2005) Loss and recovery of voluntary hand movements in the macaque following a cervical dorsal rhizotomy. *Journal of Comparative Neurology* 491: 27–45.

representation would help explain the cortical map changes. Perhaps surprisingly, only 5–15% of neurons were lost within the cuneate nucleus even up to 20 years post injury. This indicated that shrinkage by volume was associated with a loss of neuropil and axons, rather than a loss of neurons.

Spinal Cord – Dorsal Column Lesions

Injuries that involve the primary afferents at a central level provide additional insight into the role that spared primary afferents can play in reorganization. In one series of experiments in owl monkeys, a high dorsal column lesion (at C3–4) removed inputs from

the forearm and lower body from the entire extent of the dorsal column nuclei of the brain stem. Though the spinothalamic pathway remained intact, these neurons were not able to independently transmit sufficient afferent information from the forelimb to reactivate the cortical map. When even a small afferent population was spared by the lesion, this input was found to reactivate the corresponding cortex and to expand its representation into the cortical map. When no afferents were spared within the dorsal columns, preserved inputs from the face appeared to grow into denervated regions of the cuneate nucleus from the adjacent trigeminal nucleus. This took 6 months to occur. Within the cortex, face inputs expanded to utilize the adjacent silent 'forelimb' cortex. This study suggested that the spinothalamic pathway does not play a defining role in the cortical reorganization observed, though some controversy regarding the compensatory role of mechanoreceptor afferents within the spinothalamic tract remains.

In humans, spinal injuries are rarely restricted to the dorsal column, so it is difficult to assess the neural bases for acute or chronic changes following injury.

Behavioral Consequences of Somatosensory Plasticity

Surprisingly, few nonhuman primate studies have systematically examined behavioral changes following somatosensory pathway injuries, and linked these back to neuronal reorganization.

Several investigations have looked into the effects of dorsal column lesions on hand and digit use over the last several decades, but these have been inconsistent in their findings. Deficits described have ranged from subtle and insignificant to chronic and debilitating. A likely reason for the range of results stems from the lack of injury reconstruction at the completion of many of these studies, and thus a lack of correlation between the anatomical and behavioral deficits. In studies by Vierck and colleagues, who did make this link, transection of the dorsal spinal column was found to initially impair the monkey's ability to discriminate textures, or specifically the frequency or duration of tactile stimulation. Some monkeys recovered this ability over several months of testing, and others did not. In the monkeys that did recover, it was proposed that monkeys learned to use alternate cues and pathways to assess and discriminate textures.

The behavioral effects of a spinal hemisection, which also involves the dorsal column, in addition to the corticospinal tract and other ascending and descending pathways on the lesion side of the cord, have also been studied in the macaque. Monkeys with a near-complete hemisection at spinal segments C3–4 initially presented with a severe hemiparesis, but regained the ability to pick up objects with the impaired hand within 1 month of the lesion. By the end of the third postlesion month, monkeys were able to use their hand and digits quite efficiently in a reach–grasp–retrieval task, though recovery was never fully complete (up to 3 years post injury). Persistent impairments included a less direct trajectory and preshaping of the hand during the reach component of the task, and some weakness of the opposing digits. The somatosensory component of the task was also clearly impaired, but not as completely as might have been expected. Somatotopic maps of the body representation showed a considerable reorganization of the deprived cortex and a greatly reduced hand map with abnormally large cutaneous receptive fields. In these studies, previously existing 'crossover' corticospinal projections were thought, at least in part, to mediate behavioral recovery. Localized sprouting of these or other pre-existing pathways may also have played some role. In all cases, recovery of hand function likely involved significant circuitry changes and synapse modification (see Mechanisms below).

Mott and Sherrington showed in 1895 that sectioning the dorsal roots of spinal segments C4-T4 in the macaque completely blocked somatic sensation in the hand and voluntary digit movements, while sparing some controlled movements of the elbow and

Figure 3 Data from a monkey that received a larger lesion than that shown in **Figure 2**. Here the dorsal root section removed all detectable sensory input from the thumb, index, middle finger, and thenar palm of one hand. This monkey was initially unable to use its hand at all and could not successfully perform a reach–retrieval task requiring cutaneous feedback for more than 2 months. (a) The partial re-emergence of the somatosensory cortical hand map in this monkey 22 weeks following the dorsal root lesion. Note that while there was a significant re-emergence of the digit map, a silent region remained. (b) The rate of success of retrieving a target reward as a function of time following the lesion. Data are given for three resistive forces (clamp forces holding the target), that the monkey had to overcome to retrieve the object. These correlate to increasing levels of difficulty with 2.0 N force being the most difficult and last to be successfully achieved. (c) Changes in the strategy used to perform the grasp–retrieval task. The prelesion stratagem, shown in column 1, shows the target being grasped and removed by the opposing index finger and thumb. At 1 week post lesion, the monkey failed to perform the task and was unable to feel the clamp or target object, or to preshape the digits. By the 13th postlesion week, the object could be grasped using an abnormal use of the first three digits, and by the 20th postlesion week, cutaneous sensation had recovered sufficiently that the monkey was able to retrieve the object 100% of the time, using opposition of the thumb and index fingers. Adapted from Darian-Smith C and Ciferri M (2005) Loss and recovery of voluntary hand movements in the macaque following a cervical dorsal rhizotomy. *Journal of Comparative Neurology* 491: 27–45.

Figure 4 Changes in the pars rotunda of the cuneate nucleus of the brain stem of monkeys that received a DRL that removed input from the thumb, index, and middle fingers. Two weeks following the lesion, no inputs could be mapped within the cuneate nucleus on the first three digits of the hand. Twenty-nine weeks following the lesion, a silent region remained, but surrounding parts of the cuneate nucleus now responded to stimulation of the initially 'deafferented' digits. Monkeys with slightly smaller lesions also showed a substantial reorganization of the hand map in the cuneate >16 weeks following the lesion, but did not have a 'silent zone'. Electrode penetration sites are marked on photographs of the dorsal surface of the brain stem (insets). Different rostrocaudal rows of penetrations are identified with different line types. In upper panel, cutaneous RFs are shown according to their location, on the digits (D1–D5), the hand, and the forearm, as indicated in the legend. In the lower panel, RFs on the digits are shown on cartoons of the hand surface. Shaded regions in the cuneate map on the normal side outline the distribution of D1–D3 RFs. This input zone is transposed to the side of the lesion to help define the original region of input of the experimentally deafferented digits. Scale bar in photos = 1 mm; numbers refer to electrode penetrations. Adapted from Darian-Smith C and Ciferri M (2006) Cuneate nucleus reorganization following cervical dorsal rhizotomy in the macaque monkey: Its role in the recovery of manual dexterity. *Journal of Comparative Neurology* 498: 552–565.

Figure 5 Schematic of projections from macaque's index finger (and also from the adjacent thumb and middle fingers) to neurons in the cuneate nucleus, before and following the section of selected dorsal rootlets: a summary of the findings of Darian-Smith C and Ciferri M (2006) Cuneate nucleus reorganization following cervical dorsal rhizotomy in the macaque monkey: Its role in the recovery of manual dexterity. *Journal of Comparative Neurology* 498: 552–565. In group 1 experiments (column on left), the rhizotomy was extensive, but spared ~5–10% of neurons innervating the index finger. However, in group 2 experiments (right column), following a more extended rhizotomy, the index finger was completely deafferented, which is reflected in the representational map of the hand (open, unlabeled circles). Sixteen weeks later (bottom row), the cuneate circuitry had changed profoundly: (a) the central terminals of the axotomized neurons had degenerated, and (b) the central terminals of primary neurons innervating the thumb or middle finger, and those spared neurons that innervated the index finger, had proliferated ('sprouted'), and some had established sufficient synapses on cuneothalamic neurons to re-establish the cuneate representational map of the thumb and fingers (bottom left panel). In group 2 monkeys, where the index finger was completely deafferented (bottom right panel), there was extensive proliferation of afferent terminals in the cuneate nucleus, though this could not compensate for the permanent loss of input from the index finger: the cuneate representation of these monkeys remained 'silent'. As a consequence, group 1 monkeys substantially recovered a precision grip over a period of weeks to months, whereas group 2 monkeys did not. Reorganization of cuneate circuitry was matched by cuneate axon terminal labeling (Darian-Smith C (2004) Primary afferent terminal sprouting after a cervical dorsal rootlet section in the macaque monkey. *Journal of Comparative Neurology* 470: 134–150) which suggested local sprouting of spared axon terminals, and the monkey's recovery of hand function (Darian-Smith C and Ciferri M (2005) Loss and recovery of voluntary hand movements in the macaque following a cervical dorsal rhizotomy. *Journal of Comparative Neurology* 491: 27–45 – see **Figures 2** and **3**). From Darian-Smith C and Ciferri M (2006) Cuneate nucleus reorganization following cervical dorsal rhizotomy in the macaque monkey: Its role in the recovery of manual dexterity. *Journal of Comparative Neurology* 498: 552–565.

shoulder. They also observed that if a single dorsal root was cut in the same range of cervical segments, there was no identifiable impairment of voluntary hand function. In more recent studies of reaching movements following cervical dorsal root transection, some return of gross limb movement was reported in the monkey forelimb. Vierck (1982) studied the effects of a dorsal rhizotomy (C3-T3) on forelimb reaching to points in space and found an initially severe deficit, followed by a gradual recovery of some directed limb movements, after many months of training. However, voluntary hand function was not systematically examined.

Recently, in our lab, we examined the behavioral effects of a restricted cervical dorsal rootlet lesion on the macaque's ability to perform a voluntary task requiring cutaneous feedback. Monkeys were divided into two groups, and trained to retrieve a target

object from a clamp (Figure 3(c)), using the thumb and index finger in opposition. In group 1, dorsal rootlets containing fibers supplying the thumb and index finger were cut, and in group 2, additional rootlets innervating the middle finger and thenar eminence were also cut. Performance parameters were assessed before and following the lesion, and included (1) percentage of successful retrievals, (2) digital stratagem (the pattern of digit opposition), and (3) the contact time (or duration of digit contact with the object prior to retrieval). During the first postoperative week, hand function was severely impaired in all monkeys, but over the following weeks, group 1 monkeys recovered the ability to retrieve the object by opposing the index finger and thumb in >80% of trials. Figure 2 shows the gradual recovery of the prelesion digit use over 21 postlesion weeks in one such monkey. Group 2 monkeys with the larger lesion also regained function in the impaired hand. Though this recovery was sometimes dramatic, as in the case of M-3 (Figure 3), it was never complete. Each of these monkeys quickly adopted a stratagem for grasping the target, using digits that were incompletely deafferented. At the end of these experiments, hand representations were mapped within the contralateral somatosensory cortex, and in the cuneate nucleus, to define hand deafferentation and cortical reactivation. In all cases, a tight correspondence was observed between these somatotopic maps and digit use. For example, if the monkey regained function in the thumb and middle finger but never again used the index finger, digit maps consistently showed a re-emergence of input from the thumb and middle finger, and a 'silent zone' for the index finger.

The behavioral studies described above, which focus on hand sensorimotor function, consistently demonstrate that wherever small numbers of somatosensory fibers are spared, quite dramatic behavioral recovery can occur during the early postinjury months.

Neural Substrates for Reorganization in the Somatosensory Pathways

Pathway Divergence and Disinhibition

The somatosensory pathways are divergent and hierarchical in their organization, from their point of entry to the spinal cord, to the brain stem nuclei, the thalamus, and cortex (Figure 1). This divergence is undoubtedly responsible for some plasticity within the system, particularly during the acute phase of the injury. This is well demonstrated in the cortical map, immediately following a peripheral nerve cut, where a number of groups have shown that receptive fields from adjacent body parts enlarge and 'fill in' the edges of the deafferented (silent) cortex (up to 1 mm). This can occur within minutes to hours and is enabled by the normal divergence of thalamocortical afferents (up to 2 mm) within the cortex, and the 'unmasking' or 'disinhibition' of inhibitory connections that normally hold these inputs (and receptive fields) in check. Unmasking during the acute phase occurs when excitatory inputs to inhibitory neurons within the cortex are removed by the lesion. This removes local GABAergic inhibition to excitatory synapses within adjacent cortex, and 'unmasks' the underlying pre-existing circuitry (GABA, gamma-aminobutyric acid). Available data also indicate that disinhibition can operate at subcortical levels. The demonstration that GABAergic pathways are modulated following peripheral lesions (or by pharmacological blockade) demonstrates the importance of this neurotransmitter in cortical and subcortical plasticity.

Terminal Sprouting and Synaptic Changes

When a peripheral injury is large, then additional mechanisms are recruited. These processes can involve structural modifications, such as local axonal branching or sprouting, and/or structural alterations of synapses, all of which take weeks to months to occur.

Central axon terminal sprouting has been reported in monkeys, rats, and cats following amputation or nerve transection. It has also been observed within the visual and somatosensory cortex, following retinal and peripheral nerve lesions, respectively. These findings suggest that central axonal growth over short distances, and perhaps even dendritic branching, may be something of a generalized injury induced response, which can occur whether or not remaining neurons are damaged or left fully intact following the injury.

Following the dorsal root lesion described in previous paragraphs, primary afferents that are spared by the injury sprout locally within the spinal dorsal horn and cuneate nucleus. This local terminal exuberance takes several months to occur and may underlie circuitry reorganization that leads to the eventual 'recovery' of dexterity (see above). It is thought to result in the formation of additional synapses with deprived postsynaptic neurons (Figure 5). One possibility is that this amplifies an initially weak signal from the periphery to suprathreshold levels, and may involve an LTP-like process. This provides a neural substrate for the complete or partial re-emergence of subcortical and cortical maps. Importantly, if the initial deafferentation of one or more digits is complete, then no subsequent proliferation

of primary afferent terminals can compensate for this loss. Figure 5 summarizes our recent findings, and underscores the limits of this reorganization.

Terminal growth is rarely observed to extend much beyond the original axonal territory, though there are exceptions to this rule. For example, one study showed that in monkeys with dorsal column lesions or arm amputation, 'face' afferents sprouted and grew into the cuneate nucleus from the trigeminal nucleus of the brain stem.

Many studies, primarily in the cortex, have shown that synaptic strength is greatly influenced by experience or learning. This activity dependence, which appears to follow Hebbian rules, is important for altering synaptic efficacy, at all levels of the somatosensory pathway following peripheral nerve and spinal cord injury. LTP, which is normally associated with learning in the hippocampus, has been demonstrated in rodent sensory and motor cortex, and either LTP or an LTP-like mechanism is likely to contribute to somatosensory plasticity, including plasticity that occurs following skill learning.

In addition to structural and even synaptic changes, damage to the CNS initiates a cascade of cellular and molecular events, many of which play a role in the regenerative and degenerative processes that follow.

Atrophy, Transneuronal Atrophy, and Degeneration

Atrophy and degeneration (e.g., Wallerian) occur in any chronic peripheral nerve or central injury that involves the death of axons entering, or coursing through the spinal cord.

In monkeys that received large-scale dorsal root injuries (C4-T2), 12–20 years earlier, transneuronal atrophy was considerable, and occurred at the level of the cuneate nucleus and the thalamus. In these monkeys, the brain stem cuneate and thalamic VPLc nuclei were reduced in overall volume by as much as 50%, though volume loss involved neuropil more than the total neuron numbers. As expected, somatotopic maps were greatly altered in these monkeys, but after this length of time, no inactive or 'silent' regions remained. These studies indicate that following a large peripheral injury, long-term transneuronal atrophy continues over many years and is a slow but dynamic process.

In the shorter term and to some extent, chronically, a number of non-neuronal cell types (e.g., macrophages, oligodendrocytes, microglia, and astrocytes) are recruited and activated. These cells perform many roles in addition to cleaning up and managing the structural integrity of the injury site. In chronic injuries, and most obviously in traumatic injuries of the spinal cord and CNS, astrocytes are known to play a major role in gliosis and scar formation. Activated astrocytes within the scar tissue secrete molecules, that can either permit or inhibit axon terminal growth and synapse formation. Their secretion of inhibitory factors can present a major barrier to axon growth and recovery following traumatic spinal injury, and the effects of these cells on neuronal reorganization forms an important focus of investigation. Their role in somatosensory plasticity, however, is complex, and requires further investigation.

Neurogenesis?

Though neurogenesis is not generally regarded as a contributor to plasticity in the somatosensory system, recent evidence suggests that it may play a potentially important part in the process of pathway reorganization following injury. Neurogenesis is well known to play a major role in hippocampal function, and several groups have reported adult neurogenesis following a number of neuropathologic conditions, including ischemia, and nonpathologic situations including various learning paradigms. Recently, we observed that adult neurogenesis also occurs in the spinal dorsal horn following the restricted dorsal root injury model (described above), and that it accompanies other neurophysiological and anatomical changes within the 'lesion zone' of the spinal dorsal horn. This indicates that neurogenesis occurs within the adult primate spinal cord in response to injury. Emerging evidence from work in the cortex suggests that newly formed neurons in the CNS integrate into local circuitry as GABAergic interneurons. However, the functional significance of neurogenesis in the reorganization of somatosensory pathways following injury is not currently known and awaits further research.

Somatosensory Receptive Fields

S S Hsiao, P J Fitzgerald, P H Thakur, P Denchev, and T Yoshioka, The Johns Hopkins University, Baltimore, MD, USA

Introduction

A marvel of human perception is the speed and accuracy with which humans recognize and manipulate objects with their hands. This is supported by psychophysical studies showing that blindfolded subjects perform at an accuracy rate of greater than 96% and mean response times of less than 5 s when asked to identify 100 common objects that they explore using their hands. It is also supported by studies of proficient braille readers who can easily read braille text at rates greater than 100 words per minute. These findings demonstrate that it takes less than 100 ms to recognize the spatial form and texture of patterns presented to the skin. One hundred milliseconds is very rapid and suggests that there is a high-capacity spatial processing system in touch that initially encodes a peripheral neural representation of patterns on the skin, transmits those representations to the cortex, and within cortex transforms and matches those representations against all previously stored memories of objects. The process must be highly dynamic since object identification is facilitated by dynamic exploration of the pattern, and must be performed by massively parallel processes. In touch, the encoding and processing of information begins with the activation of populations of neurons with receptors in the skin that have small receptive fields. Neurons further along the pathways have fields that are larger and more elaborate as the information progresses centrally toward regions in cortex involved in perception. The concept that neurons have a receptive field was originally proposed by Sherrington (in 1906), who coined the terms exteroceptive and interoceptive fields for distinguishing between neurons that respond to internal states of the body versus neurons that respond to external environmental stimuli. Sherrington proposed that the selectivity of the exteroceptive neurons was due to the particular accessory structures that are associated with each type of neuron. Sherrington also proposed that understanding the specific relationship between external stimuli and the neural responses was a key in understanding the basis of perception. The importance of receptive fields in neural processing of visual stimuli was further elaborated in the early 1930s with studies by Hartline and others who showed that neurons exhibit selectivity for specific kinds of visual stimuli and inferred that the specificity was based on neurons having specific receptive field structures. Later, Barlow proposed that these receptive fields were the basis for neural mechanisms of visual form processing whereby features of the external world are extracted by central neurons, and that this feature representation is the basis for the representation of form in the visual system. In the 1950s and 1960s, these ideas of visual receptive fields performing feature extraction were further elaborated on by Hubel and Wiesel who showed that neurons in primary visual cortex are orientation selective and hypothesized that the orientation tuning resulted from neurons having receptive fields with separate subregions of excitation and inhibition, and they called such neurons 'simple cells.' They further hypothesized that the receptive field structures become more elaborate and complex as the processing of visual information proceeds centrally to higher visual areas. The aim of numerous studies since then has been to understand the processing functions of those cortical neurons.

The receptive fields and processing functions of neurons in touch have received significantly less attention. Anatomical studies have shown that the processing of spatial form begins with the activation of four mechanoreceptive afferents that innervate the skin. From there the information progresses centrally to neurons in the dorsal column nuclei, then to the ventrobasal complex of the thalamus, and then to primary (SI) and secondary (SII) somatosensory cortex. The processing pathways beyond SII are not well understood. Here we review the receptive field properties of neurons in the somatosensory system. We begin with a discussion of the receptive fields of the peripheral afferents that innervate the skin. Then we discuss the receptive fields of neurons in SI and then SII cortex. Both of these areas have been shown in albation studies to lie directly along the pathway leading to tactile form perception.

Peripheral Receptive Fields

Tactile perception is based on four cutaneous mechanoreceptive afferent types: slowly adapting type 1 (SA1), rapidly adapting (RA), Pacinian (PC), and slowly adapting type 2 (SA2) afferents. Two of these, the RA and PC afferents, are classified as rapidly adapting because they respond transiently to sudden indentation and removal of stimuli and do not respond to sustained indentations. The other two, the SA1 and SA2 afferents, are classified as slowly

adapting because they respond to sustained skin deformation with a sustained discharge that declines slowly, but they, like the RA and PC afferents, are much more sensitive to skin movement than to static deformation. The neural response properties of the cutaneous SA1, RA, and PC afferents have been studied extensively in both human and nonhuman primates. SA2 afferents are not found in nonhuman primates.

Sample receptive fields for each of the four mechanoreceptive afferents from humans are shown in Figure 1. These responses were recorded from humans using percutaneous electrodes that recorded the activity of single afferent fibers while the skin was stimulated using a blunt probe that systematically indented the finger pad. As shown, the SA1 and RA afferents have small receptive fields with diameters of about 4–6 mm, whereas SA2 and PC afferents have extremely large receptive fields with diameters that essentially could not be measured using punctuate stimuli. There are several other aspects of the receptive fields that should be noted in the figure. First, for all afferent types the receptive field size increases with indentation amplitude. This is to be expected since all four afferent types receive their inputs from receptors that are imbedded in the epidermis (SA1 and RA) and deeper tissues (PC and SA2) and respond to changes in mechanical stresses and strains on the skin. Thus, the changes in receptive field size with increases in indentation amplitude are directly attributed to the changes in the stress and strain profiles in the skin.

SA1 afferent fibers branch repeatedly before they lose their myelin and terminate in the basal layer of the epidermis. There, they are enveloped by specialized epidermal cells, called Merkel cells, that enfold the unmyelinated ends of the SA1 axons. Each SA1 afferent fiber receives input from multiple Merkel cells which appear as local islands of excitation in Figure 1. SA1 afferents have peaked-like receptive fields with one or more central zones of strong excitation and response sensitivities that decline as one moves toward the edge of the field. Combined neurophysiological studies of nonhuman primates and psychophysical studies of humans have shown that these afferents are suited for detecting fine details of spatial stimuli and underlie form and texture perception. RA afferent fibers also branch repeatedly as they near the epidermis, and like the SA1 afferents, each of the 30–80 or so branches loses its myelin sheath before terminating in Meissner's corpuscles, which are found

Figure 1 Receptive field characteristics of the four human mechanoreceptor afferents that innervate the glabrous skin. Top: Contour maps of receptive field sensitivities. The closed lines are isosensitivity contours that illustrate the threshold of the receptor for different amplitudes of mechanical indentation of the skin on the finger. The thin, parallel lines in the SA1 and RA plots mark the grooves between the papillary ridges. Middle: The threshold of the receptor at different distances from the center of a cross-section through the receptive field. Bottom: Relationship between indentation amplitude and receptive field size. Adapted from Johansson RS (1976) Receptive field sensitivity profile of mechanosensitive units innervating the glabrous skin of the human hand. *Brain Research* 104: 330–334.

in the spaces between the sweat-ducts and adhesive ridges. Evidence of these multiple branches can be seen in Figure 1. The sensitivity profile of the RA afferents is relatively flat compared to the SA1 afferents (Figure 1), suggesting that RA receptors are poorly suited for detecting the fine spatial details of stimuli but instead are well suited for detecting stimulus contact. Both RA and SA1 afferents innervate the skin of the finger pad densely. The estimates in humans and monkeys are not significantly different from each other with there being, at the fingertip, about 100 SA1 and 150 RA afferents per cm^2. These high innervation densities show that when the finger is in contact with an object both afferent types will encode in their discharge a dense two-dimensional representation of stimulus form indented on the skin.

A striking feature of RA responses is their sensitivity to minute skin motion. The effective operating range of indentations for RAs is about 4–400 μm; the comparable SA1 range is about 15–1500 μm or more. The neural response properties of RA afferents make them ideally suited for coding motion perception.

Each PC afferent terminates in a single Pacinian corpuscle, which occurs in the dermis or the deeper tissues. The most striking feature of the PC response is its extreme sensitivity, which derives from mechanosensitive ion channels located in the unmyelinated ending that lies at the center of the corpuscle. Pacinian corpuscles respond with action potentials to vibratory amplitudes as small as 3 nm applied directly to the corpuscle. Because of their extreme sensitivity to vibrations and movement, it is difficult to get accurate estimates of the receptive field sizes of these afferents. Some PCs have receptive fields that are restricted to one or a few digits, whereas others have receptive fields that span the entire arm. Like the RA afferents, the spatial sensitivity of PC afferents is fairly uniform across the receptive field (Figure 1), demonstrating that these afferents provide no useful information about spatial form. SA2 afferents also have very large receptive fields (Figure 1) and like PC afferents, they have unclear borders. These afferents are extremely sensitive to skin stretch and because of their large uniform receptive fields and low innervation densities, they do not provide useful information about spatial form. Interestingly, these afferents have not been found in nonhuman primates and recent studies in humans have brought into some doubt the underlying receptor and receptor mechanisms for these afferents.

The receptive field sizes of monkey SA1 afferents are significantly smaller and more uniformly shaped than the receptive fields of RA afferents. Although SA1 peripheral afferents tend to be smaller than RA afferents, there is overlap between the two populations in their sizes. The mean areas for these afferents are about 11 and 23 mm^2, respectively, with corresponding diameters of about 4.0 and 6.0 mm, which are similar to the receptive field sizes of these afferents measured in humans.

Recent studies have shown that experiments in which the receptive fields were derived using punctate probes (Figure 1) give an incomplete impression of the neuron's receptive field properties. Figure 2 shows the spatial temporal receptive fields (STRFs) for SA1 and RA neurons that were computed by performing a spike-triggered averaging of the neural response to a large array of independently controlled probes that randomly indented the skin. The receptive fields determined in this manner show in time whether a neuron is more or less likely to respond with an action potential when the probe is placed at any location within the receptive field. The response shown in Figure 2 illustrates that 5 ms after stimulus onset SA1 afferents have a central excitatory zone surrounded by a zone of mild suppression. The effect of the excitatory zone fades quickly (within 15–20 ms) and is replaced by a period of suppression where the neuron is less likely to fire action potentials. We refer to these effects as suppression rather than inhibition to distinguish them from active inhibitory mechanisms. For the peripheral afferents the initial surround suppression is due to skin mechanics, whereas the replacing suppression is due to the refractory period of the neuron. In contrast, the RA response, which also fades quickly, does not show edge-suppressed responses and like the SA1 response shows a period of delayed suppression following the excitatory response. Figure 3 shows the average total STRF area and average area for the excitatory and suppressed responses for a population of these afferents. The total receptive field area for RA afferents is similar to the area of the excitatory part alone. Further, Figure 3 shows that the inhibitory response due to the neuron's refractory period can affect the neural response for a significant period of time following excitation.

Receptive Fields of Neurons in SI Cortex

Sample receptive fields of 247 area 3b neurons mapped with scanned, random-dot stimuli are illustrated in Figure 4. In contrast to receptive fields of peripheral afferents, the receptive fields of most cortical neurons of SI cortex are characterized by having a single central region of excitation surrounded by inhibition on one, two, or three sides (Figures 4(a)–4(e)). Neurons with surround inhibition on all four sides (Figure 4(f)) were rare, as were neurons that had receptive fields like peripheral SA1 and RA afferents, which have a simple excitatory receptive field with

Figure 2 Peripheral and cortical spatiotemporal receptive fields (STRFs). Red areas denote excitation, blue areas denote inhibition/suppression, and the intensity of redness or blueness indicates the strength of the response. STRFs of a peripheral SA1 afferent (a) and a peripheral RA afferent (b). STRFs in SI cortex (areas 3b and 1) could be broadly categorized into the following three types: (c), an area 3b neuron with a purely excitatory STRF; (d), an area 3b neuron with replacing inhibition/suppression; (e), an area 1 neuron with surround and replacing inhibition/suppression. Colored bars indicate pixel intensities in spikes per second per micrometer. Adapted from Sripati AP, Yoshioka T, Denchev P, Hsiao SS, and Johnson KO (2006) Spatiotemporal receptive fields of peripheral afferents and cortical area 3b and 1 neurons in the primate somatosensory system. *The Journal of Neuroscience* 26: 2101–2114.

minimal surround inhibition (Figure 4(g)). The wide variety of receptive field structures in area 3b suggests that the representation of spatial form is significantly transformed from the peripheral response, with neurons in cortex extracting information about spatial features of the stimulus.

The relationship between the regions of excitation and inhibition is significantly more complex if one considers the STRF. This is illustrated in Figures 2(c)–2(e), which shows sample STRFs from three kinds of responses that are observed in cortex. First, for all cortical neurons the excitatory response becomes most prominent approximately 15–25 ms after stimulus onset and as expected is delayed relative to the peripheral response because of the conduction delays necessary to convey the response from the input to the cortex. The neurons shown in Figures 2(c) and 2(d) showed little surround inhibition whereas the neuron shown in Figure 2(e), which was more typical of the neural responses, showed significant surround inhibition, like the responses shown in Figure 4. The excitatory response shown in Figure 2(c) faded rapidly with little replacing inhibition, whereas the response shown in Figure 2(d) showed significant replacing inhibition that was still intense 50 ms following stimulus onset. For cortical neurons the amount and latency of the replacing inhibition cannot be easily explained by the refractory period of neurons, which suggests that it is due to active inhibitory mechanisms.

Figure 2(e) shows an example of the more common type of response that was observed in area 3b of SI cortex. This neuron showed significant surround inhibition and significant replacing inhibition. Notice in this figure that the surround inhibition evolves more slowly and persists longer than the excitatory region. The temporal evolution of regions of excitation and inhibition for cortical neurons can be more clearly seen in Figure 3(c). The figure shows that initially the response for the central neurons is dominated by excitation and that the size of the inhibitory response slowly increases. After about 25 ms the response switches to one where inhibition dominates excitation. The inhibition is due to both surround inhibitory mechanisms and replacing inhibition, with replacing inhibition becoming more dominant as time goes on. The time course of the response is

Figure 3 Temporal evolution of STRF areas. (a) Total (excitatory plus inhibitory/suppressed) STRF area averaged over all neurons of a given afferent type or cortical area. (b) Average areas of excitatory (solid lines) and suppressed (dotted lines) regions for peripheral SA1 and RA afferents. (c) Average areas of excitatory (solid lines) and inhibitory/suppressed (dotted lines) regions over time for cortical areas 3b (magenta) and 1 (green). similar but not identical for neurons in area 3b versus area 1. In area 1 the excitation appears to evolve later, as does the inhibition, suggesting that area 3b neurons project to area 1 neurons, a hypothesis that is supported by anatomical evidence.

The total receptive field area for both peripheral and central neurons in SI cortex is shown in Figure 3(a). It is clear that neurons in SI cortex have larger receptive fields and that the differences between the peripheral and central responses are due to both increased excitation and the increased role that inhibition plays in the neural response.

The fact that neurons in SI show subregions with both excitation and inhibition demonstrates that these receptive fields are more elaborate than the receptive fields of peripheral neurons, which suggests that SI neurons are further along the pathway that underlies tactile form processing.

Figure 5 illustrates the receptive fields for a subset of the neurons that showed orientation selectivity. For these neurons the selectivity, like that of simple cells in the visual system, is based on the receptive field shape. As such the orientation tuning can be explained by these neurons having an oriented excitatory subregion flanked by an oriented inhibitory subregion. These kinds of responses may underlie the high percentage of neurons in SI (about 70%) that show orientation-tuned responses when bars are indented into the center of the finger pad.

A more stringent test of the validity of these linear receptive field types is their ability to account for the neural responses to complex spatial patterns scanned across the receptive field. This is shown in Figure 6 for two SI neurons, which shows the estimated receptive field, the predicted response to scanned embossed

Figure 5 Relationship between excitatory and inhibitory receptive field lobe orientations. Only neurons with dominant excitatory and inhibitory lobes, both with aspect ratios >1.5, were included ($n = 78$ area 3b neurons). Right: Excitatory and inhibitory RF lobe orientations tended to be similar (correlation coefficient = 0.586). Sixty-five percent of the points lie within ±20° of the diagonal (within the dashed lines on the right). Left: Example neurons (a–h). Adapted from DiCarlo JJ, Johnson KO, and Hsiao SS (1998) Structure of receptive fields in area 3b of primary somatosensory cortex in the alert monkey. *The Journal of Neuroscience* 18: 2626–2645.

Figure 6 Generality of the receptive fields. The responses of two area 3b neurons studied with both random dots and embossed letters. The predicted responses to the embossed letters were determined by convolving the RF (left) determined from the random dot pattern with a template of the letter stimulus. Predicted firing rates were converted into action potentials using a Poisson spike generator, with the overall predicted spike rate adjusted to coincide with the observed spike rate. Adapted from DiCarlo JJ, Johnson KO, and Hsiao SS (1998) Structure of receptive fields in area 3b of primary somatosensory cortex in the alert monkey. *The Journal of Neuroscience* 18: 2626–2645.

letters of the alphabet, and responses that were observed when neurons were presented with the same letter stimuli. The similarity between the observed and predicted responses is striking, which suggests that these receptive fields with regions of excitation and inhibition are good linear estimates of the processing kernels in this area of cortex.

Whereas the fixed excitatory and inhibitory components of the response provide the neurons with selectivity to spatial gradients and account for the complex spatial responses shown in Figure 6, the delayed replacing inhibitory component serves a different purpose. One hypothesis is that it serves as a compensatory mechanism that increases the firing

rate with increasing scanning velocity. As scanning velocity increases, the delayed inhibition lags progressively further behind in time to expose more excitation. The consequence is that the excitatory and inhibitory components of the receptive field grow in intensity with increases in velocity, having no effect on receptive field geometry. The result is a representation of spatial form that is invariant with scanning velocity.

Receptive Fields of Neurons in SII Cortex

Most neurophysiological studies support the idea that SII is further along the pathways responsible for processing tactile form. Recently, it has been shown that this cortical region consists of multiple areas that have been given a variety of names (OP1–OP4 in humans; anterior field (SIIa), central field (SIIc), and posterior field (SIIp); or SII, PV, and PR in nonhuman primates). While the precise organization of these areas and how they are interconnected with neurons in SI is not well understood, it is clear that neurons in these areas have larger and more elaborate receptive fields than do neurons in SI cortex. What is particularly striking is that the receptive fields are much larger in the three areas (fields) that make up SII cortex than for the neurons in SI cortex which typically only span one (area 3b) or a few (area 1) finger pad(s). Recently, SII receptive fields were studied using an oriented bar that systematically indented the distal, middle, and proximal finger pads of digits 2–5 of the macaque hand. For a given neuron, each pad was classified as either orientation tuned (T), untuned excitatory (UE), untuned inhibitory (UI), or unresponsive. Figure 7 shows a random sample of receptive fields for 15 SIIc neurons (top) that only had untuned excitatory pads, as well as a random sample of 15 SIIc neurons (bottom) that had one or more orientation-tuned pads. It is clear that neurons in SII have a variety of receptive field sizes and shapes, with some neurons having their receptive field confined to a single finger pad (Figure 7, row a of column 1) and others having receptive fields that spanned multiple fingers and finger pads. Although the receptive fields tended to be contiguous, with untuned excitatory pads adjacent to each other, this was not a rule, since some neurons had noncontiguous receptive fields (Figure 7, row d of column 3). In general, neurons in SII showed a similar variety of receptive field sizes and shapes, whether their responsive finger pads were untuned excitatory or untuned inhibitory. About 36% of the neurons only had untuned excitatory pads like the ones shown in Figure 7 (top). A total of 17% had only untuned inhibitory pads and the least commonly observed type were the 5% that had both untuned excitatory and untuned inhibitory pads.

The second most common type (about 23%) were neurons that had one or more tuned finger pads (Figure 7, bottom), that is, neurons that showed different responses when the bar was indented into the center of the pad at different orientations. As shown in the figure, most neurons had combinations of tuned and untuned pads and some had only tuned pads. While some neurons had only one tuned pad, many neurons, especially those in the central field of SII, had multiple tuned pads.

Although all stimulated parts of the hand were represented in the receptive fields, there was a bias in the central and anterior SII fields for the index and middle fingers to be better represented than the other two large digits, and a bias for the distal and middle pads to be better represented than the proximal pad. This is reasonable since these are the digits and pads that are used most often when exploring objects.

A close inspection of the tuning preferences for neurons with multiple tuned pads showed that the tuning was usually similar between pads. An example of one such neuron is shown in Figure 8. This neuron had seven tuned pads, all with similar tuning preferences (Figure 8, bottom). The similarity demonstrates that neurons in SII tend to show position-invariant responses to oriented bars and indicates that neurons in SII are further along the pathway for coding the shape of objects placed in the hand. One hypothesis is that these receptive field structures represent the underlying kernels that are used for representing object shape. Thus, orientation-tuned pads could signal the edges of objects and untuned pads could signal the flat surfaces of objects.

Figure 9 shows the responses from a single finger pad for two neurons in SII cortex that were stimulated with an oriented bar at multiple positions and orientations within that pad. Both of these neurons showed orientation-tuned responses to bars indented in the center of the finger pad; however, an analysis of the vector fields that estimate the local tuning across the pad demonstrates that the mechanisms underlying the tuned responses vary greatly between neurons. For example, the tuning response for the neuron shown on the right was explained well by a single excitatory region ('hot spot' which 'attracts' the vectors), which is predicted by the linear receptive field shown in the bottom right of this figure. In contrast many neurons showed invariant orientation-tuned responses like the one shown on the left in Figure 9. The response for this neuron is not easily explained by its linear receptive field. These results show that many neurons in SII cortex show nonlinear responses to spatial stimuli.

Figure 7 SII receptive field diagrams. Shown are a random sampling of 15 central field type UE (untuned excitatory) neurons (top), and 15 central field type T (orientation tuned) neurons (bottom). Each 3 × 4 grid represents the 12 pads of D2–5 for a single neuron (as shown for the upper left receptive field diagram), with the top row of each grid representing the distal pads, and the left column representing D2. For untuned excitatory pads, redness represents the peak excitatory rate; for untuned inhibitory pads, blueness represents the peak inhibitory rate; and for tuned pads, redness or blueness represents the maximum deviation from the spontaneous rate. The orientation of each white bar represents the preferred orientation (mean angular vector) of that tuned pad. Within each type, the neurons are arranged in an ascending order based on RF size (number of pads). D, digit; d, distal; m, middle; p, proximal. Adapted from Fitzgerald PJ, Lane JW, Thakur PH, and Hsiao SS (2006) Receptive field (RF) properties of the macaque second somatosensory cortex: RF size, shape, and somatotopic organization. *The Journal of Neuroscience* 26: 6485–6495.

Figure 8 Example of an orientation-tuned SII neuron. Shown are raster plots and peristimulus time histograms (PSTHs) (top) for all 12 stimulated pads of this central field neuron, as well as orientation-tuning curves for all 12 pads (bottom). In the raster, stimulus trials are first sorted into the 12 stimulated finger pads (D2–5, d–p), and then within each pad are sorted by the orientation of the bar (see lower, extreme right). The bar stimulus indentation profile is also shown (lower right). Each PSTH graph is shown below its corresponding finger pad, where only the preferred (highest firing rate; solid line) and nonpreferred (lowest firing rate; dashed line) orientation rates are plotted after convolving these rates with a Gaussian. The short, colored bars above the raster plots indicate tuned pads, and correspond to the colored tuning curves shown in the orientation tuning plot at the bottom. Each point in each tuning curve corresponds to the mean evoked firing rate during the 500 ms indentation of the oriented bar at the given orientation on the given finger pad. The thin black lines in the orientation tuning plot represent untuned pads. D, digit; d, distal; m, middle; p, proximal; *p*, preferred orientation; *n*, nonpreferred orientation; s/s, spikes/second. Adapted from Fitzgerald PJ, Lane JW, Thakur PH, and Hsiao SS (2006) Receptive field (RF) properties of the macaque second somatosensory cortex: RF size, shape, and somatotopic organization. *The Journal of Neuroscience* 26: 6485–6495.

Conclusions and Summary

So what is a receptive field? In the simplest definition it is the area of stimulus space over which changes in the stimulus cause corresponding increases or decreases in the firing rate of the neuron. In this definition, neurons such as the SA1 afferents in the periphery simply provide information about whether a stimulus is present or absent at a particular location on the finger pad. For these neurons the responses are relatively linear and can be explained reasonably well by a central region of excitation with surround suppression. In cortex the receptive fields are significantly more elaborate and in SI can be roughly explained by neurons having spatiotemporal receptive

Figure 9 Example vector fields of SII neurons. These vector plots represent the orientation tuning at different points within a finger pad when an oriented bar was presented at different locations within that pad. Shown are an invariant neuron (left) and a hot-spot neuron (right). Within each vector field, each short line segment is a vector that represents the preferred orientation (direction) and strength (magnitude) of tuning at that point on the distal finger pad. Also shown for each neuron is the preferred orientation diagram (top right) from the 12 pad RF mapping protocol (**Figures 7** and **8**); the asterisk indicates the distal pad shown in this figure. The orientation tuning curve (middle right) is the tuning when the bar was centered on the pad and represents the mean firing rate during the 500 ms presentation of the bar at the particular orientation. The linear receptive field (lower right) for this figure was obtained using reverse correlation. Redness represents excitation and blueness represents inhibition, and the degree of redness or blueness is proportional to the magnitude of excitation or inhibition, respectively. Adapted from Thakur PH, Fitzgerald PJ, Lane JW, and Hsiao SS (2006) Receptive field properties of the macaque second somatosensory cortex: Nonlinear mechanisms underlying the representation of orientation within a finger pad. *The Journal of Neuroscience* 26: 13567–13575.

fields with a central excitatory region surrounded by one or more regions of inhibition. Furthermore, the excitatory regions are masked by replacing inhibition that gives these neurons a degree of velocity invariance. As one moves further along the pathway, the neurons tend to have receptive fields that are even larger and more elaborate, spanning multiple fingers and finger pads with complex groupings of tuned and untuned pads. A working hypothesis is that objects presented to the hand are represented across a population of such processing kernels. Future studies are needed to understand how these receptive fields are integrated to form central representations of object shape and texture.

Somatostatin and Receptors

P C Emson, The Babraham Institute, Cambridge, UK

Somatostatin

Somatostatin, or somatotropin-releasing inhibitory factor (SRIF), is a cyclic tetradecapeptide with a disulfide bridge between the cysteine residues 3 and 14 (Figures 1(a) and 1(b)). The first evidence for its existence came in 1968 when Krulich and colleagues identified a hypothalamic factor (somatotropin) that reduced the release of growth hormone (GH) from rat pituitaries *in vivo*. Subsequent work by Guillemin's laboratory in 1972 attempting to purify GH led them to isolate somatostatin from 500 000 sheep hypothalamic extracts and then to sequence and synthesize it. The synthetic peptide caused a specific and concentration-dependent inhibition of GH release from the pituitaries consistent with its name. Following the synthesis of somatostatin, a number of groups developed antibodies to the cyclic peptide and further explored its physiological roles. Somatostatin is found in a wide range of central nervous system (CNS) and peripheral tissues outside the hypothalamus. In the CNS, somatostatin is found in number of neurons in the forebrain, including neurons in the cerebral cortex, hippocampus, basal ganglia, spinal cord, and hypothalamus. In the spinal cord, the neuropeptide is localized both in the dorsal root ganglia and dorsal horn (substantia gelatinosa) of the spinal cord, where the afferents from the dorsal root ganglia synapse. In the periphery, somatostatin is found in the gut neurons of the enteric nervous system and in the endocrine cells of the intestine and pancreas. A number of stable analogs of somatostatin have been produced, for example sandostatin (octreotide), which are used in the treatment of acromegaly (gigantism), and, due to somatostatin's marked antiproliferative action, as a treatment for a variety of endocrine and other tumors expressing somatostatin receptors.

Following the isolation and sequencing of somatostatin, the prohormone (precursor) sequence was elucidated and somatostatin-14 is produced from preprosomatostatin via a tryptic cleavage of the larger precursor somatostatin-28 (see Figure 1(a)). The 13-amino-acid N-terminus of somatostatin-28 corresponds to thrittene, a novel peptide recently isolated from monkey intestinal extracts. This peptide may represent a product of alternative processing of the somatostatin precursor.

The cloning of cortistatin, a peptide very closely related to somatostatin that also occurs in two short forms (cortistatin-17 and cortistatin-14) and a longer sequence (cortistatin-29), increased the complexity of the known somatostatin system (Figures 1(c) and 1(d)). Cortistatin-14 contains the core 11-amino-acid C-terminus of somatostatin (Figure 1(d)) and acts as a full agonist at somatostatin receptors. *In situ* hybridization studies with cortistatin probes reveals that cortistatin expression is mainly localized in the cerebral cortex and hippocampus, where it is found in parvalbumin-containing interneurons as well as coexisting with somatostatin itself in some populations of interneurons. Physiologically, as might be expected, cortistatin shares a number of functional properties with somatostatin, such as inhibiting neuronal activity, but inducing slow-wave sleep and reducing locomotor activity are unique properties of cortistatin.

Also related to somatostatin and cortistatin is the fish peptide urotensin II (UII) (Figure 1(e)). Urotensin II analogs are found in the mammalian CNS, but attempts to isolate the peptides expected to be formed from UII have so far been unsuccessful; urotensin-related peptide (URP), an octapeptide containing the C-terminal motif (CFWKYCV) found in UII, was the only UII-like peptide isolated, and this originates from a distinct URP precursor. The physiological effects of UII and URP are mediated through the serpentine G-protein-coupled receptor GRP14. Their effects may include specific actions on cardiomyocytes. Comparative genomic studies suggest that UII and URP genes and the somatostatin/cortistatin genes arise from segmental duplication of two ancestral genes that were physically linked together and that themselves arose from tandem duplication of a single ancestral somatostatin gene.

Somatostatin exerts its effects through some five somatostatin receptors, termed sst_{1-5} (Table 1), with two forms of the sst_2 receptor, termed sst_{2A} and sst_{2B}, which differ only in the length and composition of their C-terminus. Genomic studies suggest that there are only five somatostatin receptor genes. Cortistatin has thus far not been shown to have a separate receptor, although it has been suggested that an orphan receptor may be a candidate cortistatin receptor. Binding studies with labeled cortistatin in mice deficient in one of the main cortical somatostatin receptors (sst2A) showed that cortistatin binding remains in the hippocampus and habenula regions of the CNS of these knockout mice, suggesting these may be regions containing specific cortistatin receptors.

Figure 1 Diagrams of somatostatin and related peptides belonging to the cortistatin–somatostatin family: (a) $SRIF_{28}$, (b) $SRIF_{14}$, (c) $rCST_{29}$, (d) $rCST_{14}$, (e) urotensin II (UII), (f) urotensin-related peptide (URP). $SRIF_{28}$ and $SRIF_{14}$ are the two major peptides derived from tryptic processing of the somatostatin precursor. $rCST_{29}$ and $rCST_{14}$ are predicted sequences of cortistatin peptides derived from the cortistatin precursor by tryptic processing. Sequences of the urotensin peptides UII and URP are based on peptide purification data and sequencing, as are the sequences of the somatostatin peptides. The peptide thrittene corresponds to the N-terminal 13 amino acids of $SRIF_{28}$. CST, cortistatin; SRIF, somatotropin-releasing inhibitory factor.

However, the possibility that the labeled peptide is binding other members of the somatostatin receptor family which have not been knocked out or may be upregulated in the sst2A knockout mouse needs to be carefully considered.

Somatostatin Receptors

All the somatostatin receptors are typical G-protein-coupled receptors (Figure 2) with the classical seven transmembrane domains and sites for glycosylation and/or palmitoylation on the N-termini. They can be grouped into two subfamilies on the basis of pharmacology: receptors sst_1 and sst_4 in one group and sst_{2B} and sst_{2a}, sst_3, and sst_5 in the other group. The peptide analogs seglitide and octreotide can be used to distinguish the subfamilies; radioligand binding studies show that sst_1 and sst_4 possess only a low affinity for both analogs, whereas sst_2, sst_3, and sst_5 display a high affinity. The homology between the groups/subfamilies is less than 50%, but within the classes sequence similarities exceed 80% in transmembrane regions. The properties of the cloned human somatostatin receptors are summarized in Table 1. Somatostatin receptors couple to signal cascades through both pertussis toxin (PTX)-sensitive and pertussis-insensitive G-proteins (e.g., G_i/G_o and G_q). The precise coupling depending on the neuronal type and the different isoforms of G-proteins available in the target cell. It is also likely that somatostatin receptors may form oligomers (e.g., heterodimers) with other G-protein-coupled receptors such as the dopamine and opioid receptors; although this has been shown to occur only in cell lines overexpressing transfected receptor cDNAs, it may account for some of the unusual pharmacological properties of somatostatin observed in some experimental systems. All the receptors have been shown to inhibit adenylyl cyclase

activity in a PTX-sensitive fashion and to couple to phospholipase C. In addition, they also activate mitogen-activated protein kinase (MAPK) pathways influencing cell growth.

Distribution of Somatostatin

Following the isolation and sequencing of somatostatin, as noted earlier, the availability of antibodies for the peptide enabled the distribution and release of the peptide to be studied by using radioimmunoassay (RIA) and immunohistochemistry. As expected, somatostatin was found in neurons in the periventricular and paraventricular regions of the hypothalamus, from which it can be released to indirectly influence GH release by acting on growth hormone-releasing hormone (GHRH)-containing neurons in the hypothalamus and to directly act on the somatotrophs of the anterior pituitary. Outside the hypothalamus, somaostatin immunoreactivity was also found to be enriched in neurons in the forebrain, including the cerebral cortex, amygdala, hippocampus, and striatum. Somatostatin was released in a Ca^{2+}-dependent manner from brain slices, suggesting a possible role as a neurotransmitter/neuromodulator in the brain. Somatostatin neurons in the forebrain (except the hypothalamus) are now known to be primarily γ-aminobutyric acid (GABA)ergic interneurons which often contain a further vasoactive peptide neuropeptide Y (NPY) and the marker for the gaseous

transmitter nitric oxide (NO), neuronal nitric oxide synthase (nNOS), and in some neuronal populations the related peptide cortistatin. The distribution of the peptide in the forebrain suggests its involvement in neurological diseases affecting these regions, including Alzheimer's and Huntington's disease. Of particular interest is the recent observation that the β-amyloid-metabolizing enzyme neprilysin may be regulated by somatostatin such that a decline in somatostatin expression with age reduces the metabolism of β-amyloid, perhaps contributing to the accumulation of undegraded β-amyloid in senile plaques and eventually to the symptoms of dementia.

In Huntington's disease, an autosomal dominant condition characterized particularly by the degeneration of the majority of output cells (medium spiny neurons) from the caudate putamen (a region particularly involved in movement control), tissue studies of the brains of affected individuals established that the somatostatin/NPY/nNOS-containing interneurons of the caudate putamen are relatively preserved. It is not known why these cells are relatively resistant to damage, but a possible explanation may include a reduced sensitivity to the excitotoxic effects of the transmitter glutamate or the expression of protective proteins such as the Huntington-associated protein HAP1. Electrophysiological studies indicate that these striatal interneurons have distinct physiological properties with low threshold spikes (LTS) and occupy a position in the organization of the basal ganglia to provide feed-forward inhibition to output cells. It is becoming increasingly clear that each subpopulation of interneurons (see **Figure 3**) has distinct physiological properties selectively influencing output neurons. In Alzheimer's disease, the concentration of somatostatin peptide falls with the development of the characteristic hallmarks of this disease (the senile plaques and neuronal tangles), although the somatostatin-containing interneurons are not themselves the main targets for the primary pathology.

Paralleling the distribution of somatostatin immunoreactivity, somatostatin mRNA is also found in the forebrain in neurons, in excellent agreement with the earlier immunohistochemistry studies. Coexpression

Figure 3 A somatostatin-positive O-LM cell in the rat hippocampus: (a) cell firing pattern; (b) reconstruction of the neurobiotin-filled cell showing the soma and dendrites in red; (c) soma cut into two sections; (d) dendrite of another recorded O-LM cell. The cell is identified on the basis of the distribution of its processes, the expression of its molecules as detected by immunocytochemistry, and its firing pattern *in vivo*. Following recording, the cell was labeled by the juxtacellular method. As shown in (a), the cell fired rhythmically on the trough of θ oscillations, but was silent during sharp wave-associated ripples. In (b), the axon restricted to str. lm. (yellow) is shown only from two 65-μm thick sections. In (c), one section of the soma shows somatostatin and mGluR1α immunoreactivity; the other demonstrates weak parvalbumin immunoreactivity. In (d), the dendrite of the O-LM cell is decorated by highly mGluR7a-immunopositive terminals (yellow). Other distinct types of somatostatin-positive cells, such as the bistratified cell, express different molecules in addition to somatostatin, establish synapses on other parts of pyramidal cells, and release transmitters at times different from the O-LM cell O-LM, Oriens-lacunosum moleculare cell; a, alveus; PV, parvalbumin. mGluR, metabolic glutamate receptor; Som, somatostatin; st. lm., stratum lacunosum-moleculare; st. or., stratum oriens; st. py., stratum pyramidale; st. ra., stratum radiatum. Scalebars = (unit) 0.3 mV; (θ) 0.2 mV, 300 ms; (shape wave) 0.05 mV, 50 ms (a), 100 μm (b), 5 μm (c, d). Reproduced from Klausberger T, Magill PJ, Marton LF, et al. studies (detection of two mRNAs in one cell) indicate that many of the somatostatin mRNA-containing neurons are, as shown by earlier immunohistochemistry studies, GABAergic neurons expressing the mRNA for the GABA synthetic enzyme glutamate decarboxylase (Gad67). GABA can influence the release of somatostatin, and this may allow both feedback and feed-forward effects on neuronal firing. In the hippocampus, somatostatin and cortistatin neurons correspond to distinct groups of partially overlapping interneuronal populations which, like the interneurons in the striatum, can coordinate the activity of their output cells (pyramidal cells) in a temporally distinct and brain state-dependent manner (Figure 3).

Distribution of Somatostatin Receptors

Like somatostatin itself, the mRNAs for several of the somatostatin receptors are concentrated in the forebrain, especially in the cerebral cortex, hippocampus, and amygdala (Figure 4), where the respective receptor proteins are also concentrated. The variant sst_{2b} in the mouse is concentrated in the pons/medulla, with only small amounts of receptor mRNA being found in the cerebral cortex. In contrast to sst_1, sst_{2a} and sst_4 mRNAs are found in the Purkinje and cerebellar granule cell layers and in the motor neurons of the spinal cord. Although small amounts of sst_5 mRNA are found in the brain, it seems to be mainly a peripheral receptor found in the lymphoid cells, pituitary, pancreas, and stomach.

Physiological Roles of Somatostatin

Somatostatin's major role in regulating the release of GH is mediated by the neurons of the hypothalamic periventricular and paraventricular nuclei. Somatostatin exerts most of its effects indirectly by regulating the release of GHRH. Based on the distribution of receptors in this region, the major receptor subtypes likely to be involved in the response of the GHRH-containing neurons are sst_1 and sst_2, with perhaps some involvement of sst_4 in the arcuate nucleus. Somatostatin can, of course, also act directly on receptors on the somatotrophs.

In the CNS, somatostatin and its receptors are important modulators of neuronal excitability, in which they influence GABA and acetylcholine release. Electrophysiological studies indicated somatostatin can inhibit neuronal Ca^{2+} currents, modulate inwardly rectifying K^+ currents, and depress excitatory postsynaptic glutamate currents. The ability of somatostatin to inhibit Ca^{2+} currents was one of the first electrophysiological effects observed for the peptide and is mediated through a PTX-sensitive receptor, indicating coupling to G_i or G_o. The most prominent electrophysiological effect of somatostatin, and also cortistatin, is probably due to the sst_2 receptor inducing a G-protein-coupled inwardly rectifying K^+ current, a response which leads eventually to the inhibition of neuronal firing. Likewise, the ability of somatostatin or its analogs to depress glutamatergic excitatory postsynaptic potentials (EPSPs) also reduces neuronal

Figure 4 X-ray autoradiograms of hybridized coronal sections of the rat forebrain at the septal level: (a) somatostatin (SOM) mRNA expressed by scattered neurons throughout the forebrain; (b) sst_2 mRNA as detected by hybridization with a probe directed against the entire coding region; (c) sst_1 mRNA highly expressed in the supra- and infragranular layers of the cortex and in the area of the diagonal band (DB); (d) sst_4 mRNA highly expressed in the cortex and striatum (CPu); (e) cortistatin (CST) mRNA expressed selectively in cortex; (f) sst_2 mRNA as detected by hybridization with a sst_{2a}-selective probe directed against the entire coding region; (g) representative image showing control hybridization with a sst_1 sense probe; (h) specific labeling not detected after hybridization with a probe for sst_5 mRNA. In (b) and (f), sst_2 mRNA is expressed at high level in infragranular layers in the cortex and in the area of the lateral septum (LS). Scale bar = 3 mm (h). (2004) Somatostatin receptor 2 is activated in cortical neurons and contributes to neurodegeneration after focal ischemia. *Journal of Neuroscience* 24(50): 11404–11415, with permission of the Society for Neuroscience.

Figure 5 Localization of β-galactosidase staining in a sst_2 knockout–knock-in mouse: (a) cerebral cortex (CX) and corpus callosum (CC); (b) caudate putamen (CP). In the sst_2 knockout–knock-in mouse, the expression of the sst_2 (SSTR2) receptor has been replaced by the bacterial reporter gene LacZ or β-galactosidase. In (a), note the strong blue staining of neurons in the CX and blue β-galactosidase fibers running in the CC. In (b), immunohistochemical staining for the cholinergic marker enzyme choline acetyltransferase (brown peroxidase reaction) shows that some cholinergic neurons contain β-galactosidase (blue) positive inclusions, indicating that some of these CP neurons express the sst_2 receptor.

firing and has a general anticonvulsant and antiepileptic effect. The localization of somatostatin-containing neurons and receptors points to possible roles in epilepsy, motor-behavior cognition, and analgesia. Individual knockout mice in which the receptor or the peptide has been knocked out by homologous recombination in general produce evidence for these three broad physiological roles for somatostatin. For example, somatostatin-deficient mice were more vulnerable to kainic acid (an excitatory toxin) and had impaired motor learning, whereas mice with the sst_2 receptor knocked out were less susceptible to seizures but so far have not been investigated for their pain thresholds. Although anatomical studies indicate that the sst_2 receptor is likely to be the receptor involved in nociceptive transmission in the spinal cord, our study of our sst_2 knockout mice indicated an impairment in fine motor control mediated, probably, through cortical inputs to the striatum (Figure 5). The sst2 knockout mice that we used had a reporter bacterial enzyme β-galactosidase (LacZ) inserted, or knocked in, to replace the missing sst_2 receptor protein so that the enzyme activity of β-galactosidase revealed on the tissue section (LacZ) reports the sites of expression of the missing receptor (Figure 5). It is clear, however, that compensatory changes often occur in knockout mice and that the lack of an obvious phenotype for the various knockout mice indicates, as might be expected, that the diverse function of somatostatin makes the clear assignment of roles for receptor types difficult. It is to be hoped that regional and inducible knockouts, as well as other genetic techniques such as the use of short hairpin (Sh) or small interfering (Si) RNA to selectively disturb regional receptor expression, may enable the physiological roles of somatostatin, cortistatin, and their receptors to be further defined.

Summary

Somatostatin, or SRIF, is a cyclic peptide which inhibits the release of GH from the pituitary. Apart from its effects in the pituitary, somatostatin is found in a number of neurons in the CNS, where it may act as a neurotransmitter/neuromodulator. Peptides related to somatostatin include cortistatin (found principally in the forebrain) and the fish peptide UII. Somatostatin and cortistatin exert their effects in the CNS through G-protein-coupled receptors, of which five ($sstr_{1-5}$) have been cloned and localized in the CNS (although $sstr_5$ is found only in a small amount in the CNS). Outside the CNS, somatostatin is found in endocrine cells of the pancreas and in the intestine, where it is also found in neurons of the enteric nervous system. Somatostatin's effects are broadly inhibitory and a number of stable analogs have been developed to treat acromegaly and endocrine tumors; these may also be of value as analgesics or in treating neurological disease such as epilepsy and stroke.

Ventralization of Naive Neural Epithelium by Signals from the Notochord and Prechordal Plate

During early development, the neural tube starts out as an epithelial sheet, the neural plate. At this early stage of development, cells in the neural plate epithelium are largely identical. Over time, this epithelial sheet rounds up to form the neural tube, and differentiated neural cells appear at stereotypic times and positions. Classic transplantation experiments have shown that the nature of the differentiated cells arising from the neural tube is dependent on molecular cues in the environment that are initially released by tissues surrounding the neural tube. In particular, the ectoderm overlying the neural tube at its dorsal aspect and the notochord located below its ventral aspect are prime sources of dorsalizing and ventralizing signals, respectively, for cells in the neural tube (Figure 1).

The notochord is a direct derivative of the node and is, like the node, an important signaling center in the developing embryo, both for the adjacent somites and for the overlying neural tissue. Transplantation of a notochord to a position dorsal to the neural tube causes a mirror image duplication of the ventral half of the neural tube, indicating that signals derived from the notochord are responsible for the induction of ventral cell types in the neural tube. The principal mediator of the inductive properties of the notochord is the signaling molecule Sonic hedgehog (Shh). Similarly, ectodermal explants can induce dorsal cell types in neural plate tissue, and it appears that most of the dorsalizing signals released by the ectoderm are members of the bone morphogenetic protein (BMP) family of signaling molecules.

Superimposed on the signals mediating the dorsal–ventral pattern are signals that mediate positional information along the anterior–posterior axis, restricting the subsequent development of the neural plate to unique identities, such as forebrain, midbrain, hindbrain, and spinal cord. Shh plays an important role in patterning of the neural tube, and at least early in development, but its main function is the induction of ventral cell types in the developing neural tube. The absence of Shh has little effect on patterning along the anterior–posterior axis, indicating that other signals are involved in inducing differentiation along that axis.

Shh Patterns the Developing Spinal Cord

The role of Shh in neural tube patterning has been most extensively studied in the developing spinal cord since this structure represents the simplest and best understood part of the central nervous system. In the spinal cord, it has become obvious that the role of Shh extends well beyond the induction of motor neurons.

In the ventral–medial aspect of the spinal cord, distinct cell types can be recognized. At the ventral midline is the floor plate, which itself starts expressing Shh. At increasing distances from the floor plate, five distinct groups of neurons can be identified: V3 interneurons, motor neurons, and V2, V1, and V0 interneurons. The ventral neural tube is subdivided into five progenitor domains by the combinatorial expression patterns of at least seven distinct homeodomain proteins. These progenitor domains generate the five ventral neuronal subtypes – V0–V3 interneurons and motor neurons. The homeodomain proteins that mediate this code are divided into class I and class II homeodomain proteins. The class I factors are induced by BMP signals originating from the dorsal neural tube, and the class II homeodomain proteins are induced by Shh. Different thresholds of induction of the class I and class II homeodomain proteins, combined with the mutual antagonism of pairs of these proteins, result in precise domains in the ventral neural tube characterized by stereotypic combinations of class I and class II homeodomain proteins. The combinations of class I and class II homeodomain proteins determine the type of neurons into which these precursor cells will differentiate (Figure 2).

The loss of the Shh gene in mice causes a severe embryonic lethal phenotype characterized in the neural tube by the almost complete absence of ventral cell types, resulting in a ventral expansion of intermediate/dorsal cell types to all positions in the neural tube (Figure 2). This loss of ventral cell types is evident along the entire anterior–posterior axis of the embryo. In the developing spinal cord, the loss of Shh results in the failure of all ventral cell types to form in the developing neural tube. The loss of multiple cells types, as a consequence of the absence of a single signaling molecule, supported the idea that Shh is present as an activity gradient away from its source, which is instrumental in the induction of pattern along the dorsal–ventral axis of the developing neural tube.

Shh Is a Morphogen

Immediately after its induction from the ectoderm, the neural epithelium is homogeneous without overt

Figure 1 Neurulation diagram. The neural plate receives ventralizing signals from the notochord (NC) and dorsalizing signals from the adjacent/overlying ectoderm (Ect). Shh derived from the Notchord and floor plate (FP) is distributed in a ventral-to-dorsal gradient, and BMP activity derived from the ectoderm and dorsal neural tube is distributed in a dorsal-to-ventral gradient.

dorsal or ventral cell differentiation. Shh released from the notochord causes stereotypical changes in the overlying neural epithelium (Figure 3). At the position where the notochord is in direct contact with the neural plate, the floor plate is induced. The floor plate is a nonneuronal structure in the ventral midline of the neural tube which concomitant with its induction also begins to express Shh (Figure 4). At longer distances from the notochord and floor plate, motor neurons and interneurons are induced (Figures 2 and 4). Importantly, all these inductive events are mediated by Shh and not secondary signals induced by Shh. The explanation by which Shh can induce several distinct cell types is deceptively simple: Close to the sources (notochord and floor plate), cells in the neural epithelium are exposed to a high concentration of Shh, and this concentration gradually declines further away from the source due to limited transport and the presence of local 'sinks,' places where Shh is degraded (Figure 3). The resulting ventral-to-dorsal concentration gradient of Shh is interpreted by the cells in the neural epithelium such that cells exposed to a high concentration of Shh differentiate in floor plate cells and cells exposed to intermediate concentrations differentiate into motor neurons, whereas dorsal to the motor neurons, cells differentiate into interneurons in response to low levels of Shh.

Experimental support for this model came from experiments using explants from the neural plate in tissue culture. In these explants, all ventral cell types could be induced using increasing concentrations of a soluble form of Shh, ShhNp. Very high concentrations (>10 nM) resulted in the induction of floor plate cells. At decreasing ShhNp concentration thresholds, the predominant differentiation in the neural tube explants was V3 interneurons, motor neurons, and V2–V0 interneurons. The latter cell types require a Shh concentration less than 1 nM.

Although this morphogen model provides a reasonable explanation of how a single inducer can cause a stereotypic pattern in a bilaterally symmetrical way with columns of specific cells running parallel to the floor plate, a complication is caused by the physical properties of Shh since its mature form has two lipophilic modifications. First, an autocatalytic proteolysis necessary to yield an active N-terminal Shh peptide (ShhNp) results in the addition of a cholesterol moiety to the C-terminus of ShhNp. Second, an acyltransferase facilitates the addition of a palmitic acid. These two lipophilic moieties cause Shh to be associated with membranes. This membrane association is not easily reconciled with the free diffusion thought to be critical in creating a morphogenic gradient. Two models have been put forward to explain how ShhNp exerts its action at multiple cell diameters away from the source. One model proposes the formation of ShhNp of soluble multimers that diffuse through the extracellular space. The second model proposes an active mechanism whereby membrane-associated ShhNp is actively transported from cell to cell – a mechanism termed planar transcytosis (Figure 5).

The membrane association of Shh requires the existence of a regulated mechanism of export. Dispatched (Disp) is a transmembrane protein that contains a sterol-sensing domain and its expression is required in cells synthesizing the sterol-modified Shh but not necessary for the secretion of a form of Shh lacking the sterol conjugation. *Disp1* null mice resemble *Shh* null mice, indicating that Disp1 is required for proper Shh signaling. Since *Disp1* null cells are equally sensitive to a mutant form of Shh that is not membrane

Figure 2 Diagram of class I/class II expression domains and the corresponding regions of ventral neuronal differentiation. A gradient of Shh signaling in the ventral spinal cord activates expression of class II progenitor proteins such as Nkx2.2 and Nkx6.1 while repressing expression of class I progenitor proteins such as Pax7, Pax6, Dbx1, Dbx2, and Irx3 (a). A gradient of BMP activity from the dorsal spinal cord is also able to alter the expression of progenitor proteins such as Pax6 and Pax7. Mutually repressive interactions between class I and class II proteins result in defined boundaries of protein expression, and the ensuing expression pattern of progenitor proteins within discrete regions establishes domains of neuronal differentiation. For example, the expression of Dbx2, Irx3, and Pax6, but not Dbx1, gives rise to the V1 progenitor domain (pV1) from which V1 interneurons (V1) differentiate. Differentiation of ventral neurons along the dorsoventral axis is marked by expression of Engrailed1 (En1) in V1 interneurons. *gli1*$^{-/-}$ mice have phenotypically wild-type spinal cords (b), whereas loss of *gli2* results in a loss of floor plate (FP) and most V3 interneurons (c). *gli3*$^{-/-}$ mice have a mild spinal cord phenotype with a dorsal expansion and intermingling of V0–V2 interneurons (d). Deletion of *shh* results in a loss of most ventral cell types (e), most of which are restored upon additional removal of *gli3* (*shh*$^{-/-}$; *gli3*$^{-/-}$) (f). This suggests that much of the *shh*$^{-/-}$ spinal cord phenotype is mediated by Gli3. MN, motor neurons.

Figure 3 Diagram of morphogen action. Shh released from the notochord (purple) establishes a gradient along the neural plate. The local gradient is interpreted by cells in the neural plate which undergoes a bilaterally symmetric differentiation. In the absence of a notochord or Shh signaling, ventral cell types are not indicated (X).

bound, it has been postulated that Disp1 only plays a role in the cells that produce Shh, possibly mediating the release of Shh multimers from Shh source cells. It remains a possibility that Disp1 also plays this role in cells that have internalized Shh as part of their response. Disp1 could be an integral part of the planar transcytosis pathway by facilitating the export of Shh of cells that have taken it up and making Shh available to neighboring cells.

Shaping the Shh Gradient

Regardless of whether Shh travels from cell to cell or diffuses long distances, it interacts with components in the extracellular space and these molecules can shape the Shh gradient (Figure 4). Known molecules that bind Shh in the extracellular space are Patched1 (Ptc1, a part of the Shh receptor complex), Scube2, Hhip, the related molecules CDO and BOC, and HSPGs (Figure 6).

Figure 4 Shh and motor neuron distribution in the developing spinal cord. Cross-section of an embryonic chicken spinal cord, with the ventral/medial aspect shown. Significant amounts of Shh are present in its sites of synthesis, the floor plate (FP) and notochord (NC), but detectible levels of Shh are present in the ventral neural tube in the domain where motor neurons (MN) are differentiating.

Ptc1 plays a particularly interesting role in the distribution of Shh. Ptc1 binds Shh and regulates the activation of the Shh response. However, this binding also results in trafficking of the Ptc1/Shh complex to endosomes and lysosomes, providing a 'sink' for Shh. This role of Ptc1 in sharpening the Shh gradient is exacerbated by the observation that Ptc1 expression is upregulated by the Shh response, increasing the sink effect on the Shh gradient. CDO and BOC are transmembrane, cadherin-associated immunoglobulin superfamily members that bind Shh and are required for the presentation of Shh to Ptc1 and thus for initiating the Shh response. The range of Shh signaling is increased in mice that lack the feedback activities of Ptc1 and also when Hhip (hedgehog interacting protein) is absent. Thus, a Shh-dependent antagonism, mediated by Ptc1 and Hhip, is critical for normal dorsal–ventral development of the neural tube. In contrast, the loss of Scube2, a molecule present in the extracellular space of the neural plate, decreases the efficacy of Shh signaling. However, it is unclear whether scube2 acts by inhibiting the activity of BMPs, and thus reducing the activity of this Shh antagonist, or alternatively by enhancing the range of Shh signaling, possibly by binding to Shh resulting in a complex that is easier to transport in the extracellular space.

A rather complex picture arises with regard to the forms of Shh present in the extracellular space, where there appear to be multiple distinct molecules around molecules that bind to Shh and they are required either for a normal response or for normal distribution. Given that due to its lipophilic modifications, Shh is a nonsoluble molecule that nevertheless travels considerable distances, it is not surprising that many molecules are involved in this process. The nature of the complexes or multimers of Shh that travel from cell to cell remains obscure.

The Shh Response

The Shh receptor complex consists of at least two proteins, Ptc1 and Smo. Ptc1 is a large protein with 12 transmembrane segments sharing structural similarity with Disp1, whereas Smo may be an atypical member of the G-protein-coupled receptor family. Ptc1 is the ligand-binding component and in the absence of Shh it inhibits Smo activity, which is the signaling component that activates the Shh response pathway (Figure 6). Smo is constitutively active in *Ptc1*-deficient cells, and in *Ptc1*-deficient embryos the whole neural tube resembles the floor plate. Although the precise mechanism by which Ptc1 inhibits Smo is unknown, there is evidence that Ptc1 functions as a pump of small, vitamin D-like molecules that inhibit Smo. Consistent with this is the Shh-induced trafficking event culminating in the segregation of Smo into an endocytic compartment not containing Ptc1, which is a critical event in the initiation of the Shh response. Most likely, this process involves the function of intraflagellar transport proteins, indicating that transport along microtubules is an integral part of the Shh response. When segregated away from the inhibitory effect of Ptc1, Smo activates the Shh response likely via an inhibitory G-protein.

Inside the responding cells, three Gli proteins (Gli1–3) which are zinc finger-containing transcription factors, are the transcriptional effectors of the Shh response. In the absence of Shh signaling, Gli2 and Gli3 are proteolytically processed into repressors of Shh target genes. A protein complex that includes SuFu tags Gli3 for cleavage at a proteosome (Figure 6). An early event in the transduction of the Shh response involves the phosphorylation of this multiprotein complex within 15–30 min after Shh binding. These phosphorylation events result in the inhibition of Gli2 and Gli3 cleavage, and thus more of the activator forms of Gli2 and Gli3 are present at the expense of the cleaved inhibitor forms. The vast majority, if not all, of the effects of Shh signaling are mediated by Gli2 and Gli3. A simple model emerges of how cells interpret the Shh activity gradient. In the absence of Shh, all Gli3 is converted into the repressor

Figure 5 Models of Shh transport mechanisms. The two fundamental mechanisms are diffusion and planar transcytosis. The pathways have in common that Shh is released from the source by Disp1. The first pathway would involve the diffusion of a multimeric, soluble form of Shh across the developing neural epithelium. The second pathway evokes the activity of Ptc1 and Disp1 to create a 'bucket brigade' for Shh, effectively handing over internalized Shh to neighboring cells, which do the same.

form, and with increasing levels of Smo activation, the ratio of Gli2 and Gli3 activator forms over the Gli3 repressor form increases in a graded manner, reflecting the Shh morphogenetic gradient.

The phenotypes in the spinal cord caused by the loss of Gli2 and Gli3 are relatively mild (Figure 2). In the absence of Gli2, the floor plate and adjacent cells fail to form, but motor neurons are present, although their domain spans the ventral midline. The loss of Gli3 has no significant effect in the developing spinal cord, although an expansion of ventral cell types can be observed in the developing brain. These relatively minor effects might seem difficult to reconcile with the dramatic phenotype observed in the *Shh* null mice. However, Shh signaling would have two independent effects on Gli activation: The ventral-to-dorsal Shh gradient would establish a ventral-to-dorsal gradient of activated Gli2 as well as a dorsal-to-ventral gradient of Gli3 repressor activity. This would result in a somewhat redundant situation in which loss of either gene causes a much milder phenotype than the loss of Shh or Smo. However, the opposing gradients of activated Gli2 and the Gli3 repressor form are required for normal dorsal–ventral patterning in the neural tube.

Is Shh Required for Neural Tube Patterning?

The severity of the phenotype caused by Smo and Shh loss-of-function phenotype makes a compelling argument that Shh is critically important for the induction

Figure 6 Diagram of Shh synthesis, posttranslational modification, export, and response. Normal processing of full-length Shh results in a molecule with N-terminal palmitic acid and a C-terminal cholesterol moiety. Disp1 is involved in the excretion of Shh. On the recipient cell, Hhip prevents binding to the receptor, whereas CDO/Boc are required for presentation of Shh to Ptc1. In the absence of hedgehog, Patched represses the activity of Smo. Gli3 is cleaved and converted to a repressor in a process that involves SuFu and scaffold proteins. The Patch-mediated inhibition of Smo is released upon binding of Shh to Patched. Gli3 is converted to a transcriptional activator and activates the transcription of hedgehog responsive genes.

of ventral cell types in the neural tube. However, in the absence of Shh signaling, some of the loss of ventral cell types can be rescued when Gli3 is also absent. This is consistent with the repressor activity mediated by Gli3 in the absence of an activated Shh response (Figure 2). In other words, the loss of Shh signaling can be partially overcome by removing the main repressor of the Shh response as well. In the absence of an activated Shh response and addition of Gli3 repressor activity, some ventral neurons such as motor neurons differentiate in the developing spinal cord. This demonstrates that the repressor activity of Gli3 is almost single-handedly responsible for the phenotype observed in the Shh or Smo null mice. Although the most ventral cell types, such as floor plate and V3 interneurons, are not present in such mice, other ventral cell types do appear, although not in the distinct dorsoventral domains characteristic for normal embryos. Nevertheless, this indicates that Shh-independent positional signals are present in the neural tube, and likely candidates for this activity are members of the BMP family, which are expressed in the dorsal neural tube and are predicted to be distributed in the neural tube in a dorsal-to-ventral gradient. It thus appears that although the Shh signaling system is not required for the formation of most

ventral cell types in the neural tube, the precise segregation of the differentiated cells into specific domains required the graded Shh signal.

During normal development of the neural tube, dorsally derived BMP signals antagonize the Shh response and vice versa. Activation of the BMP response is sufficient to induce dorsal cell types, whereas activation of the Shh response induces ventral cell types. Together, these overlapping and antagonistic gradients ensure a very robust mechanism that mediates dorsal–ventral patterning in the neural tube.

Shh and Patterning of the Brain

The forebrain (prosencephalon) is the most anterior aspect of the neural tube, and it is divided by the zona limitans intrathalamica into anterior and posterior parts. The prechordal plate is the rostral-most extension of the notochord, and it is located ventral to the anterior forebrain. The importance of the prechordal plate was already appreciated more than 70 years ago, when ablation experiments showed that the loss of the prechordal plate causes cyclopia, a disorder in which instead of two bilateral eyes, a single midline eye is present, as well as an array of associated malformations such as a single, undivided cerebral hemisphere (holoprosencephaly). The midline eye presents a barrier for the migration of the frontonasal process into its appropriate position to form the nose, philtrum, incisors, and part of the palate. Instead, this tissue accumulates in a proboscis–like structure above the single midline eye. The single midline eye is a consequence of the failure of the formation of ventral midline tissue in the anterior forebrain, which normally separates the eye fields into two bilateral domains. Homozygous loss of Shh causes cyclopia as well, indicating that much of the ventralizing activity of the prechordal plate is mediated via the Shh response pathway. As in the spinal cord, in the absence of Shh signaling the ventral forebrain acquires a more lateral phenotype.

Cyclopia is invariably associated with holoprosencephaly, a condition characterized by a single undivided cerebral hemisphere. However, holoprosencephaly is a much more developmental abnormality. Nevertheless, a principal cause of holoprosencephaly is an absent or attenuated Shh response. In line with the morphogenetic function of Shh, an attenuated Shh response can result in some loss of ventral structures, reflected in the face by malformations such as a single midline incisor, the absence of the nasal septum, and hypotelorism (closely spaced eyes). Holoprosencephaly is highly associated with these birth defects. It is unclear why the failure of the ventralizing activities of Shh to function normally is so closely correlated with holoprosencephaly, which involves the dorsal midline of the telencephalon, seemingly far away from the sources of Shh. In the ventral forebrain, prechordal plate and notochord are required for the induction of the hypothalamus, which is involved in many of the homeostatic functions of the organism.

Notochord-derived Shh also induces ventral structures in the midbrain, the tegmentum. Importantly, the ventral tegmentum is where dopaminergic neurons are localized in the substantia nigra. These neurons are preferentially lost in Parkinson's disease. Obviously, much research is being directed to recreate dopaminergic neurons *in vitro*, and invariably these approaches rely on the activation of the Shh response to generate such neurons from stem cells.

The third cranial (oculomotor) nerve also emerges from the ventral midbrain, and the motor neurons innervating the muscles that move the eyes are located in nuclei just ventral to the cerebral aqueduct. The oculomotor nuclei contain the most rostrally located motor neurons that connect to striated, voluntary muscles. Caudal to the oculomotor nuclei are a series of nuclei in the midbrain and hindbrain, which contain the motor neurons innervating the muscles in the face and neck, all of which require notochord and floor plate-derived Shh for their induction.

Small Molecule Inhibitors of Smo

More than a decade of research has demonstrated that Shh is critical for the formation of ventral cell types in the developing neural tube, and the nature of these ventral cell types is dependent on the position along the anterior–posterior axis. At any position along this axis, Shh functions as a morphogen and as such is responsible for the induction of a variety of cell types. However, because the loss of Shh signaling either through the loss of the ligand or through the loss of Smo causes the embryos to die before birth, not much is known about many of the later events mediated by Shh in neural development since this analysis requires the generation of multiple conditional knockouts.

An alternative approach has been made possible with the use of small molecule inhibitors of Smo, such as cyclopamine. Due to its ability to cause cyclopia in offspring of ruminants, this compound, which was isolated from *Veratrum californicum*, has served as a lead compound in the identification of several inhibitors of Smo. These molecules are used to address the requirement for Shh signaling at later stages of neural development as well as in normal function of neural stem cells.

Sound Localization: Neural Mechanisms

D J Tollin, University of Colorado at Denver and Health Sciences Center, Aurora, CO, USA

Auditory guided behavior depends on the ability of the nervous system to construct an accurate representation of the sounds in the environment. Toward this end, there are two primary functions of the auditory system. The first function is to determine what it was in the environment that produced a sound. The second function is to determine where in space the sound occurred. Knowledge of both the spatial position of a sound's source and what produced it facilitates the initiation of an appropriate behavioral response. For example, a predator like the cat might move toward the sound produced by a mouse rustling in the leaves while the mouse might freeze or move away from the sounds of the approaching cat.

The ability to locate sensory stimuli is not unique to the auditory system as it is also shared by the visual and somatosensory systems. The locations of visual and tactile objects are encoded directly in these systems due to the topographic, spatial organization of the receptors, the rods and cones of the retina, and the mechano-receptors of the skin, respectively. In contrast, in the auditory system, the hair cells of the cochlea are designed to encode sound frequency and intensity and cannot sense sound location directly. Therefore, sound location must be computed centrally in the auditory system based on the neural representations of the spectral and temporal characteristics of the acoustic stimuli arriving at the two ears.

In order to understand the neural mechanisms of sound location we first have to identify the acoustic information bearing elements of the sounds arriving at the two ears that specify location. There are three primary acoustical characteristics of sounds, or cues, which are used to determine the spatial position of a sound source. These acoustical cues are physically different because they are created by different ways that the propagating sound waveforms interact with the head and external ear. The fact that there are three distinct cues naturally suggests that three different kinds of neural mechanisms are needed to encode them. Indeed, the cues are encoded in anatomically separate, but parallel, pathways in the ascending auditory system. The evidence that each cue is encoded in a different pathway comes from experimental data from disparate scientific disciplines including neurophysiology, behavioral psychology, and comparative neuroanatomy.

Three Main Acoustical Cues to Sound Source Location

The acoustical cues for sound localization are generated by the interaction of the propagating sound waves with the anatomical structures supporting the receptors of the ear, namely the head and the external ear (or pinnae), and not by the topographic organization of the receptors themselves. Examples of the three cues are shown in Figure 1. Two of the cues, interaural time delays (ITDs) and interaural level differences (ILDs), result directly from the fact that the two ears themselves are sampling the sound waves at different locations due to their positions on opposite sides of the head. These two cues specify primarily sound location in azimuth. The third cue, spectral-shape, results from the way that the sound waves are distorted or filtered by the complicated convolutions and folds of the pinna. Spectral shape cues specify primarily sound location in elevation, and whether a sound is in the front of or behind the observer. Interpretation of the roles of the various auditory nuclei that process the sound localization cues requires knowledge of what the cues are and how those cues change with changes in source location.

Interaural Time Delays

ITDs result because the ears are physically separated in space by the head. Therefore, the direction-dependent differences in path lengths that sound must travel to reach each ear from the source will generate different times of arrival of the sound at the two ears, or ITDs (Figure 1(b)). For example, a sound on the right side will arrive at the right ear a short time before it arrives at the left ear, while a sound from directly ahead will arrive at the ears at the same time. The range of ITDs is directly proportional to head diameter so species with larger heads, hence larger distances between the two ears, exhibit a larger range of ITDs. For example, in cats, which have head diameters of 6–7 cm, ITDs increase monotonically with azimuth along the horizontal plane up to a maximum of 350–400 μs (Figure 1(d)). The diameter of the human head is nearly twice that of the cat, on the order of 15 cm. Consequently, the maximum ITD in humans is ~800 μs. Yet smaller mammals, like some species of bats and rodents, have head diameters <1 cm, resulting in maximum ITDs as small as 40 μs. Such small ITDs are not thought to be useful for accurate sound localization.

Interaural Level Differences

The fact that the two ears are separated by an obstacle, the head, results in the ILD cue to sound location.

Figure 1 The acoustical cues to sound location. In the example, the cues are shown for the cat, but the same three cues are available in all species, although the magnitude of the cues will be different. (a) A broadband transient sound is presented from a loudspeaker at (40°, 0°). (b) The resulting acoustical responses to the transient near the eardrums in the left and right ears. The difference in the onset times of the sounds at each ear yields the interaural time difference (ITD) cue and difference in amplitudes reflect the interaural level difference (ILD) cue. (c) The frequency spectrum of the acoustical responses in (b). The spectral shape cues are captured by the changes in the shapes of the spectra as a function of source location. The ILD cue is the difference in sound level computed at each frequency. (d) The ITD plotted as a function of sound source azimuth. ITDs are minimal near the midline and maximal for sources to either side. (e) The joint spatial and frequency dependence of ILDs for sources varying along the horizontal plane. ILDs are a complicated function of azimuth and frequency for high stimulus frequencies. For illustrative purposes, sources were restricted to the horizontal plane and only in the frontal hemisphere for frequencies between 1 and 25 kHz.

For sounds of high frequency (or short wavelength), the head essentially creates an acoustic shadow for the far ear as sounds with wavelengths on the order of the diameter of the head and smaller are reflected off the near side of the head. Consequently, the resulting sound arriving at the ear farthest from the source is effectively attenuated thereby creating direction-dependent differences in the amplitudes, or levels, of the sounds that reach the two ears (Figure 1(c)). The sound level is greatest at the ear nearest the source, and lower in the ear farthest from the source. The ILD cue is a rather complicated function of both sound location and, at any one location, sound frequency (Figure 1(e)). As expected, ILDs are small in magnitude for low-frequency sounds and increase in magnitude for high-frequency sounds (Figure 1(e)). Therefore, ILDs are primarily useful for localization of high frequencies. ILDs that are large enough to be useful for sound

localization are available even in mammals with small heads provided that the sound source contains high frequencies with wavelengths shorter than the head diameter.

Monaural Spectral Shape

The ITD and ILD cues are not useful for sound localization in elevation because their values change little with variations in source elevation. The monaural spectral shape cues, however, do change systematically with source elevation. Spectral shape cues arise from direction- and frequency-dependent reflection and diffraction of the pressure waveforms of sounds by the head, torso, and pinna that result in broadband spectral patterns, or shapes, that change with location. The most prominent direction-dependent features in the spectra are the deep notches that occur at some locations (e.g., 5.5 and 9.5 kHz for the right and left ear, respectively, in Figure 1(c)). These spectral notch cues are used both for localization in elevation as well as facilitating the distinction between sound sources in front from sound sources behind of an observer. Spectral cues are created primarily for high-frequency sounds whose wavelengths are on the order of the dimensions of the pinna and its convolutions. The frequency at which the spectral notch occurs varies systematically with sound source elevation, with lower elevations yielding low-frequency notches and higher elevations yielding progressively high-frequency notches.

Neural Processing of Localization Cues in Three Parallel Pathways

For these three acoustical cues to location to be useful for spatial perception, there must be neural mechanisms in the ascending auditory pathways that effectively encodes each of them. Each of the three different cues is encoded in different areas of the auditory brain stem (Figures 2–4). That is, there are three parallel pathways through the brain stem that appear to encode separately the ITD, ILD, and spectral cues. Neurons in these pathways are the earliest places in the ascending auditory pathways to respond selectively to each of the three cues.

ITDs Are Processed in the Medial Superior Olive

The neurons comprising the medial superior olive (MSO) receive excitatory inputs from both ears via the bushy cells of the anteroventral cochlear nucleus (AVCN) on both sides (Figure 2(a)). The bushy cells of both sides receive excitatory inputs from the cochlea via the auditory nerve fibers (ANFs) via specialized synaptic terminals called Endbulbs of Held. The AVCN is organized tonotopically. Most MSO neurons are sensitive to ITDs in sounds presented to the two ears. ITD sensitivity in MSO results from a three-stage process as first hypothesized by a model proposed by Jeffress. First, the afferent inputs to MSO neurons from the ANFs and from the bushy cells of the AVCN carry timing information in the form of phase-locked neural responses. Phase locking refers to the tendency of a neuron to fire action potentials at particular phases of an ongoing periodic sound waveform, such as the sinusoidal waveforms that are typically used in physiological studies of the auditory system. Phase locking is the mechanism by which the peripheral auditory system keeps track of the times of occurrence of the ongoing amplitude fluctuations in sounds. Second, the MSO neurons behave like coincidence detectors, responding maximally only when action potentials from the SBC inputs from the left ear and the right ear arrive nearly simultaneously at the MSO neuron. Third, the axons of the afferent inputs to MSO from the bushy cells form delay lines along one axis of the nucleus due to differences in the neural path length from the bushy cells to the MSO neuron. Differences in neural path length result in differences in neural conduction times to the MSO which are then offset by a physical ITD cue. Since the projections to the contralateral MSO have a naturally longer path length than those to the ipsilateral MSO, most MSO neurons primarily encode ITDs produced by sounds on the contralateral side where the ITD can compensate for the longer conduction time from the contralateral ear (Figure 2(b)). In addition, different MSO neurons have different length delay-line inputs, so different MSO neurons will be maximally sensitive to different ITD values. Moreover, MSO neurons have a bias toward low-frequency sounds, as most MSO neurons are sensitive to predominantly low sound frequencies. Phase locking is best for neurons sensitive to low-frequency sounds. Behaviorally, ITDs are most useful for localization for low-frequency sounds. Most MSO neurons send excitatory afferents to the ipsilateral dorsal nucleus of the lateral lemniscus (DNLL) and the ipsilateral central nucleus of the inferior colliculus (ICC). As a consequence, low-frequency sensitive neurons in the DNLL and IC encode the ITDs of sounds primarily on the contralateral side.

In recent years the Jeffress model has been challenged on several grounds, chiefly by the finding that the MSO also receives inhibitory input from both sides. Current research efforts are aimed at understanding the role of this inhibition and what modifications to the simple model are needed.

Figure 2 Illustration of a frontal section through the auditory brain stem showing the ascending pathways through the medial superior olive (MSO), which is believed to be responsible for encoding interaural time differences (ITDs). (a) MSO neurons receive bilateral excitatory inputs from both ears via the bushy cells (BC) of the anteroventral cochlear nucleus (AVCN). The bushy cells receive inputs from the auditory nerve fibers (ANFs). The AVCN and the MSO are tonotopically organized. The MSO is biased toward low-frequency sensitive neurons. The color bar and shading indicates, very roughly, the tonotopic organization and the approximate ranges of frequencies that the neurons in each nuclei are sensitive to in the cat. MSO neurons send an excitatory projection to the ipsilateral inferior colliculus (IC) and dorsal nucleus of the lateral lemniscus (DNLL). Open and closed symbols represent excitatory and inhibitory neurons and synapses, respectively. Also shown are the posteroventral cochlear nucleus (PVCN), the dorsal cochlear nucleus (DCN), the medial nucleus of the trapezoid body (MNTB), and the lateral superior olive (LSO). (b) MSO neurons encode ITDs in their response rates. Peak responses are usually found when the contralateral stimulus leads by 0–500 μs.

ILDs Are Processed in the Lateral Superior Olive

Lateral superior olive (LSO) neurons also receive afferent inputs from both ears (Figure 3(a)). The input from the ipsilateral ear is conveyed via auditory nerve synapses with the bushy cells of the AVCN, which then send an excitatory projection to the ipsilateral LSO. The afferent input from the contralateral ear also comes from bushy cells of the AVCN but in this case the bushy cells project across the midline to the neurons of the medial nucleus of the trapezoid body (MNTB). The bushy cell synapse onto MNTB neurons forms the massive calyx of Held; the large size of this unique synapse results in very fast and secure synaptic transmission. MNTB neurons are glycinergic, so their projection to the LSO has an inhibitory effect. In contrast to the MSO, both the MNTB and the LSO are biased predominantly to neurons that are sensitive to high sound frequencies where the ILD cues themselves are prominent. Because of the interplay of the ipsilateral excitation from the bushy cells and contralateral inhibition from the MNTB, LSO neurons essentially compute the difference between the neural representation of the levels of the sounds present at the two ears. Hence, LSO neurons encode ILDs. The sound level at each ear is believed to be encoded by a rate code, in that the number of action potentials elicited over a given time period is proportional to the level of the sound at the ear. Because LSO neurons are excited by sounds at the ipsilateral ear but inhibited by sounds at the contralateral ear, they will respond best to ipsilateral sound sources that produce ILDs favoring the excitatory ear (Figure 3(b)). LSO neurons project bilaterally to the DNLL and the ICC. In order to achieve the contralateral

Figure 3 Illustration of a frontal section through the cat brain stem showing the ascending pathways through the LSO, which is believed to be responsible for encoding interaural level differences (ILDs). Symbols and abbreviations as in Figure 2. (a) LSO neurons receive bilateral inputs from both ears. The input from the ipsilateral ear via the bushy cells is excitatory but the input from the contralateral ear via the bushy cells of the contralateral AVCN is inhibitory due to the additional synapse in the ipsilateral MNTB. The ipsilateral excitation and contralateral inhibition allows LSO neurons to encode ILDs (b). LSO neurons send excitatory projections to the contralateral IC and DNLL and inhibitory projections (not shown) to the ipsilateral IC and DNLL. The neurons comprising the MNTB and LSO are predominantly sensitive to high-frequency sounds.

representation of space that is a basic feature of sensory and motor areas of the brain, the high-frequency sensitive neurons of the ventromedial LSO send excitatory projections to the contralateral DNLL and ICC, while the low-frequency sensitive dorsolateral LSO sends predominantly inhibitory projections to the ipsilateral DNLL and ICC. As a result high-frequency sensitive neurons in the DNLL and ICC respond best to contralateral sound sources that produce ILDs favoring the contralateral ear.

Spectral Shape Cues Are Processed in the Dorsal Cochlear Nucleus

Less secure is our understanding of the processing of spectral shape cues. It is hypothesized that the DCN analyzes the spectral shape cues created by the interaction of the sound with the external ear in a direction-dependent fashion. The principal output neurons of the DCN are the fusiform and giant cells (Figure 4). Neural responses of the fusiform and giant cells are similar, so they are often considered as a single neural group. As a neural circuit, the DCN is more complicated than the MSO and LSO/MNTB circuits. As such, it is easier to break down the DCN circuit into a simple qualitative model (Figure 4). In this general model, the type IV neurons, the fusiform and giant cells, represent the principal output neurons of the DCN that project to the contralateral ICC. The type IV neurons are selective for the broadband spectral notches due to the way they integrate excitatory and inhibitory inputs from a variety of sources. The main excitatory inputs arise from the ANFs. Due to the ANF inputs, the type IV neurons are tonotopically organized and are predominantly sensitive to high sound frequencies. Type IV neurons also receive inhibitory inputs from two different neurons. First, the type II neurons, corresponding to the tuberculoventral neurons of the DCN, receive an excitatory input

Figure 4 Illustration of a frontal section through the cat brain stem showing the ascending pathways through the DCN, which is believed to be responsible for encoding the spectral-shape cues. Symbols and abbreviations as in Figure 2. The inset shows a qualitative model of the DCN. Type IV neurons represent the principal neurons of the DCN, the fusiform, and giant cells, which receive excitatory inputs directly from the ANFs and inhibitory inputs from the type II and W neurons. Type II neurons, representing the tuberculoventral neurons of the DCN, receive excitatory input from ANFs sensitive to similar frequencies as the direct projection to the type IV neurons and project a strong inhibitory input to the type IV neurons. Type II neurons also receive a strong inhibitory input from the W neurons. The W neurons, representing the so-called wide-band inhibitor neurons, receive excitatory ANF inputs spanning a broad range of sound frequencies, both below and above those of the direct inputs to the type IV neurons. W neurons send a relatively weak inhibitory input to the type IV neurons. The result of this neural network of excitatory and inhibitory inputs allows the type IV neurons, which project to the contralateral inferior colliculus, to respond selectively to the spectral notches that constitute the spectral-shape cues.

from the auditory nerve and send a strong inhibitory input to the type IV neurons. Type II neurons are sensitive to a narrow range of frequencies that is similar to that of the type IV neurons. Type II neurons therefore effectively inhibit type IV responses to narrowband sounds. On the other hand, the wide-band inhibitor neuron, or W neuron corresponding to the D-Stellate neurons of the posteroventral cochlear nucleus (PVCN), receives excitatory inputs from many ANFs spanning a broad range of frequency sensitivity. W neurons in turn project a strong glycinergic inhibitory input to the type II neurons but a much weaker inhibitory input to the type IV neurons. Consequently, W neurons respond best to broadband sounds, which causes a strong inhibition of the type II neurons. Therefore, broadband sounds effectively release the strong inhibition on the type IV neurons from the type II. This complicated inhibitory network from the type II and W neurons, along with a single narrow frequency-tuned excitatory input from the auditory

nerve, allows type IV neurons to respond selectively to broadband spectral notches. When the frequency of the spectral notch cue to sound elevation is aligned with the best frequency of a type IV neuron, that neuron's response is maximally inhibited. The type IV neurons of the DCN send an excitatory projection to the contralateral ICC.

Further Evidence for Processing of Localization Cues in Three Parallel Pathways

The physiological studies reviewed above showed that there are three different nuclei in the auditory brain stem, the MSO, LSO, and DCN, that selectively process each of the three cues to sound location. In support of those studies, there is also evidence from other scientific disciplines that points more to the functional aspects of the encoding of the ITD, ILD, and spectral cues by those three circuits.

Comparative neuroanatomical studies in a large number of mammalian species have found that animals with large heads (like primates) tend to have a large and well-developed MSO, whereas the MNTB and LSO are relatively small and underdeveloped. In contrast, animals with small heads (like bats and most rodents) tend to have a small underdeveloped (in some cases nonexistent) MSO while the MNTB and LSO are large and well developed. Behaviorally, small-headed animals are not able to localize low-frequency sounds based on ITDs, likely due to the fact that the ITDs are quite small and the MSO, which processes ITDs, is also relatively small. On the other hand, mammals with large heads can localize accurately low-frequency sounds based on ITDs because the ITD cues are quite large and the MSO is also well developed. In contrast, small mammals can localize very high-frequency sounds presumably due to the fact that high-frequency sounds yield useful ILD cues to location and the MNTB and LSO which processes ILD cues are well developed. Small mammals tend to be able to hear higher frequencies than large mammals. However, large mammals can also localize high-frequency sounds. The data together implicate the MSO as necessary for encoding ITDs and the MNTB and LSO necessary for encoding ILDs.

Finally, the ability to localize a sound positioned along the horizontal plane, where ITD and ILD cues are predominantly used, is severely impaired in experimental animals where the input or output pathways to the MSO and LSO or the MSO and LSO themselves were selectively lesioned. These experiments show that the interaction of the afferent inputs to the MSO and LSO are necessary for the localization of sound based on ITDs and ILDs. Moreover, in animals where the DCN was selectively lesioned, sound localization ability was impaired chiefly for sources that varied in elevation while localization was nearly normal for sources varying in azimuth.

There are three primary acoustical cues to the spatial location of a sound source. Two cues, ITD and ILD, depend on the fact that the two ears are physically separated in space by the head, which acts as an acoustical barrier. ITD and ILD cues vary maximally for sources along the horizontal plane. Neurons in the MSO and LSO encode the ITD and ILD cues, respectively. Data from comparative as well as lesion studies support the separate processing of those two cues. Spectral shape cues are used for localizing sources varying in elevation. Spectral shape cues are encoded by neurons in the DCN. Lesion studies reveal that the DCN is critical for sound localization in elevation. The MSO, LSO, and DCN send projections to the ICC in such a way that neurons in the ICC encode predominantly sounds in the contralateral field. Neurons at higher auditory stations, including the medial geniculate body in the thalamus and the primary auditory cortex, have also been found to be sensitive to the three acoustical cues to location. However, the manner in which these cues are represented systematically in these higher-order areas as well as how sound source location itself is represented in the auditory system remains elusive.

Sox Gene Expression

S R Hutton and L H Pevny, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

© 2009 Published by Elsevier Ltd.

Introduction

A suite of transcription factor families that are essential for the regulation of gene expression in both the developing central and peripheral nervous systems has been identified. One such group is the SOX family. SOX proteins serve many important functions throughout the development of the nervous system, including the induction of neural competence, the maintenance of progenitor characteristics, and cell fate determination. They were identified based upon their sequence identity to the founding member of the SOX family, the mammalian testis-determining factor SRY (sex-determining region Y). The *SRY* gene contains a single 79-amino-acid DNA-binding motif known as the high mobility group (HMG) domain. SOX family members are classified based upon their sequence similarity to the *SRY* HMG domain, with all members sharing at least 50% homology. SOX proteins are grouped into subfamilies based upon their degree of sequence similarity, with approximately 90% similarity in HMG domains within subfamilies. Currently in vertebrates, there are over 20 individual SOX proteins divided into eight subfamilies (A–H), with some subfamilies further subdivided based upon similarities outside of the HMG domain. A number of these SOX subfamilies are expressed in the developing nervous system (Table 1).

SOX factors regulate their downstream targets through multiple mechanisms, including chromatin modification, direct transcriptional activation or repression, posttranslational modification, and protein–protein interactions. All SOX proteins, as well as the related TCF/LEF family of transcription factors, contain a single 'HMG box'; these proteins have been shown to bind the DNA sequence $^{A}/_{T}$ $^{A}/_{T}$CAA$^{A}/_{T}$G with high sequence specificity compared to the classical HMG domain proteins HMGB1 and HMGB2, which contain multiple HMG domains but do not bind DNA with any sequence specificity. Generally, SOX proteins bind the minor groove of DNA, which in turn results in an acute bend in the DNA strand, suggesting that SOX proteins are capable of structurally modifying the DNA. However, SOX proteins have also been demonstrated to act as classical transcription factors, with their C-termini capable of acting as either an activator or repressor domain. In addition, posttranslational modification of SOX proteins also plays a role in their regulation of diverse genes. For example, the SUMO-1 (small ubiquitin-like modifier) protein can bind to SOX9 and SOX10 lysine residues in both the activation domain and immediately 5′ of the proposed E1 protein–protein interaction region, potentially modifying the proteins' stability, localization, and protein–protein interactions. These findings have propelled further studies to identify additional mechanisms that can modify SOX signaling.

The diverse functions of SOX proteins, as well as their broad and overlapping temporal and spatial expression patterns, suggest that SOX factors work in conjunction with tissue-specific cofactors to regulate the expression of their target genes. For instance, SOX2, a member of the SOXB1 subfamily, is expressed in multiple cell lineages and, in each tissue type, interacts with unique factors to regulate the expression of downstream targets. In embryonic stem (ES) cells, SOX2 has been shown to directly cooperate with OCT3/4 (octomer-binding factor) to regulate FGF4 (fibroblast growth factor) expression and thus maintain cell pluripotency. Similarly, in neuroepithelial (NEP) cells, SOX2 interacts with another POU factor, BRN2, in the regulation of the *Nestin* gene, a marker for neural stem/progenitor cells. On the other hand, in the developing lens, SOX2 directly interacts with PAX6 to bind and activate the expression of *δ1-Crystallin*. These data demonstrate the importance of identifying and understanding the interactions of SOX members and their binding partners and how they regulate transcription in the context of neural development.

Role of SOX Factors in Defining Neural Competence

Sox genes are expressed from the very onset of embryonic development. One family, the *SoxB*1 group (*Sox1*, *Sox2*, and *Sox3*), is essential for the acquisition of neural competence in primitive ectodermal cells and for their commitment to a neural fate. As mentioned previously, SOX2 is expressed in ES cells and is required to maintain the pluripotency of these cells in conjunction with other transcription factors, such as OCT3/4 and NANOG. During germ layer specification, both SOX2 and SOX3 are expressed in all ectodermal cells, including those that will constitute the prospective neuroectoderm. In the developing mouse embryo, the restriction of SOX2 and SOX3 expression to ectodermal cells committed to a neural fate coincides with the onset of SOX1 expression in these cells. As evidence for an evolutionarily conserved role of *Sox1*, the *Drosophila* orthologs of *Sox2* and *Sox1*, *Dichaete* (or *Fish-hook*) and *Sox-Neuro*, respectively, show similar confined expression

Table 1 SOX factor function in nervous system development

Family		*Member*	*Function*
B	1	1	Maintains neural progenitor characteristics in mouse embryonic stem and P19 cells
			Regulates migration of mouse telencephalic neurons
			Required for differentiation of neurons in mouse ventral striatum
		2	Maintenance of SOX2 expression biases *Xenopus* animal cap cells and mouse embryonic stem cells toward neural fate
			Maintains neural progenitor characteristics in embryonic stem cells, chick. spinal cord, and mouse retinal and rat oligodendrocyte progenitor cells
			Required for neuronal differentiation in anterior thalamus, dorsal striatum, and septum
			Required for maintenance of chick neural crest progenitor identity
		3	Maintains neural progenitor characteristics in chick spinal cord
			Required in a subset of mouse hypothalamic neurons that regulate the hormonal output of the anterior pituitary
	2	14	Promotes neuronal differentiation, cell cycle exit, and delamination of chick neural progenitors
		21	Promotes neuronal differentiation, cell cycle exit, and delamination of chick neural progenitors
C		4	Promotes activation of differentiated neuronal markers in chick embryonic spinal cord
		11	Promotes activation of differentiated neuronal markers in chick embryonic spinal cord
			Regulates neuronal survival and neurite outgrowth of chick neurons
D		5	Represses specification and terminal differentiation and influences mouse oligodendrocyte migration patterns
		6	Represses specification and terminal differentiation and influences mouse oligodendrocyte migration patterns
E		8	Regulates *Xenopus* and chick neural crest cell migration
		9	Required for neural crest induction in *Xenopus*, chick, and mouse embryos
			Promotes chick oligodendrocyte differentiation
		10	Maintenance and survival of neural crest progenitors in *Xenopus* and mouse embryos
			Induction and survival of glial lineages in *Xenopus* and mouse embryos
			Promotes oligodendrocyte differentiation

patterns in the developing fly. Ultimately, all three SOXB1 factors are then expressed in central nervous system (CNS) neural progenitors throughout ontogeny. Functional studies suggest that these proteins are essential for the establishment of the neural lineage, as inhibiting SOXB1 function in *Xenopus* embryos results in a lack of formation and differentiation of neural tissue. Conversely, overexpression of SOXB1 factors in naive ectodermal cells in *Xenopus* initiates neural differentiation in conjunction with FGF. The precise temporal and spatial restriction of the *SoxB1* genes to the neural ectoderm suggests that they are regulated by neural inducing signals. For instance, overexpression of the neural inducer chordin upregulates SOX2, while overexpression of the antagonistic target of chordin, bone morphogenetic protein (BMP), suppresses SOX2 expression in the *Xenopus* embryo. Similarly, Dpp and Sog, the fly counterparts of BMP4 and chordin, regulate the expression of the *Drosophila* ortholog of *SoxB1* genes, *SoxNeuro*. Furthermore, direct evidence for the regulation of SOX2 expression by factors that regulate neural induction stems from a series of elegant studies in the chick embryo showing that FGFs and WNTs can regulate a *Sox2* enhancer element and activate its expression to initiate neural plate development. Despite these findings, the precise roles of SOXB1 proteins in the extensive regulatory network controlling neural competence remain to be further elucidated.

Role of SOX Factors in the Maintenance of Identity and Differentiation of Neural Progenitor Cells of the Central Nervous System

Individual members of the SOX transcription factor family play essential roles not only in the acquisition of neural fate but also in the maintenance and differentiation of neural progenitor cells of the CNS (Figure 1). The SOXB1 proteins mark a common transcriptional state shared by diverse populations of neural progenitors throughout the CNS during development and in the adult. The expression of *SoxB1* genes directly correlates first with the commitment of cells to a neural fate. Next, after neural induction, all three genes are co-expressed in proliferating neural progenitor cells along the entire anteroposterior axis of the developing vertebrate CNS and are maintained in neurogenic regions of the postnatal and adult CNS. Furthermore, SOXB1 factors mark proliferating neural progenitors in derivatives of the CNS, including the neural retina, the olfactory epithelium, and the inner ear. The importance of SOXB1 factors in the nervous system has been highlighted both by results from misexpression and dominant interfering studies as well as by genetic analyses. Gain-of-function and dominant interference experiments in *Xenopus* and chick embryos, as well as in

Figure 1 Temporal expression of different SOX proteins in neural progenitor cells of the mouse central nervous system. The asterisk denotes SOX21 expression in the ventricular zone. Light and dark green represent low and high levels of SOX3, respectively; spirals denote proliferative capacity.

mouse cell lines, have shown that SOXB1 signaling plays an essential role in maintenance of neural progenitor identity. These data provide evidence that inhibition of SOXB1 signaling in neural progenitor cells results in their premature delamination from the ventricular zone, their exit from the cell cycle, and the onset of their neuronal differentiation. Conversely, constitutive expression of SOX2 results in the maintenance of progenitor characteristics. These experiments also provide evidence that SOXB1 factors function by antagonizing the actions of proneural genes. Specifically, studies in the chick embryo have shown that the ability of proneural genes to promote neuronal differentiation inversely correlates with the level of SOXB1 expression.

The requirement of SOXB1 factors for the maintenance of neural progenitor identity has been confirmed by genetic studies in a number of species. Analyses of conditional and hypomorphic mutations of *SoxB1* genes in *Drosophila*, zebra fish, mice, and humans have not only verified the absolute requirement of SOXB1 factors but have revealed a dosage-dependent role for them in the maintenance of neural progenitor identity. The identification of hypomorphic mutations and the generation of compound mutations in the *Drosophila Dichaete* and *SoxNeuro* genes, as well as the generation of conditional, hypomorphic, and compound mutations in mouse *SoxB1* genes, permit the assessment of the function of SOXB1 factors in the CNS. In the fly, *SoxNeuro/Dichaete* double-mutant embryos show severe neural hypoplasia throughout the CNS, as well as dramatic loss of Achaete-expressing proneural clusters. These data suggest that members of the *Drosophila SoxB1* subfamily act upstream and in parallel to genes of the *Achaete–Scute* complex. Furthermore, analysis of a *Sox2* hypomorphic allele (Dr11) and directed transgene expression has demonstrated that Dichaete function is necessary for the correct development of midline glia of the CNS. In the mouse, analysis of the tissue-specific conditional ablation of SOX2 in neural progenitor cells, dependent on the Cre–loxP system, has provided the first genetic evidence for the requirement for SOX2 in the maintenance of neural progenitor cell identity. Specifically, retinal progenitor cells with conditionally ablated *Sox2* lose competence to both proliferate and terminally differentiate. In contrast, in *Sox2* hypomorphic/null mice, a reduction of SOX2 expression causes variable microphthalmia as a result of aberrant neural progenitor differentiation. In *Sox2* hypomorphic mutant retinas the decrease in levels of SOX2 expression directly correlates with a decrease in the levels of Notch1 and its direct downstream effector, HES-5, expression. Moreover, and consistent with the observations made in the fly embryo, in mouse neural retinal progenitor cells that express decreased levels of SOX2 due to germ line *Sox2* hypomorphic mutations, the expression of proneural genes such as *Atoh7* (*Math5*) and *Neurod1* is prematurely upregulated. It is important to note that although SOXB1

factors are generally restricted to and are clearly essential for the maintenance of neural progenitor cell identity, their expression has been detected in small subsets of postmitotic neurons in the developing and adult CNS. For example, it has been shown that SOX1 is not only expressed in, but also functions to regulate, the migration of telencephalic neurons of the ventral striatum, and deletion of SOX3 in mice leads to defects in pituitary function and abnormal development of Rathke's pouch.

Unlike the members of the SOXB1 subfamily, for which expression is generally downregulated as neural progenitor cells exit the cell cycle, expression of members of the SOXB2 subfamily, including SOX14 and SOX21, and members of the SOXC subfamily, SOX4 and SOX11, is maintained in postmitotic neurons. Consistent with this, these factors have been shown to play a crucial role to promote neuronal differentiation. Misexpression of either SOX14 or SOX21 in chick neural progenitor cells results in their premature exit from cell cycle, delamination to the differentiated mantle zone, and the onset of expression of markers of mature postmitotic neurons. In contrast, SOX4 and SOX11 function further downstream of proneural basic helix–loop–helix (bHLH) proteins and are essential for the establishment of panneuronal protein expression. Misexpression of SOXC factors results in the aberrant expression of markers of differentiated neurons but does not cause progenitor cells to exit the cell cycle or commit to neuronal differentiation.

SOX factor expression and function is maintained in restricted progenitor cells of both the neuronal and glial lineages. For example, it has been shown that members of the SOXD (SOX5 and SOX6) and SOXE (SOX8, SOX9, and SOX10) families are expressed in the oligodendrocyte lineage. Interestingly, and analogous to the antagonistic function of SOXB1 and SOXB2 factors during neuronal differentiation, both genetic and molecular data suggest that SOX5 and SOX6 directly interfere with the functions of group E SOX proteins. In contrast to SOX9 and SOX10, which promote oligodendrocyte specification and terminal differentiation, SOX5 and SOX6 repress the specification and terminal differentiation of oligodendrocytes and influence their migration.

Role of SOX Factors in the Maintenance and Differentiation of Neural Progenitor Cells of the Peripheral Nervous System

The peripheral nervous system (PNS) is derived from neural crest cells, a subset of dorsal neuroepithelial cells. Similar to the initial specification of neural fate during neural induction, neural crest cell fate is also defined by the functions of SOX family members. Human neuropathies, as well as spontaneous mutations found in the mouse, have provided evidence that one SOX family, SOXE, plays a pivotal role in the PNS. In addition, group C members SOX4 and SOX11, group D member SOX5, and the group B1 member SOX2 are also found expressed transiently during neural crest development (Figure 2).

All three SOXE members (SOX8, SOX9, and SOX10) are initially expressed in the developing neural crest in *Xenopus*, chick, and mouse, although the relative timing of expression onset and the expression level of each SOXE protein is species specific. Generally, as development proceeds, SOX9 is maintained in migrating cranial neural crest progenitors (which later form cranial neurons and glia), while SOX10 is maintained in trunk neural crest progenitors (which give rise to the PNS). SOX8 is maintained in both cell populations.

As mentioned previously, SOX10 is expressed in trunk neural crest progenitor cells that give rise to the PNS. Upon differentiation, SOX10 is maintained in all cells fated for the glial lineage but lost in all neuronal derivatives. Initially, SOX10 does not appear to be necessary for neural crest specification or migration, as SOX10 knockout mice are capable of generating some migrating neural crest cells. However, SOX10 does appear essential for the survival of the neural crest cells, as postmigratory neural crest cells undergo apoptosis in these mice. This, in addition to knockin experiments in which SOX10 was replaced with SOX8, demonstrates the inability of SOX8 to compensate for SOX10 loss. Interestingly, SOX10 morpholino knockdown in *Xenopus* blocks the expression of early neural crest makers SNAIL2 (SLUG), SOX9, and FOXD3. However, given that SOX10 expression succeeds that of these markers, it is suggested that SOX10 maintains the expression of these genes in progenitors.

In addition to regulating the survival of neural crest cells, SOX10 has also been demonstrated to maintain the pluripotency of these cells and to prevent premature neuronal differentiation. Interestingly, SOX10 is also necessary for the establishment of the neuronal lineage, as demonstrated by its functional requirement for the induction of the neurogenic transcription factors MASH1 and PHOX2B in the mouse, as well as Ngn1 in *Xenopus*. Therefore, how can the loss of SOX10 be required for neuronal differentiation, yet its expression is necessary for neurogenesis? This discrepancy appears to be dependent upon the level of SOX10 expression. In mice with a single functional *Sox10* allele, the maintenance of neurogenic potential is unaltered, as evidenced by the maintenance of MASH1 and PHOX2B expression. However, in these same

Figure 2 Temporal expression of different SOX proteins in neural progenitor cells of the mouse peripheral nervous system. Expression of SOX proteins in nonneural lineages is not shown; spirals denote proliferative capacity.

animals, the ability to inhibit neuronal differentiation is decreased, as observed by a reduction in the expression of PHOX2A, a marker for autonomic neuronal differentiation. This suggests that SOX10 is downregulated in cells that begin to differentiate but is maintained at sufficient levels to drive them toward a neuronal fate.

The maintenance of SOX10 in all glial cells of the PNS is important for glial fate, and its loss results in complete ablation of all peripheral glia. Molecularly, it has been shown that SOX10 can stimulate gliogenesis by regulating ERBB3 expression and neuregulin signaling. Furthermore, similar to its function in CNS oligodendrocytes, SOX10 also regulates myelination in PNS Schwann cells by controlling myelin protein-zero expression through interactions with the EGR/KROX20 transcription factor. Connexin-32 and ciliary neurotrophic factor (CNTF) are also regulated by SOX10, the latter being important for neuronal maintenance.

Consistent with other vertebrate species, SOX10 is required in human neural crest, and mutations in SOX10 are found in some human neuropathies. For instance, SOX10 mutations result in Waardenburg–Shah syndrome, which is characterized by skin hypopigmentation, deafness, and Hirschprung's disease (aganglionic megacolon), in addition to severe dysmyelination. Mice with little or no SOX10 expression present with similar phenotypes. Additionally, Charcot–Marie–Tooth syndrome may also involve SOX10 mutations.

SOX9, on the other hand, has been shown to be important for neural crest specification, though again species-specific differences are observed. For instance, early knockdown of SOX9 in *Xenopus* and zebra fish results in a lack of induction of neural crest markers such as FOXD3, whereas SOX9 knockout mice maintain normal FOXD3 expression. In addition, ectopic expression of SOX9 in the chick neural tube can activate expression of neural crest markers in the neuroepithelium, though these cells are unable to delaminate and migrate. These results suggest that SOX9 is involved in neural crest specification, but its contributions to this process may vary by species. This is supported by recent studies that have shown that SOX9 is able to bind and activate SNAIL2, a transcription factor necessary for the epithelial–mesenchymal transition and migration of neural crest cells, as well as by the identification of a neural crest specific enhancer for SOX9 that is dependent upon Wnt–β-catenin signaling. Currently, the

role of SOX9 in the survival of neural crest cells is still unclear. Conditional ablation of SOX9 specific to neural crest cells using Wnt1/Cre-expressing mice results in cranial neural crest defects but no observable abnormalities in trunk neural crest. This suggests that either SOX9 or SOX10 (which is expressed in trunk neural crest) is necessary to maintain neural crest survival.

In the mouse, SOX8 appears to serve a minimal role in neural crest development; SOX8 knockout mice do not exhibit any neural crest phenotype, potentially due to compensation by SOX9/SOX10 expression. However, in *Xenopus*, morpholino-mediated knockdown of SOX8 results in defects in proper neural crest migration. Therefore, the relative importance of SOX8 in the developing PNS remains to be determined.

SOXB1 proteins also appear to be involved in the establishment of the PNS, though to what extent remains unclear. The most studied of these proteins is SOX2. In the chick, SOX2 is downregulated, but not extinguished, in cells as they become biased toward the neural crest fate. This low level of expression is maintained in migrating neural crest cells, but upon reaching their targets SOX2 is upregulated in neural precursors in the developing dorsal root ganglia and is ultimately maintained in some glial lineages. Furthermore, neural populations of neural crest cells contain SOX2-specific enhancer activity, and SOX2 was demonstrated to inhibit neural crest formation and to regulate proliferation and differentiation in the PNS neural progenitors. Thus, SOX2 appears to play a similar neurogenic role in both the PNS and the CNS.

The functions of other SOX factors in PNS development are still unclear. Ectopic expression of SOX5 in the chick neural tube has been demonstrated to induce the expression of many neural crest transcription factors. Also, SOX11 has been shown to function in the regulation of neuronal survival and neurite outgrowth in both neural cell lines and primary dorsal root ganglia neuron cultures. Clearly, however, our understanding of the multiple functions of SOX proteins in PNS development is far from exhaustive. The upstream and downstream targets of individual SOX members are only beginning to be elucidated, as are the numerous cofactors with which SOX proteins interact. Only by identifying these mechanisms will the role of SOX proteins in the regulatory network controlling PNS development be understood.

Conclusion

The SOX family of transcription factors is essential for the establishment, development, and maintenance of the nervous system. Though highly conserved, each member appears to serve a distinct function, depending upon the tissue it is expressed in, the level of its expression, and the cofactors that are co-expressed in the cell. The mechanisms by which SOX proteins act are equally diverse, as are the downstream targets regulated by SOX function. These highlight the importance of SOX proteins in neural development and, in conjunction with *Sox* mutations associated with human neuropathies, demonstrate the necessity for further understanding of their functions.

Spasticity

A D Pandyan, H Hermens, and G R Johnson, Keele University, Keele, UK

Published by Elsevier Ltd.

Introduction

Any lesion in the descending tracts of the central nervous system (CNS), at any level (i.e., cortex, internal capsule, brain stem, or spinal cord), can lead to a combination of sensorimotor symptoms, including spasticity (Table 1). Spasticity, a neurological impairment, is a common feature in a variety of neurological disorders, such as stroke, cerebral palsy, brain injury, spinal cord injury, and multiple sclerosis. It is believed that spasticity contributes to contracture development, exacerbates pain, and hinders recovery of functional movement. Therefore, substantial effort has been invested in managing this clinical condition and in developing an understanding of it. However, progress has been relatively modest in both of these areas. It would appear that the main barriers to progress are imprecise definitions (of spasticity) and a paucity of valid and reliable, but clinically usable, outcome measures. Our current understanding of spasticity is based in part on existing, although imperfect, animal models. Further progress is dependent on the development of valid definitions and measures, and adequate neurophysiological models.

Pathophysiology

The positive features that result from CNS lesions affect tracts in both the pyramidal and parapyramidal systems. (Note: We specifically use the term 'parapyramidal,' as suggested by both Sheean and Burke, to differentiate between (1) tracts that run in close proximity to the corticospinal tract and arise at the cortex and (2) those that arise from the basal ganglia – that is, the extrapyramidal fibers, which are responsible for rigidity.) An isolated lesion of the corticospinal tract will normally result in loss in fine control of movement and, rarely, specificity. The positive symptoms arise as a result of plastic changes in response to the lesion (e.g., collateral sprouting) and/or release effects (disinhibition) as a result of the lesion. Irrespective of the cause of the lesion, the positive features primarily occur as a result of disinhibition at the level of the spinal cord, and the following pathways have been implicated (Figure 1):

- Increased excitation in the group Ia afferents from the muscle spindles.
- Increased excitation and reduced inhibition in the group II afferents from the muscle spindles.
- Reduced autogenic inhibition from the Ib afferent from the Golgi tendon organ.
- Reduced recurrent inhibition from the Renshaw cells and motor axon collaterals.
- Reduced reciprocal Ia inhibition from the muscle spindles from the antagonistic muscle groups.
- Reduced presynaptic inhibition of the Ia terminals.
- Increased facilitation of the flexor reflex afferents involving group II, group III, and group IV cutaneous afferents.

The other contributory factors are as follows:

- Increase in the fusimotor drive (i.e., γ-motor neurons innervating the muscle spindle); however, the limited evidence available suggests that this may not happen.
- Changes in the cell membrane properties of the motor neurons and possibly the interneurons. There is growing body of evidence demonstrating that the cell membranes are not the passive structures that they were once believed to be. In particular, prolonged depolarization (plateau potentials) resulting from localized persistent inward currents produced by voltage-dependent Ca^{2+} and Na^{+} channels may be responsible for some of the abnormal patterns of muscle activation. The effects of these inward currents are chemically modulated by serotonergic and/or noradrenergic motor neurons. (Plateau behavior has not been fully demonstrated in humans. In cat and rat models, it is primarily seen in chronic spinal preparations.)
- Reduction in the postactivation depression within the Ia terminals.
- Some patients will demonstrate a continuous drive to the α-motor neuron (this has been described by some as 'spastic dystonia' and by others as 'rigidity'; of the two, we would prefer the former, as the feeling of cogwheel-type resistance is not encountered in these patients during an externally imposed movement). This may result from a loss of corticoreticular inhibition of the pathways that descend from the brain stem and/or a reduction in the spinal reflex thresholds. From the available evidence it is not possible to delineate the exact pathophysiological mechanisms that result in the tonic (and continuous) activation of muscles.

In summary, abnormal muscle activation, associated with the positive features seen following a CNS lesion, can result from a combination of reduced thresholds and/or an increase in gain in both the descending pathways and reflex pathways that converge onto the α-motor neurons.

Table 1 Sensorimotor clinical features that present following a CNS lesion

Positive features	*Negative features*
Increased reflexes	Weakness
Spasticity	Fatigueability
Altered tone	Loss of dexterity (motor control)
Spasm (flexor and/or extensor)	
Clonus	
Abnormal movement patterns during attempted voluntary movement (e.g., associated reactions and dyssynergic co-contractions)	

Originally classified, by Hughlings Jackson, as (1) 'positive features' – excess/exaggerated activity (when compared to normal) which could occur spontaneously or in response to external stimuli, and (2) 'negative features' – abnormal release of function or a deficit in performance when compared to normal.

Figure 1 A schematic illustrating the potential spinal pathways implicated in spasticity. The group II afferents from the spindle and the group III/IV cutaneous afferents are not illustrated. From Nielsen JB, Crone C, and Hultborn H (2007) The spinal pathophysiology of spasticity – from a basic science point of view. *Acta Physiology* 189: 171–180.

Definitions

The term 'spasticity' has been about for a long time, and the first formal definition of sorts was that proposed by Denny-Brown in 1960. According to this definition, spasticity, following an upper motor neuron lesion, "could be identified by the presence of a soft yielding resistance that appears only towards the end of a passive stretch, and is associated with increased amplitude stretch reflex."

Subsequently, Lance, at a conference held in 1980, initially suggested that spasticity be defined as "a motor disorder characterized by a velocity dependent increase in tonic stretch reflexes and increased tendon jerks resulting from disinhibition of the stretch reflex, as one component of an upper motor neurone lesion." This definition specifically associates spasticity with the disinhibition of the stretch reflex pathway (see the sections titled 'Biomechanical methods' and 'Electrophysiological methods').

At a later stage in the conference, this original Lance definition was modified to "a motor disorder characterized by a velocity dependent increase in the tonic stretch reflex (muscle tone) with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex, as one component of the upper motor neurone syndrome." In this revised definition (which will be described as the 'modified Lance definition'), one subtle and important assumption has been made – tonic stretch reflex activity has been equated to muscle tone. (There are two definitions of muscle tone. The first would appear to be based on Bernstien's 'innervational condition' and is defined as a state of readiness to act. The second equates muscle tone to the resistance to externally imposed movement.)

More recently, a fourth definition has emerged: the Task Force on Childhood Motor Disorders has recommended that spasticity be treated as a form of hypertonia (the other two forms being dystonia and rigidity), defined as "a velocity dependent increase in hypertonia with a catch when a threshold is exceeded." Of these four, fairly precise, definitions found in the literature, the modified Lance definition is perceived to be the most cited. However, this is by no means the most dominant definition, as only a third of the literature cites the modified Lance definition and many cite it inappropriately. Another third equates spasticity with hypertonia or increased muscle tone, defined as an increase in the resistance to passive movement. The remainder equate spasticity with one or many of the positive features associated with the CNS lesion (Table 1). In clinical practice, the term 'spasticity' is routinely used to describe one or many of the positive features of the upper motor neuron syndrome.

Resolving the Inconsistency

Data from current clinical trials, animal models, and clinical practice almost unanimously suggest that the clinical features associated with spasticity result from either intermittent or sustained involuntary (reflex) muscle activity. The original Lance definition associates one particular form of this abnormal activity (i.e., velocity-dependent increase in the tonic reflexes) with spasticity. Many others would appear to associate all forms of abnormal activity (e.g., spasm, clonus) with spasticity.

There are two other key assumptions made with respect to the Denny-Brown, modified Lance, and Task Force of Childhood Disorders definitions of spasticity: (1) the abnormal muscle activation will always contribute to a measurable increase in

resistance to passive movement and (2) the velocity-dependent increase in resistance to passive movement is an exclusive feature of spasticity. With respect to the former, from first principles, muscle activation will contribute to force production within the muscle and therefore will contribute to an increase in resistance to passive movement. The modeling of this relationship is, however, more complex, as the activation force relationship is being studied in an active muscle that is being lengthened. The more important question, which is often ignored, is related to validity of measurement. Most patients with a CNS lesion also have coexisting conditions that result in changes in the mechanical properties of soft tissue structures and joint structures. Therefore, using resistance to externally imposed passive movement to study spasticity is not valid, as this is a confounded measure. Resistance to passive movement and stiffness can be reliably measured; however, to then infer that one can reliably measure spasticity from these measurements is not correct (Figure 2).

Figure 2 The stiffness and muscle electrical activity (not illustrated) were measured before (light gray) and 4 weeks (black/dark gray) after treatment with botulinum toxin (type A) to the elbow flexors (biceps and brachioradialis). The muscle activity was fully suppressed after treatment, but the stiffness showed almost no change (1.063 *N*/degree before treatment and 1.001 *N*/degree 4 weeks after treatment).

With respect to the latter, soft tissues (i.e., the muscle tendon complex) normally demonstrate viscoelastic behavior. Therefore, to exclusively attribute velocity-dependent increase in the resistance to externally imposed passive movement to a clinical feature of spasticity is wrong (Figure 3). Further, using a simple second-order system (as many of these definitions would suggest) may not be sufficient. Instead, it is likely that a second-order system with an added time delay (to account for the reflex delays) should be considered when measuring spasticity.

If there is to be substantial progress in our understanding of spasticity, then there is need to find a way of dealing with these inconsistencies in definition. There are three positions to take in identifying a way forward: (1) abandon the term spasticity, (2) standardize to the original Lance definition, and (3) redefine spasticity in a way that reflects current usage – that is, equates spasticity with many of the positive features identified with the upper motor neuron syndrome (increased reflexes, 'abnormal' muscle activity response to an externally imposed passive movement, altered tone of any sort, clonus, and/or spasms). This leads to spasticity being defined as "disordered sensorimotor control, resulting from an upper motor neuron lesion, presenting as intermittent or sustained involuntary activation of muscles." Based on current understanding, this definition may exclude abnormal movement patterns triggered during voluntary movement, and will exclude all the negative features associated with the upper motor

Figure 3 An illustration of stiffness about the elbow flexors at different velocities. The stiffness increases as velocity increases (curves: D, 6 °s^{-1}; B, 12 °s^{-1}; A, 20 °s^{-1}). Muscle activity was only observed at velocities of 20 °s^{-1}. From Dewald JPA and Given JD (1994) Electrical stimulation and spasticity reduction. Fact or fiction? *Physical Medicine & Rehabilitation*: *State of the Art Reviews* 8: 507–522.

neuron syndrome. (Note: The phenomenon of associated reactions – the overflow-type activity – can also be observed in neurologically intact individuals and in people with reduced muscular reserve capacity, when attempting tasks involving maximal voluntary contractions. Whether to equate these associated reactions and dyssynergic movement with spasticity needs to be debated.)

The first of the three suggested positions, although a preferred one, is unrealistic due to the pervasiveness of the term 'spasticity.' Of the two remaining options, redefinition may be the way forward, as the second has not led to any convergence over the past 25 years. However, if the third option is to be adopted then there is an obligation on both clinicians and researchers to be more precise in the description and measurement of the clinical features associated with what each individual identifies as 'spasticity'.

Measurement

> When you can measure ... you know something about it – but when you cannot measure ... your knowledge is of a meagre and unsatisfactory kind it may be the beginning of knowledge but you have scarcely, in your thought, advanced to the stage of science whatever the matter may be. (Lord Kelvin)

According to the current International Classification of Functioning (ICF) definition, spasticity (as newly defined) can be classified as an impairment. It is possible that this impairment may have an impact on activity (e.g., walking, feeding) and therefore on participation (e.g., quality of life, independence, career burden). From a patient perspective, the measurement of functional activity (e.g., gait), independence, and quality of life may be more important. However, these methods of surrogate measurement methods will not be reviewed further here, as the causal association between spasticity, functional limitations, and independence is not yet fully demonstrated.

The measures currently available for quantifying or classifying spasticity can be broadly classified into three categories: clinical scales, biomechanical methods, and electrophysiological methods.

Clinical Scales

Clinical scales are commonly used, for both research and clinical purposes, to either subjectively quantify or classify spasticity. Most of these scales measure one construct of this multifaceted impairment and can be further classified as follows:

1. Scales that subjectively quantify the resistance to externally imposed passive movement (e.g., modified Ashworth scale – Table 2, Tone Assessment Scale). A key, but as yet unvalidated, assumption made when using these scales is that the resistance encountered during the externally imposed passive movement results from a reflex response to the stretch. The reliability of these scales is variable – that is, it depends on the patient population, the limb segment under test, the inertia of the limb segment, the velocity of testing, and the testing position. A variety of other factors, such as temperature, previous history of activity, and time of day, may also confound. Commonly used scales can, at best, provide an ordinal level of measurement. It is not possible to recommend any of these scales as valid and clinically relevant measures of spasticity, in their respective current formats, as resistance to passive

Table 2 Properties and limitations of the Ashworth and modified Ashworth scales

Score	*Ashworth scale*	*Modified Ashworth scale*
0	No increase in tone	No increase in muscle tone
1	Slight increase in tone, giving a catch when the limb is moved in flexion or extension	Slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion when the affected part(s) is moved in flexion or extension
1+		Slight increase in muscle tone, manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the range of movement
2	More marked increase in tone but limb easily flexed	More marked increase in muscle tone through most of the range of movement, but affected part(s) easily moved
3	Considerable increase in tone – passive movement difficult	Considerable increase in muscle tone passive, movement difficult
4	Limb rigid in flexion or extension	Affected part(s) rigid in flexion or extension

An assessor is required to move the limb segment through full range of movement in 1 s and then subjectively grade the resistance encountered using the respective descriptors. Data from Ashworth B (1964) Preliminary trial of carisoprodal in multiple sclerosis. *Practitioner* 192: 540–542; Bohannon RW and Smith MB (1987) Interrater reliability of a modified Ashworth Scale of muscle spasticity. *Physical Therapy* 67: 206–207. Reproduced from Pandyan AD, Johnson GR, Price CIM, et al. (1999) A review of the properties and limitations of the Ashworth and modified Ashworth Scales. *Clinical Rehabilitation* 13: 373–383.

movement will be confounded by the mechanical properties of the soft tissue structures (muscles and tendons) and joints and the ability of the person to relax voluntarily.

2. Scales that classify a combination of the amplitude of the reflex response and the type of reflex response (e.g., National Institute of Neurological Disorders and Stroke myotatic reflex scale – Table 3), frequency of spasms (e.g., Penn spasm frequency scale, spasm frequency scale – Table 4), and clonus score. These scores have validity and provide an ordinal level of measurement of either spasms or clonus frequency. The diagnostic importance, sensitivity, reliability, responsiveness, and clinical usefulness of these scores have not been studied in great detail, especially in the context of their usefulness as an outcome measure that can inform evidence-based practice. Some of the scores may have potential as either nominal level classification measures or ordinal level measures. However, more work on validity and sensitivity is required. Attention will need to be paid to the relevance of the deep tendon reflexes (also termed 'stretch reflex' or 'tendon jerk reflex'), as evidence seems to suggest that the variability of the response in a population with spasticity overlaps with that of a normal population.

3. The final dichotomous measure that has been used in the diagnosis of people with an upper motor neuron syndrome and/or spasticity is the 'extensor toe sign.' The Babinski and the Gonda–Allen methods (Table 5) are the most reliable methods of eliciting this response. These methods have good predictive validity with respect to the presence of an upper motor neuron lesion and may provide a marker for one aspect of spasticity.

There are two other scales that attempt to measure multiple constructs associated with spasticity. The first of these produces a composite score of spasticity by multiplying the Ashworth score with the spasm frequency score. Until we have a better understanding of the component parts of this composite score, it is not advisable to use such methods of measurements. The second is the Tardieu method of measurement, which is often, inappropriately, reported as the 'Tardieu scale.' In this method of measurement the assessors are required to passively stretch a limb using two standardized velocities, one slow (which is done first) and one fast (which is done second) (Table 6). The assessor then classifies the reaction to the fast movement and quantifies the angle of the reaction in the fast movement with reference to the slow movement.

Table 3 Descriptor for the National Institute of Neurological Disorders and Stroke myotatic reflex scale

Score	*Descriptor*
0	Reflex absent
1	Reflex small, less than normal; includes a trace response, or a response brought out only by reinforcement
2	Reflex in lower half of normal range
3	Reflex in upper half of normal range
4	Reflex enhanced, more than normal; includes clonus if present, which optionally can be noted in an added verbal description of the reflex

Data from Hallet M (1993) NINDS myotatic reflex scale. *Neurology* 43: 2723.

Table 4 Descriptors associated with the ordinal level scales used to quantify the frequency of spasms

Score	*Penn spasm frequency scale*	*Spasm frequency score*
0	No spasms	No spasms
1	Mild spasms at stimulation	One or fewer spasms per day
2	Irregular strong spasms less than one time/hour	Between one and five spasms per day
3	Spasms more often than one time/hour	Five to less than 10 spasms per day
4	Spasms more than 10 times/hour	Ten or more spasms per day, or continuous contraction

Data from Penn RD, Savoy S, Corcos D, et al. (1989) Intrathecal baclofen for severe spinal spasticity. *New England Journal of Medicine* 320: 1517–1521; Snow BJ, Tsui JK, Bhatt MH, et al. (1990) Treatment of spasticity with botulinum toxin: A double blind study. *Annals of Neurology* 28: 512–515; Biering-Sørensen F, Nielsen JB, Klinge K, et al. Table 5 Two possible methods for testing for the extensor toe sign

Stimulation methods considered to produce the reflex most reliably	*Reflex response*
Babinski: Stimulation of the plantar surface of the foot with a blunt point from the heel forward, crossing the metatarsal pad from the small to the great toe	The normal response is a flexion (curling down) of all toes ('downgoing toe')
Gonda–Allen: Downward snapping of the distal phalanx of the second or fourth toe	In people who have an upper motor neuron lesion there is an extension of the great toe ('upgoing toe') with fanning of the other toes (abnormal)

Reliable for identifying a corticospinal tract lesion.

Table 6 The Tardieu method of assessment

Muscle reaction (X)[a]	*Description*
0	No resistance throughout the course of the passive movement
1	Slight resistance throughout the course of the passive movement, with no clear catch at precise angle
2	Clear catch at precise angle, interrupting the passive movement, followed by release
3	Fatigable clonus (<10 s when maintaining pressure) occurring at precise angle
4	Infatigable clonus (>10 s when maintaining pressure) occurring at precise angle

[a] The velocities used when assessing with the Tardieu method are *V*1, as slow as possible so as not to trigger a stretch reflex; *V*2 the limb segment is allowed to fall under the influence of gravity; and *V*3, as fast as possible (faster than the rate of the natural drop of the limb segment under gravity). The assessor should use *V*1 (to assess range of movement) and either *V*2 or *V*3 (to assess spasticity). The reaction to stretch for each muscle group is rated at a specific stretch velocity with parameters *X* (muscle reaction) and *Y* (angle of muscle reaction). Scores *X*, from 0 to 4, are based on quality of muscle reaction when assessing spasticity using either *V*2 or *V*3. The angle of muscle reaction *Y* is measured relative to the position of minimal stretch of the muscle (corresponding to angle), where it is relative to the resting anatomic position. (The muscle reaction is expected to occur earlier in the range of movement with greater spasticity.)
Often, inappropriately, called the Tardieu Scale as currently described. This method of measurement was originally developed by Held and Pierrot-Deseilligny and was based on a method of assessment developed by Tardieu and colleagues. Data from Held JP and Pierrot-Deseilligny E (1969) *Reeducation Mortrice des Affections Neurologiques*. Paris: J.B. Baillière et fils; Gracies J-M (2001) Évaluation de la spasticité. Apport de l'échelle de tardieu. *Motricité Cérébrale* 22: 1–16; Morris S (2002) Ashworth and Tardieu scales: Their clinical relevance for measuring spasticity in adult and paediatric neurological populations. *Physical Therapy Reviews* 7: 53–62. Adapted from Haugh AB, Pandyan AD, and Johnson GR (2006) A systematic review of the Tardieu Scale for the measurement of spasticity. *Disability and Rehabilitation* 28: 899–907.

While this scale is growing in popularity within both clinical practice and research studies, there is a need to urge caution in use, as the validity, reliability, sensitivity, and responsiveness of this scale have not yet been studied in a systematic way.

In summary, clinical scales are very popular, as they are easy to use and cheap. However, most scales cannot be recommended for routine use, as validity remains unproved. The clinical scales that quantify resistance to passive movement are confounded measures and depend on characteristics which are poorly defined (e.g., catch, catch when a threshold is exceeded, and increased resistance end range of movement). The dichotomous scale for the extensor toe sign and the scales that quantify spasms and clonus have the potential to be of use for both clinical practice and research, but more fundamental work on the measures and descriptors is required.

Biomechanical Methods

The biomechanical approaches indirectly measure spasticity by quantifying the resistance to the externally imposed passive movement. As pointed out with clinical scales, until we are able to provide evidence of validity and sensitivity we will need to use extreme caution when using these methods for quantifying spasticity.

Biomechanical methods of measurement are underpinned by four basic principles. The first involves the use of a velocity-controlled external perturbation, during which the relationship between the imposed moment and angular displacement is quantified using standard curve fitting techniques. (The best fit lines used to estimate stiffness in Figure 2 uses the least-square estimate of the slope of the force angle curve.) The second involves the use of a constant moment external perturbation, during which the relationship between the velocity and angular displacement is studied (Figure 4). The third involves studying the damping of displacement when a relaxed limb is dropped against gravity (Wartenberg Pendulum Test and its variations – Figure 5). The fourth involves quantifying the kinematic and kinetic response of the stretch reflex to a controlled tap or vibratory stimulus.

With respect to the first two methods, the external perturbation can be applied using either a manual or motorized system. It is not entirely clear as to whether motorized methods are superior to manual methods of perturbation, and more comparative work is required to explore the relative merits of these approaches in terms of sensitivity and accuracy of measurement. (Note: The muscle spindle primarily responds to a linear stretch. However, it is not possible to ensure that the linear velocity of stretch presented to the muscle spindle ensemble is controlled when the angular rotation is controlled. The variations in linear velocity occur due to variations in the center of rotation, the radius of rotation, and the dimension of the tendon and ligamentous structures. Furthermore, the muscle–tendon unit dimension will vary as a function of time (postinjury) and the level of functional capabilities. This would imply that, even for the same individual, the stimulus to the muscle spindle ensemble will vary indeterministically in longitudinal studies.) The little evidence that is available to date would suggest that manually imposed external perturbations provide similar levels of measurement when compared to

Figure 4 The output (a) from a measurement method (b) in which the externally imposed torque (moment) was standardized, and the resulting variations in both displacement and velocity were estimated (EMG, electromyelography). The resonant frequency method was developed by Walsh as a method of quantifying stiffness. From Walsh EG (1992) *Muscles, Masses and Motion. The Physiology of Normality, Hypotonicity, Spasticity and Rigidity*. London: Mac Keith Press. From Bajd T and Vodovnik L (1984) Pendulum testing of spasticity. *Journal of Biomedical Engineering* 6(1): 9–16.

Figure 5 (a) Quantifying the response from the pendulum test when applied to the knee. There are two approaches to calculating the relaxation index (R_1 and R_2). (b) The (normalized) relaxation index is seen to vary with time. (c) Calculating the relaxation index is not straightforward, as the response to the pendulum test can be variable.

velocity-controlled displacement methods. The one advantage of using a motorized control system for perturbations is the ease at which random/pseudorandom perturbations can be applied, and these may help in the development of innovative methods of exploring the correlation between the neurological and biomechanical responses – a first step in studying validity of the indirect methods. More work is required to explore the reliability of manual techniques, as these have the potential to lead to the development of clinically relevant measures. While manual techniques are easy to apply for the distal joints of the upper and lower limb, they have limited value in taking measurements about the shoulder and hip. Furthermore, the mass of the lower limb segments and the inherent stiffness of the tendo achilles make manual perturbations in the lower limb more difficult when compared to the upper limb.

The gravitational method was first described by Wartenberg in the 1950s and was instrumented by Bajd and Vodovnik in the 1980s. In this test the examiner positions the individual such that the limb segment is hanging freely over an examination couch. The examiner then lifts the limb segment against gravity and lets it drop (the stimulus is the influence of gravity). The resulting damping is then quantified using relaxation indices (Figure 5). The damping will be influenced by two factors – the mechanical properties of the soft tissues and the neural activation of the muscle groups being stretched. The validity of this method has been tested only against unvalidated scales and therefore remains unexplored. The reports on reliability suggest a degree of variability, and the relaxation indices are known to vary with time, position of testing, time of testing, and a myriad of other conditions (e.g., ability to relax, temperature), emphasizing that a detailed protocol of the measurement is required. The primary assumption that the damping is primarily influenced by the quadriceps and hamstring group reflex activity needs to be further explored (Figure 6).

The instrumentation of the deep tendon reflex is also relatively easy, and displacement, velocity of displacement, and force of muscle contraction are all potential outcome measures. However, given the variability in response, more work needs to be done prior to adopting these outcome measures in routine use.

The criticism that biomechanical measures may be more cumbersome when compared to clinical scale-based methods may not be well founded. Some of these methods of measurement are relatively easy and inexpensive to carry out, especially the methods based on manual perturbations. The time investment within the clinical context is not significant (single joint measurements can be taken in less than 5 min). However, there is a need for more research to substantiate validity before these measures become clinically relevant.

Electrophysiological Methods

The only direct approach to measure spasticity is by studying the electromyographic (EMG) response (using surface or fine wire electrodes) of the neuromuscular system to an external stimulus or by monitoring EMG activity over a continuous 24 h period. While there are some advantages to using fine wire techniques to study motor unit properties and responses, there is a need to reflect on their clinical relevance. The discomfort associated with these recordings reduces their clinical potential significantly; more importantly, it is possible that the discomfort associated with these methods confounds the response measures obtained.

Figure 6 An illustration of the inconsistent relationship between the biomechanical measures of spasticity and the complex nature of the muscle response during the pendulum test. The muscle activation patterns observed for a child before treatment (a) and 4 weeks after treatment (b) for spasticity involving selective dorsal rhizotomy. The dotted lines represent angular displacement, the gray lines are extensor electromyelogram (EMG; rectus femoris) responses, and the black lines are the flexor EMG (hamstring) responses. The patterns of muscle activation pattern have changed: the hamstrings, which were silent during the preparation and hold phase prior to surgery, were active after treatment. The relaxation index (R_2) had increased and damping had reduced, showing a reduction in spasticity.

Whether one should take measurements from relaxed or active muscles is a moot point. From a clinical perspective, most people who are classified as having troublesome spasticity are often incapable of producing a controlled voluntary contraction, so that, by necessity, one will need to examine a relaxed muscle. Many patients with active, independent movement will probably not need to be treated for troublesome spasticity! So, on balance, there is a need to develop a combination of measurement protocols that can be used in a patient population with varying functional capabilities.

A variety of external perturbations can be used for studying the response of the neuromuscular system to an external perturbation. The perturbation signals can involve the stretching of a muscle (manual or motorized), a tendon tap (T-reflex), or an electrical stimulation (H-reflex and F-waves) (Figure 7). The

response can be quantified by using, amplitude (of EMG related to stimulus), time delay/response times, durations, and thresholds (related to either response or stimulus). If continuous activity is being monitored, the outcome measures could include a count/frequency of abnormal activity bursts (e.g., algorithms to identify clonus and spasms), duration of abnormal activation, characterization of activation patterns, and timing of these events.

There is a misconception that electrophysiological methods of measurement are complex. While this is true for some of the protocols involving fine wire recordings, most electrophysiological methods can be applied for routine clinical use (e.g., one effective method to select patients for intrathecal baclofen pump therapy is to identify the response of the H-reflex – which is normally abolished if a person responds to baclofen – to a bolus of intrathecal baclofen prior to surgically implanting the pump; further, this method can also be used to monitor effectiveness of the therapy over time). However there are some simple pitfalls that need to be avoided when using electrophysiological recordings:

Figure 7 The muscle response to electrical stimulation, a tendon tap, and an externally imposed stretch. Note the relative delays in onset times. This results from the variations in the pathways stimulated by the signals. From Biering-Sørensen F, Nielsen JB, and Klinge K (2005) Spasticity-assessment: A review. *Spinal Cord* 44: 708–722.

- Using amplitude of the EMG response, in the absence of standardization, requires a very strict protocol to be used. Interindividual and intraindividual variabilities are due to the variabilities associated with the confounding factors, including skin impedance, muscle geometry, the placement of the electrodes with respect to motor endplate zones and tendons, interelectrode distance, possible muscle morphology changes, and joint position (i.e., resting length of the muscle). In addition, it has been shown that factors such as posture, joint position, and even head position and orientation do affect the EMG responses elicited by mechanical or electrical stimulation.
- It may be possible to reduce the variability of the amplitude response. Current methods involve referencing the amplitude of the EMG response to the amplitude of an EMG response to a maximal motor stimulus or EMG amplitude corresponding to a maximal voluntary contraction. However, using methods of standardization involving maximal voluntary contraction or a percentage of maximal voluntary contraction will be of limited use in patients who have weakness or paralysis.
- When using latencies (or onset delays), a bulk of the literature focuses on first deflection from baseline, and much of this identification is done manually. The development of reliable burst detection algorithms is essential to reduce impact of human error associated with visual identification.
- When measuring latencies, one should work within the constraints of the discrimination set by the sampling frequency (e.g., to measure latency to a sensitivity of 1 ms it is essential to measure at a sampling frequency of 2 kHz or greater – ideally, 4 kHz).
- Caution is urged when applying smoothing EMG data methods, as this can introduce variability and affect latency estimations (Figure 8).
- With some modern amplifiers, skin preparation is no longer critical (i.e., skin abrasion is no longer required). However, the site where the electrode is placed must be cleaned well.

Treatment

The management of spasticity is often multifaceted and can be broadly classified into pharmacological methods, surgical methods, and rehabilitation therapy-based methods. These are very briefly described in Table 7. The evidence base associated with each treatment method remains limited, as most sub-

stantial research has been underpinned by measures of limited validity and poor design. Most Cochrane reviews have also reported inconclusive findings. There is a need to reexamine, and in certain circumstances repeat, the studies exploring efficacy of individual treatments using valid measures of spasticity and patient-centered outcome measures.

Figure 8 An illustration of differences when electromyelographic (EMG) signals are smoothed using two different techniques. The gray curve was obtained after notch filtering at 50 Hz and then smoothing using a root-mean-square procedure. The black curve was obtained after notch filtering, then rectifying and low-pass filtering at 10 Hz.

Future Work

A key finding from a century of research investment into the phenomenon of spasticity is the huge variability associated with the phenomenon. For example, the reflexes in people with spasticity are often documented to fall within the ranges of spasticity found in people with no known pathologies. It is possible that such variability results from the pathophysiological basis of this phenomenon being variable and the measures lacking specificity.

If we are to find a way forward, the first stage is to address this variability, which, in our view, has resulted from inadequate definitions. We have therefore suggested that spasticity be defined as "disordered sensorimotor control, resulting from an upper motor neuron lesion, presenting as intermittent or sustained involuntary activation of muscles." Clinicians and researchers will need to identify the specific features under treatment or investigation and use valid outcome measures.

Table 7 Currently available methods to treat spasticity

Method	*Description*
Pharmacological	
Baclofen	Acts pre- and postsynaptically at the level of the spinal cord; there are two methods of administration, oral and intrathecal
Benzodiazepines (diazepam)	Acts postsynaptically at the level of the spinal cord; oral administration
Dantrolene sodium	A muscle relaxant
Clonidine/tizanidine	Acts centrally on α2-adrenergic receptors; it is believed that this enhances central inhibition via the cerulospinal pathways
Cannabinoid	Mechanism associated with the reduction of spasticity not fully elucidated
Phenol	Neurolysis of the lower motor neuron
Botulinum toxin (types A and B)	Blocks the release of acetylcholine at the motor neuron junction with the muscle
Surgical	
Selective dorsal rhizotomy	Usually carried out at the level of the lumbo-sacral plexus
Peripheral neurectomy	This is rarely carried out as there are alternatives such as a treatment with botulinum toxin
Intrathecal baclofen therapy	Acts pre- and postsynaptically at the level of the spinal cord; there are two methods of administration, oral and intrathecal
Rehabilitation therapy	
Electrical stimulation	Electrical stimulation can be applied to a variety of sites in the central nervous system (deep brain stimulation, cortical stimulation, cerebellar stimulation) and the peripheral nervous system (muscle, antagonistic to those affected with spasticity, or muscles with spasticity); mechanism of action has not been elucidated
Orthotic devices	Traditional splints that hold muscles with spasticity in a stretched or neutral position, lycra splints, dynamic splints, or static progressive orthoses and serial casting; mechanism of action has not been elucidated
Rehabilitation therapies	There are many methods of treatment described under this category (e.g., Bobat method, strength training, peripheral neuromuscular facilitation, positioning and seating system), but the content and impact of these therapies are not clearly described; mechanism of action has not been elucidated

Some of the treatment methods are better described than others, but there is a paucity of evidence-based guidelines.

Evidence from some carefully controlled studies has shown that altered motor control, including the loss of reflex modulation and weakness, may be the key problem following CNS lesion. Despite this, the focus on spasticity has been driven by the assumption that persistent spasticity is responsible for contractures, pain, and loss of functional independence. While there are theoretical possibilities that this may be the case, experimental evidence (especially from robust longitudinal studies) is needed to substantiate these hypotheses. Such evidence will depend on valid measures which can be used in a clinically relevant population of patients – and these measures need to be developed. A substantial part of our understanding has developed from animal models, and it is likely that this work will still be required for some time to come. One would hope that our understanding will progress at a slightly faster pace than that in the past century. However, when collecting new evidence, it is important not to lose sight of the possibility that spasticity may be an 'epiphenomenon'!

Behavioral Studies of Spatial Cognition in Humans

Spatial Abilities

Spatial cognition involves not one but many specific abilities. These include locating points in space, determining the orientation of lines and objects, assessing location in depth, appreciating geometric relations between objects, and processing motion, including motion in depth. These spatial skills can be applied to imagined objects as well as to external stimuli, as in the classic experiments on mental rotation. These experiments showed that observers take longer to determine whether two objects are identical when the degree of mental rotation needed to align them increases. Similar kinds of basic processes contribute to spatial cognition in the auditory and somatosensory domains.

Multiple Frameworks for Spatial Representation

Our subjective experience strongly suggests that we have direct access to a single coherent and overarching representation of space. Whether we locate an object by sight, smell, hearing, or touch, we can respond to it with equal ease and with any motor system at our command. This introspection is misleading. There is no evidence for the existence of a single, explicit, topographic representation of space suitable for incorporating every kind of sensory input and generating every kind of motor output. On the contrary, the evidence points to multiple representations of space, in a variety of coordinate frames, each closely linked to separate output systems designed to guide specific motor effectors.

The particular representation of space in use at any time depends on the task the subject is trying to perform. For example, if you were to draw out a route for a hiking trip on a map, the route would be in the coordinates of the map, the piece of paper. If you were then going to walk along that route, you would have to begin by locating your current position within that coordinate frame and constructing a representation of the route with respect to your starting point. The first, map-based representation is an example of an allocentric representation, in which locations are represented in reference frames extrinsic to the observer. Allocentric representations include those centered on an object of interest (object-centered) and those in environmental (room-centered or world-centered) coordinates. The second representation, the one in the coordinates of the hiker's current position, is an example of an egocentric representation, in which locations are represented relative to the observer. Egocentric representations include those in eye-centered, head-centered, hand-centered, and body-centered coordinates. Experimental work in humans indicates that multiple reference frames can be activated simultaneously.

Neural Basis of Spatial Cognition

Impairments of Spatial Cognition in Humans

Much of our knowledge about the neural basis of spatial cognition comes from observations in patients with spatial deficits following brain damage. These include a wide range of perceptual and motor deficits, such as poor localization of visual, auditory, or tactile stimuli; inability to determine visual or tactile line orientation; impaired performance on mazes; impairment on tests of mental spatial transformations; right–left confusion; poor drawing; impaired eye movements to points in space; misreaching; defective locomotion in space; and amnesia for routes and locations. As can be seen from this partial list, spatial behavior involves many kinds of skills, and not surprisingly, a number of brain regions have been implicated in spatial cognition and performance.

Broadly speaking, the parietal lobe is responsible for spatial perception and representation of immediate extrapersonal space, whereas temporal and parahippocampal cortices are more involved in topographic memory and navigation. The frontal lobe receives input from both parietal and temporal cortex and is responsible for generating actions. An important point about deficits in spatial cognition in humans is that they are far more common after right hemisphere damage than left. Although patients with left hemisphere damage may also exhibit spatial deficits, it is clear that the right hemisphere in humans has a superordinate role in spatial processing and behavior.

Impact of Parietal Lesions in Humans on Spatial Cognition

Two kinds of spatial deficits following parietal lobe damage are particularly illuminating. First, a common sensorimotor deficit is difficulty in using visual information to guide arm movements, referred to as optic ataxia. Patients with optic ataxia have difficulty with everyday tasks that require accurate reaching under visual guidance, such as using a knife and fork. They both misdirect the hand and misorient it

with respect to the object, and they are most impaired when using the contralesional hand to reach for an object in the contralesional half of space. A second, classic disorder of spatial cognition in humans is the tendency to ignore one half of space, called hemispatial neglect. The most common form of neglect arises from damage to the right parietal lobe and is manifested as a failure to detect objects in the left half of space. Neglect is more than just a visual deficit, however. It can occur separately or jointly across many sensory modalities. Moreover, neglect occurs with respect to many different spatial reference frames. A patient with right parietal lobe damage typically neglects objects on the left, but left may be defined with respect to the body, or the line of sight, or with respect to an attended object. Furthermore, this neglect is dynamic, changing from moment to moment with changes in body posture and task demands.

Neglect is apparent even in the purely conceptual realm of internal images. Patients exhibit neglect when asked to imagine a familiar scene, such as a city square, and describe the buildings in it. The portion of space that is neglected changes when they are asked to imagine the scene from a different viewpoint. As Figure 1 illustrates, neglect can occur with respect to an internal image constructed by the individual. Patients with neglect show evidence of using multiple reference frames, just as intact individuals do.

Impact of Parietal Lesions in Monkeys on Spatial Cognition

The role of parietal cortex in spatial cognition has been explicitly tested in animal studies. Monkeys with posterior parietal lobe lesions exhibit many of the same deficits seen in humans, including deficits in the appreciation of spatial relations between objects and impairments in eye movements and reaching. They perform normally on tests of object discrimination but are selectively impaired on a spatial task that requires them to judge which of two identical objects is closer to a visual landmark. In contrast, monkeys with temporal lobe lesions are unimpaired on the spatial task but fail to discriminate between or recognize objects. This double dissociation between the effects of lesions, in combination with the discovery of distinctive cortical inputs to the parietal and temporal lobes, led to the concept of the dorsal and ventral visual-processing streams. The ventral stream processes information about object form and color and is necessary for object recognition. In contrast, the dorsal stream processes information

Figure 1 A test for object-centered neglect. When asked to copy the two drawings on the left, a patient made the two copies on the right. Detail is omitted from the left half of each object rather than from the left half of the drawing as a whole. Reproduced from Marshall JC and Halligan PW (1993) Visuo-spatial neglect: A new copying text to assess perceptual parsing. *Journal of Neurology* 240: 37–40, with permission.

about where objects are located and how to acquire or avoid them.

Neurons in the dorsal stream encode several types of visual information important for spatial perception. Neurons in specific dorsal stream areas are selective for orientation, depth, direction and speed of motion, rotation, and many other stimulus qualities appropriate for perceiving spatial information. The dorsal visual-processing stream leads to posterior parietal cortex, where many kinds of visual information converge, including information about stimulus shape. An equivalent set of somatosensory processing areas send tactile information to anterior parietal cortex.

Visual and somatosensory signals converge on single neurons within the intraparietal sulcus, which divides anterior and posterior parietal cortex. Auditory signals have also been demonstrated to contribute to spatial processing in monkey parietal cortex.

Spatial Information Is Encoded in Multiple Reference Frames

The standard approach for investigating the role of parietal neurons in spatial processing is to record electrical activity from individual neurons while the monkey performs a spatial task. Because brain tissue has no sensory receptors, fine microelectrodes can be introduced into the brain without disturbing the animal's performance. By recording neural responses during carefully designed tasks, neural activity can be related directly to the sensory and representational processes that underlie spatial behavior. The general conclusion from these studies is that the function of parietal cortex is to transform spatial information from its original sensory coordinates into the motor coordinates necessary for the guidance of action. The specific kind of coordinate transformation depends on the anatomical area within parietal cortex and the task to be accomplished. Several cortical areas have been defined within the parietal lobe in monkeys. Two examples of parietal areas with distinct forms of spatial representation are described next.

Head-centered spatial representation in the ventral intraparietal area The ventral intraparietal area (VIP) is located in the floor of the intraparietal sulcus, where inputs from high-order visual and somatosensory cortex converge. In the visual domain, VIP neurons are characterized by direction and speed selectivity, and they resemble neurons in other dorsal stream visual areas that process stimulus motion. Surprisingly, these same neurons were discovered to respond to light touch on the head and face. The somatosensory and visual receptive fields of individual neurons exhibit strong spatial correspondence: they match in location, size, and even their preferred direction of motion.

The existence of spatially matched receptive fields raises an interesting question: What happens when the eyes move away from primary position? If the visual receptive fields were simply retinotopic, they would have to move in space when the eyes do and so would no longer match the location of the somatosensory receptive field. Instead, for many VIP neurons, the visual receptive field moves to a new location on the retina when the eyes move away from the straight-ahead position. For example, a neuron that has a somatosensory receptive field near the mouth and responds best to a visual stimulus moving toward the mouth will continue to respond to that trajectory of motion regardless of where the monkey is looking. The conclusion is that these neurons have head-centered receptive fields: they respond to stimulation of a certain portion of the skin surface and to the visual stimulus aligned with it, no matter what part of the retina is activated. Neurons in area VIP send projections to the region of premotor cortex that generates head movements. Area VIP neurons contribute to the visual guidance of head movements and may play a special role in hand, eye, and mouth coordination. They operate in a head-centered reference frame in order to generate appropriate signals for a particular motor effector system, namely that which controls head movements.

Eye-centered spatial representation in the lateral intraparietal area In contrast to area VIP, neurons in the lateral intraparietal area (LIP) construct an eye-centered spatial representation. Individual neurons become active when a salient event occurs at the location of the receptive field. This can be a sensory event, such as the onset of a visual or auditory stimulus; a motor event, such as a saccade toward the receptive field; or even a cognitive event, such as the expectation that a stimulus is about to appear or the memory that one has recently appeared. The level of response reflects the degree to which attention has been allocated to the site of the receptive field.

As discussed for area VIP, the animal's ability to make eye movements raises an interesting question about spatial representation. Neural representations of space are maintained over time, and the brain must solve the problem of how to construct an accurate spatial representation when a receptor surface moves. With each eye movement, every object in our surroundings activates a new set of retinal neurons. Despite this constant change, we perceive the world as stable. Area LIP neurons contribute to this perceptual stability by using information about the metrics of the eye movement to update the spatial representation

Figure 2 Remapping of visual memory trace activity in area LIP. The activity of a single neuron was recorded under three different conditions. (a) Simple visual response to a constant stimulus in the receptive field, presented while the monkey is fixating. The rasters and histogram are aligned on the time of stimulus onset. (b) Response following a saccade that brings the receptive field onto the location of a constant visual stimulus. (c) Response following a saccade that brings the receptive field onto the location where a stimulus was presented previously. The stimulus is extinguished before the saccade begins so it is never physically present in the receptive field. The neuron responds to the updated memory trace of the stimulus. H, horizontal eye position; V, vertical eye position. Reproduced from Duhamel JR, Colby CL, and Goldberg ME (1992) The updating of the representation of visual space in parietal cortex by intended eye movements. *Science* 255: 90–92, with permission.

of a salient location. In a simple saccade task, LIP neurons are activated when the monkey makes an eye movement that brings a previously illuminated screen location into their receptive field. These neurons respond to the memory trace of the earlier stimulus: no stimulus is ever physically present in the receptive field, either before or after the saccade. The explanation for this striking finding is that the memory trace of the stimulus is updated at the time of the saccade. Before the saccade, while the monkey is looking straight ahead, the onset of the stimulus activates a set of LIP neurons whose receptive fields encompass the stimulated screen location. They continue to respond after the stimulus is extinguished, maintaining a memory trace of the stimulus. At the time of the saccade, a corollary discharge, or copy of the eye movement command, containing information about the metrics of the saccade arrives in parietal cortex. This corollary discharge signal causes the active LIP neurons to transmit their stored representation of the stimulus to the new set of LIP neurons whose receptive fields will encompass the stimulated screen location after the saccade. The representation of the stimulated location is dynamically updated from the coordinates of the initial eye position to the coordinates of the final eye position (Figure 2).

The significance of updating lies in what it reveals about spatial representation in area LIP. It demonstrates that the representation is dynamic and is always centered on the current position of the fovea. Instead of creating a spatial representation that is in purely retinotopic (sensory) coordinates, associated exclusively to the specific neurons initially activated by the stimulus, area LIP constructs a representation in eye-centered (motor) coordinates. The distinction is a subtle one but critical for the ability to generate accurate spatial behavior. By representing visual information in eye-centered coordinates, area LIP neurons tell the monkey not just where the stimulus was on the retina when it first appeared but also where it would be now if it were still visible. The result is that the monkey always has accurate spatial information with which to program an eye movement toward a current or remembered target. The transformation from sensory to motor coordinates puts the visual information in its most immediately useful form. Compared to a head-centered or world-centered representation, an eye-centered representation has the

significant advantage that it is already in the coordinates of the effector system (oculomotor) that will be used to acquire the target. Humans with unilateral parietal lobe damage fail on an eye movement task that depends on an eye-centered representation of a remembered target position. This failure presumably reflects an impairment of the updating mechanism in parietal cortex.

In summary, posterior parietal cortex plays a critical role in spatial cognition. Physiological studies in monkeys show that parietal neurons represent spatial locations relative to multiple reference frames, including those centered on the head and the eye. Individual neurons combine spatial information across different sensory modalities (in area VIP), and specific spatial reference frames are constructed by combining sensory and motor signals (in area LIP). In accord with the physiology, human neuropsychological studies show that neglect can be expressed with respect to several different reference frames.

Frontal Lobe Mechanisms of Spatial Cognition

The parietal lobe transforms sensory representations of attended objects into the motor coordinate frames most appropriate for action. It does not actually generate those actions. Dorsal stream outputs to frontal cortex provide the sensory basis, in the correct spatial framework, for producing specific motor outputs. The following sections describe different types of spatial representations found in distinct regions of frontal cortex.

Head-centered and hand-centered visual receptive fields in premotor cortex Two different forms of spatially organized visual responsiveness have been described in ventral premotor cortex. First, in a subdivision representing facial movements (area F4), neurons respond to visual stimuli at specific locations relative to the head, much like those described

Figure 3 Data from a neuron in the premotor cortex with a head-centered visual receptive field (RF). (a) While the monkey was looking straight ahead at a fixation point (F), an object approached and receded, traveling either along trajectory 1 (T1, to the right of the head) or along trajectory 2 (T2, to the left of the head). The neuron fired strongly only when the object approached along trajectory 1. (b) When the monkey looked at a new fixation point on the far left, the neuron still responded only when the object approached along trajectory 1, indicating that the receptive field is tied to the location of the head and not to the location of the retina. The timelines above each raster and histogram show the horizontal and vertical eye position during one trial. The timeline below shows the position of the visual object as it comes toward and then moves away from the monkey. Adapted from Fogassi L, Gallese V, di Pellegrino G, et al. (1992) Space coding by premotor cortex. *Experimental Brain Research* 89: 686–690, with permission.

previously in area VIP. These neurons have been characterized by recording activity while objects approach the monkey's head along various trajectories. The preferred trajectory is constant with respect to the head, and it is not affected by changes in eye position. This specific zone of premotor cortex receives inputs from area VIP and uses the same form of spatial representation. In both cases, stimuli are represented in the motor coordinate frame that would be most useful for acquiring or avoiding stimuli near the face by means of a head movement (Figure 3).

A different kind of spatial representation has been observed in a subdivision of premotor cortex involved in generating arm and hand movements (area F5). Here, neurons respond to visual stimuli presented in the vicinity of the hand. When the hand moves to a new location, the visual receptive field moves with it. Moreover, the visual receptive field remains fixed to the hand regardless of where the monkey is looking, suggesting the existence of a hand-centered representation. A fascinating observation indicates that some neurons in this area are capable of even more abstract forms of representation. Some neurons in premotor cortex are activated both when the monkey grasps an object, such as a raisin, and when the monkey observes the experimenter performing the same action. These mirror neurons encode not just the monkey's own motor actions but also the meaning of actions performed by others.

Object-centered spatial representation in the supplementary eye field Actions are directed toward objects in the environment and toward specific locations on an object. Picking up your coffee cup requires that you locate both the cup in egocentric space and the handle in relation to the cup. The spatial reference frame that guides such movements is not limited to the egocentric representations described previously. Evidence from the supplementary eye field (SEF) demonstrates that single neurons can encode movement direction relative to the object. The SEF is a division of premotor cortex with attentional and oculomotor functions. Neurons here have visual responses and are also active before and during saccades. In monkeys trained to make eye movements to particular locations on an object, SEF neurons exhibit a unique form of spatial selectivity: they encode the direction of the impending eye movement

Figure 4 Data from a neuron in the SEF selective for the object-centered direction of eye movements. The monkey was trained to make eye movements to the right or left end of a horizontal bar. A cue appeared on the small sample bar shown in the lower right of each panel (1–8) to tell the monkey which end of the target bar (top in each panel) was relevant on a given trial. The arrow in the panel next to each histogram indicates the direction of the eye movement. The neuron fired strongly when the eye movement was directed to the left end of the target bar (left column) regardless of whether the physical movement of the eye was up and to the right (panels 1 and 5) or up and to the left (panels 3 and 7). Reproduced from Olson CR and Gettner SN (1995) Object-centered direction selectivity in the macaque supplementary eye field. *Science* 269: 985–988, with permission.

as defined relative to an object-centered reference frame. For example, a given neuron may fire when the monkey looks toward the right end of a bar placed at any of several different locations on the screen, regardless of whether the eye movement is a rightward or leftward saccade. Moreover, the same neuron will fail to respond when the monkey makes a physically identical eye movement toward the left end of the bar stimulus (Figure 4).

This remarkable result indicates that single neurons can make use of quite abstract spatial reference frames. Object-centered spatial information could potentially guide arm movements as well as eye movements. Moreover, neuropsychological evidence indicates that an object-centered reference frame can be used to direct attention: some patients exhibit object-centered neglect after parietal lobe damage. Parietal lobe lesions in monkeys likewise produce impairments on tasks that require an object-centered spatial representation.

Conclusion

Behavioral and neuropsychological studies indicate that we make use of multiple spatial representations in the perception of extrapersonal space. Neurophysiological studies are beginning to uncover the neural mechanisms underlying the construction of these egocentric and allocentric spatial representations. We can conclude that spatial cognition is the product of many brain areas with distinct representations of space.

Introduction

Representing and exploring the space around us is fundamental to human cognition. The study of spatial cognition, both at the psychological and neural level, is extensive, encompassing parallel investigations of many different types of spatial knowledge and many different spatial tasks. For example, there is now a large literature concerned with the processes involved in deriving spatial relations between objects or between parts of objects, and with the way these processes differ from other mechanisms involved in object recognition, such as the representation of the parts alone.

A rather different form of spatial processing, which is also the topic of much current investigation, concerns the nature of the spatial representations engaged during the learning of the spatial layout of the environment. Two forms of spatial knowledge, both of which are deemed critical for navigation purposes, have been described in these investigations of spatial cognition: survey knowledge (based on an external perspective or an aerial or maplike view), which allows access to the global spatial layout, and route knowledge, which is the perspective represented by a ground-level observer. Recent functional neuroimaging studies have suggested that these two spatial processes recruit both a common network of cortical regions but also additional, differentiable regions of cortex. Consistent with this, in individuals with unilateral hemispheric lesions, several brain areas appear to be involved in retracing a route from the end to the beginning, including the right hippocampal formation, the right posterior parietal cortex, the right dorsolateral prefrontal cortex, and the right temporal lobe. The hippocampus also plays a particular role in path integration; specifically, individuals with lesions to the right (but not left) hippocampus are inconsistent in their navigation to previously viewed targets, and they also show a systematic underregistration of linear displacement (and/or velocity) during walking. Whereas the hippocampal coding appears to be specific to certain places in the field, parietal neurons code route maps in a more scalable and versatile form, independent of the size and spatial configuration of the navigational field.

A further strand of experimental studies concerned with spatial cognition has explored the psychological and neural mechanisms mediating spatial working memory. Keeping spatial information active online (even for extended periods of time) engages dorsal areas of lateral prefrontal cortex, posterior parietal cortex, and possibly even the hippocampal formation, and damage to these areas significantly impairs working memory. Finally, much research is concerned with delineating the nature of the underlying spatial representations, with specific emphasis on determining the reference frames or spatial coordinates employed for sensory information encoding. In some regions of cortex, the spatial position of the input is defined with respect to an eye-, head-, and/or body-centered frame of reference or sometimes some mixture of these different reference frames. While parietal cortex appears most involved in these egocentric forms of representation, in which the reference frame is centered on the observer, superior parietal cortices represent information allocentrically, independent of the observer, although, of note, these egocentric and allocentric representations appear to be somewhat interdependent. Of great interest, too, are the means whereby spatial information is updated – as the eyes move or as the observer navigates, the spatial positions of items in the environment change. To achieve a stable and robust representation, information must be constantly updated, and studies concerned with spatial updating have been (and continue to be) conducted with humans and nonhuman species, using a variety of methods, including lesion studies, functional magnetic resonance imaging, and single-unit recording.

As is evident from this brief overview, spatial cognition is multifaceted, and spatial representations are derived in the service of many different forms of cognition. Importantly, too, these different spatial representations are not mutually exclusive and much research remains to be done to specify the differences and commonalities among these representations and the spatial tasks in which they are engaged. This article focuses specifically on the spatial representations mediated by parietal cortex, often assumed to be the preeminent area involved in spatial processing. Two major lines of investigation are summarized, with one set of data primarily derived from studies of individuals with parietal lesions and the other set of data acquired from functional brain imaging studies (mostly functional magnetic resonance imaging).

Parietal Lobe and Spatial Representations

Anatomical Delineation of Parietal Cortex

The parietal lobe forms about 20% of the human cerebral cortex and is divided into two major regions, the somatosensory cortex and the posterior parietal cortex (Figure 1). Posterior parietal cortex, located at the junction of multiple sensory regions and projecting to several cortical and subcortical areas, is engaged in a number of cognitive operations, many of which involve spatial representations. Parietal cortex is separated from the frontal lobes by the central sulcus and from the occipital lobes by the parieto-occipital fissure. Since the 1940s, hundreds of studies have documented the behavioral consequences of parietal lesions in humans and monkeys, with primary emphasis on the perturbation of perceptual and action space following these lesions.

Parietal Lobe and Spatial Representations: Evidence from Hemispatial Neglect

In humans, the deficit that affects the representation of space following unilateral hemispheric lesion is referred to as hemispatial neglect ('neglect,' for short). Following brain damage, particularly to the right hemisphere (see Figure 2 for examples of lesions giving rise to neglect), individuals typically exhibit a variety of symptoms, including impaired representation of information appearing on the side of space contralateral to the lesion. These individuals may fail to report or to orient to sensory information on the contralateral side of space. Standard bedside tests, such as having the patients draw a clock from memory or copy a clock, bisect some lines, or cancel lines on a page, are typically used to elicit neglect (see Figure 2(b) for examples of patients' performance on such tests). Individuals may also show neglect of information appearing in contralesional personal space, in that they may eat, dress, and/or shave only the ipsilesional side. Furthermore, the eye and hand movements of such individuals may also be somewhat restricted to the ipsilesional side, and there is a perseverative tendency (perhaps induced by the failure to keep track of spatial locations) to revisit the same regions on the ipsilesional side. Interestingly, even in the absence of sensory input, neglect may be evident: the patients report only ipsilesional information in tasks of mental imagery and may show a paucity of contralesional saccades even when moving their eyes in the dark. Note that the neglect disorder does not arise from a primary motor or sensory deficit *per se* and is generally thought to arise from a deficit in attending to and representing the contralateral information.

Neglect also occurs more frequently and with greater severity following right than left hemisphere lesions (see also evidence from functional imaging studies on hemispheric asymmetry of parietal activation), and so we refer to neglect of left-sided information as a convenience throughout the following discussion. The scientific study of hemispatial neglect has been especially captivating over the past few decades and has continued to shed light on the mechanisms supporting spatial representation.

A critical question repeatedly addressed in the neglect literature is whether spatial information from different sensory modalities is processed in similar fashion. Although a majority of the studies have explored visual neglect, the question of interest is whether the underlying spatial map, perturbed by parietal damage, is specifically visual or utilized by other modalities as well. If the latter holds, then one might expect to observe neglect across multiple sensory modalities. Indeed, the consensus is that the representation of and awareness of space involve input from multiple sensory

Figure 1 (a) Schematic depiction of relevant anatomical landmarks projected onto the (a) lateral and (b) medial surfaces of the human brain. Parietal cortex (PC) is located posterior to the postcentral sulcus (PCS), which lies posterior to the central sulcus (CS), and superior to the occipital lobe (OL). It is divided by the intraparietal sulcus (IPS) into the superior parietal lobule (SPL) and the inferior parietal lobule (IPL). The continuation of the SPL on the medial side, anterior to the parieto-occipital sulcus (POS), is called the cuneus. The frontal lobe (FL) is divided into the middle frontal gyrus (MFG) and the inferior frontal gyrus (IFG). The superior temporal gyrus (STG) runs along the superior extent of the temporal lobe (TL) and terminates at the temporoparietal junction (TPJ).

Figure 2 (a) Examples of structural scans from three different individuals, all of whom show hemispatial neglect following right parietal lobe lesions. Note that the right hemisphere is on the left of the image. (b) Examples of performance of three different patients with hemispatial neglect, using bedside tests of line bisection, line cancellation, and clock drawing from memory.

modalities: patients with visual neglect have difficulty localizing sounds and also experience problems in specifying the location of tactile input. Also, prism adaptation (see later for more details) appears to affect visual as well as proprioceptive input, further attesting to the cross-modal nature of spatial representation. Of course, one cautionary note in reaching this conclusion is that the lesions in humans are typically large and may implicate many regions of parietal cortex (in contrast to the lesions in nonhuman primates or the single-unit recording studies wherein the target areas are more circumscribed). With the advent of high-resolution structural imaging, we can start delineating better, in the neglect patient, the exact site of the lesion, the extent to which different parietal regions are affected, and the consequences of these more limited lesions on behavior.

Given that parietal cortex appears to derive a representation of space, one issue that has been under considerable investigation concerns the nature of competitive interactions between information appearing further on the ipsilesional or contralesional side of space. Consistent with ideas emerging from 'biased competition' accounts, there is a view that suggests that information appearing more contralesionally is assumed to compete with more rightward information, perhaps 'extinguishing' it entirely. If the contralesional information appears temporally in advance of the more rightward information or is much more salient than the rightward information, it might not be so readily extinguished and might ultimately be reported. It is also the case that if the contralesional information can be integrated or perceptually grouped with the rightward information, it, too, might survive the competitive interaction and be reportable. Although much of the emphasis has been on a spatial gradient with greater activation as one proceeds from left to right, there is also growing consensus that there is a temporal delay in representing spatial information (enhanced or prolonged 'attentional blink'), even when the information appears in the midline.

One recent domain in which considerable progress has been made concerns the nature of recovery of spatial attention deficits in individuals with hemispatial neglect. An intervention procedure used in some recent studies to ameliorate hemispatial neglect is to adapt the patients to prisms, which serves to induce a rightward displacement of the visual field. Several studies have successfully reported reduction in the severity of hemispatial neglect following prism adaptation and have shown that the eye movements postadaptation (in individuals with right-sided lesions and left-sided neglect) are significantly more rightward deviated than was the case prior to the intervention. Although many questions remain as to the mechanisms that give rise to this lateral-displacement postadaptation (Is it a redistribution of spatial attention? Is it visuomotor in nature?), and even though the consequences of adaptation are not very prolonged, the technique has proved to be remarkably valuable in flexibly altering the behavior of the patients with neglect, and much remains to be done in this domain.

Even without prism adaptation, following standard rehabilitation procedures, individuals with hemispatial neglect do show a decrement in the bias to orient rightward as well as showing a significant improvement in attention reorienting to the contralateral space. Of particular interest in recent investigations, as revealed in functional imaging studies, is that the

behavioral improvement even in these standard treatment procedures is correlated with reactivation of multiple cortical areas, which previously evinced weak or no task-related activity (even though some of these areas were anatomically intact). The opportunity to use functional imaging procedures to track recovery and perhaps to identify the optimal procedures for reinstituting cortical activation is promising and offers a new method for developing and assessing rehabilitation procedures.

Parietal Lobe and Spatial Representations: Evidence from Lesion Analyses

The advent of high-resolution imaging (and its relative ease of accessibility) has also enabled investigators to track the lesion site in greater detail than has been possible in the past and to reevaluate the anatomical underpinnings of hemispatial neglect. While neglect has been most commonly associated with the inferior parietal lobule and also the temporoparietal junction (TPJ; see Figure 1), the underlying anatomical substrate has come under increased scrutiny. For example, some findings suggest that the superior temporal gyrus (STG) is the critical site of cortical damage associated with neglect and subcortical sites, including the putamen, and, to a lesser extent, the caudate nucleus within the basal ganglia and the pulvinar within the thalamus have also been implicated. Yet others have argued that a disconnection between the frontal and the inferior parietal region, brought about by a lesion of the superior longitudinal fasciculus, gives rise to chronic neglect. A further set of investigations has suggested that parietal cortex has a more dorsal and a more ventral stream and that each may play a slightly different role, with more superior regions engaged in voluntary, goal-directed attention and more inferior regions more engaged in bottom-up detection of salience or novelty. Finally, large-scale studies report that neglect arises after lesions to any one of multiple nodes making up a distributed spatial-attentional network, including temporal, parietal, frontal, and occipital cortices as well as basal ganglia and thalamus (in order of incidence). The continued development of more sophisticated imaging techniques and methods of lesion analysis will be critical in outlining the neural substrate of spatial representation and possibly even in differentiating subtypes of neglect and their cortical signatures.

Parietal Lobe and Spatial Representations: Evidence from Functional Imaging Studies

Thus far, the role of parietal cortex in spatial representation has been considered based on findings from human lesion studies. Converging evidence from functional imaging studies has recently contributed enormously to elucidating the mechanisms underlying spatial representation. For example, one robust finding is that when cues direct an observer to a spatial location in which an upcoming target is likely to appear, activation is noted in superior frontal, inferior parietal, and superior temporal cortices. Spatial attentional selection serves to facilitate perception of stimuli (e.g., objects), as reflected in enhanced speed of processing of attended information. Given the increased access to functional imaging, researchers have spent considerable effort to shed light on the mechanism subserving spatial attentional orienting. A primary focus of such studies has been to determine the anatomical loci within the human cortex that give rise to the attentional biasing signal (i.e., the source or process that directs or shifts attention) that ultimately initiates the sensory enhancement of the selected stimulus (i.e., the effect). In this next section, we summarize findings from these studies, showing the differential involvement in the source versus the effects of attentional manipulations.

Effects of Spatial Selection: Enhancement of Sensory Signals

Studies of the effects of visual attentional selection have revealed behavioral facilitation and enhanced cortical responses to information appearing in attended spatial locations. Neurophysiological studies investigating the effects of top-down attentional bias have demonstrated that when a cell is presented with a stimulus in its receptive field (RF), the neural response to that stimulus is increased when attention is covertly directed to it as compared to when the stimulus is in the RF but attention is either unfocused or is diverted elsewhere. For example, in their seminal study, Moran and Desimone first identified the classical RF of a V4 neuron and its corresponding effective and ineffective stimuli (i.e., stimuli that drive the cell strongly and weakly, respectively). The monkeys were trained to attend to stimuli in a specific location within the visual field while ignoring stimuli at another location. Both effective and ineffective stimuli were presented within the RF and the responses of the V4 neurons were strongly modulated by the spatial attentional locus: the firing rate to the preferred stimulus was only one-third as great when the monkey did not attend to it as compared to when the preferred stimulus was attended. In fact, what was particularly interesting about this study is that when attention was directed to one of two stimuli in the receptive field of a V4 cell, the effect of the unattended stimulus was attenuated, as if the receptive field had contracted to include only the attended stimulus. This type of spatial

attentional enhancement was found to increase with task difficulty and was observed throughout early sensory regions within the visual cortex.

Several neuroimaging studies in humans have also documented early sensory enhancement following top-down spatial attentional allocation. In the majority of these experiments, individuals are presented with stimuli appearing to the left or right of fixation and are asked to direct their attention to either side of the fixation point (i.e., shifting their attention either to the left or the right side of space) (Figure 3). Directing spatial attention to the left hemifield results in increased stimulus-evoked neural activity of the early visual areas in the right hemisphere, whereas directed spatial attention to the right hemifield is accompanied by increase of activity in the early visual areas of the left hemisphere. Studies employing event-related potentials (ERPs) take advantage of the fact that visual stimuli typically elicit two early waveform components, which are termed P1 (first positive, occurring 100–200 ms after stimulus onset) and N1 (first negative). These effects are robust and are observed even during passive viewing of input. Of relevance, the P1 and N1 components are modulated (i.e., increase in negativity and/or positivity) when visual stimuli are being attended to, as opposed to when spatial attention is diverted elsewhere in the scene. The modulation is manifest by a change in the amplitude of these components, while the component latency remains the same when the stimuli are attended or ignored.

In summary, spatial attention serves to modulate sensory signals elicited by the stimuli in the early sensory cortex (i.e., areas V1–V4) and also in higher order areas such as the motion-sensitive region (MT+), fusiform face area (FFA) selective for face processing, and other higher order regions within the human cortex.

Sources of Spatial Orienting Signal

Several regions within monkey and human posterior parietal cortex (PPC) have been identified as coarsely representing spatial topography as it relates to the source or trigger of a spatial attentional orienting signal. For example, neurons in the lateral intraparietal area (LIP) of the monkey cortex fire in response to the location in space to which attention was cued, representing the voluntary allocation of attention to a specific region in space. Several regions within the human parietal and frontal cortices – inferior parietal sulcus (IPS), superior parietal lobule (SPL), and the frontal eye fields (FEFs) – are also identified as playing a critical role in spatial attentional selection. Functional magnetic resonance imaging (fMRI) studies have demonstrated that activity in these frontal and parietal regions is spatially selective, such that stronger activity is noted when attention is directed toward spatial locations in the contralateral field.

Several fMRI studies support the proposal that the top-down attentional signal (the implementation of the cue) arises at least partially from the parietal

Figure 3 (a) A representative slice through a high-resolution reconstructed brain of an individual performing an attentional shifting task. The activation (shown in red) is obtained by contrasting activity during shifts of attention between the sensory stimuli (could be, for example, from left side of space to right side of space, or from auditory stimuli presented to the left ear and to the right ear) with activity when holding attention within a sensory stimulus. The cluster of activated voxels encompassed within the white circle is in the right superior parietal lobule. (b) Blood oxygen-level-dependent signal extracted from the right superior parietal lobule reflects transient activity elicited within this region following shifts of attention from one sensory stimulus to another. Note that activity within this region remains low for sustained attention (hold trials). From Shomstein S and Yantis S (2006) Parietal cortex mediates voluntary control of spatial and nonspatial auditory attention. *Journal of Neuroscience* 26(2): 435–439.

cortex, with an additional contribution from the frontal cortex – what has been termed the frontoparietal attentional network. For example, when individuals are asked to covertly direct their attention following a cue to a spatial location in the visual display in preparation for a target, areas in the occipital lobe respond transiently to the cue, while areas in the posterior parietal cortex along the inferior parietal sulcus exhibit a more sustained response. The sustained activity in the PPC is assumed to reflect the source of the attentional orienting signal: it could not be linked to either visual stimuli or motor responses *per se* and its activity was time locked to the period during which individuals paid attention to the peripheral future target location.

It is important to understand the precise function of the parietal lobe's involvement in attentional control. At least two possibilities regarding the time course of parietal lobe activity following spatial shifts of attention must be considered. The first possibility is that the PPC provides a continuous signal that maintains the locus of attention at a specific spatial location – the 'sustained hypothesis.' In other words, once the individual has decided to change the locus of spatial attention, the PPC issues a signal that will be sustained until another change in the locus of spatial attention is made (i.e., sustained increase in neural activity). Another possibility is that the PPC issues a transient brief signal to shift the attentional state – the 'transient hypothesis,' such that once the locus of spatial attention needs to be redirected elsewhere, the PPC issues a transient signal that dissipates quickly once the attentional shift has been made. This latter hypothesis also predicts that the locus of attention is maintained by other areas, presumably frontal areas within the frontoparietal network.

Several recent studies examined the exact involvement of the PPC in attentional shifting tasks by adjudicating between these two hypotheses. In a typical task, individuals are shown two streams of input presented peripherally to the left and right of fixation and are initially instructed to monitor one stream for a cue (for example, a digit among the stream of letters). The identity of the cue indicates to the individuals whether they should maintain attention on the current stream or shift attention to the other stream. The critical finding is revealed when one compares cortical activity related to shifting the attentional focus from one spatial location to another with activity related to maintaining the attentional focus on a single stream. When attention was shifted between spatial locations, the time course of the blood oxygen-level-dependent (BOLD) signal in the right SPL and inferior parietal lobule (IPL) exhibited transient activity (see Figure 3). The transient nature of the signal elicited by the SPL suggests that this area of the parietal cortex is the source of a brief attentional control signal to shift attentive states to a new spatial position, and is not the source of a continuous signal to actively maintain the new attentive state.

Sources of Nonspatial Orienting Signal

Although the focus thus far has been on spatial representation and attending to spatial regions containing input, the top-down attention-shifting signal is not restricted to spatial shifts alone, and this region is activated when individuals shift their attention between any two dimensions of the input. For example, shifts between superimposed houses and faces, shifts between two different features of an object, or shifts between two different sensory modalities all selectively activate the PPC. Whereas spatial shifts are accompanied by increased activation in the SPL region of the parietal lobe, nonspatial shifts are accompanied by increased activity in the precuneus region, the continuation of the SPL on the medial side of the parietal lobe (see Figures 1 and 3). This anatomical distinction between spatial and nonspatial shifts of attention clearly deserves a more thorough investigation. We should note that additional attentional functions could be mediated by some of the same subareas of parietal cortex already described. For example, both an anterior part and an inferior part of the intraparietal sulcus appear to be activated in a visual conjunction task, even in the absence of multiple distractors, and this occurs to a greater extent in the left than in the right hemisphere. By contrast, activation of a more posterior region of the intraparietal sulcus appears to be contingent on the presence of distractors. Much work remains to be done to outline the various attentional functions mediated by the parietal cortex and also, in parallel, to map out the behavioral and neural mechanisms associated with spatial representation.

Conclusion

Spatial cognition is a complex, multifaceted set of processes that are engaged in a large variety of tasks, including, for example, mental rotation, spatial navigation, and spatial working memory. The exact nature of the spatial knowledge implicated in these different tasks remains to be determined. We have focused on behavioral and neural mechanisms involved in representation of spatial locations, with evidence drawn from neuropsychological studies of individuals with hemispatial neglect and neuroimaging studies of spatial attentional selection (and the ensuing sensory enhancement). As is evident, the

findings are probably more complicated than we might have thought, given the progress made to date on these topics. In particular, better use of structural and functional imaging has led to fine-grained reconsideration of previous findings. Some of the received wisdoms regarding hemispatial neglect have come under scrutiny, and the fMRI findings have opened new avenues of investigation. Among the outstanding issues are the mechanisms giving rise to the neglect in the first place (for example, a deficit in spatial attention, a problem in spatial updating, or competition between inputs). The neural locus of neglect has also come under reconsideration and many questions remain. Findings from functional imaging studies have also opened new domains of investigation. In particular, the imaging studies have suggested that spatial positions in the world can be selectively attended and that these attentional effects are robust and are present throughout the visual (and auditory) system, and attending to specific stimuli modulates the cortical areas involved in processing the input. The posterior parietal cortex appears to play a dominant role in signaling and implementing the attentional shift from one location (or feature or object) to another, as reflected in the transient activity in posterior parietal cortex.

Spatial Cognitive Maps

Introduction

Several theories have been developed to account for spatial learning. For S–R theorists, spatial learning consists of chaining together a number of motor responses linking relevant external stimuli (stimulus–response associations). This view was challenged by Tolman in 1948, who argued that rats do not merely base their actions on S–R associations, but internally reorganize acquired spatial information so as to form cognitive representations of the environment. In other words, rats learn the location of a place where they have been rewarded independently of the specific movements necessary to reach it. Tolman explained this ability by introducing the notion of a cognitive map, a mental representation held by the rat in which it encodes the elements of a task and the spatial relationships between these elements. An important property of cognitive maps is that they allow animals to react to stimuli that are not immediately present since the relationship of such stimuli to those actually perceived is maintained in the representation. Thus, the rat can be aware of the properties of the environment beyond their field of perception. The major consequence of such a representation is that it bridges informational gaps about the environment, thus conferring greater flexibility and efficacy to behavior.

Tolman's notion of cognitive map was further developed by O'Keefe and Nadel in 1978, who proposed a theoretical framework to account for spatial behavior and its neural bases. They made a distinction between two main processes used by rats to perform spatial tasks. They proposed that rats can use either a taxon system or a locale system. The taxon system is based on S–R associations, whereas the locale system is based on spatial relationships in the form of a cognitive map (Figure 1). They further proposed that the brain regions subserving these forms of spatial navigation are different and at least partially independent.

Spatial Strategies

The number of studies which support the hypothesis that animals form a mental representation of their environment is quite impressive. This does not mean, however, that animals rely exclusively on spatial representations to orient in space. Performing specific responses, approaching particular cues, or even learning conditional associations about the sensory consequences of specific movement sequences may be efficient strategies in a number of situations. Nevertheless, in spite of their efficacy, such strategies do not confer behavior with the degree of flexibility afforded by the use of a cognitive map.

Selection of appropriate navigational strategies is primarily determined by the perception of space, that is, by the nature of the cues that can be used for navigation. There are two main categories of spatial cues: allothetic and idiothetic cues. Allothetic cues are provided by the environment and include visual, olfactory, and auditory information. Idiothetic cues are derived from the animal's own movements, including information provided by the vestibular, proprioceptive, and somatosensory systems, efference copies of motor commands, and external motion-related information such as optic flow. Although this article is about navigation based on cognitive maps, it is useful to briefly describe other strategies useful for moving efficiently in space.

Cue Navigation

The simplest navigational strategy is to move toward or away from a directly perceived cue. The use of such a system requires a radial stimulation gradient field centered on the source. The notion of gradient field refers to the variation of intensity of the source as a function of the distance. In the simplest case, intensity varies monotonically with the distance. The animal can therefore reach the goal, that is, the origin of the gradient, by navigating in the gradient direction or conversely, avoid a place by navigating in the opposite direction. A gradient field may originate from auditory and olfactory cues. Navigation toward a conspicuous visual cue has similar characteristics. The visual cue is considered to be at the center of a radial gradient where the gradient direction corresponds to the direction of the light flux. Then, reducing the distance from the visual cue (that leads to an increase of the apparent cue size) is equivalent to navigating along the axis of greatest intensity. The animal can also use a similar mechanism to reach a hidden goal that is closely associated with a salient landmark (called a beacon). A landmark is therefore considered as an intermediate goal whose spatial contiguity with the real goal has been learned through an associative process.

Figure 1 The two systems for encoding spatial information proposed by O'Keefe and Nadel in 1978. Cognitive mapping (locale system) involves building a representation of a part of space that encodes the relationships between environmental landmarks (e.g., the nest, a tree, and a food source), independently of the animal's location (allocentric coding). Using a route (taxon system) involves encoding the location of landmarks relative to the animal's position (egocentric coding).

Guidance

If the goal cannot be directly perceived and if there is no landmark closely associated to the goal, the animal must rely on environmental landmarks to navigate. One strategy is to use landmarks as directional cues. Guidance, therefore, requires that the animal directs its attention to particular landmarks and maintain some egocentric (i.e., relative to the animal) spatial relationships with respect to these landmarks to reach the goal. A place-recognition process is then needed to identify the goal location. Rats may be guided either by individual or configurations of landmarks. For example, they may be able to memorize a view (or snapshot) of the spatial arrangement of landmarks seen from the goal and so adjust movements until a current view matches a memorized view.

Routes

To reach a remote goal, cue navigation and guidance may be elaborated into route learning. In route learning, rats may memorize a sequence of associations coupling specific landmarks and motor responses, for example, "after reaching the rock, turn left." Each landmark is considered as an intermediary goal and the sequence of these goals constitutes a route. Routes allow rapid navigation at the expense of behavioral flexibility, however. Environmental changes altering the sequence of landmarks may be fatal to successful navigation. In addition, retracing the route cannot be achieved by simply inverting the order of the landmarks, but requires active learning of a new sequence.

Path Integration

Path integration, or dead reckoning, relies on an 'egocentric' (self-centered) coding process, which allows an animal to memorize a location (usually the starting point of its journey) in relation to its own position. This form of navigation relies on idiothetic (self-motion) cues, which are used to update a vector that specifies, in egocentric coordinates, the distance and head-referred direction of the goal from the animal's current location. Its major drawback is that the computation of these parameters is subject to cumulative error. If the cumulated error is great enough, the animal may miss its target. Although the egocentric coding process is unreliable, its precision can be improved if information is recalibrated from visual or other sensory information available from the environment. It is not clear, for rats or humans, whether any reliance is placed on path integration except when external sensory information is missing or inadequate.

Allocentric (Place) Navigation

Allocentric navigation refers to the process of determining and maintaining a course or trajectory from one place to another by using environmental cues. It requires formation and use of a map-like representation of the environment (a cognitive map) which encodes the allocentric relationships between landmarks and places, independently of the animal's position. The use of a mapping strategy allows an animal to reach a goal from a variety of points, including over trajectories that it has not previously used. A rat is thus able to infer its location relative to particular places whose position is encoded in the representation and compute optimal trajectories to reach these places. Place navigation is flexible because if a possible path is obstructed, or if a landmark is missing, the animal is still able to generate successful trajectories by performing detours and short-cuts and by adapting its navigational behavior to environmental changes.

One of the most versatile test to study place navigation is the Morris water maze task, in which the animal swims in a circular tank filled with opaque water in order to reach a submerged or visible platform, which is the only place to which it can escape from the water. In the place version of the task, there is no cue closely associated with the platform. Localization of the hidden platform can only be performed

Figure 2 Role of exploration in updating cognitive maps. A typical protocol involves the rat exploring an enclosed apparatus containing a set of objects in stable locations. After the rat is familiar with this object configuration, a change is made in the spatial arrangement of objects (here a single object, D, is slightly moved from its original location). When reintroduced into the apparatus, animals usually display an exploratory reaction toward the moved object, indicating that they detect the change and update their cognitive map accordingly.

and learned by using distal room cues. To prevent the animal from using a local view for guidance, different starting places are used on successive trials. It is therefore assumed that learning results in the elaboration of a cognitive map. Acquisition of the Morris navigation task however also requires procedural memory and working memory. Procedural memory allows the rat to learn that it must swim, find an escape platform, climb on the platform, etc. Working memory results in learning that the platform is at a specific location, which rats can often do in a single trial after mastering the procedural details of the task.

Exploration and Spatial Cognitive Maps

Although an obvious function of cognitive maps is to indicate where potentially important objects are located in space, they can be used for other purposes. As a matter of fact, animals need to be familiar with the surroundings and will not behave according to their primary motivation, such as hunger or thirst, until they recognize and identify where they are in space. This ability to locate oneself in the current environment depends on prior exploration. In fact, navigation and exploration are so intimately related that accurate navigation cannot occur without preliminary exploration of the environment. The major function of exploration is information gathering and storage and so it is necessary for the formation of spatial representations. An advantage of such storage is that it may allow detection of unexpected new information in an otherwise familiar environment. For example, if place recognition is not achieved, exploration occurs again so that the cognitive map comes to match the real environment as closely as possible, therefore providing the animal with spatial invariants. Exploration may lead either to a new representation or to the updating of a former spatial representation.

An illustration of the updating process is provided by studies which show that changing the spatial configuration of objects in a previously explored arena induces a renewal of exploratory activity mostly aimed at the displaced objects (Figure 2). The protocol consists of two successive phases: habituation and spatial change. First, repeated exposure to the same configuration of objects results in habituation of exploratory activity, that is, a decrement in the response with increasing familiarity. It is hypothesized that during this phase, rats acquire some knowledge of the spatial characteristics of the environment. Habituation thus reflects the elaboration of a spatial representation. Once habituation is achieved, the animals are exposed to a new configuration of the same familiar objects. A renewal of exploration following this change is assumed to reflect that the animal (1) encodes certain spatial relationships and (2) is able to compare the previous and current situations. Such renewal is thus an adaptive behavior aimed at updating the spatial representation of the environment. It is therefore clear that there is a constant interplay between exploration and the cognitive map, with exploration allowing for initial buildup and subsequent updating of the map, which in turn drives further spatial behavior, including exploration, within the animal's current environment.

What Is the Information Stored in Spatial Cognitive Maps?

That animals are able to use representations of their environment does not mean that they encode all aspects of the spatial surroundings. In fact, evidence suggests that the information content of spatial cognitive maps can be quite selective.

Configurations of Cues and Geometry

In most spatial tasks, performance appears to rely on configural rather than on individual landmarks. Up to a point, removing specific cues in tasks such as the water maze place navigation task (or the radial arm

maze tasks) usually does not alter animal's performance to a great extent. In contrast, rearranging these cues can be quite detrimental to task solution. Based on the analysis of exploratory patterns, it can also be demonstrated that changing the spatial configuration of discrete objects in a familiar arena induces a renewal of exploratory activity. Further analyses of exploratory responses confirm that the animal keeps a record of the spatial arrangement of the objects, but that this record is specific to certain classes of spatial relationships. In general, changes that induce the strongest responses are those that affect either the overall geometrical arrangement of the object set, or the topological relationships among the objects. The configuration seems to be privileged over the absolute position of objects. Thus, spatial geometry seems to constitute an important piece of information contained in the map. In other studies, rats were placed in a rectangular chamber and were required to visit the four corners of the chamber. Each corner contained a different amount of food and was associated with a distinctive visual insert. Two opposite corners had the most bait while the remaining two opposite corners had the least bait. After the animals mastered the task (i.e., visited each corner according to a decreasing order from the most baited to the least baited arm), a number of probe tests were conducted based on transformations of the initial distribution of the inserts. The rats' patterns of visits to the food locations were remarkably insensitive to the modifications made in the spatial arrangement of the inserts. Rather, the animals used the rectangular shape of the experimental chamber as a means to locate the various food sources. Thus, rats ignore obvious landmarks and attend to landscape features instead in reorienting themselves in symmetric environments. Although they are aware of the landmarks, they simply do not appear to use them for certain purposes. The rules governing when landmarks or landscapes are used in behavior remain to be fully explicated. Current thinking suggests that local landmarks are not used to determine directions in space, nor to define a spatial framework within which such directions can be nested. Rather, landscape features are seemingly used for these purposes.

Distal versus Local Landmarks

Landscape features are not the sole markers of the spatial arrangement. Distal landmarks provide another major source of information on which spatial navigation can rely. In general, animals will preferentially use such distal information when it is available, to the detriment of local cues. As an example of the greater efficiency of distal cues in guiding spatial behavior, consider the navigation performance of rats trained in the water maze navigation task. In this task, a swimming rat can escape from water by locating a safe platform relative to the array of visual cues located 'outside' the swimming pool. After a few training trials (usually fewer than 30), the rat swims almost directly toward the platform. In contrast, when the task is changed so that rats have to rely on three objects placed directly in the swimming pool (local cues) to locate the platform, many more trials are required before the rat displays direct navigation paths.

Distal information also predominates when it conflicts with movement-related information such as that provided by path-integration mechanisms. While path-integration-based homing behavior in hamsters is barely altered by the manipulation of local cues, it can be easily altered by manipulating distal information. To understand why distal cues are so effective in controlling place navigation, it is necessary to realize that only distal cues maintain their reciprocal relationships with respect to the animal during its motion. Thus the perceived reciprocal relationships between distal cues are minimally affected by an animal's movements. On the contrary, the perceived reciprocal relationships between local cues are subject to strong changes during movements. Since a cognitive map contains absolute topographical information rather than information about egocentric locations relative to the animal, it becomes evident that distal cues provide a more reliable source of information for localization since they retain relatively stable relationships as the animal moves about the environment.

Metrics and Topology

The evidence reviewed above indicates that rats possess a representation of the configural aspects of the distal environment. This representation is not homogeneous, however: animals process certain locations in a more detailed way during exploration. This is not very surprising because space is not homogeneous. It is more surprising, however, that the topological relationships among such locations (e.g., whether they are in the same vicinity) often have stronger control over spatial behavior than do metric relationships (e.g., their absolute distance in Euclidean space). It is therefore possible that spatial representations can be both topological, therefore affording relatively unstructured information about the connectivity within space (e.g., place A is directly connected to place B but not to place C), and metric (e.g., place A is a certain distance and direction from place B), affording more detailed information about specific

Figure 3 Metric and topological information can be used separately to describe space. The left part of the figure shows a environment in which a set of spatial locations (a–f) are connected to each other by specific paths. An arbitrary topological transform of the spatial network is shown in the right part of the figure. The topologically equivalent network preserves the topological properties of vicinity and connectivity between the locations, but not the metric relationships (i.e., angles and distances between locations).

Figure 4 Main properties of place cells, head direction cells, and grid cells. Cells are usually recorded as a rat explores a cylindrical environment in which a single landmark (a cue card) is attached to the apparatus wall (shown as an arc at 12:00 in the figure). The left-hand and right-hand parts of the figure show the typical positional firing rate map and directional polar plot for each type of cell, respectively. Place cells discharge only at a specific location (shown as concentric colored circles at 3:00 in the positional firing rate map) but have no strong directional selectivity (the directional polar plot does not reveal strong direction variability). On the contrary, head direction cell firing depends on the heading of the animal (e.g., at 180°) independently of its location (no specific place is associated with increased firing). Finally, the discharge of grid cells resembles that of place cells but they have multiple, regularly spaced fields. Note that other cells exist that can combine these different properties (e.g., have both location and direction correlates).

relationships among places (Figure 3). The advantage of this dual format is that topological information is more rapidly acquired than metric information because metric encoding would largely rely on motion-related signals provided by repeated movements between places. However, direct empirical support for dissociation between topological and metric encoding of spatial information is still awaited.

Neural Bases of Spatial Cognitive Maps

Damage to almost any portion of the brain can result in impairments in spatial navigation. The question, however, is whether the brain is organized so that the two modes of spatial coding, egocentric and allocentric, are dissociated. This question is not trivial because it is not easy to disentangle the contribution of motion-related signals (which provide the basis for egocentric coding) to the allocentric coding of spatial information which likely involves movements in space. In spite of this difficulty, several studies have shown that the two systems may be distinct. Substantial evidence suggests that taxon navigation is subtended by basal forebrain structures such as the dorsal striatum, whereas locale navigation is subtended by temporal lobe structures including the hippocampus. Striatal lesions in rats impair the performance of egocentric localization tasks, while leaving unaffected the performance of equally difficult tasks that did not require egocentric localization. In contrast, hippocampal lesions produce place learning impairment in place navigation tasks, such as the water maze, but generally do not affect performance in egocentric tasks (e.g., cue navigation). Recent evidence for a functional dissociation between the effects of lesions of the striatum and lesions of the hippocampus confirm that these two brain regions are involved in egocentric coding processes (cue, guidance, and route strategies) and allocentric coding processes (place strategy), respectively.

The role of the hippocampus in spatial navigation based on a place strategy is further supported by the existence of cells that carry a spatial signal. Such cells are found in the hippocampus proper and closely related structures, and can roughly be classified as place cells, head direction cells, and the more recently discovered grid cells.

Place cells are hippocampal pyramidal cells whose firing is strongly correlated with the location of a freely moving rat in its environment. Head direction cells are primarily found in the postsubiculum, and the anterior and lateral dorsal thalamus. Their firing depends on the heading of the animal independently of its location. Finally, grid cells are found in the dorsocaudal medial entorhinal cortex. These cells are activated whenever the animal's position coincides with any vertex of a regular grid of equilateral triangles spanning the surface of the environment. Together, grid cells provide a directionally oriented, topographically organized neural map of the spatial environment (Figure 4). A common feature of all

these cell populations is that their firing is primarily controlled by salient visual cues and motion-related signals although other sensory cues can be used to maintain coherent activity. In addition to these populations of cells, the hippocampal formation contains neurons whose spatial signals are more complex. For example, cells in the subiculum have both location and direction correlates. It appears, therefore, that the hippocampus and related structures form a system where spatial information is processed and coherently organized and lies at the core of a widespread neural network concerned with the processing of spatial information. Although current evidence suggests that normal hippocampal function is required for place navigation, its exact role is still a matter for debate. In addition, it is not clear how the information processed in the hippocampus is passed onto other brain areas involved in spatial processing. A number of other cortical structures (e.g., entorhinal, retrosplenial, prefrontal, or parietal cortex) and subcortical structures such as several thalamic nuclei have been hypothesized to contribute to place navigation. The specific role of these structures in relation to the hippocampus remains to be elucidated. Nevertheless, recent findings suggest that the human hippocampus hosts cells that look very much like hippocampal place cells in the rat, thereby strengthening researchers' interest for a better understanding of the computational properties of these systems.

Conclusion

The hypothesis that the hippocampus is the locus of a cognitive map has resulted in a growing interest into the neural basis of animal spatial cognition. Current evidence suggests that rats are able to build spatial representations of their environment so as to navigate with efficiency. Data on the neural mechanisms potentially associated with the processing of spatial information are accumulating rapidly. We currently know many pieces of the puzzle, but are still far from understanding how they are put together. Nevertheless, neuropsychological studies of spatial cognition in the rat routinely provide new data likely to shed light on how spatial information is handled by the brain, and therefore to help us understand how complex human behaviors are implemented in neural activities.

Spatial Memory: Assessment in Animals

C M Bird and N Burgess, University College London, London, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Spatial memory supports retrieval of the locations of objects and places in the environment, an essential aspect of behavior in humans and other mobile animals. Foraging for food, returning to sites of storage or safety, and avoiding sites of danger within a complex and changing environment present a daily challenge to many species. The study of spatial memory in animals has also made important contributions to the understanding of human memory more generally, due to the straightforward transfer of spatial paradigms between species. Here we review several of the paradigms used and the insights they have provided. We start by focusing on paradigms developed to test rats, but also consider testing in other species, including humans. Many of these paradigms were developed to test hypotheses regarding the functions of brain regions associated with spatial memory, most notably the hippocampus, the results of which we comment upon in passing.

Is Spatial Memory Special?

In an influential review, Edward Tolman proposed in 1948 that rats are able to construct and store 'cognitive maps' of their environments. It had been observed that rats could learn to associate a location in space with a reward. Using a sunburst-shaped maze, Tolman and colleagues elegantly demonstrated that rats appeared to be able to make detours using maplike representations (see Figure 1). Latent learning of the layout of a maze, via exploration in the absence of externally provided rewards, could also be shown to improve navigation to subsequently rewarded locations.

Learning the locations of places within a cognitive map exemplified a type of cognitive memory, which contrasted with the learning of stimulus–response associations, the bedrock of classical models of animal learning. Perhaps unsurprisingly, many researchers were reluctant to accept that this reflected a qualitatively different process. One of the paradigms used to test whether rats remembered places, or simply responses, was the T-maze.

T-Mazes and 'Place' versus 'Response' Learning

A T-maze challenges the rat to choose either the left or right arm to collect a reward such as food (see Figure 2). The rat may learn to go to a specific location within the room, or to make a specific motor response at the choice point. However, if the rat approaches the choice point from the other direction in a 'probe trial,' the two behaviors will lead in opposite directions and so can be distinguished from each other. In such probe trials it is important neither to reward the animal nor violate its expectation of reward, if learning in the standard configuration is to continue unchanged. For this reason the animal might be removed from the maze after the choice point, or might be unrewarded if the experiment is run with a partial (i.e., intermittent) reinforcement schedule.

Using the T-maze, MG Packard and JL McGaugh have demonstrated a double dissociation between brain areas underpinning place and response learning as rats learn to approach a consistently baited arm from the start arm. In probe trials after 8 and 16 days of training, healthy rats shifted from approaching the 'place' associated with food after 8 days, to making the turn 'response' associated with food after 16 days. Injections of lidocaine to inactivate the hippocampus abolished place learning, while injections in the dorsal striatum (part of the basal ganglia) left place learning intact, but abolished the shift to turn responses. Thus, both place and response learning are present in parallel, with the former dominating behavior early in learning and requiring the hippocampus, and the latter dominating behavior after several trials and requiring the dorsal striatum.

Egocentric and Allocentric Representations of Location

Spatial locations can be represented 'egocentrically' in relation to the observer or 'allocentrically' in relation to environmental landmarks. Both types of representation appear necessary for normal behavior, with most aspects of perception, movement, and short-term memory associated with egocentric representations, and allocentric representations required for memory over longer durations or movements. In these terms, response learning would be egocentric while place learning would be allocentric.

Insight into the operation of these representations has come from recording the activity of individual

Figure 1 Sunburst maze, illustrating detour behavior. (a) Prior to testing, the rat learns to run via an elevated pathway to the goal location at position H. (b) At test, the elevated pathway is blocked and a number of straight pathways are opened. Most rats choose pathway 5, which leads directly to the goal location, displaying classic 'detour' behavior. However, in the original experiments the presence of a light at position H had left open the possibility that rats had learned only to run toward this. From Tolman EC, Ritchie BF, and Kalish D (1946) Studies in spatial learning. I: Orientation and the short-cut. *Journal of Experimental Pyschology* 36: 13–24.

Figure 2 A T-maze, illustrating 'place' and 'response' behaviors. Rats are trained to retrieve food from one arm of a T-maze. The content of learning can be assessed by moving the starting arm to the other side of the maze on a probe test. The animal may enter the arm corresponding to the location of the reward during training (place strategy) or the arm corresponding to the turning response that was reinforced during training (response strategy). From Yin HH and Knowlton BJ (2006) The role of the basal ganglia in habit formation. *Nature Reviews Neuroscience* 7: 464–476.

neurons in behaving animals. Thus, for example, O'Keefe and colleagues have found the activity of neurons (place cells) in the hippocampi of freely moving rats to reflect an animal's location relative to the orientation cues and boundaries of its environment: this finding provided the impetus for O'Keefe and Nadel's proposal that the hippocampus supports a cognitive map of the environment. Equally, egocentric representations of the locations of objects relative to an animal's receptors and effectors in sensory and motor cortex, as well as representations in parietal and prefrontal cortices, reflect the short-term storage and manipulation of egocentric locations. In parallel with these developments, paradigms were developed to distinguish between the behavioral expression of these representations.

Radial-Arm Mazes: Dissociating Working, Reference, and Associative Memory

A classic paradigm for assessing spatial memory is the radial arm maze used by Olton and colleagues. In this test, a number of arms (e.g., eight) radiate outward from a central arena, extramaze cues are visible for orientation, and all arms are baited with food. Most healthy rats learn to collect the food without reentering a previously visited arm, and do not resort to obvious (nonspatial) strategies such as always taking the next arm to the left. Thus they are able to keep track of multiple locations in space so as not to revisit them, while rats with hippocampal lesions are severely impaired. This version of the task requires a 'win-shift' strategy: the rat must enter a different arm to get the next reward. In an alternative 'win-stay' version of the task, certain arms are always associated with reward within a trail, and rats acquire the habit of always visiting these arms. This type of learning is impaired by dorsal striatal lesions, again consistent with the dissociation between place and habit learning.

Despite the spatial nature of the standard task, it remains possible that rats use a nonspatial strategy to solve it. Thus, rats examine the entrances to the arms rather than simply moving directly between arms using distal cues for orientation, suggesting that more general deficits in working or associative

memory underpin the impairment shown by hippocampal rats. Accordingly, the task was adapted to distinguish between these possibilities. For example, long-term or reference memory and working memory can be dissociated by placing food rewards only in some of the arms. Long-term memory is required to learn which of the arms are never baited over several learning trials, whereas working memory is required to prevent reentry of previously visited arm within a single trail. Associative memory and spatial memory can be dissociated by making the arms distinct through the use of intramaze cues such as textured floor inserts. In 'spatial' trials, obvious fixed extramaze but not intramaze cues specify the rewarded arms, while the opposite is true in 'associative' trails. Rats appear to make use of both extramaze cues (or place learning, consistent with cognitive mapping) and intramaze cues (or cue learning, consistent with nonspatial associations). However, neurotoxic lesions of the hippocampus reveal greater impairment of place learning (encompassing both working memory and long-term memory), compared to cue learning, for which the effect was milder and restricted to working memory.

Recent advances in imaging neural activity have also been applied to these spatial questions. For example, expression of the immediate-early gene c-*fos* has been used to investigate which regions are active while rats perform the radial arm maze task. A critical issue here is the choice of control task – is there a task with sensory and motor demands similar to those of the radial arm maze, but without involving spatial learning? To address this issue, Aggleton, Brown, and colleagues compared c-*fos* expression in a group of test rats tested on a standard radial arm maze with a group of yoked control rats that only ran up and down one arm of a maze and received food rewards at the same frequency as experienced by the test rats. In another study, a test group learning the maze in a new room (with new extramaze cues) was compared to a group which had already learned it in the same room previously. Under these conditions, the test group would be expected to be learning more about the extramaze cues. In both studies, test rats showed significantly more c-*fos* expression in the hippocampus, as compared to control rats.

The Water Maze

Despite its successes, the radial arm maze also has some drawbacks. Behavior is constrained to the finite number of paths available (e.g., ruling out detours), while odor trails and other intramaze cues need to be carefully controlled and the desire of rats to explore can interfere with attempts to measure their memory for the target location. To address these issues, another paradigm, the water maze, has proved popular (see Figure 3).

Figure 3 Water maze, for testing allocentric spatial memory. The rat or mouse must swim in a large circular tank of opaque water until it finds the escape platform, located just below the water surface. Healthy rodents learn to use extramaze cues to swiftly locate the platform, irrespective of their start position. Examples of typical paths swum by control rats, rats with cortical lesions, and rats with hippocampal lesions are shown. In probe trials, the platform is removed, and the search behavior is noted. Control rats concentrate their search in the area where the platform has been located on previous trails, whereas rats with hippocampal lesions tend to swim around the whole of the arena. From Morris RG, Garrud P, Rawlins JN, and O'Keefe J (1982) Place navigation impared in rats with hippocampal lessions. *Nature* 297 (5868): 681–683.

Hippocampal lesions dramatically impair performance on the water maze, although hippocampal rats can learn to locate the submerged platform if the starting position is held constant across sessions (suggesting intact egocentric memory) and can learn which of two differently colored visible platforms is safe (indicating that this form of cue learning is intact). They can also learn to find a submerged platform located at a fixed bearing from a single intramaze cue which is moved within the maze every four trials. MacDonald and White had rats learn to swim to a visible and a submerged platform. Damage to the hippocampal system impaired navigation to the submerged platform, but not to the visible platform, even when it moved within the maze. By contrast, damage to the dorsal striatum resulted in rats that could navigate to both platforms, but when the visible platform moved, they swam to the submerged platform. Thus, as with place and response learning in the T-maze, allocentric memory depended on the

Figure 4 Star maze, showing multiple potential strategies. (a) All alleys are partially filled with water. The animals were placed in alley 1 and learned to find the hidden platform located in alley 7 by the shortest path (indicated with an arrow). To learn this trajectory, the animal could use different strategies that can be dissociated and identified during the probe test. (b) To distinguish which strategy the animal used to solve the task, the departure point was changed to alley 5. The positions of the extramaze and intramaze cues remained constant during the entire training session. When departing from alley 5, an animal had to choose between using the extramaze visual cues (5–6–7 trajectory, corresponding to an allocentric strategy), following the intramaze cues (5–6–8–9 trajectory, corresponding to guidance), executing a sequence of left–right–left body movements (5–4–2–1 trajectory, indicated as sequential–egocentric strategy), or visiting all radiating alleys successively (5–4–3–2–1 trajectory, indicated as serial strategy). Other behaviors were considered as representing no clear strategy. From Rondi-Reig L, Petit GH, Tobin C, et al. (2006) Impaired sequential egocentric and allocentric memories in forebrain-specific-NMDA receptor knock-out mice during a new task dissociating strategies of navigation. *Journal of Neuroscience* 26: 4071–4081.

hippocampus, while egocentric spatial memory depended on the dorsal striatum.

An ingenious combination of the radial arm and water mazes, the star maze, has been recently developed by Rondi-Reig and colleagues for testing spatial memory in mice (see Figure 4). The construction of the star maze allows use of the probe trials, to dissociate a number of possible strategies. After 20 days of training, healthy mice tended to use one of two strategies, navigating according to allocentric cues or executing a sequence of body turns. Mutant mice with a gene knockout targeting the *N*-methyl-D-aspartate (NMDA) receptors in the CA1 field of the hippocampus failed to learn the allocentric strategy, could learn an egocentric strategy when it involved just one turn, but were unable to learn sequences of two or more turns.

Spatial Manipulations of the Environment

Most of the aforementioned tasks involve static environments, although the animal's start position may vary. However, a powerful way to probe the representation that an animal is using is to change the positions of the potential cues and observe the effect upon behavior. For example, the positions of distal cues can be rotated relative to the local environment. Using a four-arm radial maze, it was shown that rats could learn to use six moving distal cues (that rotated *en masse*) to locate the rewarded arm. When hippocampal place cells were recorded in this task, they also rotated, showing a good correspondence to behavior, even on error trials. Aside from its overall orientation, the place cell representation of location seems to reflect location relative to extended barriers present in the environment: firing locations move and deform in order to maintain fixed distance from the nearer barriers following manipulations where the environment is deformed in shape. In contrast, firing locations do not move or reform when discrete intramaze cues are manipulated. By using a water maze with transparent sides in a room containing extramaze landmarks, Maurer and Derivaz showed that rats used the angular separation and apparent dimensions of landmarks to locate the escape platform, and that the distance of the platform from the wall was also a strong cue to its location.

Path Integration and Reorientation Paradigms

Path integration, sometimes known as dead reckoning, is the ability to keep track of a start location on the basis of subsequent self-motion information. Thus, a cumulative estimate of the distance and direction moved during foraging can allow an animal to return

to the nest. Desert ants provide some of the most impressive examples of this, aided by environmental orientation cues such as the polarization of ambient sunlight. In mammals, path integration may be used by animals foraging from the nest during darkness, but is severely constrained by the rapid accumulation of angular errors in the absence of orientation cues. Nevertheless, during navigation through an environment containing detectable landmarks, path integration provides an important moment-to-moment continuity to the sense of self-location.

Reorientation paradigms are used to investigate the mechanisms by which animals use environmental cues to reorient themselves in the absence of a reliable path integration signal. Figure 5 illustrates a typical setup. Following disorientation by rotation in the absence of sensory cues, the animal searches for a goal location.

Figure 5 Reorientation testing. (a) The task in a rectangular arena as seen from above. In attempting to relocate the goal after disorientation, the rotational error is frequently committed. This is the location at 180° rotation through the center from the correct location. However, featural information (landmarks in the corners) specifies which is the correct location. (b) The geometric information is contained in the broad shape of the arena. The featural information is what is not shown: patterns on the panels, different brightnesses of walls, smells in the corner, and the like. In using a 'map' containing only geometric information, the goal and the rotational error cannot be distinguished. From Cheng K and Newcombe NS (2005) Is there a geometric module for spatial orientation? Squaring theory and evidence. *Psychonomic Bulletin and Review* 12: 1–23.

Reorientation paradigms have been used in a wide variety of animals, including rats, chicks, fish, monkeys, and humans. All of these animals are able to make use of the geometry of an environment to reorient. However, they differ in the extent to which they use featural information (e.g., landmarks, patterns and other information that can specify location). For example, Cheng and colleagues found that rats tend to make little use of featural cues, while chicks use them very effectively. When geometric cues and featural cues are pitted in opposition, Vallortigara and colleagues found that chicks can make use of both types of information, with featural information processed in the left hemisphere via the right eye and geometric information processed in the right hemisphere via the left eye. In humans, preverbal toddlers also appear to use only geometry, at least in small enclosures, while adults can also make use of features in most situations.

Exploration and Novelty

Most of the paradigms discussed so far have involved animals searching for a target – either a place rewarded by food, or a means of escape from an unpleasant environment, such as water. Many similar paradigms involve avoidance of a location associated with an unpleasant stimulus such as an electric shock to the foot. An alternative to these paradigms comes from some animals' spontaneous exploration of novelty in the environment. Eacott and Norman investigated the sensitivity of rats to changes in objects, their spatial locations, and the contexts in which they were encountered (altering the color and texture of the arena). The rats' spontaneous exploratory behavior demonstrated sensitivity to all three changes. Rats with lesions to the hippocampal system were insensitive to novel configurations of object locations in different contexts.

Primate Studies: Object-in-Place Tasks

The preceding paradigms were largely developed to test spatial memory in rats. They made use of the fact that rats forage for food, and the studies often employed designs that paralleled search behaviors in the wild. Convenient testing of spatial memory in primates requires more constrained paradigms. For example, a test tray containing food wells might be placed in front of a monkey, which would be required to remember the location of a rewarded well, or the object covering the baited well. Some more recent studies have employed computer touch screens, enabling the background to be changed trail by trail,

providing a rich selection of contexts within which locations or features had to be remembered (object-in-place tasks).

Single-unit recording from awake primates performing spatial memory tasks has provided valuable insights into how and where spatial information is represented in the brain. A popular paradigm is to train the monkey to fixate at a point while one or more locations are cued. After a delay, during which fixation is maintained, the monkey indicates the cued position with either an eye movement or an arm reach. Studies have revealed neural populations in regions of the lateral frontal lobe and posterior parietal lobe that respond during the delay, suggesting that they are encoding the target location, or at least the intention to make a motor response to that location. Careful manipulations of the target location and the position of the eyes, head, or limbs with respect to the rest of the body have revealed that the delay activity can reflect the intention to make a particular movement to the target location, rather than simply attending to the location. These manipulations can also reveal how the locations are encoded. Andersen and colleagues found neurons in the intraparietal sulcus that are tuned to the locations of targets with respect to several different coordinate frames. For example, in area 7a, the response to stimuli presented in a neuron's retinotopic receptive field can be modulated by the orientation of the eyes in the head, the head on the body, or even by the orientation of the monkey's body within the testing room. These multiply-modulated responses are consistent with translation of information between retinotopic, head-centered, body-centered, and world-centered reference frames. This type of translation is required to determine where a visual stimulus is located relative to an effector such as hand or mouth that might be required to act on it: this is consistent with parietal involvement in sensorimotor integration. In addition, egocentric to allocentric translation would be required for integration of information between the largely egocentric parietal representations and the largely allocentric representations in anterior parieto-occipital sulcus, parahippocampus, and hippocampus.

Recently, a study explicitly contrasted the performance of young humans with that of other species of great apes on a task that shares similarities with object-in-place tasks (Figure 6). The main question was to ascertain whether participants would use a spatial strategy or a landmark strategy to search for a reward. The results were striking. All of the great apes and prelinguistic children (aged 12–13 months) favored the spatial strategy. In contrast, 3-year-old children favored the landmark strategy. These results suggest that the common ancestor to all great apes

Figure 6 Testing spatial and featural representations in the Hominidae. (Top) Adult orangutan male performing the task. (Bottom) Three distinct objects are placed in front of the participant and a reward is hidden under one. During occlusion, the positions of two of the three objects are swapped. The X indicates the hidden reward before and after occlusion. Experimental conditions consist of place and feature. For place, two containers are swapped while the reward remains in its original location. For feature, two containers are swapped but the reward moves with its container. From Haun DB, Call J, Janzen G, et al. (2006) Evolutionary psychology of spatial representations in the Hominidae. *Current Biology* 16: 1736–1740.

would have also favored a spatial strategy when searching for food. However, at around the time of language development, humans switch strategies and associate reward more with specific objects rather than the location where reward was previously obtained.

A common factor to all of these object-in-place paradigms is that they can be solved using egocentric strategies. As reviewed earlier, the brain systems underpinning egocentric and allocentric spatial memory are not the same. This may account for the fact that some primate studies show little effect of hippocampal damage on spatial memory. In order to tease apart egocentric and allocentric representations, it is

necessary to move either the testee or the environmental landmarks between the initial encoding and subsequent test. Accordingly, a recent study involved monkeys foraging in an open-field arena for food located in hidden 'wells.' When the food wells were marked by local visual cues, monkeys with hippocampal lesions had no difficulties solving the task. However, when distal cues were the only means to locate the food wells, hippocampal lesions did impair performance. As with studies in freely moving rats, recordings from individual neurons in primates during motion through their environment have also revealed place cells. Other types of cells, termed 'spatial view' cells, have also been reported to respond whenever a monkey views a specific location in space, and may extend the function of place cells, to the representation of places remote from the animal's current location.

Translation to Assessment of Human Spatial Memory

Traditionally, human spatial memory tests have employed a two-dimensional format, involving, for example, remembering the locations of unrelated objects on a tabletop. Others have involved the learning by trial and error of a path across a regular grid of identical bolts. Similar to the majority of nonhuman primate tasks described previously, such paradigms can be solved by an egocentric strategy. Accordingly, some other tests have looked to the allocentric paradigms developed in rats such as the water maze. Recently, virtual reality (VR) has enabled spatial exploration and search behavior in specially designed, large-scale environments to be studied, and has allowed several paradigms developed for animals to be translated to humans.

Both the radial arm maze and water maze have been adapted for use with humans, including patients with brain damage. For example, in a version of the water maze, patients learn the position of a sensor hidden under the carpet. Patients with parahippocampal or hippocampal damage show impairments in various aspects of this task. Manipulations of the experimental configuration between presentation and test have been used in humans as well as in other animals. Wang and Simons had participants view an array of objects and subsequently report which object had moved. Between presentation and test, the participant might move to another viewpoint and the array might be rotated so that the test view is consistent either with egocentric perceptual representations or with egocentric representations of location that are automatically updated by self-motion. A further study by Burgess and colleagues also manipulated an environmental landmark to measure the contribution of allocentric representations of location. The performance benefit from consistency at test with all three types of representation indicates the parallel presence of (1) egocentric perceptual representations, (2) self-motion related representations, and (3) allocentric representations. These three representations all underlie our ability to keep track of locations as we move through the environment.

VR allows good experimental control and monitoring of responses in simulated navigation and can also allow participants to keep their head still, albeit at the expense of the vestibular component of navigation. One use for this is functional brain imaging. Using a VR version of an eight-arm radial maze, Bohbot, Iaria, and colleagues found that healthy adults who used an allocentric strategy (detected by increased errors when distal cues are removed) showed increased right hippocampal activation, while patients with lesions to this area either did not use this strategy or, if they did, performed very poorly. By contrast, healthy adults who used a nonspatial strategy activated parts of the dorsal striatum. Similar findings were obtained when Hartley, Spiers, Burgess, and colleagues investigated wayfinding compared to route-following in a virtual town in imaging and neuropsychological experiments, again paralleling the findings on place and response learning in rats. VR navigation has also allowed recording from individual neurons in epilepsy patients requiring intracranial electrodes for localization of the seizure focus. These studies showed responses resembling place cells, clustered in hippocampus, as well as spatial view cells and 'goal' cells responding to the current target of navigation.

VR also permits experimental manipulations that are impractical to carry out in reality. Hartley and colleagues had participants see an object in a rectangular arena surrounded by distant landmarks, and subsequently report where they thought it had been. On some trials, the dimensions of the arena were varied between presentation and test. The effects of these spatial distortions on participants' responses were consistent with a model of spatial memory based on storing hippocampal place cell representations. King and colleagues used the ability to instantaneously change viewpoint within VR to assess the use of allocentric representations of location in the absence of motion-related spatial updating. Participants viewed objects located within a 'town square' and subsequently indicated which of several copies of each object was in the correct location. While healthy volunteers could perform the task when tested from the same viewpoint as presentation, or from a suddenly imposed new viewpoint, a patient with hippocampal damage was severely impaired when tested from the new viewpoint.

Overall, these findings demonstrate both the power of spatial manipulations for testing models of memory and the cross-species and cross-methodology convergence of understanding in this field.

Conclusions

Spatial memory is essential for adaptive behavior in humans and many other animals. Studying spatial memory in animals has provided enormous insights into the processes and neural mechanisms of memory and provides a starting point for the understanding of human memory more generally. Our knowledge about how these systems interact has proceeded hand in hand with the development of different tests to tease them apart. Advances in neuroscientific techniques to assess the involvement of different brain areas in aspects of task performance have cross-validated and extended older findings. Similarly, new technologies such as VR have allowed the convenient extension of some paradigms from animals to humans.

Spatial Orientation: Our Whole-Body Motion and Orientation Sense

D Merfeld, Massachusetts Eye & Ear Infirmary, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Our sense of body motion and orientation can be divided into two overlapping and interacting systems – one that senses head motion and head orientation with respect to the external world and a second that senses relative motion and orientation of the various body segments. This article focuses on our sense of motion and orientation with respect to the external world. This sense has nine degrees of freedom. It includes our sense of motion – three dimensions of rotational motion and three dimensions of linear motion. It also includes our sense of three-dimensional orientation, which we explicitly define as the combination of heading direction (i.e., which way am I facing? or yaw orientation) as well as tilt of the head with respect to gravity (e.g., pitch and roll with respect to the normal upright posture).

Although somatosensory cues provide a substantial influence on our sense of motion and orientation, the predominant contributors to our sense of motion and orientation are the vestibular and visual systems. This article focuses on the contributions of the vestibular system because this sensory system is often overlooked, compared to the more commonly known sensory systems. The vestibular system is made up of specialized sensory end organs dedicated to measuring head motion and orientation. In brief, the vestibular system in each inner ear consists of three semicircular canals, which sense three dimensions of head rotation, and two otolith organs, which sense three dimensions of head linear acceleration and gravity. The anatomy and physiology of the vestibular end organs are discussed very briefly next.

In addition to perceptual contributions, the vestibular system makes crucial contributions to several reflexive motor responses. These include (1) reflexive eye movements, called vestibuloocular reflexes, that improve visual acuity by helping stabilize images on the retina; (2) reflexive cardiac and respiratory responses, called vestibulo-autonomic reflexes, that help stabilize autonomic tone; and (3) reflexive postural responses, called vestibulo-spinal reflexes, that help stabilize our head and body with respect to gravity, assisting us as we walk and stand upright.

Although the vestibular system makes critical contributions to the forementioned reflexive responses, the vestibular system is also a sensory system that contributes to our perception of motion and orientation. This sense is often neglected relative to the commonly known five classical senses. This may be due to the inconspicuous nature of vestibular function, which almost always operates at an automated level. Patients suffering from rapid-onset vestibular disorders often become acutely aware of the fundamental contributions of the vestibular system to perception only when the vestibular system fails. The importance of the vestibular system is also emphasized by the fact that it appeared very early in evolutionary terms. The fossil record shows the presence of morphologically distinct vertical semicircular canals – not unlike mammalian vertical semicircular canals – dating back 400 million years.

Because the vestibular system is often overlooked as a sensory system, we compare the principal characteristics of the vestibular system to the principal characteristics shared by other sensory systems. First, as defined by Johannes Müller, physical stimuli activate specific nerve fibers that connect to the central nervous system to yield specific sensations – a concept referred to as specific sense energy. As a related concept, detailed in the *Principles of Neuroscience*, all sensory systems share "three common steps: (1) a *physical stimulus*, (2) a *chain of events* transforming the stimulus into nerve impulses, and (3) a response to this signal in the form of a *perception* or conscious experience of the sensation" (p. 412, 4th edn.). The relevant specific sense energy is discussed for the canals in the section titled 'Specific sense energy – semicircular canals' and for the otolith organs in the section titled 'Specific sense energy – otolith organs.' Second, all sensory systems mediate four stimulus characteristics – modality, location, intensity, and timing – that can be quantitatively correlated with perception. The relevant stimulus characteristics of the vestibular system are discussed in the section titled 'Vestibular senses information coding.' Because rotation yields changes in orientation, physical rotation and physical orientation are directly coupled to one another. If any observer knows the orientation of the head at some time point (time A) and also knows the head's complete rotation history between time A and a second time point (time B), we can correctly calculate its orientation at any time between times A and B). On the other hand, our perceptions of motion and orientation can, unlike true physical motion, be inconsistent.

Such inconsistencies are illustrated in the next section, which also provides compelling evidence for the contributions of the visual and vestibular systems to our sense of motion and orientation.

Example

Imagine that a human subject is upright with respect to gravity and looks at the inside of a sphere that is rotating in roll about an Earth-horizontal axis (Figure 1(a)). At first, the subject reports that he or she is stationary and that the visual display is rotating; both perceptions are veridical. However, if the subject continues to observe the rotating visual display for just a little longer (~10 s or more), he or she typically begins to perceive a sensation of self-rotation in the direction opposite the rotation of the visual display (Figure 1(b)). This illusory perception of self-motion evoked by visual motion is called vection, or more specifically rotational vection, and it demonstrates the visual contributions to our sense of self-rotation. Similarly, if subjects view a visual scene that is translating (e.g., the train next to theirs) while they are stationary, this often induces a perception of linear motion called linear vection, or, if subjects view a stationary display that is tilted (e.g., a tilted room), this can induce an illusion of self-tilt.

Paradoxically, subjects experiencing rotational vection, like that just described, seldom report that they are tumbling head over heals as they would if they truly were rotating to the extent that they perceive. In fact, subjects typically experience a simultaneous illusory sensation of tilt that gradually builds up to some relatively constant level (Figure 1(c)). These perceptions are often described as a sensation of motion without getting anywhere. These sensations are contradictory because if the perceived rotational motion were real it would yield continuously varying changes in perceived tilt, not a stable perception of some constant amount of tilt. This demonstrates that our sense of motion and orientation is not limited to perceptions that are consistent with physically possible motions and orientations.

This example can also be used to illustrate the role played by the vestibular system in our sense of motion and orientation. First, patients who have severe and complete damage in the vestibular periphery often report greater vection than normal subjects. Second, astronauts report greater vection when weightless than when on Earth. Third, astronauts experiencing rotational vection in weightlessness report a head-over-heals tumbling sensation, which is absent on Earth. This shows that the body's detection of gravity, which is measured by the otolith organs, inhibits the head-over-heels tumbling sensation here on Earth. Taken together, these findings show that the vestibular system makes a substantial contribution to our sense of motion and orientation. This is not surprising because the vestibular system is specialized to sense head motion and head tilt with respect to gravity.

Specific Sense Energy – Semicircular Canals

Like most sensory receptors, the semicircular canals respond primarily to a single physical stimulus, which for the semicircular canals is rotational motion. More specifically, the physical stimulus is angular acceleration, although the fluid mechanics of the canal yield a mechanical integration such that the neural response

Figure 1 Roll vection: (a) sketch of a subject viewing a visual display rotating in roll; (b) subject beginning to experience vection (a sense of self-rotation in the direction opposite the rotation of the visual display); (c) roll vection is often accompanied by an illusion of roll tilt that is induced by the perceived roll rotation. For demonstration purposes, the visual display is shown as being transparent. Initially, subjects correctly sense that they are stationary and the visual display is rotating. In (c), the direction of the perceived tilt is consistent with the tilt direction that would have occurred if the subject were truly rotating in roll.

in first-order vestibular afferent neurons represents angular velocity over a broad range of physiological frequencies. A brief description of the physiological chain of events leading to peripheral transduction in the semicircular canal follows: (1) angular acceleration of the head yields fluid movement in the canals with respect to the head, which (2) deflects the cupula, which (3) deflects hair cell cilia, which (4) gates mechanically sensitive ion channels, which (5) alters the receptor potentials, which (6) alters the neurotransmitter release rate, which (7) alters the firing rate of afferent neurons innervating the canal.

Finally, there is no question that we perceive rotation. Skeptics can be rotated on a rotating chair (e.g., bar stool) with their eyes closed to show them that they perceive rotation even in the absence of cues providing a visual reference. Although the actual motion thresholds in the dark depend on the frequency content of the motion, at physiological frequencies, many normal subjects perceive angular velocities above 1–2 $^\circ s^{-1}$ and angular accelerations above approximately 0.2–1 $^\circ s^{-2}$. Consistent with Müller's notion of specific sense energy, a similar sense of rotation is evoked when the neurons innervating the canals are activated via electrical stimulation.

The perception of rotation about an Earth-vertical rotation axis has dynamic characteristics that mimic a high-pass filter (Figure 2); this is expected because the first-order afferent neurons from the canals are known to have high-pass response dynamics when the afferent response is compared to angular velocity stimuli. More specifically, at frequencies below approximately 0.025 Hz, little or no rotation is perceived. As the stimulation frequency increases, so does the perceived rotation. At moderately high frequencies (between 0.2 and 0.8 Hz), the sensation of rotation appears to plateau at a level that slightly underestimates the rotation.

That the semicircular canals are a predominant contributor to rotational sensation is demonstrated by the fact that patients in the dark with complete bilateral absence of vestibular function do not perceive rotational motion that would be detected easily by normal subjects. These patients do maintain the ability to perceive rotation in the light, when visual cues are available, especially at lower frequencies. In fact, it has been shown that signals from the visual periphery indicating visual motion (as opposed to foveal visual motion cues) converge with the afferent canal neurons in the vestibular nuclei, which is in the brain stem one synapse from the vestibular periphery.

The semicircular canals sense head rotation and evoke a perception of rotation. (Although we can argue that the perceived quantity is angular velocity, whereas the physical stimuli is actually angular acceleration, which is then mechanically integrated by the end organ such that the neural response most closely relates to angular velocity, this is not a critical distinction.) Hence, the dimensionality of the physical stimulus and the perceived quantity are the same. This direct relationship between the physical stimuli and the perceived quantity is interesting; no other sensory system has a more direct relationship between the perception and the primary physical stimulus. For example, the dimensionality of the perception evoked by physical stimulation (hearing, sight, smell, taste, and touch) and the actual physical stimulation (pressure waves, photons, chemical, and pressure) is not identical for any of the commonly known sensory systems.

Figure 2 Magnitude of yaw rotation perception as a function of rotation frequency during sinusoidal rotations of the whole body. The three curves represent three different assays of perceived rotation, each of which yields a very similar measure of perceived rotation. Trace a shows perceived rotation in complete darkness; trace b shows perceived rotation when a single head-stationary object was viewed; and trace c shows perceived rotation when a single object rotated at twice the angular velocity of the subject. From Mergner T and Becker W (1990) Perception of horizontal self-rotation: multisensory and cognitive aspects. In: Warren R and Wertheim A (eds.) *Perception & Control of Self-Motion*, pp. 219–263. Hillsdale, NJ: Lawrence Erlbaum.

Specific Sense Energy – Otolith Organs

While most sensory receptors respond primarily to a single physical stimulus, the otolith organs, which sense both gravity and linear acceleration, provide an interesting exception. All linear accelerometers, including the otolith organs, respond equivalently both to gravity and linear acceleration, which is consistent with Einstein's equivalence principle which posits that linear acceleration and gravity have equivalent effects.

While probably important only to aficionados, it is interesting to note that one can define the physical stimulus to the otolith organs as the vector difference between gravity and linear acceleration. The corresponding force is called the gravito-inertial force. Under this definition, one could consider gravito-inertial force as the operating stimulus, which would mean that otolith organs, like the majority of sensory systems, respond primarily to a single stimulus. However, gravity and linear acceleration are different physical stimuli from a perceptual viewpoint. Nonetheless, they are indistinguishable in their effects from a physical viewpoint. There is no way, without separate information, to dissect the gravito-inertial force into portions due to each source. This is not an axiom of physics, but an inference from the observation that the gravitational and inertial masses (defined by Newton's law of gravitation and Newton's second law, respectively) have been measured to be equal to a very high degree of precision. Einstein made the assumption of perfect equality explicit in his equivalence principle, and built the theory of general relativity upon this assumption.

The physiological chain of events that yield neural responses in the otolith organs is similar to the cascade previously described for the semicircular canals. A brief description of the chain of events leading to peripheral transduction in the otolith organs follows: (1) linear acceleration of the head and/or the presence of a gravitational field deflects a membranous gel layer that is embedded with calcium carbonate crystals called otoconia, which (2) deflects hair cell cilia, which (3) gates mechanically sensitive ion channels, which (4) alters the receptor potentials, which (5) alters neurotransmitter release rate, which (6) alters the firing rate of afferent neurons innervating the otolith organ.

Because the otolith organs respond equally to two classically distinct forms of stimulation – linear acceleration and gravity – two distinct 'perceptual' responses are evoked by otolith stimulation. The issue of how this sensory ambiguity is resolved by the nervous system is discussed elsewhere.

The otolith organs contribute to tilt perception – the perception of the orientation of the head with respect to gravity. This sensation is both stable and relatively precise. Most young normal subjects can – even in a dark room – correctly estimate when tilted from upright by as little as 1–2° or so. Furthermore, for static tilts, subjective indications of perceived tilt more or less accurately reflect the actual physical tilt for tilts up to 90° (Figure 3), although consistent overestimates and underestimates of tilt angle are reported. If the subjects are tilted dynamically using sinusoidal stimuli, the subjective tilt responses remain somewhat constant across the frequency range of 0.005–0.8 Hz, although subjective tilt was accurately reported for high frequencies and somewhat overestimated at low frequencies (Figure 4). Because of the equivalence of gravity and linear acceleration, subjects report an illusion of tilt in the dark when they are dynamically accelerated using sinusoidal stimuli, even in the absence of actual physical tilt. This illusion is large at low frequencies (<0.05 Hz) before declining precipitously, such that almost no tilt illusion is experienced at frequencies of 0.2 Hz and higher (Figure 4).

The otolith organs also contribute to translation perception. In the absence of vision, normal subjects perceive linear motion having linear accelerations as small as approximately 0.05–0.10 m s^{-2} (510 mG) and linear velocities as small as approximately 0.02 ms^{-1} (<0.05 mph). In addition, when humans are exposed to steps of linear acceleration, the time that it takes to detect the direction of the motion (i.e., Is the motion to the left or right?) decreases as the magnitude of the linear acceleration increases (Figure 5).

Vestibular Senses Information Coding

As stated in the *Principles of Neuroscience*, "all sensory systems convey four basic types of information when stimulated – *modality*, *location*, *intensity*, and *timing*. Together these four elementary attributes yield sensation" (p. 412, 4th edn.). We look at vestibular function here as it relates to our sense of motion and orientation from the perspective provided by these four basic sensory system characteristics.

Generally, modality defines the general class of stimulus. As already discussed, the vestibular system has three modalities because it responds to rotational motion, linear acceleration, and gravity – with three dimensions for each of the three modalities. More specifically, the semicircular canals respond to rotation, with the nearly orthogonal canals sensing rotation in each of the three spatial dimensions, whereas the otolith organs respond to gravity in each of three dimensions and respond to linear acceleration in each of three dimensions.

Generally, location refers to the spatial distribution of the energy spectrum for each individual modality. For example, for touch and vision, the spatial distribution of the afferent neurons encodes the spatial location of the object (vision) or point of body contact (touch). For hearing, the spatial distribution of the afferent neurons represents the frequency of the acoustic stimulation. For the vestibular system, the spatial distribution of the afferent neurons represents the direction of motion or the direction of gravity. To use a specific example, neurons innervating the lateral canals respond nearly exclusively to yaw head

Figure 3 Tilt perception for static pitch (top row), roll (middle row), and yaw (bottom row) tilts: (a) sketches defining pitch, roll, and yaw and associated conventions; (b) tilt perception provided by subjects using a handheld haptic device; (c) tilt perception provided by subjects verbally. To first-order, perceived tilt accurately reflects the actual tilt for all three tilt directions, although roll tilts were slightly overestimated and yaw tilts were slightly underestimated. BKW, backward; FWD, forward; LED, left ear down; RED, right ear down. Figure 4 Magnitude of roll tilt perception, which is tilt to the left or right, provided by subjects using a two-handed task as a function of frequency between 0.005 and 0.7 Hz. Tilt stimuli: Roll tilt perception during applied sinusoidal roll tilts are shown (indicated by x) with a modeling prediction overlaid in green. Translation stimuli: Illusory roll tilt perception reported during sinusoidal linear accelerations (indicated by o), with no actual tilt stimuli, are shown with a modeling prediction overlaid in red. Adapted from Park S, Gianna-Poulin C, Black FO, Wood S, and Merfeld DM (2006) Roll rotation cues influence roll tilt perception assayed using a somatosensory technique. *Journal of Neurophysiology* 96: 486–491. Roll tilt modeling prediction from Merfeld DM, Park S, Gianna-Poulin C, Black FO, and Wood S (2005) Vestibular perception and action employ qualitatively different mechanisms I: Frequency response of VOR and perceptual responses during translation and tilt. *Journal of Neurophysiology* 94: 186–198.

rotations, responding minimally to rotations that do not include yaw head rotations. Similarly, the other semicircular canals, the anterior and posterior canals, respond only to rotational motion aligned with the anterior and posterior canal planes, respectively. A similar relationship holds true for the otolith organs. Individual neurons have spatial tuning characteristics that result in the neuron firing when a component of

Figure 5 Latency between the start of a linear acceleration step and the subjective indication of the direction of linear motion, shown as a function of the level of linear acceleration; this latency is often called the time-to-detect. The time-to-detect decreases as the magnitude of the acceleration step increases. In this paradigm, the relationship between the time-to-detect and the linear acceleration magnitude covary in a manner consistent with the subjects correctly detecting the direction of motion when they attain a velocity of approximately 0.20 m s^{-1}. SD, standard deviation. From Young L (1984) Perception of the body in space: Mechanisms. In: Darian-Smith I (ed.) *Handbook of Physiology: The Nervous System*, pp. 1023–1066. Bethesda, MD: American Physiological Society.

gravity or linear acceleration aligns with that neuron's axis of maximal sensitivity, which is determined by the polarity of the innervated hair cell(s).

Generally, stimulus intensity is signaled by the firing rate of the afferent neurons. Neurons in the vestibular system of primates have a relatively high tonic baseline activity of approximately 100 action potentials per second. The firing rate of these neurons increases for motion in one direction and decreases for motion in the opposite direction. Within the normal physiological range, the magnitude of the change in the neural firing rate of each individual neuron represents the intensity of the motion. For rotations at physiological frequencies (circa 0.1–5 Hz), the magnitude of the neural firing rate for neurons innervating the semicircular canals scales nearly linearly with angular velocity until the stimulus becomes so large that saturation effects predominate. Similarly, for the otolith organs, the magnitude of the neural firing rate scales roughly linearly with (1) the component of linear acceleration aligned with the sensitive direction of each neuron innervating the otolith organ and/or (2) the gravitational component aligned with the sensitive axis of each otolith neuron. It is interesting to note that, saturation effects aside, the vestibular afferent responses change roughly linearly with stimulus intensity. This differs from most other sensory systems, in which the afferent response varies with the logarithm of the stimulus intensity.

The timing of the physical stimulus is nearly instantaneously indicated by changes in the neural firing rate of vestibular neurons. At physiological frequencies, the firing rate of each neuron innervating a semicircular canal increases and decreases in near synchrony with increases and decreases in the angular velocity. Similarly, the firing rate for neurons innervating the otolith organs increases and decreases in near synchrony with linear acceleration and/or gravitational stimulation.

Summary

The vestibular system is a sensory system that makes crucial contributions to our sense of motion and orientation. The subjective experiences evoked by the vestibular system include perceptions of angular velocity and linear velocity and perceptions of both tilt and heading. These subjective experiences are evoked by objective physical stimuli; the semicircular canals sense angular acceleration, whereas the otolith organs sense both linear acceleration and gravity. These physical stimuli lead to sensory transduction, which cause changes in the neural activation of the vestibular afferents. This neural activation is a first step in the physiological processes that lead to neural representations of the physical stimuli, which are sometimes called internal representations. Such internal representations are the brain's way of storing and processing the external physical stimuli and combining the vestibular information with other information – like information provided by visual cues, somatosensory cues, and/or cognitive cues – to best inform us about our motion and orientation.

Spatial Transformations for Eye–Hand Coordination

G Blohm, A Z Khan, and J D Crawford, York University, Toronto, ON, Canada

© 2009 Elsevier Ltd. All rights reserved.

Introduction

One of the most important ways in which humans interact with our environment is through the use of our hands, regardless of whether we manipulate objects directly or whether we use tools. In order to accurately reach and grasp objects of interest, we require precise egocentric information about where the object is relative to our body. The direction of an object is specified by the location on the retina that it stimulates. The distance of the object is provided through stereoscopic vision arising from the slightly different views of the two eyes. The eyes, however, only provide the spatial locations of objects relative to the retinas, which depends on the orientation of the eyes in space (gaze). In contrast, the arm is attached to the shoulder and, therefore, muscle contractions need to be specified with respect to this fixed point. Therefore, information about an object's location must be transformed from a gaze-centered representation into one that is centered on the insertion points of the arm muscles (shoulder and elbow). For simplicity, we will refer to the latter as a shoulder-centered representation.

We begin the following sections by discussing the gaze-centered encoding of reach space as well as some of the implications of this particular choice of representation. Next, we consider how motor output is specified in shoulder-centered coordinates by the brain. Finally we examine the transformation required to map the gaze-centered representation of space onto a shoulder-centered movement plan.

Visual Representations of Reach Space

Gaze-Centered Encoding of Reach Targets

Because the projection of a visual object on the retinas changes with the direction of the eyes, the spatial information that reaches visual cortex depends on gaze direction. This gaze-centered representation of reach targets is not only present in the early visual pathway (i.e., retina, lateral geniculate nucleus, striate cortex) but also later on in the visual pathway (e.g., extrastriate and parietal cortex). Thus, the spatial location of an object that we want to reach to or point at is initially encoded relative to the fovea (Figure 1(a)). The persistence of gaze-centered representations at intermediate levels such as parietal cortex might seem surprising considering that alternative representations, such as a head-centered coding, would be independent of intervening eye movements and thus more stable (in theory, a head-centered representation adds eye position to the gaze-centered target position to specify its position relative to the head). However, an advantage of gaze-centered representations is that, unlike head-centered ones, they do not require such an integration of eye position until one actually reaches, and so are computationally less expensive for the brain. It is worth mentioning that the sensorimotor system also encodes auditory and proprioceptive targets in gaze-centered coordinates, even though these senses are not fixed to the eye.

How is this gaze-centered representation encoded in the brain? In order to accurately reach for an object, the brain requires knowledge about the object's direction relative to the fovea (horizontal and vertical angular eccentricity) and how far it is from the eyes (egocentric distance). The visual field is projected onto the retina and is transmitted to the visual cortex in a topographically arranged fashion. Whereas eccentricity in this topographical map defines the direction of a potential reach target, the distance of this target is specified both by monocular (accommodation, relative object size, shading, perspective, etc.) and binocular (retinal disparity and convergence) information.

Early visual areas (yellow areas in Figure 1(b)) compute angular eccentricity based on the retinal images from both eyes, synthesized to provide target direction as seen by a virtual (cyclopean) eye located between the right and left eye. On the other hand, retinal disparity is calculated from the difference between the two eyes' images. Different areas in the early visual pathway carry out the computations related to target direction and disparity. In early movement planning, these signals appear to be recombined into a single 3-D representation of gaze-centered space in the posterior parietal cortex (orange area in Figure 1(b)); different neurons in the monkey parietal cortex have receptive fields that encode a specific angular eccentricity of a target and their activity is modulated by target distance. To summarize, early visual and visuomotor areas compute different spatial aspects of the 3-D location of reach targets in gaze-centered coordinates.

Updating of Spatial Memory

As mentioned in the previous section, the drawback of a gaze-centered representation of space is that it needs to be constantly adjusted as we move. This is

Figure 1 Gaze-centered encoding of reach space. (a) Drawing depicting the egocentric visual directions of the hand, an orange, and an apple, as shown by the gray arrows. (b) Side view of a human brain showing areas (highlighted in yellow and orange) that encode reach space in gaze-centered coordinates: V1, striate cortex; PPC, posterior parietal cortex. (c) The consequence of an eye movement on the gaze-centered representation of the visual field. The head/eye diagrams depict current gaze position; the circles represent the gaze-centered representation of this visual scene (dotted lines represent visual horizontal and vertical axes and intersect at the fovea). If the person in the upper diagram looks at the orange, the hand and apple are represented in the left visual field (upper circle). In contrast, if the person fixates the apple (lower diagram), the orange and hand are now represented in the right visual field (lower circle). If the orange and the hand were no longer visible when the eye movement occurred, the brain would need to remap their position by taking the intervening eye movement into account. (d) Remapping in optic ataxia. The fixation task (first row, blue) shows a typical pattern of reaching errors (identical blue bars in both graphs) for this disorder, where errors are greater when the reach target is in the contralesional (opposite to the lesion) visual field (left half of each graph). The remapping task (second row, yellow) required the person to view the target peripherally in one visual field and then make an eye movement to the opposite side before reaching to the target. If no remapping takes place, then errors (yellow bars) should be greater when plotted as a function of reach target location relative to initial gaze (first graph), whereas if the reach target is remapped with the eye movement, then errors should be greater when plotted against reach target relative to the final gaze position (second graph). The reaching errors in the second graph match very well to the control task errors, suggesting that the location of the reach target in the internal representation was indeed remapped during the eye movement. (d) Adapted from Khan AZ, Pisella L, Vighetto A, et al. (2005) Optic ataxia errors depend on remapped, not viewed, target location. *Nature Neuroscience* 8(4): 418–420, with permission.

necessary to maintain a stable representation of our environment despite shifts and rotations of the eyes. This adjustment of the gaze-centered representation through different types of movements is called updating or remapping. Remapping has been demonstrated to be a general phenomenon that occurs during different types of eye movements – that is, slow eye tracking movements (smooth pursuit) and fast orientation movements (saccades). Updating also occurs for both the rotation and the translational components during head and body movements. Consider the example in Figure 1(c); if the viewer initially looks at the orange (upper left panel), the apple is located to the left and down of it. In the internal representation of this visual scene (represented by the schematic in the upper right panel), the orange is represented at the center of the representation – that is, the fovea – and the apple is mapped onto the lower left quadrant of the visual field. After a saccade to the apple (lower left panel), both the apple and the orange are remapped by the same amount of rotation as the saccade, but in the opposite direction. As a result, the apple is now represented at the fovea and the orange is mapped onto the upper right quadrant. In everyday life, incoming visual information usually contributes to specify the new target location for these internal representations, but many experiments have shown that the brain can accomplish this remapping internally, even if vision is removed, by using eye movement signals from the oculomotor system. Also, it has recently been shown that remapping and vision give better performance compared to vision alone. Psychophysical evidence suggests that about four targets can be represented and remapped in this way.

Intuitively, it would make sense to simply shift the locations of the internal representation by the same magnitude as the eye movement, but in the opposite direction. However, recent studies have shown that because of the kinematics of eye movements (i.e., there is a nonzero torsional component about the line of gaze in noncentral eye positions), shifting the locations by the eye movement vector does not produce correct remapping. Moreover, during pointing to remembered targets, subjects perform in a manner that suggests that they do remap correctly after eye movements, which reveals that the brain does take the rotational component of the eye movement into account during remapping.

It is generally accepted that the areas in and around the medial bank of the intraparietal sulcus of the parietal cortex play a major role in representing and remapping reach targets in gaze-centered coordinates. The receptive fields (a receptive field corresponds to the visual locations in space that activate the neuron) of individual parietal neurons have been shown to shift during an eye movement to correspond to the remapped location of the target. At the population level, the remapping of individual receptive fields results in an updated memorized target position. Remapping of target location across saccades has also been shown in the posterior parietal cortex through human functional magnetic resonance imaging studies. Moreover, recent neural recordings in the monkey show evidence of updating in a number of extrastriate visual areas such as areas V3A, V3, and V2. This leads to the question of the specific roles these different areas could play in the remapping process for reach movements.

One way to demonstrate the role that parietal and occipital cortex play in remapping is to test unilateral optic ataxia patients with damage to the (right) superior parietal cortex. Optic ataxia generally manifests itself as a deficit in performing accurate visually guided movements to peripherally viewed objects in the contralesional (opposite side to the lesion) visual field. Figure 1(d) depicts reach errors in such a patient. After an intervening saccade, errors to previously memorized targets were better explained by the remapped gaze-centered representation than by the initial retinal encoding pattern. The fact that this patient was able to remap despite damage to the right superior parietal cortex is consistent with a distributed remapping process that involves both extrastriate visual and parietal areas. Occipital cortex probably plays a more general role for remapping in perception and action, whereas remapping signals in parietal cortex might be specific for actions like reaching and saccades. In summary, the complete 3-D locations of reach goals are represented in gaze-centered coordinates and these representations are updated during various movements of the body.

Motor Coding of Reach Movements

Shoulder-Centered Encoding of Reach Plans

In order to understand eye–hand coordination, we must also consider the physiology of limb control. A gaze-centered representation of a reach target is inappropriate for reaching because muscle activations which move the arm are determined with respect to the shoulder. Consequently, the brain needs to specify the desired movement vector in a coordinate system relative to the shoulder, which is defined as the difference between the current and desired hand position (Figure 2(a)). In this section, we illustrate how and where such shoulder-centered motor plans are encoded. The subsequent section briefly describes how these motor plans are transformed into the appropriate muscle activations.

Figure 2 Motor representation of reaches. (a) The diagram depicts the position of the hand and apple encoded relative to the shoulder (gray solid arrows) as well as the desired movement vector (gray dotted arrow). (b) Schematic of the human brain (side view) showing areas (highlighted in red) that encode the desired movement vector in shoulder-centered or musclelike joint-centered coordinates: PMd, dorsal premotor cortex; PMv, ventral premotor cortex; M1, primary motor cortex. (c) Tuning curve of an example neuron in PMv. In this experiment, nonhuman primates where trained to perform wrist movements to visual targets in different spatial directions (x-axis) and the posture of the wrist was modified systematically. The three panels on the right show the three different postures used – pronation, midway (between pronation and supination), and supination. Each curve in the graph corresponds to the tuning curve of the same neuron recorded under those three different postural conditions. Clearly, this PMv neuron does not modulate its discharge rate with posture, which is consistent with a shoulder-centered representation of the desired reach. (d) Example neuron in M1 showing musclelike tuning curves. Here, the neuron's discharge was modified by the three different postural conditions. The directional shift of the tuning curve is in phase with the muscle activations required for a specific movement direction. Therefore, this M1 neuron shows a musclelike joint-centered encoding of the desired reach. (c, d) Adapted from Kakei S, Hoffman DS, and Strick PL (2003) Sensorimotor transformations in cortical motor areas. *Neuroscience Research* 46(1): 1–10, with permission from Elsevier.

Early neural recordings in the primary motor cortex (M1; Figure 2(b)) of the monkey during reach movements showed that individual neurons respond best to a certain movement direction, which is known as the neuron's preferred direction. The activity of such neurons decreases as the angular distance between the movement vector and the preferred direction increases. This pattern of activation forms

what is known as a cosine tuning of neural activity. The preferred directions of populations of neurons encoding movement seem to be uniformly distributed, thus all possible movements are represented. In summary, neurons with preferred directions and cosine-tuning properties provide the essential neurophysiology for movement encoding in the premotor and motor cortices.

To specify a complete 3-D reach plan one also needs to know the amplitude of the desired movement. Most psychophysical studies seem to indicate that direction and amplitude might be encoded independently, a conclusion drawn from the observation that errors in movement direction are generally smaller than errors in movement amplitude. On the other hand, neurophysiological recordings of neural activity in the dorsal premotor cortex (PMd; Figure 2(b)) during reach planning have shown that amplitude and direction are always coded together within the same neuron, where the activity related to a fixed movement direction simply increases or decreases depending on movement amplitude. One unifying solution for these seemingly contradictory findings might be that, at the neuronal level, direction and amplitude are coded together, but are read out by different mechanisms to generate muscle activation.

A large portion of neurons in the monkey ventral premotor cortex (PMv; Figure 2(b)) encodes extrinsic movement direction (i.e., the movement vector in an explicit shoulder-centered representation). Figure 2(c) shows this pattern for wrist movements where the tuning curve of a neuron in PMv reflects movement direction independent of hand posture (e.g., the palm turned up or down). Apart from the PMv, smaller portions of neurons in the PMd and the primary motor cortex (M1) also show such extrinsic spatial behavior. This shoulder-centered code coexists (in PMd and M1) with other, more muscle-related representations, which may reflect the gradual transformation of those codes into muscle activations. An abstract shoulder-centered programming of a motor plan is a fundamental stepping-stone for the brain to generate the appropriate muscle activations for the actual reach movement.

Planned Movement Vectors and Kinematics

As mentioned earlier, the shoulder-centered motor plan needs to be converted into the appropriate pattern of muscle activations to move the arm. The conversion has to correctly determine not only which muscles to activate (to specify direction) but also the correct force for each set of muscles (to specify amplitude). In addition, the brain has to overcome a series of dynamic constraints, such as the limb inertia and different arm loads due to the load of various hand-held objects. To generate accurate muscle activations, the brain must account for the current posture of the arm. Figure 2(d) shows a neuron in M1 with an activity that reflects the influence of posture on its cosine-tuning curve. This particular neuron does not code movement in shoulder-centered coordinates, but instead seems to represent a motor plan with respect to the muscles required for a particular movement. The shoulder-centered motor coding and the muscle-centered movement planning represent the two ends of a continuum, demonstrating the gradual conversion of extrinsic movement information into muscle activation patterns. This conversion involves large portions of neurons in PMd and M1 as well as the cerebellum.

To summarize, the brain represents motor plans in shoulder-centered coordinates in the premotor and motor cortices and then converts those representations of the desired reach into muscle activations. However, since the visual input to the brain specifies the location of a reach target in gaze-centered coordinates, the brain first must transform the early visual signals into appropriate motor commands for the arm in shoulder-centered coordinates. As we will see, simply using a gaze-centered movement vector to move the arm directly would produce large reach errors as a function of eye and head orientation. This visuomotor transformation is the topic of the following section.

The Visuomotor Transformation

Comparison between Hand and Target Positions

To reach out for a visual object, the brain needs to specify the required movement vector by computing the difference between the current hand location and the position of the object in space. This comparison between hand and target positions must satisfy two requirements. First, the areas in the brain that carry out this computation must contain signals providing the complete spatial information of both hand and target locations. Second, this comparison requires that hand and target locations are represented in the same reference frame in order for both to be combined in a spatially consistent manner. However, it is not yet clear which areas in the brain are involved in this comparison and in which reference frame the comparison is made.

There are three possibilities by which the brain could fulfill these requirements. One way could be to compare the hand and target positions as early as possible in the visuomotor pathway (i.e., compare the hand position to the target position in gaze-centered coordinates). As mentioned earlier, in the second section, target position has been shown to be encoded in gaze-centered coordinates at the level of the posterior

parietal cortex (PPC). Areas in the monkey PPC that code visual objects in gaze-centered coordinates have also been found to code hand position, even when the hand was not seen. This is particularly interesting because it means that the brain can derive the current hand position in gaze-centered coordinates from muscle-related proprioceptive signals. A neural substrate for a comparison between hand and target positions in gaze-centered coordinates has recently been identified in areas closer to the cortical surface of the intraparietal sulcus in the PPC. The activity of neurons in this area depends on both hand and target positions, which is consistent with the formation of a desired movement vector in gaze-centered coordinates.

Alternatively, hand and target positions could be compared at a much later stage (e.g., in shoulder-centered rather than in gaze-centered coordinates). This would require target position to be first transformed from gaze- to shoulder-centered coordinates. The hand position signal used for this comparison could be derived either from visual signals, which go through the same transformation process as target position, or from proprioceptive inputs. The latter joint- or muscle-related signals would require an intermediate transformation into shoulder-centered coordinates through an inverse model of the arm, and then a further transformation into gaze-centered coordinates would be unnecessary. Evidence for a late comparison of hand and target positions in shoulder-centered coordinates comes from several psychophysical experiments. If the hand is unseen, error of reaching toward memorized target locations are compatible with a shoulder-centered hand and target comparison. In contrast, simply providing visual hand position feedback shifted the errors toward a pattern compatible with the comparison of hand and target locations in gaze-centered coordinates.

Finally, the comparison between hand and target could be a distributed process involving multiple stages of representations taking place across several brain areas. This might seem redundant or contradictory, but it is well known that the brain can derive information from multiple sources (e.g., in sensory integration) and combine these inputs using Bayesian-like algorithms to compute the most reliable estimate. This scheme potentially enables the brain to access the same information encoded in different frames of reference, which would allow it to use the different representations, depending on task requirements. This is supported by behavioral findings which show that task context can alter the reference frame in which the comparison between hand and target locations is carried out. Regardless of where this comparison is done, a reference frame transformation between the gaze- and shoulder-centered representations is necessary. This visuomotor transformation could either be carried out for hand and target locations independently or for the combined signal (i.e., the desired movement vector).

Reference Frame Transformations

To transform gaze-centered into shoulder-centered signals, the brain has to perform a cascade of conversions which require knowledge about the 3-D orientation of body parts. Theoretically, the transformation involves a set of serial steps which gradually combine eye-in-head, then the head-on-neck, orientation, and subsequently the shoulder rotation with the visual representation, to produce a head-centered, body-centered, and ultimately shoulder-centered representation. But how do we know that these reference frame transformations are even necessary?

To answer this question, consider the example depicted in **Figure 3(a)**, where a study participant is asked to reach out to a target toward the left. When the head is upright and the eyes are fixating straight ahead, the gaze-centered coordinate system has the same orientation as the shoulder-centered coordinate system and is only translated with respect to the latter. Therefore, the desired movement vector is the same in both reference frames and no explicit reference frame transformation would be required. But what would happen if the head was tilted, say, toward the left shoulder, and the person maintained straight-ahead gaze? Since the eyes remain more or less in the same position relative to the head, the retinas are now tilted in space. Therefore, the projection of hand and target onto the retina would be rotated (in gaze-centered coordinates) in the opposite direction as the head – that is, toward the right. If this vector was directly used to guide the reach, the arm movement would be inaccurate and the move would be up and to the left instead of simply horizontally. Everyday experience and experimental evidence suggests that people generally do not make such errors, which demonstrates that the brain performs a reference frame transformation of the desired movement vector.

The preceding example illustrates a simplified portrayal of a reference frame transformation. However, this visuomotor transformation is actually much more complex. A large part of this complexity arises because body parts rotate around their anchor points; for example, the eye rotates in the ocular cavity and the head rotates around the base of the skull. Since rotations are nonlinear and noncommutative (sequence matters) operations, the relationship between gaze-centered and shoulder-centered coordinates can become quite complicated. In addition, the anchor points for different body parts are offset one from another. For example, if the head rotates, the eyes shift their position in space. Not taking translations into account could

result in a mislocalization of target position during the reach. In sum, an accurate visuomotor transformation has to take into account the rotational and translational aspects of body geometry.

Brain areas involved in this transformation would necessarily require extraretinal signals about the rotation of the eyes and head in addition to representing the 3-D hand and/or target locations. The

Figure 3 Continued

translational components are also implemented, probably acquired through experience. How would the brain purposefully combine these different signals in a population of neurons? A potential window into the distributed processing in neural populations is provided by the analysis of artificial neural networks trained to perform reference frame transformations. Artificial neural networks are highly simplified mathematical analogies of real networks of neurons and are believed to reflect fundamental mechanisms underlying brain function. Probably the most important finding is the discovery of neurons (both real and simulated) which alter their response magnitude based on extraretinal eye and/or head position signals, without changing the gaze-centered location of their visual receptive fields. This modulation of response magnitude is known as a gain field and is illustrated in Figure 3(d).

Mathematically speaking, gain fields operate through a nonlinear combination of different sources of information (e.g., visual input, eye position, head position) within the same neuron. If many different neurons incorporate multiple combinations of these signals, then the neural population has a complete distributed representation of space relative to different body parts. The individual multimodal neurons inside this population act like basis functions in that they provide a unique representational set and can be combined (by linear summation) in different ways to produce the desired reference frame output. Thus, using the same population of basis functions, it is possible to extract target position in multiple frames of reference.

The shortcoming of the concept of basis function neurons is that every possible combination of signals must be represented, which could lead to a large number of units in the population, a dilemma called the curse of dimensionality. Therefore, it is believed by some that the brain compromises between basis function neurons – implying the presence of gain fields – and explicit representations (e.g., shoulder-centered encoding of the desired movement vector) in various reference frames. Evidence for this comes from brain areas such as the PPC, which contains many neurons encoding reach space in gaze-centered coordinates. A significant proportion of PPC neurons with gaze-centered receptive fields also show eye-position-dependent gain fields. Neurons in the premotor and motor cortices show movement coding in shoulder-centered coordinates, which constitute another form of explicit representation of reach space. Gain fields are thought to be the implicit code that implements the visuomotor transformation between an explicit gaze-centered code and an explicit shoulder-centered reach plan.

Conclusions

Visually guided reaching involves the transformation of sensory information from the eyes and hand into movement commands for the arm. The early representation of sensory input is gaze-centered and appears to be remapped during body movements in order to ensure a stable internal representation of the visual environment. The arm motor plan is calculated by comparing the desired target position to the current hand location. This motor plan is spatially accurate because the brain accounts for eye and head posture through a distributed internal model of body geometry. As a result, the motor plan is specified in shoulder-centered coordinates and then further transformed into muscle activation patterns. This cascade of different representations and mechanisms (e.g., gaze centered, shoulder centered, updating) may seem complex and perhaps redundant at first glance. However,

Figure 3 Visuomotor transformation. (a) Diagram depicting two different possible head roll postures (head upright and rolled toward the left shoulder) while a person viewing an apple and an orange is planning to reach out for the apple (gray dotted arrow). The corresponding gaze-centered representation is shown schematically in the circle. Note that the same shoulder-centered movement plan (diagram of person, dotted arrow) leads to different gaze-centered desired movement vectors in the circle, depending on head posture (head upright, black arrow; head roll, faded gray arrow). (b) Schematic of the human brain (side view) showing the visuomotor transformation pathway from early visual to motor structures: PMd, dorsal premotor cortex; PMv, ventral premotor cortex; M1, primary motor cortex. (c) Model of the visuomotor transformation. Visual (target and hand position), nonvisual (proprioceptive hand position), and extraretinal (eye and head position) information is combined in the posterior parietal cortex (PPC) and also in the premotor and motor cortices (PM/M1) to produce an accurate movement. (d) Gain field modulations in area 7a of the posterior parietal cortex. The top circles depict the gaze-centered receptive field of one example neuron. The overlapping circular shapes show different levels of activation for this cell as a function of horizontal and vertical gaze-centered target location. Based on this information, a stimulus (red squares in the lower diagrams) was placed at the location of the highest activity in the neuron's receptive field. The animal fixated at one of nine locations and the activity in response to the stimulus was measured in the neuron's receptive field. The stimulus was always presented at the same location relative to gaze (i.e., in the receptive field, which moved with fixation), as can be seen in the two lower diagrams for two example fixation locations (center left and straight ahead). The graphs on the right show the cell's activity over time (red arrows signify stimulus onset) for the nine fixation locations. The figure shows that the cell's activity for the same stimulus location (relative to gaze) was modulated by eye position, as predicted by the gain field theory. (d) Data modified from Andersen RA, Essick GK, and Siegel RM (1985) Encoding of spatial location by posterior parietal neurons. *Science* 230(4724): 456–458, with permission. Copyright 1985 by AAAS.

this appears to be the most cost-efficient way to deal with the large amounts of information in the system – that is, by solving distinct computational problems at different stages of the visuomotor transformation, such as making cognitive comparisons between multiple targets at early visual stages and specifying detailed limb dynamics at later stages.

One of the remaining challenges for neuroscientists is to understand the theoretical requirements and mathematical algorithms the brain employs to carry out these transformations. Without such a theoretical framework, it is difficult to interpret the observed properties of individual neurons in the parietal to frontal network. This framework in turn is necessary to explain what goes wrong in patients with neurological disorders affecting visually guided reaching. Further, the field of visuomotor neuroscience is now at a point where we can begin to tackle more complex problems, such as the influence of other sensory modalities, mechanisms engaged when reaching to targets in movement, decision making, target selection, and the role of attention.

Spectrin: Organization and Function in Neurons

A Das and R R Dubreuil, University of Illinois at Chicago, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Spectrin is an abundant protein in the nervous system, comprising 2.4% of total protein in mammalian brain homogenates. Spectrin is an unusually large protein with a native molecular weight greater than 1 million. The contour length of the purified protein when viewed by electron microscopy is ~200 nm. Spectrin is intimately associated with the cytoplasmic surface of the plasma membrane in many cell types, including neurons. There are also many cases in which spectrin is associated with intracellular structures, including the Golgi apparatus and nucleus.

Spectrin was originally discovered in human erythrocytes, where it is the major component of a submembrane protein scaffold known as the membrane skeleton. Biochemical studies of purified erythrocyte spectrin yielded a wealth of information on the structure and physical properties of the molecule as well as its interactions with other components of the erythrocyte membrane. The biochemical approach led to a model in which spectrin molecules are cross-linked by short actin filaments to form the submembrane scaffold. The model was eventually confirmed by electron microscopy of artificially spread preparations of the erythrocyte membrane (a simplified schematic is shown in Figure 1(b)). The abundance of spectrin in mammalian brain made it possible to purify the protein and subject it to the same kinds of biochemical approaches employed with its erythrocyte counterpart. That approach revealed that brain spectrin is capable of nearly all the protein interactions that occur in the erythrocyte. However, it has not been possible to establish the precise structural arrangement of spectrin molecules in any cells other than erythrocytes.

There are two kinds of linkages between neuronal spectrin and the plasma membrane. The best-characterized interactions occur through the peripheral membrane protein ankyrin, which indirectly couples spectrin to integral membrane proteins. There are also direct links between spectrin and membrane lipids as well as integral membrane proteins such as the neural cell adhesion molecule.

Structure

The native spectrin molecule is a tetramer composed of α and β subunits (Figure 1(a)). The subunits associate laterally to form antiparallel $\alpha\beta$ heterodimers. Dimers, in turn, associate head-to-head to form $\alpha_2\beta_2$ tetramers. Each subunit is composed of discrete structural domains, referred to here as segments, numbered in order from the N-terminus of each polypeptide (α1–22; β1–19).

Amino acid sequence analyses of the two spectrin subunits have produced considerable insight into the structure of the native protein. Much of the body of the protein is composed of a degenerate 106 amino acid spectrin repeat. Atomic structures for individual repeats established that they have a triple-barrel alpha helical structure. There are 20 repeats in α spectrin and 16 repeats in β spectrin. Another repeat is formed by the end-to-end interaction between α and β spectrin during tetramer formation. Here, a partial repeat near the C-terminus of β spectrin associates with a partial repeat near the N-terminus of α spectrin. Note that the numbering scheme for an α spectrin segment begins with its first full spectrin repeat. It has been suggested that the two subunits arose by fracturing of the coding sequence of a much larger ancestral gene. Apart from insertions of nonrepetitive sequence elements (described below), the individual repeats of α and β spectrin are distinguished from one another mainly by variations in their amino acid sequence. One exception is segment 16 of β spectrin (the fifteenth repeat; shaded in Figure 1(a)), which has been identified as the binding site for ankyrin.

There are several nonrepetitive sequence elements in the α and β spectrin subunits. The N-terminal region of β spectrin (~300 amino acids; segment 1) contains the actin binding site. The actin binding domain includes two copies of a calponin homology (CH) actin binding motif, which is present in many different cytoskeletal proteins that bind to filamentous actin. The C-terminal region of most β spectrin isoforms (~200–300 amino acids; segment 19) includes a pleckstrin homology domain (PH domain). Since the PH domain occurs downstream of the tetramer formation site, and since it is thought to interact directly with the plasma membrane, it is drawn here as a globular projection from the long axis of the spectrin molecule. The PH domain is likely to correspond to the small globular projections observed by electron microscopy of rotary shadowed specimens of native spectrin. However, the major splice variant of β spectrin expressed in human erythrocytes lacks that domain and consequently is small (2137 amino acids) compared with most other β spectrins (>2300 amino acids). The α spectrin subunit (2429 amino acids in human αI spectrin) includes an Src homology 3 (SH3) domain (~75 amino acids long; segment 10) inserted between the α-helical barrels of the ninth repeat.

Figure 1 Spectrin structure, its interactions with the plasma membrane, and its distribution in neurons. (a)The spectrin tetramer. The typical spectrin molecule is a tetramer composed of two copies of the α and β subunits. Most of the sequence of each subunit consists of repetitive structural segments that are each ~106 amino acids long and folded into a three-barrel structure. A partial repeat near the C-terminus of β spectrin (2 barrels) associates with a partial repeat at the N-terminus of α spectrin (1 barrel) at the tetramer formation site near the center of the molecule. The sixteenth segment of β spectrin (shaded) binds to ankyrin. The C-terminal segment of β spectrin includes a pleckstrin homology (PH) domain, shown projecting from the spectrin tetramer near the center. The N-terminal domain (segment 1) of β spectrin includes 2 calponin homology domains that mediate binding to actin filaments. The adjacent C-terminal domain of α spectrin (segment 22) includes two EF hand domains that are aligned with the actin binding site. An SH3 domain (segment 10) is inserted between α-helical barrels of repetitive segment 9 of α spectrin. A loop containing a calmodulin binding site and a calpain cleavage site is found in segment 11 of α spectrin. (b) Spectrin in the human erythrocyte is arranged in a hexagonal submembrane network through interactions with short actin filaments. Ankyrin (ANK) serves as an adapter that links spectrin to the cytoplasmic domain of the major integral membrane protein in erythrocytes, band 3. Additional interactions link nonerythroid spectrins to the plasma membrane via the PH domain (arrow) and other ankyrin-independent membrane binding sites (not shown) (c) Spectrin is localized within discrete domains of the neuronal plasma membrane. Some spectrin isoforms are segregated to the soma and dendrites, and others are found in the axon and nerve terminal. βIV spectrin is concentrated within the axon initial segment (AIS) and the node of Ranvier (NR), and βII spectrin is concentrated within paranodal contacts.

The C-terminal domain of α spectrin (~155 amino acids; segment 22) includes two copies of an EF hand calcium binding motif. The EF hand domain is thought to be intimately associated with the N-terminal actin binding domain of β spectrin. The nonerythroid αII spectrin in humans is somewhat longer than αI (2472 amino acids), primarily because of inserted sequences found within segment 11 (described in the section titled 'Calpain cleavage site/calmodulin binding domain').

The Spectrin Gene Family

Spectrin is related to a large superfamily of actin cross-linking proteins that all share the CH domain actin binding motif. A closer-knit spectrin family of

proteins shares the same general domain structure and molecular shape as human erythrocyte spectrin. In humans there are five known β spectrin genes and two α genes. The αI and βI spectrin genes are primarily expressed in erythrocytes but are also expressed in muscle and some cells in the brain. The remaining α and β products are expressed in other cell types, such as neurons and epithelia. Invertebrates such as the fruit fly have a smaller repertoire of genes, including a single α spectrin that forms tetramers with two different β subunit gene products. The overall domain structures of spectrins from vertebrates and invertebrates are nearly identical to one another, with sequence identities in the range of 42–63%, suggesting that spectrins in different species are likely to have overlapping functions. Another, more distant relative of spectrin is the protein dystrophin, whose defects are responsible for Duchenne muscular dystrophy. While dystrophin is related to β spectrin, it appears to have evolved independently and is not known to associate with any other subunits or to form tetramers.

Spectrin Function

Mutations in the genes encoding erythrocyte α and β spectrin cause inherited anemias such as hereditary spherocytosis and hereditary elliptocytosis. Red blood cells from these patients have an abnormal shape and are unusually fragile, which ultimately causes anemia. These observations led to the conclusion that spectrin has important roles in cell shape and membrane stability.

Based on similarities to erythrocyte spectrin, the 'nonerythroid' forms of spectrin are also thought to contribute to the structure and stability of the plasma membrane. However, there are also some important differences between spectrins, and these differences led to an expanded model for spectrin function. First, whereas spectrin uniformly coats the plasma membrane in erythrocytes, spectrin is restricted to specialized membrane subdomains in most other cell types, such as the lateral domain of epithelial cells or the node of Ranvier in neurons. Second, there are only limited interactions between the spectrin cytoskeleton and integral membrane proteins in the erythrocyte. In contrast, nonerythroid spectrins are attached via ankyrin to many different integral membrane proteins. It is interesting that many of these proteins are involved in membrane transport (e.g., the Na,K ATPases, voltage-dependent sodium channels, potassium channels, and Na/Ca exchangers). Based on these observations, spectrins are thought to be involved in the establishment of plasma membrane polarity. Once assembled within a specific region, spectrin is thought to capture and stabilize other interacting membrane proteins to form a membrane domain with specialized composition and function.

Functional Sites in the Spectrin Molecule

Actin Binding Domain

The actin binding domain is the site of greatest amino acid sequence conservation among spectrins, presumably because of the importance of actin binding activity to spectrin function. This region of spectrin also interacts with other proteins, including members of the protein 4.1 family and synapsin. It is important to note that spectrin does not codistribute with bulk actin in cells. Instead, a subpopulation of actin filaments associates with spectrin to help form a plasma membrane-associated spectrin scaffold. A potential regulatory mechanism for the interaction of spectrin with actin is suggested by the behavior of the related actin cross-linker α actinin. There is a similar juxtaposition of actin binding and EF hand domains, and calcium binding to the EF hands of nonmuscle α actinin is known to downregulate the actin binding activity of the adjacent actin binding domain. It remains to be established whether the EF hand domain of spectrin modulates binding to actin.

Ankyrin Binding Domain

Most spectrins, with the exceptions of βV spectrin in mammals and β_H spectrins in invertebrates, possess binding sites for the adapter protein ankyrin. Ankyrin includes an N-terminal domain composed of 24 ankyrin repeats. The repeat domain is responsible for many of the known interactions between ankyrin and integral membrane proteins. Another domain of ankyrin, downstream of the membrane binding domain, has been shown to mediate binding to spectrin. *In vitro* binding assays were used to map the binding site for ankyrin to the sixteenth segment of β spectrin (sometimes referred to as the fifteenth repeat). Studies in mammalian heart suggest that spectrin targeting occurs through its interaction with ankyrin at this site, placing spectrin downstream of ankyrin. However, other evidence (described in the section titled 'PH domain') places ankyrin assembly downstream of spectrin.

A remarkable diversity of membrane proteins have been found to interact with the spectrin cytoskeleton through ankyrin. Many of these proteins are membrane transporters and channels that have important physiological activities in excitable cells such as neurons and cardiomyocytes. It is also remarkable that in several cases, defects in ankyrin and spectrin have phenotypic consequences as dire as defects in the

transporters themselves. Another class of ankyrin-interacting membrane proteins is the L1 family of neural cell adhesion molecules. L1 family members have diverse roles in axon fasciculation, axon guidance and neurite extension, synaptogenesis, and myelination. Mutations in human L1 are implicated in a host of symptoms, including mental retardation and hydrocephalus. Some of the initially described characteristics of the L1 family–ankyrin interaction made L1 proteins seem promising candidates in regulating spectrin cytoskeleton assembly. However, subsequent genetic analysis of ankyrin and spectrin mutants has suggested that L1 family members, like the other ankyrin binding membrane proteins, are downstream interacters that depend on spectrin and ankyrin for their accumulation and function.

Intersubunit Interactions

Two main classes of subunit interactions have been characterized in detail. One is found near the ends of the spectrin tetramer, mediating lateral interactions between terminal repeats of the α and β subunits. The second class is found near the center of the tetramer, where a partial repeat from β spectrin (helices A and B) interacts with a partial repeat from the N-terminus of α spectrin (helix C) to form an intact triple-barrel α-helical structure resembling the other spectrin repeats.

PH Domain

The PH domain found at the C-terminus of β spectrin resembles a broadly conserved sequence motif found in hundreds of other proteins. Many, but not all, PH domains have been shown to possess phosphoinositide binding activity and to participate in signal transduction pathways. The PH domain of β spectrin has been shown to bind to phosphatidylinositol bisphosphate and when expressed as a fusion protein with green fluorescent protein, was shown to have plasma membrane targeting activity *in vitro*.

The PH domain corresponds to one of the ankyrin-independent membrane binding sites identified in biochemical studies using purified spectrin and NaOH-stripped brain membrane vesicles. Additional binding sites were identified near the N-terminus of β spectrin. A recent genetic study in *Drosophila* demonstrated that the PH domain is required for targeting of spectrin to the plasma membrane in midgut epithelial cells. Whether targeting occurs through a lipid or protein target remains to be determined. Surprisingly, ankyrin binding activity was not required for targeting of spectrin to the plasma membrane. The same study revealed that another ankyrin-independent site in the β subunit was responsible for targeting spectrin in the salivary gland epithelium. That site may correspond to the N-terminal membrane association domain identified in biochemical studies. This line of evidence supports a model in which polarized assembly of spectrin is mediated by its direct interactions with membrane lipids and/or proteins, with effects on ankyrin and interacting membrane proteins occurring downstream.

SH3 Domain

The SH3 domain is another conserved sequence module found in many different signal transduction proteins. It was first identified in the Src oncogene. The SH3 domain provides another class of potential protein interaction sites in the spectrin molecule, and proteins that interact with the spectrin SH3 domain have been identified.

Calpain Cleavage Site/Calmodulin-Binding Domain

Calcium-dependent protease with papainlike activity (calpain) belongs to a family of cytoplasmic cysteine proteases that are activated by calcium ions and translocate to the plasma membrane. Calpain cleaves a range of substrates including spectrin and other membrane-associated proteins. The observations that spectrin is highly enriched in brain and undergoes calpain-mediated proteolysis in neurons have led researchers to use spectrin as a readout for the physiology and pathology of neuronal cells. A calpain cleavage site has been mapped between Tyr1176 and Gly1177 of segment 11 of α spectrin. Cleavage occurs near the middle of the αII spectrin polypeptide, and the cleavage products are easily identified in Western blots probed with sensitive antispectrin antibodies. Cleavage occurs rapidly in response to physiological stimuli, as in *N*-methyl-D-aspartate (NMDA)-induced excitotoxicity in which cleavage products can be detected as soon as 2 min after exposure to NMDA. While the physiological role of α spectrin cleavage remains to be established, it has proven to be a valuable and widely used marker of calpain activation.

The calpain-cleavage site in αII spectrin occurs within a 35 amino acid loop inserted between α-helical domains of segment 11 (**Figure 1(a)**). Neither the loop nor the cleavage site is found in human αI erythroid spectrin. This loop is also one of the main structural differences between mammalian αII spectrin and invertebrate α spectrin. The loop also includes a high-affinity calmodulin-binding site, and calmodulin binding enhances the susceptibility of spectrin to calpain cleavage. This calmodulin binding activity is absent in both αI spectrin and invertebrate α spectrin, suggesting that it too is a product of a relatively recent step in spectrin evolution.

EF Hand Domain

The C-terminal EF hand domain of α spectrin resembles the calcium-binding EF hand domain of the related protein α actinin. In both proteins, the EF hand domain is thought to interact with the adjacent actin-binding CH domain on the neighboring subunit. A mutation in *Drosophila* α spectrin that truncates the C-terminal 100 amino acids leads to essentially the same lethal phenotype as a null mutation, suggesting that the EF hand domain is critical to the structure and function of spectrin. The effect of the mutation is likely to be mediated through its effect on the adjoining actin-binding domain on the β subunit.

Distribution of Spectrin in Neurons

Soon after the discovery of spectrins in the nervous system, it became apparent that different isoforms of spectrin are differentially distributed within individual neurons. As a rule, antibodies recognizing erythroid forms of spectrin stained cell bodies and dendrites and antibodies recognizing 'nonerythroid' spectrins stained axons and presynaptic nerve terminals (Figure 1(c)). These observations provided the first clues that distinct targeting mechanisms acted on different isoforms of spectrin and raised the possibility that there were isoform-specific functions as well.

The nonerythroid form of spectrin in neurons was originally named fodrin, before its relationship to erythrocyte spectrin was recognized. In their elegant initial description, Levine and Willard established that fodrin was axonally transported. Now, three different 'nonerythroid' isoforms of spectrin appear to be present in axons. So far, isoforms containing the βIV subunit have been characterized in the greatest detail. The βIV spectrin is found in myelinated neurons, where it colocalizes with ankyrinG at axon-initial segments and the node of Ranvier in both central and peripheral neurons (Figure 1(c)). A membrane undercoat is visible at the node of Ranvier, and the undercoat was greatly diminished in neurons from βIV spectrin mutant mice, suggesting that spectrin forms a structure analogous to the erythrocyte membrane skeleton. It is interesting that loss of βIV spectrin was also associated with abnormal membrane shape and vesiculation in the vicinity of the node. A similar complex of αIIβII spectrin with ankyrin-B was recently identified in the paranodal region of central and peripheral nerves. The βIII isoform of spectrin is also present in axons and elsewhere, including intracellular sites such as the Golgi apparatus. The remaining β spectrin isoform, βV, was detected in the outer segments of photoreceptor rods and cones but is present at very low levels in mammalian brain.

Genetic Studies of Spectrin Function in the Nervous System

Invertebrates

Phenotypes have been analyzed for mutations in all three of the spectrin genes in *Drosophila* and *C. elegans*. Knockouts of α and β spectrin are lethal, establishing the essential function of spectrin. While the exact cause of death is not known, several defects have been described in the nervous system. First, physiological studies established that spectrin mutants have a presynaptic defect that blocks synaptic vesicle release. That study did not detect a significant effect of spectrin mutations on postsynaptic function at the embryonic neuromuscular junction. However, a subsequent study of neuromuscular junctions later in development revealed that spectrin is necessary for long-term stability of the synapse. Recently a defect in axonal pathfinding was observed in *Drosophila* β spectrin mutants. It is interesting that the spectrin mutation was phenotypically similar to defects in Robo and Slit, a ligand and receptor mediating repulsive guidance during development of the embryonic central nervous system. There was no apparent effect of the β spectrin mutation on Robo expression, and the deficit was not corrected by expression of β spectrin in glial cells which normally express the Slit ligand. Thus the β spectrin mutation may exert its effect on a downstream component of the Robo signaling pathway in neurons.

Human βIII Spectrin

Sequencing of candidate mutations revealed that defects in the βIII spectrin gene are responsible for human spinocerebellar ataxia type 5. Three mutations were identified in three independent lineages. Two affected repetitive segment 4, and the other affected the actin binding domain (Figure 1(a)). It is interesting that one of the mutations was traced through the pedigree of Abraham Lincoln, raising the possibility that the former US president may have suffered from this disease. βIII spectrin was originally described as a novel spectrin isoform associated with intracellular vesicles and the Golgi apparatus in tissue culture cells. However, less is known about the subcellular distribution of the protein *in vivo*. A yeast-2-hybrid study detected βIII spectrin in a screen for proteins that interact with the glutamate transporter EAAT4. The effects of the spinocerebellar ataxia mutations on EAAT4 behavior were assayed biochemically and in a tissue culture cell assay for protein mobility in the plasma membrane. The βIII spectrin mutations did not appear to affect the quantity of EAAT4 in autopsy samples of brain tissue, but the extraction properties of EAAT4 were

altered, suggesting a possible change in its subcellular distribution or perhaps altered interactions with other brain proteins. The mobility of glutamate transporters in the plasma membrane of HEK293 cells was greatly reduced with co-expression of wild-type βIII spectrin but not with the mutant version of spectrin. These results suggest that βIII spectrin has effects on interacting membrane activities at the plasma membrane, beyond any additional effects it may have within intracellular compartments.

Murine βIV Spectrin

Studies in the mouse established that the βIV subunit of spectrin codistributed with ankyrin-G at the node of Ranvier and at the axon initial segment. Truncations in mouse βIV spectrin were shown to be responsible for the mutant phenotype in quivering mice which exhibit ataxia, tremor, and deafness. Studies of βIV spectrin knockout mice revealed that βIV spectrin interacts with ankyrin-G and that neither ankyrin-G nor voltage-gated sodium channels were correctly targeted to the axon initial segment or node of Ranvier in the mutants. It is interesting that knockout studies also demonstrated that βIV spectrin was mislocalized in ankyrin-G mutant mice, indicating that the targeting of ankyrin and spectrin was mutually dependent. The phenotype of quivering mice appears to be caused by the effect of the βIV spectrin mutation on voltage-dependent sodium channel targeting or stability. These observations suggest that βIV spectrin and ankyrin exert their effects on interacting membrane proteins in a coordinated fashion.

There also appear to be multiple isoforms of βIV spectrin. In fact, the 'conventional'-size βIV product (288 kDa) was a relatively minor component relative to an unusual variant (~150 kDa) in which the N-terminal half (including the actin binding domain and ten repeats) was absent. Yet the phenotype observed at the node of Ranvier appeared similar whether knockouts affected all βIV spectrin isoforms or just the largest isoform. These observations raise the possibility that the novel small isoform may have unique functions that are distinct from conventional β spectrins.

Speech Perception: Adult

L L Holt, Carnegie Mellon University, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

As adult listeners, we comprehend the messages conveyed by spoken language with little effort. However, the ease of everyday conversation masks the perceptual and cognitive complexities involved in perceiving speech. Upon examination of the acoustic speech signal, it becomes immediately clear that this everyday skill is a demanding perceptual task.

A spoken syllable may persist in the world for a mere tenth of a second. Yet, as adult listeners, we are able to gather a great deal of information from these fleeting acoustic signals. We may apprehend the physical location of the speaker, the speaker's gender, regional dialect, age, emotional state, or identity. These spatial and indexical factors are conveyed by the acoustic speech signal in parallel with the linguistic message of the speaker. Although the spatial and indexical characteristics of the spoken message are of much interest in their own right, speech perception most commonly refers to an understanding of how the physical patterns of acoustic energy evoke perception of a linguistic message. Thus, the study of speech perception concerns the mapping between a time-varying acoustic signal received from a talker and linguistic meaning.

Units of Speech Perception

Some accounts of speech perception have suggested the possibility that adult listeners map the acoustic signal directly onto lexical entries, the words of the language. However, most models of language comprehension assume that the acoustic speech signal is translated into an intermediate unit that is used to access the words forming the lexicon. There has been much debate regarding the best characterization of these intermediate units and, for the most part, the possibilities have related closely to the natural classes described by linguistic theory, whether distinctive features, phonemes, or syllables. Despite these theoretical distinctions, the vast majority of research in speech perception has focused on the mapping from acoustics to phoneme or phonetic category as in the distinction between /b/ and /p/ in 'bin' versus 'pin.' It is likely that the concepts understood from this research apply similarly to other possible basic units. At all levels thus far investigated in-depth, research has demonstrated that the mapping from acoustics is very complex.

Context in Encoding

The complexities of speech perception begin with the nature of the acoustic signal. A great deal of early research documented the considerable variability inherent in the acoustics of speech. To summarize this broad literature very briefly, there do not appear to be acoustic signatures that uniquely specify phonetic categories, syllables, or words. Thus, listeners are faced with the perceptual challenge of mapping highly variable acoustic signals onto speech units in a many-to-one manner.

The variability inherent in the acoustics of speech arises from multiple sources. One notable source of acoustic variability is due to demands on speakers. Part of the efficiency of spoken language is the fluent nature with which it may be expressed. Speakers produce 10–15 consonants or vowels per second at typical rates of speech, and they may even double this rate in hurried speech. The rapid nature of speech production affects the acoustic signal that reaches the ear of a listener. In fluent speech, speakers articulate sounds such that movements of the vocal tract overlap in space and time across the production of different consonants and vowels. This overlap is known as coarticulation; its result on the acoustic speech signal is to cause the information for speech units to be spread across the acoustic signal. Phonetic elements of a spoken word (e.g., the three sounds in 'bin,' /bIn/) are not presented discretely as are the letters of a written word. Rather, the acoustic information for phonetic categories overlaps within the acoustic signal such that any particular time slice of an acoustic speech signal may contain information about multiple vowels and consonants. For example, the particular acoustic signature of a consonant /g/ as in 'gum' is greatly influenced by whether it is preceded by a word such as 'feel' or 'fear,' as in 'feel gum' and 'fear gum.' To describe this simply, consider the placement of the tongue body in these articulations. In articulating 'feel gum,' the tongue must move quickly from a more anterior position in the /l/ of 'feel' to the more posterior position of the /g/ in 'gum.' The resulting articulation is a compromise between where the tongue has been and where it is going. This is in part a consequence of physical constraints such as mass and inertia on the articulators, but speakers may also actively adjust articulation.

In the example, the result is that the articulators do not reach quite the same position in articulating the /g/ in 'gum' when it is preceded by 'feel' as when it is preceded by 'fear.' As a result, the acoustic signature of the /g/ in 'gum' is quite different across these two contexts. One issue for speech perception is how the perceptual system recognizes the functional equivalence of these two acoustically distinct /g/ sounds.

In addition to coarticulation, other sources also contribute to variability of the acoustic speech signal. Rate of speech, speaker idiosyncrasies, dialect, accent, emotion, gender, and room reverberance influence the acoustics of an utterance. One of the most significant challenges for understanding speech perception is that despite the radical effect these diverse sources of variability have on the acoustic signal, listeners somehow identify speakers' intended meaning. There has been considerable research investigating how listeners accomplish this feat. At the broadest level, it appears that listeners overcome the perceptual obstacles of acoustic variability by perceiving speech in a wholly context-dependent manner. The same speech signal may be perceived as belonging to different phonetic categories when it is heard in different contexts. Consider the example discussed previously. When listeners are presented with a set of speech stimuli that have been acoustically manipulated to vary perceptually along a /g/ to /d/ series as in 'gum' to 'dumb,' the endpoints of the series are perceived consistently as /g/ and /d/. The intermediate stimuli are perceptually ambiguous, being identified as both /g/ and /d/ some of the time. The boundary is steep, as is typical of identification of consonants. This pattern of perception is illustrated in **Figure 1** by the green line.

Figure 1 Listners identification of consonants varying perceptually from 'ga' to 'da' changes as a function of the speech that precedes it. A preceding 'l' shifs identification toward more 'ga' identifications whereas a preceding 'r' shifs identification of the same sounds toward 'da'. Data after Mann VA (1980) Influence of preceding liquid on stop-consonant perception. *Perception & Psychophysics* 28: 407–412.

Many experiments have demonstrated that listeners' perception of such sounds is influenced greatly by the preceding context. Preceded by /l/ as in 'feel,' listeners tend to label the sounds along the /g/ to /d/ series more often as /g/ as in 'gum' (**Figure 1**, red line). The same sounds are more often labeled as /d/ when /r/ is the context stimulus (**Figure 1,** blue line). Thus, physically identical acoustic speech stimuli are perceived very differently as a function of adjacent context.

The association between such phonetic context effects and coarticulation is intimate. Notice that the direction of these phonetic context effects in perception is opposite the coarticulatory effects on speech articulation described previously. In the utterance 'feel gum,' the /g/ is coarticulated such that it is articulated at a more anterior position than it is in isolation. This causes its acoustics to be more similar to the anterior articulation typical of /d/ in isolation; coarticulation of 'feel gum' results in a more /d/-like articulation of /g/. However, perception pulls in the opposing direction. A perceptually ambiguous /g/–/d/ speech token is pulled perceptually toward /g/ when preceded by an /l/ precursor, as in 'feel.' Thus, this contrastive perception works in opposition of coarticulation, in essence compensating for the assimilatory coarticulatory effects that draw neighboring utterances to be more similar to one another. Coarticulation causes /g/ to be acoustically more similar to /d/ in the context of a preceding /l/, whereas speech perception of consonants in the context of /l/ is shifted so that syllables are perceived more often as 'g' than 'd.' Context effects of this sort are ubiquitous in speech perception and have been documented for many speech segments. Moreover, they are observed in infants; therefore, neither experience producing coarticulated speech nor a well-developed lexicon appears to be prerequisite. Perhaps even more surprising, the influence of /l/ and /r/ on consonant perception is evident even among adult listeners for whom /l/ and /r/ are not phonologically distinct. Japanese listeners unable to accurately distinguish English /l/ from /r/ exhibit a phonetic context effect of the same magnitude as native English listeners. Listeners need not be able to classify the context syllables into distinct native phonetic categories (or even be able to hear a difference between precursors) for them to have an influence on perception of following speech.

Of interest in understanding the mechanisms that give rise to such effects, Japanese quail (*Coturnix coturnix japonica*) trained to peck a lighted key in response to presentation of /g/ endpoints of a /g/ to /d/ stimulus series pecked more vigorously to novel ambiguous midseries speech stimuli when they were preceded by /l/. A second set of birds trained to peck

Figure 2 Ovail trained to peck to 'g' for 'd' sounds exhibit context-dependent pecking when 'l' and 'r' precede the target sounds. The influence of context is the same as that plotted for human listeners in Figure 1. Data from Lotto AJ, Kluender KR, and Holt LL (1997) Perceptual compensation for coarticulation by Japanese quail (*Coturnix coturnix japonica*). *Journal of the Acoustical Society of America* 102: 1134–1140.

in response to /d/ responded more robustly to the same novel stimuli when they were preceded by /r/. Thus, as illustrated in Figure 2, birds exhibit context-dependent shifts in responses contingent on a speech precursor, and the directionality of this effect is the same as that observed for human adults and infants. The extension of phonetic context effects to a nonhuman species suggests that mechanisms specific to human speech may not be necessary to accommodate the complex variability present in speech. To pose the results in a general way, context sounds with higher frequency acoustic energy (e.g., /l/) shift perception of the following syllable toward the alternative with greater low-frequency energy, /g/. Thus, processes by which the auditory system exaggerates change in the acoustic signal may be sufficient to explain perceptual compensation for coarticulation. This conclusion is supported by research demonstrating that adult human listeners shift phonetic categorization responses not only as a function of neighboring speech contexts but also as a function of nonspeech tones, chirps, and noises that precede or follow speech. In the case of human and nonhuman perception of speech and nonspeech contexts, speech perception appears to be relative to and contrastive with the acoustics of context sounds, whether speech or nonspeech.

Thus, there is evidence that some of the perceptual challenges of the variability within the acoustic speech signal may be met with general perceptual processes that produce contrast. Experiments investigating listeners' sensitivity to distributional regularity in sentence-length acoustic contexts indicate that such contrastive processing may also provide a means of adjusting perception in response to variability in the acoustic speech signal introduced by different speakers. Overall, these results indicate that listeners retain information about context stimuli across multiple timescales and adjust speech perception in relation to this information. The exact nature of the mechanisms by which listeners retain context across multiple timescales remains to be determined, but empirical findings suggest that the mechanisms may rely on perceptual processing general to speech and nonspeech acoustic signals (and, indeed, available to even quail) rather than processing specialized to accommodate acoustic complexities of the speech signal.

Speech and Expertise

A great deal of research has been directed at identifying invariants, unique acoustic cues indicative of a particular phonetic category. However, despite these attempts, it appears that phonetic categories, by and large, are signaled by multiple cues that vary with the context of the spoken utterance, with no single cue being necessary or sufficient to signal phonetic identity. The case of English /b/ versus /p/ is illustrative: 16 distinct acoustic cues have been cataloged as differentiating these two categories in syllable-initial position. Recalling discussion in the previous section, it is also the case that acoustic cues signaling a particular phonetic category are quite dependent on the context in which the acoustic signal is presented. However, the existence of multiple acoustic cues to category identity does not imply that all of these cues are equally informative to listeners. For example, both spectral and temporal cues differentiate the English vowels /i/ and /I/, but listeners rely much more on the spectral cue than the temporal cue in categorizing these vowels. The precise nature of perceptual weighting of acoustic cues appears to depend, at least in part, on experience with the distribution of cues within the native language. There is evidence that the developmental trajectory of this learning is protracted; preschool-aged children apply very different perceptual weights to acoustic cues than do adults. Insight into how listeners learn to weight acoustic cues differentially may come from studies of other complex sounds, such as music and novel nonspeech categories, for which there is also evidence that listeners learn to weight acoustic cues based on cue distributions in the input.

The details of the acoustic distributions of the native language community play a very significant role in adult speech perception. In the first year of life, well before infants are speaking, they are already beginning to perceive speech in a native language-specific manner. As mentioned previously, this attunement to the native language continues into later childhood before reaching adult-like performance

and may, some argue, require learning to read to produce the kinds of phonetic categorization typically studied in investigations of adult speech perception. Among adults, perception of the acoustic speech signal is very significantly influenced by experience with the native language. Identical acoustic signals may be perceived very differently by listeners with different language or even dialect backgrounds. The classic example of this was alluded to previously. Japanese does not make a phonological distinction between the English sounds /r/ and /l/. Experience with the structure of Japanese shapes the way that adult Japanese native listeners hear speech such that many Japanese listeners are unable to distinguish English /r/ from /l/ even following significant training. Expertise with a native language has a strong influence on the manner by which speech is perceived. The relative interaction of native language experience with perception of nonnative sounds depends significantly on the degree to which the nonnative sounds overlap with native sounds in perceptual space. Understanding these phenomena and investigating the degree to which adult listeners may or may not exhibit plasticity in learning second-language sounds are active areas of research.

This is a significant challenge because adult listeners are experts in perceiving speech, having spent the greater part of their waking hours engaged in perception of speech and being exposed to the speech signal since their later prenatal months. Exposure to the acoustic systematicities of a language is thought to organize perception in terms of phonetic categories or equivalence classes. Due to the acoustic variability of speech, there is no one-to-one mapping between acoustics and phonetic category. The mapping of a set of variable acoustic signatures onto a common phonetic label (or syllable or word), as described previously, is an example of categorization; physically distinct acoustic signals may be treated by listeners as instances of the same phonetic category. These categories appear to have graded internal structure such that utterances of a particular vowel or consonant may be perceived to be more or less representative of the category. Despite general agreement on these observations, it has proven difficult to determine the precise learning mechanisms by which this organization occurs because adults, and even young infants, possess a great deal of phonetic experience. Without characterization or control of the acoustic distributions of this experience, it is difficult to tease apart how experience with different distributions of speech input may shape phonetic categorization. It is possible to observe that experience with different native languages produces very different phonetic organizations, but the means by which this occurs is not well understood. Several empirical inroads to these issues have been made by investigating learning in nonhuman animal models of speech perception and by investigating the boundaries and constraints on human adults' general ability to categorize complex nonspeech sounds. The findings from this growing literature suggest that listeners (both human and nonhuman) are able to extract regularities from distributions of complex acoustic signals such that categorical responses may be made. For example, European starlings trained to respond to the vowels /i/ and /I/ (as in 'beet' and 'bit') respond to the vowels in a graded manner, as do human adults. The strength of the starling responses to individual vowels correlates very strongly with native English human adults' ratings of the 'goodness' of these vowels. Thus, a nonhuman species is capable of learning to respond categorically to speech stimuli and does so in a way that mirrors the graded internal structure of human adult perception.

The virtue of nonhuman animal models is that there is a greater possibility of experimental control over the histories of experience such that firm conclusions about the course of learning may be drawn. A complementary approach that shares this virtue is training human adults to categorize novel nonspeech acoustic stimuli such that the constraints imposed by auditory categorization, in general, may be understood. Investigations of nonhuman animal models and adult human novel sound category learning may play an important role in understanding phonetic categorization because of the experimental control afforded. A challenge will be to balance this control with the ecological validity of studies of infant phonetic category acquisition and nonnative adult listeners' phonetic categorization to work toward an understanding of how adult perceivers become expert with the speech signals of their language community and how this expertise shapes speech perception.

Categorical Perception

Categorical perception is perhaps the best-known pattern of speech perception. The speech series illustrated in Figure 1 serves as an example. Although the speech sounds along the series vary gradually in their acoustic characteristics, listeners' pattern of identification changes abruptly, not gradually; this sharp identification function is one of three hallmarks of categorical perception. A second defining characteristic of categorical perception is the pattern of discrimination across the series. When listeners discriminate pairs of stimuli drawn from the series, the resulting discrimination function is discontinuous. Discrimination is nearly perfect for stimuli that lie on opposite sides of the sharp identification boundary, whereas it is very poor for pairs of stimuli that are equally

acoustically distinct but lie on the same side of the identification boundary. The final characteristic of categorical perception is that identification performance predicts discrimination performance; speech sounds that are identified with the same label are difficult to discriminate, whereas those identified with different labels are discriminated.

Categorical perception was formerly thought to be a peculiarity of speech perception. However, categorical perception has since been observed for perception of human faces and facial expressions, music intervals, and artificial stimuli that participants learn to categorize in laboratory tasks. It is observed in the behavior of nonhuman animals as well. Rather than a speech-specific phenomenon, categorical perception is a far more general characteristic of how perceptual systems respond to experience with regularities in the environment.

Influences from Other Sources of Information

As described previously, the mapping between acoustic speech signal and intermediate representation (acoustics to phonetics, in most characterizations) is complex. It is also the case that this mapping may be influenced by higher-order linguistic information, such as the knowledge of words within the language. An ambiguous sound that might be perceived as /g/ or /k/, for example, is more likely to be identified as /g/ if it is followed by 'ift.' The same sound is perceived as /k/ if it is followed by 'iss.' The direction of this influence is to shift phonetic categorization toward the alternative that forms a real English word. The influence of lexical information on phonetic perception has been established in a variety of paradigms, and the mechanisms by which these effects arise are hotly debated. Specifically, there is significant controversy between interactive accounts, which posit that such effects arise via feedback from the lexicon that directly influences the mapping from acoustics to phonetics, and strictly bottom-up autonomous accounts, whereby the influence of lexical information on phonetic responses emerges only at a later decision stage and does not directly influence the mapping from acoustics to phonetics (Figure 3). As in other domains of cognitive science that are modeled by these two approaches, distinguishing between interactive and autonomous accounts in speech perception has been difficult because the two models make many similar predictions. However, there is a domain in which the predictions of the models depart quite radically. Interactive accounts posit that lexical information may influence prelexical processing directly via feedback from the lexicon to prelexical processing. In autonomous models, this kind of direct modulation is impossible because information from phonetic and lexical processing is combined only at a later decision stage. If lexical information influences a prelexical phenomenon, it may be taken as evidence for interactive models.

Figure 3 Schematic diagrams of interactive and autonomous models of speech perception.

There is one empirical paradigm in which this proposition has been tested, retested, and much debated. The phonetic context effects described previously are widely considered to arise from the mapping from acoustics to phonetic categories; that is, they are prelexical in the sense that they do not require information from the lexicon and operate at a level below that of words. Several lines of research have investigated whether lexical knowledge of the words of English influences phonetic context effects and thus whether lexical information modulates a prelexical effect, as predicted by interactive models. At the prelexical level, a preceding /s/ or /ʃ/ (as in 'sip' vs. 'ship') influences phonetic categorization of subsequent sounds as /t/ or /k/. Preceded by /s/, listeners more often categorize the speech as /k/, whereas preceded by /ʃ/, the same sounds are more often categorized as /t/. Of interest regarding the issue of the role of lexical processing in influencing prelexical effects, a single ambiguous speech sound between /s/ and /ʃ/ is heard as /ʃ/ if it is preceded by 'fooli__' but as /s/ if it is preceded by 'Christma__.' Knowledge of the English language, which includes the words 'foolish' and 'Christmas' but not 'fooliss' or 'Christmash,' serves to disambiguate the acoustically ambiguous speech sounds. Of critical importance, however, is the effect of this on listeners' perception of subsequent sounds as /t/ or /k/. When the ambiguous /s/–/ʃ/ sound is presented in the word contexts and precedes the /t/ to /k/ sounds, there is a shift in listeners' phonetic categorization such that preceded by 'Christma__' listeners respond /k/ more often,

whereas preceded by 'fooli__' the same sound is labeled as /t/. Thus, there is a phonetic context effect on the second sound that is driven by the lexical information, as predicted by interactive models. There has been considerable debate over findings such as these, resulting in replications and alternative conclusions more consistent with autonomous models. Recent investigations have tipped the scales back in favor of an interactive account because these effects have held up to empirical scrutiny.

Another source of influence on speech perception comes from the visual modality. Although speech perception is most often considered from the perspective of the acoustic signal, visual information from a speaker's face can also greatly influence perception of speech. The classic example of this is the McGurk effect, whereby an acoustic /ba/ and a visual /ga/ collaborate to produce a percept of /da/, unique from either unimodal source. A great deal of research illustrates the advantages of perceiving acoustic speech with synchronous, matched visual information of the face producing the speech. Speech presented in noise, for example, is more intelligible when a face producing the speech is visible. Some of the same issues and debates present in understanding why lexical influences on speech perception emerge in considering how the perceptual system integrates optic and acoustic information for speech perception; there are both autonomous and interactive models of the phenomenon. In addition, an important theoretical question that is under investigation is the degree to which auditory–visual integration for speech is a result of the two types of information sharing a common source or whether it is a result of learning about the natural covariance of these visual and auditory signals. This question is important in distinguishing among the theoretical accounts of speech perception. The question is very difficult to address because acoustic speech is intrinsically linked with the visual signals from articulating faces, but adult listeners also have vast experience with the covariation between articulating faces and acoustic speech. This has been investigated by examining whether listeners are able to learn to associate novel visual signals, not in any way associated with faces or with production of speech, with acoustic–phonetic categories. With sufficient training, listeners do, in fact, learn this relationship and, with learning, begin to integrate the novel visual information for the phonetic categories with acoustic speech. The phonetic category membership of an ambiguous acoustic stimulus is disambiguated by the newly learned visual signals. Moreover, the learning results in benefits to intelligibility of acoustic speech in noise when a newly learned visual signal associated with the phonetic category is paired with it. Further work is necessary to determine the relationship of speech expertise with auditory–visual integration in speech perception.

Theoretical Approaches

The challenges of speech perception have been addressed by multiple theoretical accounts of how listeners accommodate the complexities of the speech signal. Landmark studies detailing the relationship between speech acoustics and phonetic perception revealed the complex mapping. These data convinced many that this mapping was far too complex for acoustics to provide a plausible object for speech perception; the objects of speech perception were thought to need to be more or less invariant with phonetic categories. From this tenet arose the motor theory of speech perception. Given the radical variability in the mapping from acoustics to phonetic categories, the motor theory holds that the only tenable object of perception is the intended articulatory gesture of the speaker, as exemplified by the neuromotor command to the articulators. By this view, the objects of speech perception are the articulatory events of a speaker rather than the acoustic or auditory events presented to the listener. Another important aspect of the motor theory is that speech perception is uniquely human and cannot be ascribed to general auditory processing or perceptual learning. Instead, it is said to rely on a modular decoder that is part of the innately specified biological specialization for language, distinct from other forms of auditory processing.

Another theoretical approach, direct realism, shares with motor theory the claim that the objects of speech perception are articulatory rather than acoustic events. However, distinct from motor theory, direct realism posits that the articulatory objects of speech perception are the phonetically structured vocal tract movements, or gestures, and not the neuromotor commands. Direct realism is also very distinct from motor theory in that it denies that specialized processes are necessary to account for speech perception. Rather, following in the Gibsonian tradition of direct perception in the visual modality, this theory asserts that the articulatory gestures of a speaker that shape the acoustic signal serve as information for the listener to directly recover these gestures. This act of perception is not mediated by processes of inference or hypothesis testing but, rather, is direct in the sense that the gestures are apprehended without cognitive mediation from the rich information present in the acoustic signal that specifies a speaker's phonetic gestures. This theory is realist in the sense that perceivers are thought to recover the actual physical properties of the articulatory gestures from the acoustic signal.

The general approach to speech perception is distinguished from motor theory in that it does not invoke specialized mechanisms or modules to explain speech perception. Rather, its working hypothesis is that acoustic speech sounds are perceived with the same mechanisms of auditory perception and cognition that have evolved to handle other classes of complex environmental sounds. Insofar as speech is perceived as a multimodal event, the objects of perception in other modalities are hypothesized to also be general and not specific to speech. The general approach assumes that mapping from signal to meaning is not mediated by the perception of articulatory gestures but, rather, involves mapping the complex structure of the acoustic signal to regularities learned through experience with the distributions of the ambient language community. This general theoretical perspective embraces general perceptual and cognitive mechanisms, not specific to speech but neither limited to solely low-level sensory processing and psychophysics. The account is 'general' in the sense that it suggests that the broad perceptual/cognitive processing of the central nervous system and also the considerable feedback that higher centers have to lower levels of processing are brought to bear in perceiving spoken language.

A great deal of empirical research has called into question the necessity of specialized, modular mechanisms for speech perception. Nonhuman animals exhibit many of the hallmark perceptual phenomena previously thought to be indicative of specialized processing by humans for speech. Moreover, nonspeech acoustic contexts influence human adult speech categorization, a finding that would not be expected if speech processing is modular. There remains a very active debate among the proponents of direct realism and the general approach. However, both theories make predictions about the expected patterns of speech perception, so empirical research promises to increase understanding of speech perception and either further refine these accounts or suggest new thinking.

Neural Processing

One source that many believe will provide theory refinement is the study of the neural processing underlying speech perception. A great deal of research has been directed to understanding the neural bases of speech perception, and many of the efforts have been applied to the theoretical distinctions discussed previously. Research using neuroimaging techniques, for example, has compared auditory processing of speech versus processing of environmental sounds matched along multiple acoustic and perceptual dimensions, including rhythm, content, and duration. Common brain regions are activated by both stimulus types, but of possible theoretical interest, some regions are activated more by speech than by environmental sounds. Some have argued that these sorts of data demonstrate that human adults have specialized neural mechanisms for perceiving speech. However, it is worthwhile to keep in mind that these brain regions may take part in nonlinguistic processing but simply be more engaged by speech stimuli than other nonspeech sound sources. In fact, further investigation of the regions that are activated more by speech than nonlinguistic sound stimuli has found that these areas are also activated by pitch, melody, environmental sound, and/or nonauditory conceptual processing. In summary, caution must be used in interpreting brain regions as indicative of speech-specific processing based on limited controls. The differential activation of brain regions by speech versus nonspeech acoustic signals may arise from differential demands on auditory and conceptual processes brought to bear by speech versus nonspeech signals or by the vast differences in experience listeners have with speech compared to the nonspeech control stimuli.

Speech Perception: Cortical Processing

Introduction

The perceptual processing of speech has been long associated with the posterior temporal lobe. More recent work has suggested that Wernicke's area can be usefully fractionated into different functional streams of processing, and that this may be a helpful framework within which to think about speech perception. This approach has been motivated by developments in the neurophysiology of primate auditory processing and functional imaging studies of human speech perception. For practical reasons, work dissociating streams of processing in the primate auditory system has lagged behind the many developments in visual neurophysiology. The primate primary auditory cortex (PAC) is located on the supratemporal plane making it difficult to access and it does not show a strong response to pure sine tones. Recent technical developments have permitted these problems to be overcome, including the crucial realization that pure sine tones were not the optimal stimulus for driving auditory cortical responses, because most sounds encountered in the environment – especially communicative vocalizations – are highly complex. Unlike the visual system, the auditory system computes many aspects of sounds in the ascending auditory pathway, such that the representation at the cortical level is typically of a more complex auditory object. This has implications for the optimal stimuli to drive neurons in the PAC.

Since these developments, it has become clear that there are some general parallels between the cortical organization of sound and vision, in the sense that both hierarchical and parallel processing can be seen in auditory processing, and this has some degree of functional specialization. The core of the auditory cortex receives all its input from the auditory thalamus, and is organized as three distinct core fields in a rostral–caudal orientation. These core areas are connected to surrounding belt and parabelt regions. The rostral–caudal organization is maintained within these connections, such that the most rostral core field projects to the rostral and rostral lateral belt, but not to the caudal belt, and vice versa. The same is true for projections from the belt and core to parabelt regions.

In terms of connectivity, there is both hierarchical and parallel processing in the PAC. The rostral–caudal organization of the PAC is also maintained in the projections to frontal cortex. There are projections from rostral belt and parabelt to ventral prefrontal regions, and adjacent but nonoverlapping projections to the dorsal prefrontal and premotor cortex from caudal belt and parabelt. These two broad streams of processing are associated with different functions. Moving from medial to lateral auditory fields, responses are driven by progressively wider bandwidth sounds. It has been demonstrated that antero-lateral parabelt cells respond to conspecific vocalizations, while a greater number of more posterior lateral parabelt cells respond preferentially to the localization of calls. This is strong evidence for functional streams, perhaps similar to those in the visual system, with an anterior 'what' stream being functionally and anatomically distinct from a posterior 'where' stream. In addition to these, there is also a suggestion of further types of auditory processing. In the medial caudal belt regions, auditory neurons have been identified which respond to touch, and these may form a route for sensorimotor integration of sound and action.

Several recent approaches to the neural basis of speech perception have used evidence for anatomical and functional streams of processing as a framework for thinking about the early perceptual processing of speech. This approach has the strength of moving away from simplistic anatomical terms like Wernicke's area, and permits the results of functional imaging studies to be interpreted within an anatomical context. Arguably, an anatomical framework is essential when interpreting functional imaging data, because methods such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) are anatomical tools, and the locations of activations are of critical importance. Second, the work from primates indicates that the primate brain processes sounds in (at least two) different ways – for identity and for location. This suggests that, in the human brain, one might well not expect speech – which is first and foremost a sound – to be processed along one single route. Third, although language has no animal model, the finding that the 'what' pathway in primates is sensitive to conspecific vocalizations suggests that early acoustic processing of speech, distinct from language abilities, might have developed in a neural system already important in auditory communication. Indeed, there is even evidence that as speech and language are left lateralized in humans, so is the processing of conspecific vocalizations left lateralized in macaques. This suggests that understanding the neural systems important in processing vocalizations by

nonhuman primates may well be useful when interpreting data from functional imaging studies of human language.

The Processing of Intelligible Speech

Early functional imaging studies of speech showed a surprising degree of bilateral activation when speech was contrasted with silence. This was surprising because a left lateralized system was expected, given that left, not right, hemisphere lesions result in aphasia. Of course, the bilateral activation seen was because the results of functional imaging studies are highly dependent on the baselines used, and comparing speech to silence fails to control at all for acoustic stimulation, let alone the acoustic structure of speech.

Several more recent studies, utilizing more sophisticated baselines, have been able to delineate neural systems which seem to be important in early perceptual processing of intelligible speech. Regions within the superior temporal sulcus (STS), typically left lateralized, tend to show an enhanced response to intelligible speech in such contrasts. Some of these studies have argued that the response in left anterior STS shows the strongest response, and that this has a direct analog with the anterior 'what' pathway seen in the primate literature. Studies have also suggested that there is a hierarchical response to the speech signal. There is an area lateral to the PAC, in the superior temporal gyrus (STG), which shows a heterogeneous response to structure (e.g., harmonic structure) and modulations (e.g., amplitude modulations) in sound. Several studies have also shown a response here to speech sounds. From this response in early auditory areas, activation lateral and anterior to the PAC becomes progressively more selective to intelligible speech. Interestingly, in the STS, there is no differentiation between the response to intelligible speech from a human voice and the response to speech from a robotic-sounding harsh whisper. Thus the anterior STS seems to be strongly activated by intelligible speech and less sensitive to whether this sounded like a 'real' human talking. In parallel, several studies have associated perceptual processing of voice information (e.g., speaker identity) with right STS, an area which does not commonly show a sensitivity to intelligibility in speech.

However, because these studies used intelligible sentences, we cannot dissociate the precise representational characteristics of this response, which could include lexical, semantic, and syntactic factors, although similar activation is seen using unconnected single words. Intelligibility is a useful construct in speech processing, because it captures a global level of speech comprehension and can be easily quantified. More fine-grained approaches try to unpack how specific lexical factors are processed in these dorsolateral temporal lobe areas. For example, responses have been demonstrated to both semantic and syntactic violations along the left anterior dorsolateral temporal lobe, which might suggest that more linguistic elements are being processed in addition to purely phonological and acoustic processing. However, direct contrasts of these two types of violations did not reveal significant differences in the temporal lobes (although greater responses were seen in the basal ganglia for syntactic violations), suggesting that semantic and syntactic processes may be difficult to precisely distinguish in the temporal lobes (at least with the resolution of current fMRI techniques and subtraction methodologies). Consistent with this, a recent study addressing the effect of predictability on the intelligibility of speech has identified regions in the left inferior frontal gyrus (IFG), medial prefrontal cortex, and parietal lobe that are activated when context helps the comprehension of speech. This suggests that more high-level linguistic factors modify speech intelligibility from areas beyond the temporal lobe, and that these may represent candidate areas for 'top-down' modulation of speech perception.

These studies have identified an important role for the STS in the processing of speech, along with re-entrant processes in the left IFG, medial prefrontal cortex, parietal lobe, and basal ganglia in the processing of intelligible speech. The next sections address more specifically targeted processing of the speech signal along phonetic and psychological bases.

Phonological Information: Phonological Features

From a phonetic perspective, information in speech can be categorized in different ways, for example, by characterizing the manner or the place of articulation. This in turn is a candidate cue to which the speech perception system is sensitive. There is some evidence to support this as an aspect of the perceptual processing of speech. For example, both magnetencephalography (MEG) and fMRI studies have indicated that vowels and consonants are apparently processed perceptually using these abstract representations of the place of articulations, despite considerable surface variation due to speaker differences and articulatory variation. In these studies, multiple exemplars of consonants and vowels were used from different speakers, so the consistency in results was not due to basic acoustic properties of individual tokens. Thus, although different speakers produce quite different speech sounds with respect to the acoustic pattern,

there are responses in the lateral STG which are selective to the place of articulation across different vowels and consonants. This approach is attractive, as it suggests that we can successfully use theories of phonetics to drive investigations of the neural basis of speech perception. It also suggests that responses in the lateral STG, which is the auditory association cortex and contains the homolog of primate auditory parabelt regions, may well be tuned to specific properties of speech sounds. It also raises the possibility that we might be able to identify a topographic map of phonetic features in the auditory association cortex.

Phonological Information: Phonotactic Structure

A second theoretical issue in the speech sciences is the combinatorial structure of speech sounds – phonotactics. This describes how, in different languages, different sequences of speech sounds are possible, and can also govern overall syllable structure. For example, in British English, a syllable can be formed with up to three consonants before a vowel, and up to four afterward (e.g., 'strengths'). Such a structure would be impossible in some other languages; for example, Japanese does not permit clusters of consonants before or after a vowel. Phonotactics thus describes properties of syllable structure at both local and global levels.

These properties of syllable structure have been used to distinguish the neural bases of sensitivity to linguistic versus perceptual information in speech. The power of this approach is enhanced by using two language groups, such as French and Japanese. French is a language that does not distinguish vowels as different based on their length: thus, the nonwords ebuzu and ebuuzu sound like the 'same' nonword in French. In Japanese, however, vowel length is linguistically contrastive: ebuzu and ebuuzu are two different nonwords. However, as noted earlier, Japanese does not permit clusters of consonants, unlike French: when presented with the nonword ebzu, the bz sequence is illegal in Japanese, and an epenthetic vowel is heard – Japanese listeners presented with ebzu 'hear' ebuzu. Thus, to Japanese listeners, ebuzu and ebzu sound like the same nonword, while to French listeners these are two different nonwords. In an fMRI study, French and Japanese listeners were presented with pairs of nonwords, which had to be classified as the same or different. Elegantly, the nonwords that could be distinguished linguistically for one group were an acoustic difference for the other group, and vice versa. Using this design, neural responses can be identified in left STG, immediately lateral to the PAC, which were sensitive to the linguistically relevant stimuli comparisons, but not to the acoustically different but perceptually identical comparisons in both language groups.

What this study is thus able to show is a sensitivity to syllable-level structure that is from one's native language. Importantly, this activation is early in the perceptual processing of speech, in brain regions which would correspond to the parabelt in the primate brain. The hierarchical processing of speech not withstanding, this indicates there is some sensitivity to the structural properties of speech early in auditory cortical fields. As mentioned earlier, this region of the auditory cortex, lying lateral to the PAC, has also been shown to be sensitive to amplitude modulation (and other forms of auditory structure). Amplitude modulation is a very important aspect of the speech signal, reflecting global characteristics of the amplitude envelope of speech. That the neural processing of linguistically relevant changes in phonotactic structure overlaps with the neural processing of amplitude modulation suggests that early auditory areas may be tuned for linguistically relevant properties of sound. This opens the possibility that responses in the STG will reveal the processes and representations important in the fast, plastic, hierarchical, and parallel processing of the speech signal which must occur prior to comprehension.

Psychological Factors: Categorical Perception

More psychological approaches to speech perception have also been attempted in cognitive neuroscientific investigations. Categorical perception has been used as an approach to identify neural responses to consonant–vowel (CV) stimuli. Categorical perception describes the phenomenon of perceptual discrimination being best at the boundary between two classes of sounds, such that a dimension spanning both categories is not classified linearly. This is considered by psychologists to be an important property of speech perception and potentially explains how listeners cope with the variable speech output produced by speakers. Using fMRI, a recent study employed sounds which varied along a ba-da series, a series which is perceived categorically by English speakers. A form of spectral rotation was used to give an acoustically similar but nonintelligible series, which was established not to be perceived categorically. The results showed left lateralized response to the ba-da stimuli, in the mid STS, when contrasted with the rotated stimuli. This is an important study as it indicates that the STS response to speech is not driven by sentential or complex lexical structure. It will be interesting to establish whether the neural

regions identified demonstrate categorical neural responses to the speech series, which would be powerful evidence for the categorization of speech sounds in the auditory cortex. It would also permit a comparison with the data on featural/phonotactic structure, which tend to give activations somewhat earlier in the auditory cortex.

Psychological Factors: Auditory Word Forms

Another approach to the neural basis of speech perception is that of identifying candidate 'auditory word form' areas. This approach is motivated by cognitive neuroscience investigations and cognitive models and has gained support from PET and fMRI studies of reading, which have consistently identified a response in the left extrastriate cortex to written words and orthographically legal nonwords. While there is much less work concerning auditory word form areas, the phenomenon of repetition suppression, whereby the neural response is reduced to the second presentation of a stimulus relative to the first presentation of the same stimulus, has been used to try and identify candidate areas. This approach has revealed a selective response in the left anterior STS, in a region very similar to previous demonstrations of a neural response to intelligible speech signals. It seems plausible to consider that the two results are essentially addressing different aspects of the same perceptual phenomenon – not lexical identity *per se*, but a point along the anterior 'what' pathway in the auditory system, consequent to acoustic, sequential, and featural processing, which is sufficiently well specified that it can form the basis for access to the lexical and semantic system. From here, one might propose, there is access to and feedback from the lexical and semantic system in ventral temporal areas, and links with attentional and executive systems in the prefrontal and parietal cortex.

Speech Perception: Production Links

One of the most striking effects in speech perception is the link between speech perception and production. For example, if our language does not distinguish two speech sounds linguistically, we can have problems hearing or producing the sounds accurately. This is the basis for Japanese mispronouncements of r/l distinctions: these two sounds are two different consonants in English but two variations of the same consonant in Japanese, which leads to problems in accurate articulation. Some perspectives suggest a role for perception production links in human language organization. It has been demonstrated that silently mouthing a written word primes a later auditory lexical decision task, suggesting that articulation itself is sufficient to activate the representation of word forms. Indeed, one entire approach to modeling speech perception, the motor theory of speech perception, is focused on the primacy of motor representations in the perception of speech, such that a speaker's intentions for articulation are perceived.

A candidate route for such phenomena would be some point in the brain where there are shared resources for the perception and production of speech, be those representational, process based, or both. The previous sections of this article have suggested that functional imaging studies have been successful at delineating structures important in the neural basis of speech perception; the following section is targeted at the possibilities for the neural basis of speech perception and production links.

Perception Fields Important in Production

As outlined in the previous sections, early acoustic processing of speech involves regions in the dorsolateral temporal lobes. We have seen that a specific route for speech comprehension runs lateral and anterior to the PAC. In stark contrast to this, many previous studies have ascribed an important role for the planum temporale (PT) in speech perception. Lying lateral and posterior to the PAC, the PT has been shown by functional imaging studies not to be a site for speech-specific perceptual processing. Indeed, much of the interest in this region has derived from anatomical studies which have indicated that the PT is larger on the left than on the right, an approach which has suffered considerable criticism. However, more recent work has suggested that there may well be some speech-specific functions in the medial planum. A region of the auditory cortex, posterior and medial to the PAC, has been shown to respond to speech production – both speaking aloud and silent mouthing. This is a striking activation of the auditory cortex in a motor output task, and it is all the more impressive for it being seen when the output is mouthed – that is, the response is not solely to the subjects hearing their own voices. One interpretation of such activation is that it indicates a guidance of articulation by speech perception mechanisms – that the motor act of speech is guided by representations of the target sound of the utterance. The medial PT is in an optimal place to act as a sensorimotor interface in speech perception and production, being part of the posterior stream of auditory processing, linking into the parietal and motor cortex; it also lies just ventral to the secondary face area in the sensory cortex. In nonhuman primates, these medial and

caudal auditory areas are activated by multimodal sensory stimulation, again consistent with a role for sensorimotor integration. A recent review has suggested that this area may be representing 'possible' articulations, and it has been suggested that it may form a posterior 'how' stream of processing. This posterior–medial planum activation has also been identified as a component of a verbal working memory system, which may not be speech specific.

Production Fields Activated in Speech Perception

Primary speech motor recruitment has been suggested in another recent study in which participants were scanned listening to syllables and producing syllables aloud. A region-of-interest (ROI) analysis on the brain regions activated during speech production revealed peaks in the left motor and premotor cortex that were also activated during speech perception. This indicated that speech perception recruits the motor cortex in a very direct fashion, perhaps along the lines of the classic motor theory of speech. However, a study of nonverbal emotional vocalizations (such as laughs and screams) has also shown a strong response in the motor and premotor cortex to these nonlinguistic stimuli, suggesting that the recruitment of speech production areas during speech perception may not necessarily reflect linguistic processing of the speech signal.

Summary and Conclusions

Overall, therefore, we can see a crucial role for the human STS in speech perception, showing responses to CV syllables, words, and sentences, and potentially being the location of auditory word forms. Consistent with a hierarchical response in the auditory pathway, we can see phonological properties of speech processed in lateral STG areas; thus, the perceptual mapping from sound to acoustic-phonological forms arguably occurs in these areas. In posterior and medial auditory areas, as well as in frontal motor control areas, the speech signal seems to be processed as an action. These areas may form the basis for sensory motor integration of speech sounds with the motor representation of speech.

Speech Perception: Development

Introduction

The speech signal is complex. There is no one-to-one mapping of acoustic signal to linguistic unit. Moreover, the acoustic signal is filled with environmental sounds that are not relevant to speech. Yet, speech perception abilities develop quite rapidly in young children. Research on infant speech and word perception supports the importance of audition and exposure to speech stimuli in resolving complex mappings and discovering relevant linguistic units. This article details the emergence of language-specific sound categories, sound combinations, rhythmic patterns, and words during the first year of life; describes several theoretical accounts of the development of speech perception; and comments on current issues in the field.

Perceptual Abilities at Birth

Infants demonstrate a number of speech perception capabilities at birth. Typically developing infants are able to discriminate, categorize, and store subtle phonetic speech contrasts in long-term memory. In order to facilitate speech perception, it is useful for infants to separate and identify different sound sources in the acoustic signal, beginning with distinguishing speech from nonspeech. From birth, infants listen longer to speech than to nonspeech sounds that are comparable in complexity and spectral frequency. This is evidence that infants possess some of the raw psychoacoustic and cognitive capacities necessary to perceive speech at or just before birth. To account for the special status of speech, it has been posited that infants possess a bias for listening to speech over other types of sounds. A predisposition to attend to speech would enable infants to tune in to important properties of the speech signal, thus guiding acquisition.

Newborns also demonstrate sensitivity to rhythmic properties of language. Any language falls into one of several rhythmical classes: stress-timed, syllable-timed, or mora-timed. In stress-timed languages, including English and German, speech is timed to create roughly equal intervals between stressed syllables. Syllable-timed languages, such as French and Catalan, have syllables that are relatively equal in duration, with lengthening rules for the ends of phrases or utterances. Mora-timed languages, such as Japanese, have subsyllabic timing units. As early as birth, infants are sensitive to rhythm information and show a preference for listening to languages that conform to the rhythmical class of their native language but do not distinguish their native language from others within the same rhythm class. Sensitivity to native-language rhythm patterns at birth is evidence for infants' use of knowledge acquired during prenatal language exposure.

Learning Language-Specific Sound Categories

Infants are able to perceive a number of speech contrasts from birth, but these contrasts may not coincide with the contrasts that are used by the individual languages that the infants are learning. Before 6 months of age, infants discriminate a range of consonant and vowel contrasts present in their native language as well as contrasts found in other languages. Young infants between 1 and 4 months of age, like English adults, are better able to discriminate two different /ba/ and /pa/ syllables that vary only in voice onset time (VOT; the time between the release of articulators and the onset of voicing) if the syllables are instances of two different adult phonemic categories than if the two syllables are from within a single adult category. This is true even though within- and across-category tokens differ by equal VOT intervals. In discriminating contrasts from unfamiliar languages, infants are better able to discriminate across- than within-category differences, even though adults often have difficulty discriminating nonnative contrasts. For example, Kikuyu-learning infants of 4 months are able to discriminate an English voiced-voiceless contrast (/ba/ vs. /pa/) even though this contrast is not used in the Kikuyu language. It is interesting that when tested on the voicing distinction in both English and Spanish, which uses different cues from English to distinguish voicing contrasts, 4.5- to 6-month-old Guatemalan infants were able to discriminate the English VOT contrast but not the Spanish one. This result might suggest that infants are not sensitive to fine-grained details in the signal. However, if this were the case, then Spanish-learning infants would not be able to acquire the language's voicing distinction. Rather, it is more likely that the English contrast, which is readily discriminated, is aligned with a language-general voicing boundary, and infants learning the Spanish voicing distinction require resetting or shifting of their perceptual categories. This would explain both the inability to discriminate the Spanish contrast by Guatemalan infants and the ability

to discriminate the voicing contrast by Kikuyu infants. Moreover, 3- to 6-month-old infants show graded, within-category perception of VOT under appropriate testing conditions, indicating that although categorical perception is most easily revealed, graded perception is also possible.

These classic findings in categorical perception laid the foundation for a broad picture of infant speech perception. Infants discriminate minimal phonetic differences not just in salient initial position in words but in medial position as well. They discriminate minimal differences in both consonants and vowels. Infants of 6–8 months can categorize multiple but distinct instances of stimuli from within a phonetic category as equivalent and distinct from a set of stimuli for a different phonetic category, but they are unable to make such divisions at arbitrary points along an acoustic continuum.

Functional reorganization from language-general to language-specific perception of consonant contrasts occurs by 10–12 months of age. English-learning 6- to 8-month-olds are able to distinguish contrasts that are not used in English, performing like adults who speak languages in which the contrasts are meaningful. On the other hand, English-learning 10- to 12-month-olds perform like English-speaking adults: they distinguish contrasts that are meaningful in English but do not demonstrate behavior consistent with discrimination for other contrasts. This decline in infants' ability to distinguish contrasts has been replicated using a number of contrasts. Similar to consonant perception, infants are able discriminate across a range of vowel categories within the first few months of life, even vowels that are acoustically similar or not phonemically relevant in the native language. Young infants are also able to detect vowel pattern differences across syllable sequences. However, by 6 months of age, looking-time data suggest that infants are already less sensitive to nonnative vowel contrasts. The reorganization process, the interaction between the perceptual/cognitive starting point and experience, appears to occur earlier for vowels than for consonants. One explanation for this is that vowels carry much of the basic prosodic information that infants are attracted to in early infancy. For example, English and Swedish 6-month-old infants exhibit a language-specific perceptual bias when tested on discrimination within vowel categories. Similarly, English-learning 4-month-old infants discriminate non-English vowel contrasts found in German, whereas 6- to 8-month-olds show more sensitivity to English than to German contrasts, and 10- to 12-month-old infants do not appear to discriminate the German contrasts. Though 4- to 12-month-olds can discriminate all vowel contrasts presented (native and nonnative), an asymmetry is observed by 6 months of age, with native prototypical vowels biasing the perception of nonprototypical vowels when the two are heard in a sequence.

Figure 1 Learning distributions. Acoustic cues that have a bimodal distribution encourage learners to form two categories, while cues that have a unimodal distribution encourage the formation of a single category. When asked to discriminate two sounds along an acoustic continuum (A and B), infants exposed to the bimodal distribution distinguish the sounds, while infants exposed to the unimodal distribution do not categorize them differently, even though the sounds are equally frequent in the input.

During the first year of life, reorganization of speech perception takes place, but how might this be accomplished? One possibility is that infants are sensitive to statistical patterns and use this ability to track the distribution of speech sounds in a language. If so, they should be able to use this information to determine the linguistic relevance of various acoustic properties. Exposure to different distributional patterns should promote a category distinction (see Figure 1). Specifically, a group of sounds characterized by a unimodal distribution along some acoustic dimension should indicate that the acoustic property is uninformative for distinguishing speech sounds in a given language, and therefore that property need not be attended to. On the other hand, bimodal distributions should signal the linguistic importance of a contrast. In fact, infants are sensitive to the frequency distribution of speech sounds in the input, and this sensitivity is present during the age range in which developmental changes in speech perception are observed. Therefore, attention to the statistical distribution of speech sounds in the input is one factor driving the development of speech perception over the first year of life.

Learning Language-Specific Syllable Patterns

During the first year of life, infants not only begin to figure out the specific sound categories of their language, but also legal sound combinations (phonotactics) and prosodic properties (rhythm and stress). They also segment sequences that make up emergent syllable and word forms and begin to learn basic relationships between forms. Infants use their emerging speech perception abilities to learn the distributional properties of their native language. For example, phonetic distribution of the target language affects

the perception of vowels by 6 months of age, and by 9 months infants can discriminate between speech sound sequences based on the frequency with which the sounds occur in the language.

Infants learn the phonotactics of their language in the first year of life. Phonotactics refers to the co-occurrences allowed by specific languages in different syllable positions (i.e., pt does not occur word initially in English but can occur at the end of a word, such as in kept). Between 6 and 9 months, infants develop knowledge of phonotactic regularities in their language. For example, an English-learning infant will listen longer to a word beginning with the legal *str* sequence than the unacceptable *rst* sequence and will show the opposite pattern for word endings, just as an adult does. Infant's phonotactic preferences are most parsimoniously explained by frequency in the input. When presented with nonsense words with two equally legal phonotactic sequences, infants of 10 months consistently prefer stimuli with the more common sequences. Bilingual infants 10 months old prefer the phonotactic patterns of the language that they hear most often. Converging evidence from artificial language learning research also supports the use of distributional statistics to learn permissible phonotactic patterns.

Infants also learn the stress patterns of their native languages rapidly. Between 1 and 4 months of age, infants are sensitive to changes in stress patterns, and sometime between 6 and 9 months of age, infants begin to orient to the predominant stress pattern of their language. English is classified as a trochaic stress system (strong/weak syllable patterns), and English polysyllabic words tend to have strong initial syllables. Strong syllables in English have higher pitch, greater amplitude, and longer duration than weak syllables. Thus, by 9 months of age, English infants prefer trochaic patterns. Infants' sensitivity to the distributional and stress-related properties of language suggests that infants' exposure to syllables that differ in their acoustic properties (i.e., for lexical stress, the change in duration, amplitude, and pitch) results in differing perceptions of these syllable types.

Learning about Words

Parsing the continuous speech stream into individual words is a fundamental task for the language-learning child. Discovering word boundaries is a nontrivial problem due to the lack of direct marking of word boundaries in the acoustic signal, unlike the way that white spaces mark boundaries in written text. However, between 6 and 8 months of age, infants begin segmenting sequences from the speech stream. Strategies based on prosodic cues (including pauses, segmental lengthening, metrical patterns, and intonation contour) have been proposed as means of detecting word boundaries. Other recent proposals have focused on the statistical properties of the target language that might be utilized in early segmentation.

After being familiarized to words spoken in isolation, 7.5-month-old infants who hear passages containing familiar words (cup) and passages that contain novel forms that differ minimally from familiar words (tup) prefer to listen to the passages containing the familiar words, suggesting they extracted these words from the passage. Further evidence that infants use familiar words to help segment speech is seen when a highly frequent form such as mommy precedes an unfamiliar word. When this happens, infants' segmentation of the unfamiliar word is facilitated. This is not the case when two unknown adjacent words are presented. Similarly, when novel words are preceded by a highly frequent function word, such as the, infants are better able to segment and remember the novel words. Being able to use familiar word information facilitates the segmentation of the speech stream. There are a variety of other cues to segmentation, such as prosodic, rhythmic, and segmental information; transitional probabilities; phonotactics; and stress. These cues are part of the distributional properties of the linguistic input.

Statistical information about the co-occurrence of syllables aids infants in segmenting the speech stream. When exposed to an artificial language of trisyllabic nonwords with no cues to word boundaries other than probabilistic co-occurrence information, infants at 8 months were able to segment word forms from the speech stream. Even when co-occurrence is the only type of information present, infants can successfully segment the speech stream.

Syllables themselves carry other information, such as phonotactic and prominence information (word stress). Probabilistic information in the form of phonotactics is used for segmentation by 9 months of age. When infants are presented with CCVC sequences in a highly probable word boundary context (C#CVC) and a low probability one (CCVC), they prefer the CVC sequence that originated from the highly probable word boundary context. Prior to this, 7.5-month-old English-learning infants use strong syllables to determine the presence of certain words in fluent speech. When infants are exposed to only the strong syllables of a two-syllable word (e.g., king for kingdom) and then to passages containing the entire word, they do not listen any longer to these passages than to passages that contain novel targets. This is also the case when presented first with passages containing words like kingdom and then to just the strong syllable in isolation (king). These results suggest that

infants are doing more than just matching strong syllables; they are matching the entire word.

The items used in these experiments corresponded to a trochaic pattern, and it might be the case that the infants were segmenting the speech based on this pattern. This type of language-specific preference for a particular rhythmic pattern may guide segmentation. Infants exposed to a predominately iambic language, such as Canadian French, segment only weak-strong (wS) words. English infants, on the other hand, misparse iambic wS patterns and treat the S syllable as word initial. For example, in a word like guiTAR, infants segment the strong syllable, TAR, as a word-initial syllable. Moreover, if TAR is consistently followed by an unstressed word (e.g., is), infants will treat TAR#is as a single unit. However, if two strong-syllable monosyllabic words are adjacent to each other (COLD ICE or PACK ASH), infants will not missegment these items. By the time English-learning infants are 11 months old, they no longer missegment wS words. The preference for trochaic patterns has been further demonstrated using an artificial language-learning task. Both 9- and 7-month-old infants successfully parse the stream and prefer syllable sequences at test that correspond to an initially stressed syllable from the familiarization phase, even though the test sequences had equally prominent syllables. Taken together, these results support the hypothesis that word stress is a salient cue for segmentation that can be used by the infant to parse the continuous stream of speech.

Inevitably, any partially predictive cue to word segmentation is not completely reliable, and cues differentially influence segmentation throughout development. Stress, independent of other cues, can be used to segment sequences at 7 months of age, but co-occurrence cues dominate stress cues at this age. Coarticulation and stress cues take precedence over raw co-occurrence patterns in 8-month-old infants' parsing strategies. Regardless of the dominance of one cue or another at a given age, it is likely that infants use all available cues to segment speech throughout development.

Infants' capabilities for learning about language-specific sound categories and syllable patterns facilitate the segmentation of speech. As sequences are segmented from the speech stream, these units in turn help refine knowledge about the categories and structures being acquired. Though infants demonstrate some proficiency in speech perception, these abilities continue to evolve throughout development (see Figure 2).

Theoretical Approaches

In 1980, Aslin and Pisoni outlined four possible models for the development of speech perception. (1) Universal theory corresponds to the model in which infants are born with sensitivities to native and nonnative phonetic contrasts, and only those biases that receive support from experience persist. Without relevant listening experience, initial sensitivities are lost. (2) Attunement corresponds to a model in which general biases exist at birth, but experience functions to shape them more precisely to match adult categories. Early experience drives the ability to discriminate contrasts according to (3) the perceptual learning theory. Rate of development is dependent on frequency of contrasts as well as acoustic discriminability of contrasts and the infant's attention. Finally, (4) the maturational theory argues that development occurs according to a predetermined schedule; thus, discrimination of a contrast is independent of experience. None of these theories can account for all the findings related to speech sound contrasts. Rather, it is likely that a combination of these approaches is required to explain infants' abilities.

Other models followed, some specifically linguistic in nature, others focusing on the interface between acoustics (or articulatory gestures) and subsequent representations of speech sounds. Best's perceptual assimilation model (PAM) and Kuhl's native language magnet model (NLM) were proposed to explain general and language-specific perception of speech sounds. PAM provides a 'direct realist' account of native and nonnative speech perception, in which infants perceive speech categorically by recovering information about the speaker's vocal tract configuration. PAM predicts nonnative speech segments will be perceived according to how they might be assimilated to native categories. If the nonnative sounds are assimilated to two different native language phonological categories, they will remain discriminable. If, however, the nonnative sounds are assimilated to a single intermediate category, they will not be discriminable.

The NLM uses acoustic cues as the source of information available to the listener. According to NLM, categories are defined by groupings that emerge in multidimensional space. Initially, this type of category structure results in asymmetries in discrimination. Later, nonnative speech sounds will be collapsed into native ones. Repeated experience listening to speech helps create a category based on category goodness. The best instances of a phonetic category act as perceptual magnets and pull nearby token into their perceptual space, making them less discriminable for infants. Thus perceptual asymmetries are predicted. Poorer performance in a discrimination task is expected if a central member of the category is used as a standard than if a more peripheral token is used.

Figure 2 Milestones in speech perception in the first year.

Both PAM and NLM focus exclusively on speech perception of sound categories and do not consider the role of speech perception in learning about the structure of words. To provide a unified account of how language experience affects perception of native language sound categories and also word recognition in infancy, Jusczyk proposed word recognition and phonetic structure acquisition (WRAPSA). As the signal (speech and nonspeech input) enters the auditory system, a set of auditory analyzers provides a description of the signal. During acquisition, the output of the auditory analyzer is weighted to give prominence to features that are required for contrasting words. Once the signal has been weighted, pattern extraction takes place whereby the signal is segmented into units that temporally group together prominent features into syllabic units. WRAPSA assumes that infants first have access to prosodic information, then syllabic, and only later phonetic. Word recognition occurs by the use of representations that act as probes. Probes are matched against any existing representations of known words. If a close match is obtained, then a word is recognized, and its meaning, if represented, is accessed. If no match can be found, the probe will either be reprocessed or stored as a new entry with or without meaning.

Werker and Curtin recently proposed processing rich information from multidimensional interactive representations (PRIMIR), a theoretical framework designed to explain infant speech perception and word learning. PRIMIR assumes that the same general statistical learning mechanisms are operating over the different levels of analysis simultaneously. Thus, prosodic analysis, segmentation of the speech stream, extraction of syllables, formation of phonetic categories, and storage of word forms happen simultaneously, with each level further influencing category formation and information pickup at each other level. PRIMIR stores exemplar-based word forms in a similar fashion to WRAPSA. Word forms

are sequences that have been identified as possible lexical candidates that eventually or simultaneously become linked to meaning. In this way, WRAPSA and PRIMIR are comparable. The models diverge in the way phonemic categories are formed. WRAPSA assumes that phonemes emerge from the weighting scheme prior to the extraction of potential word forms. PRIMIR argues that phonemic categories are formed once distinguishing properties are detected after a number of word form and meaningful word linkages occur.

Challenges

During the first year of life, infants demonstrate a shift from general speech perception abilities to preferences for categories and structures that occur in the language they are learning. The past few decades have yielded numerous empirical findings that have provided the field with a solid foundation for understanding this development. However, some challenges remain. The speech stream is abundant with rich information, including acoustic properties and segments that pattern statistically. Researchers have identified some of the information that infants can use in experimental settings. Individual properties may not be necessary and sufficient for language and speech development. Research in this area has just begun to scratch the surface of what might and might not be available to and used by infants. Further challenges include understanding how developmental changes occur over time and whether there are maturational or other developmental events that affect the infants' ability to pick up and use the information available to them.

Speech Perception: Neural Encoding

D G Sinex, Utah State University, Logan, UT, USA

Introduction

The responses of individual auditory neurons to speech sounds were first described in the 1970s. The earliest reported measurements were obtained from second-order neurons in the cochlear nucleus, followed a few years later by studies of the responses of large populations of auditory nerve fibers (ANFs). ANFs are primary auditory neurons that constitute the only pathway for conveying information from the cochlea to the brain stem. Many subsequent studies of the responses of ANFs have been carried out, but the influence of the early population studies extends to the present day. Much is known about the representation of speech by ANFs, but there have been relatively few definitive studies on the responses of central auditory neurons. This article provides some background information about the acoustics of speech sounds and presents a view of the neural encoding of speech that emphasizes the representation of the amplitude envelope by ANFs. It also addresses a topic in translational neuroscience by relating observations in experimental animals to the delivery of speech information by intracochlear electrical stimulation.

Speech Acoustics

Speech is often described as being produced by a source and a filter. The source is air from the lungs which is forced through the larynx. Forcing air through vocal folds that are held close together causes them to open and close repetitively, producing a glottal pulse on each cycle. Sounds such as vowels produced in this way are said to be voiced. A sequence of glottal pulses produces a quasi-periodic waveform. The rate at which glottal pulses occur establishes the fundamental frequency (f_0) of the vowel or other voiced sound, and f_0 determines the sound's pitch. In speech, f_0 varies within and across talkers, but it is generally on the order of 120 Hz for adult male talkers and 250 Hz for children and adult females.

During the production of stop consonants, there is an interval during which the vocal tract is constricted. Vocal folds may begin vibrating before this constriction is released, coincident with the release, or sometime after the release. The length of that interval, referred to as voice onset time (VOT), is under the speaker's control and is the basis for the perceptual distinction between pairs of consonants produced at the same place of articulation. Bilabial stop consonants, for example, are produced by constricting the vocal tract at the lips. If the consonant is produced with a short VOT, it is heard as /b/, a voiced stop. If the consonant is produced with a long VOT, it is heard as /p/, a voiceless stop. Other voiced–voiceless consonant pairs include /d/–/t/ and /g/–/k/. An important acoustic correlate of the onset of voicing is a significant increase in overall amplitude, especially in the lower frequencies.

The spectrum of the sound that is radiated from the lips may have a distinctive pattern of peaks and valleys as a result of filtering by the supraglottal vocal tract. The peaks are produced by resonances called formants. Formant frequencies are determined by the physical characteristics of the vocal tract and by the locations of constrictions produced primarily by the tongue, teeth, and lips. Formants are designated in frequency order as F1, F2, F3, and so on. Here, these abbreviations are used to refer to spectral peaks in the resulting acoustic signal. The locations of the first two to three spectral peaks provide cues that help distinguish one phoneme from another.

In natural speech, the configuration of the vocal tract rarely reaches a steady state. In addition, ongoing speech includes sequences of both voiceless and voiced segments. As a result, the spectrum and the temporal envelope of speech fluctuate at a rate typically between 5 and 50 Hz. Frequency and amplitude change are illustrated in Figures 1 and 2. Figure 1(a) is the waveform of a two-syllable vowel–consonant–vowel nonsense word, 'eetah,' spoken by a male talker. The waveform is scaled to represent sound pressure when the sound's overall sound pressure level (SPL) was 60 dB, which is within the range of conversational speech. Amplitude varied over time and was highest during the intervals from −210 to −120 ms (during the vowel /i/) and from 0 to +100 ms (during the vowel /a/). Periodicity associated with glottal pulses can also be seen during the vowel segments. In this example, the average f_0 was approximately 120 Hz. Between the two vowels, the tongue was placed behind the upper teeth to occlude the vocal tract briefly. During that interval, the waveform became aperiodic and its overall amplitude decreased substantially.

Figure 1(b) shows the spectrogram of the same word. As noted previously, ongoing changes in the configuration of the vocal tract lead to short-term changes in the formant frequencies. These changes, called formant transitions, are visible in the spectrogram,

Figure 1 (a) Waveform of a two-syllable utterance consisting of the vowel /i/ as in 'heat,' the consonant /t/, and the vowel /a/ as in 'hot.' The timescale is normalized to the onset of voicing in the second vowel. (b) Spectrogram for the same utterance shown in (a). Relative level is color coded, from black to red to yellow.

Figure 2 (a) Short-term spectrum of the vowel /a/, calculated over the interval from 20 to 40 ms of the waveform shown in Figure 1(a). Spectral peaks corresponding to the first three formants were located at 0.6, 1.4, and 2.6 kHz. (b) Temporal envelope in a limited frequency band. The envelope was computed with a gammatone filter centered at 2.3 kHz. A gammatone filter approximates the filtering that occurs at a single location along the cochlea.

especially in and around the interval between the vowels. An estimate of the short-term spectrum taken near the temporal center of the vowel /a/ is shown in Figure 2(a).

Because formants move, amplitude in any particular frequency band will also change across time. Within a band, amplitude changes over time may be larger than the amplitude changes observed across the frequency range of the first three formants (Figure 2(a)). This is illustrated in Figure 2(b) for a band centered at 2.3 kHz. In this example, the level within the band varied over a range of approximately 50 dB, and changes of 20–40 dB could occur within a few milliseconds. Other bands exhibit changes of the same or even greater magnitude, although with different temporal patterns. This kind of amplitude variation contributes to speech recognition, and the following sections discuss how it is represented in the responses of ANFs.

Basic Response Properties of Auditory Nerve Fibers

The responses of individual ANFs to speech sounds reflect intrinsic properties of the cochlea and of neurons, as well as the spectrotemporal pattern of the speech stimulus. Individual ANFs are tuned to a narrow range of frequencies at low SPLs, and the range expands asymmetrically toward lower frequencies as the level increases. The frequency at which the ANF is most sensitive is called its characteristic frequency (CF). CF is determined by mechanical properties of the cochlea, and it increases exponentially along the spatial array of ANFs from the apex to the base. Each individual ANF is driven (although in a nonlinear way) by the stimulus energy that falls within a frequency band around its CF.

ANFs can be categorized into two or three groups based on their intrinsic rates of firing in the absence of sound, the spontaneous discharge rates (SRs). Thresholds, defined as the stimulus levels that elicit a constant increase in discharge rate, are lowest for ANFs with SR greater than approximately 20 spikes s^{-1}; these are referred to as high-SR neurons. Thresholds are slightly higher for ANFs with SR between 1 and 20 spikes/s, referred to as medium-SR neurons. ANFs in the low-SR group generate less than 1 spike/s and

may have substantially higher thresholds. In cats, three SR groups can be distinguished, but in other mammals, medium- and low-SR ANFs are sometimes treated as a single group.

During the presentation of suprathreshold steady-state tones, discharge probability increases at stimulus onset and then adapts slowly over the duration of the stimulus. Discharge rate averaged over stimulus duration increases with SPL until it saturates. Rate saturation may be flat; that is, at some SPL, average discharge rate reaches a maximum and does not increase with further increases in SPL. Flat saturation is common in high-SR fibers. In sloping saturation, rate continues to increase with SPL, although it reaches an inflection point above which further increases in intensity produce more gradual increases in discharge rate. Sloping saturation is common in medium-SR fibers. The range of SPL between threshold and the level that produces rate saturation is termed the neuron's dynamic range. Within the dynamic range, changes in stimulus level can be encoded as changes in discharge rate; however, level changes that fall exclusively outside the dynamic range cannot. Dynamic range can be as narrow as 20 dB for high-SR fibers, but it is slightly larger for low- and medium-SR fibers. Rate saturation and the limited dynamic ranges of individual ANFs have significant consequences for the representation of speech information.

ANF discharges synchronize with the fine structure of the stimulus waveform, at least for frequencies less than 2–4 kHz. Because of the relation between the stimulus waveform and the neural response, information about the frequency content of the stimulus is present in the temporal discharge pattern. Discharge synchrony is important for the localization of low-frequency sounds based on interaural time differences, for the segregation of competing sounds, and for producing the sensation of pitch. Discharge synchrony has the potential to convey information about spectral shape, and this possibility is considered in the following sections.

Responses to stimuli more complex than pure tones are also affected by cochlear nonlinearities, including rate suppression and synchrony capture. Rate suppression is a reduction in the response to one tone or frequency band caused by energy in a tone or band at a different frequency; frequencies below CF are particularly effective suppressors. The component producing suppression may or may not elicit an excitatory response when presented alone. In responses to speech stimuli, spectral peaks associated with F1 may suppress the overall discharge rates of neurons that would otherwise respond to F2 or F3.

Synchrony capture occurs when the pattern of synchronized discharges is dominated by a high-amplitude component. Spectral peaks associated with formants may capture the synchronized discharges of neurons tuned to other frequency regions, especially those regions in which spectral peaks are lacking. In responses to speech, the synchronized response may be captured so completely by a component near a spectral peak that it is indistinguishable from the synchronized response to a pure tone at the same frequency.

Responses of Auditory Nerve Fibers to Speech

Steady-State Vowels

If discharge rate did not saturate, and responses were not affected by cochlear nonlinearities, each ANF would discharge at a rate proportional to the band-limited energy in the stimulus. That would lead to a relatively simple spatial representation of a stimulus such as the vowel in Figure 2(a), whose spectrum consists of a series of amplitude peaks and valleys. Neurons whose CFs were aligned with the peaks in the spectrum would respond at high rates. Neurons whose CFs were aligned with the valleys in the spectrum would respond at lower rates. Across the ordered array of ANFs, the spatial profile of discharge rate would match the shape of the spectrum. Increases in the overall level of the stimulus would be reflected in the overall discharge rates of the neurons, but the locations of peaks and valleys in the spectrum would be preserved in the spatial profile of discharge rate.

A representation similar to the ideal one described previously is observed in the responses of ANFs, but only when the effective level of the stimulus is low relative to the neurons' dynamic ranges. However, at levels that are higher but still within the range of normal conversational speech, the representation breaks down as a consequence of rate saturation and suppression. The effects of these factors on the representation of steady-state vowels can be seen clearly in the population response of the auditory nerve. In influential studies performed in the 1970s by Murray Sachs and Eric Young, responses of hundreds of ANFs were obtained from individual cats. The average discharge rate of each ANF was plotted as a function of its CF, a display referred to as a rate–place profile. Several rate–place profiles are illustrated in Figure 3. At low SPLs, the shape of the rate–place profile preserved the pattern of peaks and valleys in the vowel spectrum. However, as level increased, response peaks associated with the formants were lost in the rate–place profiles of the most sensitive, high-SR fibers (Figure 3(a)). Because the locations of spectral peaks became more difficult to discern, the rate–place profiles for two easily discriminable vowels looked similar.

Figure 3 Rate–place profiles for high-SR ANFs (a) and cochlear nucleus chopper neurons (b and c) responding to the steady-state vowel /eh/, as in 'head.' The arrows in panel (a) mark the frequencies of the first three spectral peaks in the vowel. Responses obtained at 35 dB SPL are highlighted in green in each panel. At this level, the spectral peaks in the vowel were preserved as local peaks in discharge rate by all the neurons. Responses obtained at 75 dB SPL are highlighted in red. At this level, the locations of the spectral peaks were no longer identifiable in the responses of high-SR ANFs, but they were preserved by the chopper neurons. Adapted from Blackburn CC and Sachs MB (1990) The representations of the steady-state vowel sound /e/ in the discharge patterns of cat anteroventral cochlear nucleus neurons. *Journal of Neurophysiology* 63: 1191–1212, with permission.

At the time it was reported, this finding suggested that the simple discharge rate representation implied by the rate–place profile might be inadequate for representing speech information, and alternative coding mechanisms were considered. One possibility noted immediately was that the rate–place profiles of less sensitive, low- and medium-SR neurons preserved the shape of the vowel spectrum up to higher stimulus levels than did the profiles for high-SR ANFs. A rate–place representation of vowel spectra would be feasible if the responses of high-SR neurons could be processed separately from those of medium- and low-SR neurons in the central auditory system. Interestingly, one type of second-order neuron recorded in the ventral cochlear nucleus appears to combine information from all SR groups to produce a spatial representation of vowel spectra with a larger dynamic range than that of any single subgroup of ANFs. The rate–place profiles of these neurons, called choppers, resemble those of high-SR ANFs at low SPL and resemble those of low-SR ANFs at high SPL (**Figures 3(b) and 3(c)**). The rate–place profiles of chopper neurons preserve information about the locations of spectral peaks over a larger dynamic range than any subgroup of ANFs.

It was also noted that information about the locations of spectral peaks could be extracted by analyzing the synchronized responses of ANFs. The discharge patterns elicited by steady-state vowels and consonant–vowel syllables provided precise information about the spectral content of the stimulus, and the representation was robust over a large dynamic range. However, although the frequency content of synchronized responses is easily identified by techniques such as Fourier analysis, it is not known how or whether the central auditory system extracts comparable information to determine spectral shape. For this reason, potential coding strategies in which discharge synchrony conveys information about spectral shape lack the simplicity that is inherent in a code based on the spatial profile of average discharge rate.

Subsequent observations suggest that average discharge rate can convey more information about speech than was apparent in the original studies of the representation of steady-state vowels. For example, the olivocochlear efferent system acts to extend dynamic range, and this feedback system may exert a greater effect on the representation of speech in awake animals or humans than it does in anesthetized animals. Also, the dynamic range of the initial onset portion of the responses of an ANF is larger than the dynamic range of the same neuron's adapted response. This is potentially important because abrupt changes in the amplitude envelope (**Figure 2(b)**) can be viewed as a series of onsets. Both of these factors extend the effective dynamic ranges of ANFs, which would improve the representation of spectral shape at higher stimulus levels. Another observation is that small changes in the locations of spectral peaks are detectable as small changes in the discharge rates of individual ANFs. Relative discharge rate preserves information about spectral changes that are small enough to approach the psychophysical difference limen for the frequency of a spectral peak. Finally, as discussed previously, the frequency and amplitude

changes that are typical of ongoing speech are often more salient than those that distinguish one steady-state vowel from another. If discharge rate can preserve spectral information down to the range of psychophysical thresholds for steady-state vowels, then it can also be expected to preserve the highly salient frequency and amplitude cues that are present in normal, time-varying speech.

Time-Varying Stimuli

Additional evidence in support of the utility of the spatial pattern of average discharge rate has been obtained in studies of the neural representation of a specific amplitude cue that occurs at VOT in stop consonant–vowel syllables. As noted previously, VOT is under the speaker's control. However, the distribution of VOTs produced in normal speech is highly nonuniform. For example, English speakers produce the voiced consonant /d/ with VOT less than approximately 30 ms and produce the voiceless consonant /t/ with VOT of 50 ms or longer (a positive number indicates that the onset of voicing lags the release of the stop consonant). Speakers of English reliably do not produce VOTs in the intermediate region between 30 and 50 ms.

Series of syllables can be synthesized such that the correlate of VOT varies in equal steps across a range that includes the intermediate values that are rarely produced in normal speech. Humans, monkeys, chinchillas, and birds all exhibit nonmonotonic psychophysical acuity for VOT when tested with syllables from those series. Acuity is low for syllables with short VOTs in which the consonant is heard as /b/, /d/, or /g/ and for syllables with long VOTs in which the consonant is heard as /p/, /t/, or /k/. However, acuity is higher for syllables with VOT in the intermediate region where the label assigned to the consonant changes. This has led to the suggestion that a natural psychoacoustic or physiological boundary underlies the perceptual distinction between voiced and voiceless stop consonants.

Sinex and colleagues measured the responses of ANFs to tokens from synthesized VOT continua. They found that for low-CF neurons and for VOTs of 20 ms and longer, the onset of voicing produced robust discharge rate increases whose latencies increased with VOT. The rate increase was attributable to the rise in amplitude of 20 dB or more that occurs in the frequency region of F1 at voicing onset. There was no evidence in the responses of individual ANFs for a natural physiological boundary between syllables heard as /d/ and those heard as /t/. However, when responses were pooled across populations of low-CF neurons, a relation between the variance of the responses and psychophysical acuity was observed. Syllables for which psychophysical acuity is high elicited responses with low across-neuron variability. The low variability meant that it was easy to distinguish the neural responses elicited by pairs of syllables that are easily resolvable in psychophysical experiments (Figure 4(a)). However, syllables for which psychophysical acuity is low elicited responses with high variability across neurons; higher response variability meant that there was extensive overlap in the neural responses elicited by pairs of syllables that are difficult to resolve (Figure 4(b)). This pattern of results suggests that the amplitude cues in these syllables are represented by subpopulations of neurons in

Figure 4 Differences in the precision with which the onset of voicing is represented by ANFs. Each cross-hatched area encloses the mean ±1 standard deviation of the average discharge rates of a subpopulation of ANFs from one animal. (a) Representations of two syllables with voice onset time (VOTs) of 30 and 40 ms, a 10 ms difference in VOT. For these syllables, which are perceptually distinct, there was little overlap between the responses around the onset of voicing (note the gap indicated by the asterisk). (b) Representations of two syllables with VOTs of 60 and 70 ms, again a 10 ms difference in VOT. In this case, the syllables are perceptually similar, and there was extensive overlap between the responses around the onset of voicing. Adapted from Sinex DG, McDonald LP, and Mott JB (1991) Neural correlates of nonmonotonic temporal acuity for voice onset time. *Journal of the Acoustical Society of America* 90: 2441–2449, with permission.

a way that promotes the perceptual separation of the VOT continuum into two easily distinguishable parts. There was no indication that this distribution of responses arose from any specialization on the part of the neurons to process these sounds; rather, it appeared that the patterns were a reflection of specific acoustic properties of the syllables that varied with VOT.

The representation of stop consonants differing in VOT by central auditory neurons has also been studied. Cortical neurons in primates have been reported to respond categorically to VOT syllables. Neurons responded to syllables with VOTs of 0 and 20 ms, which are heard as /da/, with a simple transient response at the syllable onset. The same neurons responded to syllables with VOTs of 40 and 60 ms, both heard as /ta/, with a pattern that included two transient components – one at syllable onset and another at voicing onset. However, cortical neurons in cats studied with syllables from a /ba/–/pa/ continuum did not exhibit comparable categorical response patterns. It is not likely that the use of a different consonant pair accounts for the difference in response patterns, nor does it seem likely that this is simply a species difference, given the apparent similarity of psychophysical processing of VOT by both mammals and birds.

Another possibility is that the responses of cortical neurons across studies seemed to be different because the stimuli were not comparable. Synthesized syllables with the same nominal VOT may differ in other important properties; for example, formant transitions may be simple or complicated. It follows that when one summarizes the response patterns elicited by a set of speech sounds, one is summarizing the responses to those particular tokens, which may or may not be representative of a larger set of instantiations of the same consonant or vowel. Generalizations from the responses to any limited set of speech sounds to larger issues in speech perception should be made with caution.

The increase in F1 amplitude associated with the onset of voicing in stop consonants is a special case in that the pattern of amplitude change is highly consistent across talkers within one language and, to a lesser extent, across languages. The representation of equally salient but less highly constrained amplitude information is also of interest, again because psychophysical observations suggest that the amplitude envelope plays an important role in speech perception. Studies by Robert Shannon and others indicate that speech may be highly intelligible even after processing that removes precise information about the locations of spectral peaks. These investigators found that in quiet listening conditions, as few as four to six frequency channels are sufficient to support high levels of speech recognition. The processing that removes frequency information, called vocoding, preserves only the amplitude envelope in each channel, and that information must account for the intelligibility of vocoded speech.

To a first approximation, the signal seen by an individual primary auditory neuron responding to speech resembles the signal transmitted in one channel of vocoded speech. When the input signal is normal time-varying speech, the range of amplitude variation in each channel is large relative to the dynamic ranges of individual ANFs, as shown in Figure 2(b). The magnitude of variation is large enough to minimize the effects of rate saturation and limited dynamic range that are significant for the representation of spectral details in steady-state vowels. When speech is presented at conversational levels, it is likely that most ANFs will respond at their saturation rates at some times, but it is also likely that no neuron will respond at its saturation rate all the time. In that case, discharge rate can convey quite good information about the amplitude envelope in a restricted frequency band. This is illustrated in Figure 5, which shows the time course of average discharge rate for three representative ANFs, each tuned to a different frequency band, responding to the stimulus shown in Figures 1 and 2. Each neuron exhibited a range of discharge rates in response to the stimulus. Changes in discharge rate generally followed the pattern of amplitude change and thus preserved the kind of amplitude information that supports the recognition of vocoded speech. Since amplitude changes over time are large relative to the dynamic ranges of neurons, they are reflected in discharge rate changes despite the existence of response properties such as rate saturation that limit the transmission of information about steady-state vowels.

Because discharge rate varies over time in a frequency-dependent manner, the spatial pattern of discharge rate in populations of neurons will also vary over time, as shown in Figure 6, which compares rate–place profiles generated from responses occurring at two different times during the word 'heed.' The location of the F1 peak in the vowel spectrum was preserved, but F2 and F3 were represented as one broad peak. Considered in isolation, the loss of resolution in this profile might be viewed as arguing against the utility of a discharge rate code. The second rate profile, generated from responses obtained during the time the vocal tract was constricted to form the consonant, is clearly different from the first, both in shape and in overall discharge rate. As implied previously, the change in the rate–place profile from vowel to consonant was larger than the changes across place during the steady-state vowel or the

Figure 5 Responses of three ANFs to the two-syllable stimulus shown in **Figures 1** and **2**, presented at 60 dB SPL. Each ANF had a different characteristic frequency (CF), and each responded with a different temporal envelope. The CF of the neuron shown in panel (b) matched the center frequency of the analysis filter used to compute the stimulus envelope shown in **Figure 2(b)** and replotted here as the red line. Changes in the neuron's discharge rate generally followed the stimulus envelope. Adapted from Sinex DG and Narayan SS (1994) Auditory-nerve fiber representation of temporal cues to voicing in word-medial stop consonants. *Journal of the Acoustical Society of America* 95: 897–903, with permission.

Figure 6 Rate–place profiles obtained at different times during a vowel–consonant syllable, presented at 60 dB SPL. The blue line labeled 'vowel' depicts the spatial pattern of responses during the vowel; the arrows indicate the frequencies of the first three spectral peaks at that time. The rate profile had one peak corresponding to F1 and another single peak in the region of F2–F3. The red line labeled 'cl' depicts the spatial pattern of responses approximately 150 ms later, during the consonant closure interval. Discharge rates were much lower during the consonant than during the vowel, especially for high characteristic frequency (CF) neurons whose rates did not exceed their spontaneous discharge rates (line labeled 'sr'). Adapted from Sinex DG (1993) Auditory nerve fiber representation of cues to voicing in syllable-final stop consonants. *Journal of the Acoustical Society of America* 94: 1351–1362, with permission.

changes in the rate–place profiles elicited by two steady-state vowels.

Representation of Speech by Cochlear Implants

It is reasonable to think that an understanding of how speech is encoded by auditory neurons could be applied to the practical problem of designing cochlear implants, devices intended to deliver sounds including speech to the profoundly deaf. Experiences of cochlear implant users may also provide insight into what is most important in the neural encoding of acoustic speech signals.

Speech undergoes extensive processing before being delivered to the electrode array of a cochlear implant. Modern processors begin by separating the signal into frequency bands, similar to the vocoding process described previously. Within each band, the temporal envelope is extracted and used to modulate the amplitudes of pulses presented at a constant rate at a single cochlear location. If the range of amplitudes is correctly matched to the dynamic ranges of neurons, then envelope peaks can be assumed to generate high discharge rates, and envelope valleys will generate lower rates or no response at all. Many implant users can achieve nearly normal speech recognition with this kind of stimulation, at least in the most favorable listening conditions. In these cases, speech presented via a cochlear implant apparently elicits a pattern of discharge rate increases and decreases that has much in common with the responses that the original acoustic sound would have elicited.

Cochlear implant users receive less benefit from their devices when listening to speech in unfavorable conditions: in the presence of noise, reverberation, or other competing sounds. Contemporary devices also are less successful at reproducing music than speech. In these listening situations, the normal auditory system likely makes use of the information about the fine structure of the stimulus that is present in the pattern

of discharge synchrony. That information is not presently available to implant users because of the loss of waveform fine structure during processing. These results and others suggest that synchronized discharges must play a critical role in the representation of speech in the presence of noise or other competing sounds. Discharge synchrony is known to contribute to neural processing that underlies the segregation of nonspeech sounds, and implant users have difficulty in noisy situations largely because they cannot segregate the competing signals as well as listeners with normal acoustic hearing. Pitch perception is also based in large part on patterns of discharge synchrony. Pitch obviously is critical for the perception of music, but pitch also contributes to the segregation of sounds with different f_0. Together, these observations suggest that the significance of discharge synchrony for the representation of speech is that it aids in the segregation of competing sound sources. It also contributes to generating the perception of pitch and is essential for the localization of sounds including speech. In this view, discharge synchrony is critically important, but it does not make a major direct contribution to the representation of spectral shape.

Speech Production: Adult

S M Barlow and S Stumm, University of Kansas, Lawrence, KS, USA

Introduction

The adult speech motor control system (including the chest wall (abdomen and rib cage), larynx, velopharynx, tongue, jaw, and lips) represents an anatomically diverse collection of connective tissue–muscle subsystems regulated by a phylogenetically elaborated and distributed neural system. More than 100 muscles are involved in the precise and rapid timing of these muscle subsystems to produce temporally complex speech sounds which are characterized by transitions as short as 10 ms, articulatory velocities approaching 20 cm s^{-1}, and an average speaking rate of approximately 8–12 sounds per second. As a sensorimotor skill, speech is performed with speed and accuracy, improved with practice, highly adaptive in achieving spatiotemporal goals, and relegated to automaticity in the adult speaker. Speech also exhibits the Hebbian principle of motor equivalence, which is defined as the capacity of the motor control system to achieve the same goal or end product with considerable variation among individual components that contribute to that output. In achieving a particular vocal tract goal, the specific contributions of individual speech articulators may vary from one production of a particular element to another, as long as the desired end product is achieved.

Compensatory vowel articulation – presumably involving the operation of motor equivalence between the lips, tongue, and jaw – is defined as the ability of speakers to generate acceptable vowel qualities despite a fixed position of the mandible or other structures. Producing vowels which require a relatively closed jaw position, such as /i/ or /u/, with a spacer held between the teeth fixing the jaw into a very open position confronts a speaker with a new, or at least unfamiliar, task compared with producing the same vowel under normal, nonconstrained conditions. Remarkably, speakers are able to produce vowels which are acoustically correct with regard to formant frequency locations at the first glottal pulse. These studies clearly demonstrate that the tongue is capable of reorganizing motor output to achieve the acoustic product. At least for adult speakers, goal-oriented motor reorganization appears to require no learning since speakers are able to produce the correct vowels under bite-block conditions on the very first attempt, only a few seconds after inserting the bite-block and being cued for what vowel to produce.

Damage to select areas of the nervous system involved in the selection, sequencing, and activation of articulatory muscles will degrade speech production and may reduce intelligibility. Measurement of articulatory muscle performance variables, including kinematics, is central to advancing our understanding of the development of speech movements over the life span and the response to neurological disease and traumatic injury.

Vocal Tract Dynamics

Generating the source excitation and shaping the anterior portion of the vocal tract to achieve a sequence of acoustic targets involves coordinated muscle actions and movements of the chest wall, larynx, velopharynx, tongue, jaw, and lips. The integrity of the underlying performance anatomy (including contractile elements, connective tissue, bone, and the neural substrate) is central to a discussion of motor proficiency during speech. In some instances, the accurate positioning of one structure (i.e., the lower lip) may be dependent on another structure (i.e., the mandible). Motor goal acquisition often involves reorganization of motor patterns for individual structures during the course of speech production. Kinematic studies of speech typically involve recording from multiple structures in an attempt to understand the trading relations between structures, patterns of organization, and reorganization during development or following brain injury or neurological disease. Feedback and predictive or 'forward looking' neural mechanisms are hypothesized to play an important role in the acquisition and maintenance of speech movements.

Measures of Muscle Output

Activation of the articulatory muscles yields a number of measurable outputs, including force, displacement, heat, vibration, and electrical activity. Speech kinematic variables typically studied include the amplitude of displacement, velocity, acceleration, phase and relative timing among multiple articulators, spatiotemporal variability, phase relations to electromyography muscle patterns, and spectral properties of movement (frequency domain).

X-Ray Tracking of Orofacial Movements

The X-ray microbeam is a computer-controlled system available in the United States and Japan that uses

a narrow beam of X-rays to localize and track the two-dimensional movements of small gold pellets attached to select speech structures, including the lips, jaw, tongue, soft palate, and eustachian tube. Two additional pellets are attached to the bridge of the nose and a maxillary incisor to serve as reference points that are immobile relative to the skull. The focal X-ray beam (0.4 mm diameter) is scanned at a high rate across a pellet producing a recognizable 'shadow' that is registered on a sodium iodide crystal detector. The path of the X-ray beam toward a pellet is determined by predictions of the position of the pellet generated by current and previous locations.

The X-ray microbeam system has been used successfully to study the relation between speech rate and velocity profiles of movements of the lower lip and tongue tip during the production of stop consonants in young normal adults. Fast speaking rates yielded symmetrical, single-peaked velocity functions, whereas slow speech produced asymmetrical, multipeaked velocity profiles. Speech produced at fast rates appears to involve unitary movements that may be preprogrammed and executed with little or no dependence on sensorimotor integration, whereas articulatory gestures produced at slow speaking rates may be influenced by feedback mechanisms.

X-ray microbeam data have also been combined with cinefluorography to examine the displacement of the tongue body during opening articulatory gestures in deaf and hearing subjects. Speech samples consisted of consonant–vowel–consonant syllables embedded within a carrier phrase. Displacement patterns in deaf and hearing subjects were examined for variation in vocalic contexts between subjects. Deaf speakers had less flexible tongue bodies as a result of compensatory and incorrectly learned principles for constraining tongue movement during speech.

The question of functional regionality within the tongue during speech and swallowing was studied by quantifying the strength of coupling among four different tongue locations. Tongue-surface movement patterns characterized by calculating the covariance between the vertical displacement time histories of all possible pellet pairs show that speech and swallowing kinematics are clustered into distinct groups based on their coupling profiles.

Orofacial Magnetometry

Alternating magnetic field devices known as magnetometers have been used to capture elements of speech production where movements of the face, jaw, tongue, soft palate, and chest wall are tracked in real time. Part of the magnetometer's appeal in speech physiology research and clinical application is due to the fact that the kinematics of intraoral structures (tongue and velopharynx) can be observed and recorded in real time without the biohazards associated with radiological imaging methods (i.e., cineradiography). Historically, the study of speech kinematics has been problematic because movements within the mouth are difficult to measure and visualize.

Orofacial magnetometry is also a valuable therapeutic tool. For example, individuals with hearing loss can observe a visual feedback analog of their tongue movements on a computer in real time. This approach can be applied to the rehabilitation of certain forms of dysarthria, craniofacial disorders, or second language acquisition.

Optical Three-Dimensional Tracking of the Face

Developmental studies of lip and jaw coordination during speech production have benefited directly from the emergence of sophisticated multichannel video-based movement tracking systems. High-speed video cameras are used to register marker location using either reflective markers or infrared source tracking. An algorithm has been developed by researchers at Purdue University to index the spatial and temporal variability in the kinematic trajectory patterns for facial articulators during repeated productions of select speech utterances. When applied to the development of functional synergies among labial–mandibular systems, they found that the time course of development for speech motor coordination is protracted and does not reach 'adult-like' performance until after age 14 years for both males and females, with males lagging on the spatiotemporal variability index.

Tracking Tongue Movements

From the late 1940s through the mid-1970s, our understanding of tongue movements in adult speakers relied heavily on studies using radiography and tongue contact devices such as the dynamic palatometer. Since then, technological advances have been made in optics, magnetometry, ultrasound, X-ray microbeam, and functional magnetic resonance imaging (fMRI) for tracking the tongue during speech and swallowing.

Palatometry has been used to show that each vowel in English is associated with a unique stationary lingua-palatal contact map. For example, during the stable contact portion of [i], the tongue is in contact with sensors extending from the cuspid–bicuspid region of the palate to the posterior border of the alveolar ridge. During the [ae], the contact is against the most posteriolateral sensors. Diphthongs are

characterized by movements between two stable monophthong positions. Optical and contact pattern (tongue–palate) tracking devices have been used in training or retraining vowel space and consonant production in hearing-impaired adults.

Ultrasonic Imaging of the Tongue

Ultrasound provides real-time images of the tongue surface in a digital video format during speech and swallowing. Images are combined with estimates of the hard palate boundary using ultrasound during the production of command swallows to establish a reference within headspace for coregistration among subjects and calculation of select phonetic measures.

Ultrasound results indicate that cross-sectional tongue shape is directly related to the position of the tongue and the lateral and sagittal shape of the tongue. In general, midsagittal grooving is evident for all vowel types, with posterior grooves being deeper than anterior grooves. Posterior grooving is greater in the /p/ context than in the /s/ context. Grooving for vowels in the /p/ context demonstrated a continuum, whereas in the anterior /s/ context two groups of vowels were identified (high group/shallower grooves and back group with deeper grooves). In the anterior /s/ context, tongue shape for /i/ and /u/ was convex.

Considerable progress has been made with high-speed three-dimensional (3-D) reconstruction of tongue ultrasonic images. In adult speakers, this work has focused on defining predictable mathematical relations between midsagittal tongue contour shapes and up to five cross-sectional (coronal) contours. A concatenation of these coronal slices permits the reconstruction of a 3-D tongue surface. When compared among four tongue shape phonemic categories (i.e., front raising /i/, back raising /ŋ/, continuous grooving /ae/, and two point displacement /l/), it was found that transitional values exist that predict tongue arching versus midsagittal tongue grooving. Even better predictions are possible using three anterior coronal slices in which strong correlations exist between midline displacement and groove depth to arch height. Knowledge of both category and midsagittal displacement provides good prediction of coronal tongue shape.

Tracking Velar and Laryngeal Movements

Kinematic studies of the 'invisible valves' of speech, including the velopharynx and larynx, is technically challenging due to small size and inaccessibility. Acceptable sampling methods in humans usually reflect a concession between the invasiveness of the instrument and the quality of the acquired signals. Whereas it is acceptable to attach small sensors to the lips and jaw in the form of radio-opaque pellets, reflective balls or tape, infrared diodes, cantilevers, or magnetic coils to the rib cage or abdomen, no such electromechanical device or sensor is acceptable to the delicate tissue boundary of the human vocal fold because this would disrupt the behavior and health of the organism. Instead, techniques have evolved that rely on imaging, acoustics, and/or fluid mechanics. These procedures are described in the following sections.

Velopharynx

The velopharynx (VP) is a complex muscular valve that is strategically situated to divert acoustic and aerodynamic energy through the oral and nasal cavities. The size of the velar port determines the oral or nasal nature of speech sounds. Movements of the velum, lateral pharyngeal walls, and the posterior pharyngeal wall collectively determine the size of the velar port.

Methods aimed at measuring the size and/or movements of the velum and lateral and posterior pharyngeal walls roughly fall into one of two categories: direct and indirect. Direct methods include imaging techniques such as cineradiography, video nasendoscopy, and electromechanical, optomechanical transduction of velar displacement. These transducers for measuring velar activity and radiographic imaging techniques share a common limitation in only resolving movement in a single plane. In most radiographic studies, discrete points are tracked on a frame-by-frame basis, which is useful in resolving velocity and displacement profiles. However, because the radiographic methods are limited to one plane or slice through the velopharynx, one is never certain if closure has occurred. Velar apertures may exist at locations opposite the lateral pharyngeal walls on one or both sides. The patterns of VP closure are highly variable both within and across adult speakers.

Complete VP closure is not always obtained during vowel production. Pioneering work aimed at characterizing normal patterns of VP closure using cineflourographic techniques revealed that high vowels exhibit greater VP closure than low vowels, regardless of consonant context. Complete closure of the VP is not always present during production of the low vowels nor attained on vowels adjacent to a nasal consonant (assimilation). Speech rate is another factor which can significantly influence the degree of VP closure.

Flexible fiberoptic nasoendoscopy is a powerful imaging tool which helps to resolve some of the uncertainty regarding the dynamics of the velopharyngeal

port. Advanced camera, fiberoptics, and digital recording technology provides high-resolution color images of the velopharynx in real time during speech production. Image recognition software routines assist the investigator in accurate identification of tissue boundaries and kinematic properties of the velopharynx, including computation of portal area and boundary velocity, displacement, and calibration schemes for scaling distance. This information will be invaluable for studies of velopharyngeal motor control in patients with sensorimotor speech disorders.

Aerodynamic measures of velopharyngeal port function offer some unique perspectives on the fluid dynamics of this valve during speech in adults and children. Current aerodynamic protocols and instrumentation provide reasonably accurate estimates of the subglottal driving air pressures (P_s) and airflows acting on the velopharynx during speech in fluid mechanics terms without the biohazards associated with radiation or the invasiveness of a fiberoptic bundle inserted into the nasal cavity. Area functions, resistance (impedance) estimates, and temporal pattern studies have been used effectively to characterize the activity of the velopharynx during speech.

Numerous reports have described some of the temporal relations between pressure–flow variables during nasal-plosive blends to stress the velopharyngeal mechanism and reveal the coarticulatory dynamics between velopharynx and other upper airway structures in normal and cleft palate speakers. For example, studies of VP aerodynamics in repaired cleft palate adults and normal controls revealed that the magnitude of mean intraoral air pressures tends to be slightly less than that of control speakers. Articulatory timing errors were evident as the nasal airflow pulse overlapped into the rising phase and peak of the pressure pulse associated with /p/ in the word 'hamper.' A decrease in respiratory effort may represent a compensatory strategy used by patients with repaired cleft palates to achieve adequate velopharyngeal closure and minimize shunting (air leak) through the velopharyngeal port. This conclusion was based on careful study of the temporal relations between the airflow and pressure curves associated with production of the nasal-plosive blend.

Laryngeal Kinematics

The larynx represents a microcosm of the entire speech mechanism in that it provides a sound source in coordination with the respiratory system, acts as a dynamic 'articulator' capable of rapid adductor and abductor adjustments, modulates pitch (male f_0 ~125 Hz, female f_0 ~225 Hz), and conveys emotion and personal identity. Endoscopy is an important tool in the assessment of laryngeal movement disorders affecting speech/voice. Laryngeal aerodynamics is a useful adjunct which provides quantitative data on the articulatory dynamics of laryngeal engagement for consonant–vowel transitions, vocal efficiency, and chest wall function for P_s regulation. Use of fiberoptic nasopharyngoscopy, laryngoscopy, and stroboscopy in conjunction with low-light cinematography allows observation of the dynamic processes of speech production. This technique allows the investigator to visualize the overall articulatory dynamics of the larynx during speech and other behaviors such as swallowing, coughing, and respiration. Information obtained during the nasendoscopic examination has proved to be useful for biofeedback in the remediation of select laryngeal and velopharyngeal impairments affecting speech.

Videokymography

A relatively new technique that takes advantage of digital video recording and processing in strip kymography (the recording of wavelike motions or undulations) of the glottis is videokymography (VKG). This method permits visualization of the individual cycles of phonation by analyzing only a small segment of the vibrating vocal folds. Developed in The Netherlands by Drs. Harm Schutte and Jan Švec of the University of Groningen, VKG uses a modified charge-coupled device camera to record images of selected cross-sections of the vocal folds during motion. The position of the horizontal measuring line is maintained throughout the analysis. VKG systems use standard videolaryngoscopic setups with a continuous light source and record images to a digital storage device. In place of recording the entire image of the vocal fold, however, VKG systems allow for the collection of a single line of the image (orthogonal to the longitudinal axis of the fold) at rates of 8 kHz, thus allowing for sampling rates great enough to cover the entire frequency range of fold oscillation. Successive lines are temporally aligned and cascaded in real time on a conventional monitor, thus showing the vibratory pattern of the selected region of interest on the vocal fold for a preselected time period. The resulting 'kymogram' displays a spatiotemporal image of the vocal folds at the scanned line over time. Videokymography and digital kymography allow for true cycle-by-cycle analysis of vocal fold vibratory patterns. Analysis of the resulting kymograms can provide information on right–left vocal fold asymmetries, open and closed quotients, ventricular fold and/or mucous interference, mucosal wavefront propagation, frequency, amplitude, speed quotient, and within-cycle perturbations.

Electroglottography (EGG) has been used with success to assess laryngeal activity. This instrument consists of a flexible neck collar supporting an array of electrodes and a signal conditioning unit. In EGG, a small DC bias current is fed through the tissues of the neck and the conditioning unit senses changes in the electrical resistance in the region of the larynx. Essentially, the EGG signal is correlated with vocal fold contact area and is regarded as a useful assessment technique in drawing inferences about patterns of vocal fold vibration during speech.

Electroglottographic measures have been used to measure timing between voiced segments and for analysis of the cycle-by-cycle dynamics of voicing, and they are usually obtained in combination with inverse filtered flow signals (AC flow) for the purpose of detailing the organization and timing of the open and closed phases of the glottis during voice production. Because information derived from EGGs is based on the vocal segment and changes in vocal fold contact area, it offers limited information concerning the aeromechanical events underlying vocal fold engagement. Furthermore, the reliability and validity of the EGG signal associated with the early phases of laryngeal engagement are questionable. The beginning phases of arytenoid rotation are associated with displacement of the vocal folds in glottal space. During this interval, one would not expect appreciable increases in vocal fold contact area until arytenoid advancement results in actual tissue approximation. Therefore, the EGG output during this phase of engagement may yield little or no output signal even though significant displacements of the vocal folds have occurred.

Laryngeal Aerodynamics

The utility and noninvasive nature of aerodynamics is underscored in adults with neurogenic speech disorders. Voice disorders range from hyperfunctional (excessive medial compression, hard glottal attack, and groping voice quality) to hypofunctional (soft glottal attack, breathy, and soft or weak voice) and disturbances in the timing and coordination of arytenoid–VF medialization (basal ganglia (BG), cerebellar disease, upper motor neuron syndrome, and others). For example, speakers with Parkinson's disease often exhibit air loss when attempting to engage (adduct) the vocal folds for voice production. In contrast, patients with adductor spasmodic dysphonia manifest exaggerated medial compression of the vocal processes of the arytenoids. This pattern of hyperadduction may include the ventricular or false folds and results in a sudden interruption of the breath stream during voicing. Disruption of this important articulatory adjustment due to neural and/or biomechanical factors can dramatically influence the manner in which the vital capacity is used for speech. In cases of slow or mechanically limited engagement, significant portions of the lung vital capacity may be wasted by a defective laryngeal articulatory apparatus independently from the pressure–flow dynamics associated with voice production.

Real-time digital speech aerodynamic recording and analysis tools are available to measure articulatory proficiency during laryngeal engagement and phonation. This technique, based on the simultaneous sampling of intraoral air pressure, translaryngeal airflow, and voice acoustic signals, has been used effectively to reveal the reorganization of laryngeal function in patients with amyotrophic lateral sclerosis, idiopathic Parkinson's disease following posteroventral pallidotomy, and bilateral subthalamic nucleus deep brain stimulation. The magnitude and time course of translaryngeal flow, described mathematically as air volume and flow rate declination functions, are presumed to reflect the underlying kinematics of vocal fold adduction toward the phonatory phase. Measures of pressure–flow dynamics and laryngeal airway resistance can also be determined for the phonatory phase of syllable production to provide for a comprehensive evaluation of the articulatory dynamics of laryngeal behavior. The net result of a hypokinetic adductory mechanism is that lung volume is wasted during translation of the arytenoids to achieve vocal fold approximation. The lung volume available for speech is depleted and overall utterance length is decreased. Therefore, the evaluation of laryngeal function in patients with sensorimotor speech disorders benefits from an analysis of the kinematic properties of transitory (engagement–disengagement) and phonatory (voice efficiency) phases.

Chest Wall Kinematics

The chest wall includes, except for the lungs and airways, all parts of the respiratory apparatus – the rib cage, diaphragm, and the abdomen and its contents – and is regarded as one of the principal articulatory systems that provide a pressure–flow source to support speech and voice production. The rib cage and diaphragm constitute the thoracic cavity. The abdominal cavity is defined by the diaphragm and abdominal wall bounding an incompressible mass of liquid. According to Hixon's model, the chest wall is reduced to a two-structure model consisting of the rib cage and 'diaphragm-abdomen.' Isovolume maneuvers are

used to calibrate the chest wall size against lung volumes and involve equal and opposite volume displacement by the surfaces of the abdomen and rib cage under a closed system. Movement outputs from the rib cage and abdomen can be adjusted to account for the difference in volume displacements from these two parts. Once the chest wall has been calibrated, lung volume calibrations can be achieved by measuring integrated flow at the airway opening during simultaneous chest wall kinematic measurements to establish the relationship between chest wall movement and various static inspiratory or expiratory lung volumes.

Magnetometry

Changes in the anterior–posterior diameters of the rib cage and abdomen are transduced with two-channel electromagnetic devices consisting of small coils (2×0.5 cm) set up in pairs, one for signal generation and the other for sensing changes in inductance due to displacement. The generator coils are attached midline on the anterior surface of the chest wall at the level of the nipples and to the abdomen immediately above the umbilicus. An alternative transducer system that has been used to measure chest wall kinematics is the strain gage belt pneumograph. Setup is simple and involves a clip gage attached to a circumferential belt with an elastic strap.

Speech breathing kinematics using magnetometers has been studied in individuals with profound hearing impairments, voice disorders, motor neuron disease, flaccid paralysis, parkinsonian dysarthria, cerebellar ataxic dysarthria, traumatic brain and spinal cord injury, and in a variety of normal subgroups in which factors such as age, body type, and sex are the dependent variables.

Functional Neural Systems for Speech Motor Control

The encoding of force and movement by the brain is central to models of movement and highly relevant to our understanding of speech motor control. The relation between force control and neural firing patterns in primate motor cortex is strongly correlated with the rate and direction of force change and preferred torque directions. Primary motor cortex has also been shown to encode functional muscle synergies. The cortical mechanisms involved in the regulation of muscle dynamics during the early phases of force recruitment have been shown for orofacial muscles. The complex articulatory force dynamics evident among facial muscles during speech is similar in many ways to the precise movements and forces generated by hand and fingers during manipulation. During speech production, the muscles of the perioral system exhibit a streaming repertoire of phasic adjustments in force from resting tonic activation to approximately 10% of the maximum voluntary contraction level.

Mounting evidence also suggests that the sensorimotor cortex may participate in the modulation of the reflexive compensatory motor responses in lip muscles during speech. The orofacial apparatus appears to utilize mechanosensory information differentially for the early versus later phases of lip force output. During speech articulation, longer latency reflex actions presumably involving primary motor cortex correct for the effects of external movement disturbances. Mechanical inputs delivered to a dynamically contracting lip muscle produce a compound evoked perioral response characterized by phases of excitation and suppression that are absent during static force conditions. Under these conditions, compensatory lip movements demonstrate a well-calibrated readjustment.

Velocity is one kinematic variable which has been explored in some detail and appears to have a definable neural network. Positron emission tomography mapping of regional cerebral blood flow has demonstrated a velocity subcircuit within the motor control system, including the bilateral sensorimotor cortex, BG (putamen and globus pallidus (GP)), and the ipsilateral cerebellum. Increases in velocity are associated with parallel increases in BG activation. The BG motor circuit may be preferentially involved in controlling or monitoring the scale and/or dynamics of arm movements and may also control articulatory movements at lower frequencies. A dysfunctional BG circuit (i.e., Parkinson's disease (PD)) may result in hypophonia (lowered speech volume) and bradykinesia. Functional brain imaging of patients with PD during velocity control tasks reveals a significant disruption to the BG circuitry which may partially account for the pathophysiology of bradykinesia. Unilateral lesions of the GP internal and GP external result in slowness of movement and abnormal co-contraction of agonist and antagonist muscles and often impair movements of the orofacial, laryngeal, and chest wall systems for speech production.

A positive relation also exists between increases in speech rate and cerebellar activation, suggesting this brain structure plays a significant role in the velocity of articulatory movements within the frame of time-critical adjustments. Motor speech symptoms resulting from cerebellar pathology may reflect a distorted process of articulatory planning and coordination. Cerebellar posterior lobe syndrome is often

associated with speech that is perceived as having an 'intoxicated-like' quality.

The brain imaging and neurocomputational literature is proliferating rapidly with studies of speech production and sensorimotor control of the upper airway. The production of simple vowels and simple oral movements results in similar activation patterns among cortical and subcortical motor systems. More complex, polysyllabic utterances are associated with additional activation of the bilateral cerebellum, presumably reflecting increased demands on speech motor control, and additional activation of the bilateral temporal cortices thought to subserve phonological processing.

The hemodynamic effects associated with paced syllable production during fMRI have been compared with passive listening of pacing signals. Cerebral structures associated with speech motor control included the supplementary motor area (SMA), primary sensorimotor regions, dorsolateral prefrontal cortex (including Broca's area), anterior insula, thalamus, putamen/pallidum, and cerebellar hemispheres. Dorsolateral prefrontal and intrasylvian cortex displayed lateralization toward the left side, whereas the other components showed a bilateral activation pattern. The cerebral correlates of speech motor control based on connectivity analyses appear to be organized into two separate networks – motor preparation (SMA, dorsolateral frontal cortex (Broca's area), anterior insula, and superior cerebellum) and a motor execution processor (sensorimotor cortex, BG, thalamus, and inferior cerebellum). Broca's area is thought to contribute to orthographic-to-phonological transformation, whereas motor cortex, SMA, and the cerebellum play critical roles in phonetic encoding and articulation of speech. Functional imaging studies show that pre-SMA and SMA are engaged in the control of externally triggered movements. Moreover, SMA shows a frequency effect and may indicate that this region is involved in the generation of the motor program for an entire spoken word, with the level of activation in SMA influenced by how often this motor program is implemented. Motor cortex appears to represent articulatory gestures at the syllable or phoneme sequence level. Clinical data support this dichotomy of motor preparation/motor execution.

Speech production is dependent on auditory, somatosensory, and visual feedback for its development and maintenance. These mechanisms are also crucial

Figure 1 Schematic of the DIVA model of speech acquisition and production. Projections to and from the cerebellum are simplified for clarity. to invoke mechanisms of plasticity following a sudden insult to the brain (ischemia reperfusion or hemorrhage) or during the course of a progressive neuromotor disease (i.e., PD). A simulation has been developed to test many of these conditions as given by the Directions into Velocities of Articulators (DIVA) model of speech motor control, shown schematically in Figure 1. The DIVA model includes a feed-forward network, composed of the premotor and primary motor cortices and cerebellum, and feedback control systems which encode auditory and somatosensory inputs with comparator functions to assist in the specification of speech articulatory velocity and position. A central feature of the DIVA model that differentiates it from other computational models of speech production is that all components of the model have been associated with specific neuroanatomical loci. The DIVA model generates simulated fMRI activations associated with small populations of synchronously firing neurons from the model's cell activities during computer simulation. It features adaptive control mechanisms to effect the learning of auditory and somatosensory consequences during babbling or syllable productions which are eventually incorporated into feed-forward mechanisms. According to the DIVA model, outputs from premotor cortex (left frontal operculum) and cerebellum to motor cortex constitute feed-forward motor commands for syllable production. In infants, feed-forward commands for a syllable are tuned on each production attempt. Initial attempts rely heavily on auditory feedback. With changes in body plan (i.e., growth of the speech articulators), the auditory feedback control system continues to provide corrective tuning of the feedback controller over the life span. Consistent with research in other laboratories, it is clear that somatosensory information is central to achieving the precision requirements of speech movements, including consonant and vowel position targets. The neural control of stiffness appears to be a key factor to consider for the somatosensory precision involved in speech production. Future work by the developers of the DIVA model will incorporate the anterior cingulate cortex, SMA, BG, and anterior insula into the scheme of feedback and feed-forward control of speech movements.

Speech Production: Development

R D Kent and K C Hustad, University of Wisconsin–Madison, Madison, WI, USA

Introduction

Speech may be defined as the production of vocal sounds for communication through the processes of respiration, phonation, resonation, and articulation. This definition links several fundamental concepts, including sound (the acoustic signal of speech), communication (the purpose of speech), and underlying physiology (the biological systems involved in speech production). The development of speech can be described in varying levels of detail for each of these components. From the point of view of the neurosciences, speech is particularly interesting for several reasons. First, speech is a remarkable motor skill. Ordinary conversational speech can be produced at rates of up to six to nine syllables (20–30 individual speech sounds) per second. No other discrete human motor performance rivals that rate. Speaking also commands more motor fibers than any other human mechanical activity, and there is growing evidence that the motor fibers are uniquely equipped for the requirements of speech. The muscles used in speech production differ from skeletal and limb muscles in their developmental patterns, functional properties, and molecular phenotypes. Perhaps most important, speech is the primary modality of language in the vast majority of human societies (one important exception being the manual communication systems used by the deaf). Speech and language are often confused by laypersons, partly because they seem inextricably linked in the learning and use of language. In fact, it is difficult to study speech separate from language.

At a relatively abstract level, speech development can be charted with respect to the child's mastery of its phonemes. A phoneme is a basic sound unit that has the linguistic function of distinguishing morphemes (the minimal units of meaning in a language). The words 'cat,' 'hat,' 'mat,' and 'sat' are four morphemes that differ in their initial phonemes. To become a competent speaker of American English, a child must master the 44 phonemes that are used to form the morphemes and words of the language. The primary goal of the perceptual characterization of speech is to describe what speech sounds like to listeners. To describe speech development using perceptual methods, the most important tool is the human ear. Perceptual features of speech can be considered according to a number of different dimensions related to the speech subsystems. However, for children who are neurologically normal or typically developing, a primary interest is how production of phonemes, or articulatory competence, emerges developmentally.

Studies of phonetic development have primarily taken two approaches. The first is a relational paradigm in which speech segments (phones) produced by children are compared with adult forms. This approach has yielded normative data that have been used to identify several acquisition points, primarily for consonants. These include the point at which children acquire 'mastery-level' production accuracy (i.e., the ability to produce an individual segment correctly in all occurrences) and the point at which children acquire 'customary' production accuracy (i.e., the ability to produce individual segments correctly more often than incorrectly). The second paradigm for studying speech development has been called the independent approach. In this paradigm, the phonetic repertoire of children's speech is described without comparison to adult forms; thus, mastery is not of interest. Instead, the goal is characterization of phones produced in the child's spontaneous speech. The primary vehicle for describing acquisition of speech sounds in both approaches is phonetic transcription of elicited and/or spontaneous productions. Similar methods have been used to describe the perceptual characteristics of speech from infancy through adulthood.

At a more detailed and concrete level, speech development can be specified in terms of a host of anatomic changes (such as those relating to the growth and maturation of the anatomy of speech production), a gradual refinement of perceptual systems, and an expanding capacity to produce sounds flexibly. Much of the recent progress in the understanding of speech development has come through the application of tools to study the anatomy, physiology, acoustics, and perception of speech. The discussion in this article synthesizes these sources of knowledge, using phonetic accomplishments at different ages as both developmental milestones and a conceptual framework.

Developmental Anatomy and Physiology of Speech

Speech is produced through the coordinated actions of muscles in three major systems – respiratory, laryngeal, and articulatory. Each of these is introduced briefly as background information for the subsequent sections on speech development. As will be seen, each system has its own developmental pattern so that speech development must be understood against the composite development of a complex biological system.

For basic life purposes, the respiratory system exchanges blood carbon dioxide (CO_2) with air oxygen (O_2), but it is also used to provide the aerodynamic energy for speech. The major adjustment for speech breathing, as opposed to rest breathing, is that the expiratory phase is prolonged for speech so that several syllables can be uttered on each expiration. That is, the basic pattern of speech breathing is for a quick inspiration and a long, controlled expiration. Major life span aspects of respiratory anatomy and physiology are summarized in Figures 1–4. Anatomic and functional changes in the respiratory system are substantial, especially in the infant and young child. By approximately 7 years of age, children have respiratory patterns resembling those of adults, and subsequent changes are mostly increases in capacity.

The larynx, or voice box, is not only the source of vibratory energy for speech sounds but also an important valve that regulates airflow into and out of the lungs. The birth cry is typically a child's first venture into vocalization. This sound is made with air that is expelled from the inflated lungs to produce vibrations of the vocal folds (often called vocal cords, but the term vocal folds is anatomically more accurate). Despite this early use of the larynx, its anatomy and physiology have a protracted development that includes some remarkable features such as the adolescent voice change. Major developmental events relating to the larynx are summarized in Figures 1–4. One point to be emphasized is that the laminated structure evident in the adult vocal folds (and a feature that is central to modern theories of vocal fold vibration, such as the body-cover model) is not completed in children until approximately 12 years of age.

If the respiratory organs and the larynx are considered to be the major source of energy for speech, then the articulatory apparatus, or vocal tract, can be regarded as the place where the distinctive properties of most speech sounds are formed. It is through the actions of the articulators (tongue, velum, lips, and jaw) that vowels and consonants are made. The growth and development of the articulators involves not only an increase in size but also a number of reconfigurations that affect their individual shapes and their relationships with one another. Humans begin life with a vocal tract resembling that of a chimpanzee, but this system is gradually remodeled during childhood until the distinctively human vocal tract is formed. The word 'distinctively' is apt because no other creature has a vocal tract with similar anatomic and physiologic properties. Moreover, the distinctiveness may even be found at the level of molecular biology, given that human speech muscles appear to have muscle fiber compositions unlike those of homologous muscles in nonhuman species. Some of the most important developmental features are identified in Figures 1–4. Growth and maturation of this system continues until at least 16 years in females and 18 years in males.

Methods for Studying Speech Development

Speech development has been studied with a variety of approaches, primarily the methods of perceptual phonetics, acoustics, and physiology (including aerodynamics, kinematics, and electrophysiology). Perceptual methods usually focus on sound mastery – the degree to which a child's productions match adult sound patterns. Mastery is described according to a statistical criterion, such as 75% correct, which means that a child's productions of a sound match the adult target 75% of the time. With such a criterion, it can be shown that certain sounds are mastered at an early age of 2 or 3 years, whereas other sounds may not be mastered until the age of 7 or 8 years. The perceptual method is easy and inexpensive but not necessarily valid or accurate, especially when applied to infant vocalizations such as babbling.

Acoustic analysis is typically done with the techniques of digital signal processing. Acoustic analysis has an objectivity and quantification that give it several advantages over perceptual methods such as phonetic transcription. However, it requires sophistication on the part of the user and can be rather tedious if a large set of measures is obtained. Acoustic analyses are an effective complement to perceptual analysis in that both are derived from the same acoustic signal.

Several physiological methods have been used to study speech in adults, but relatively few of these have been extensively used with children. Aerodynamic analysis is a type of physiological method that makes use of recordings of air pressures, airflows, or air volumes that are associated with the production of speech sounds. Like acoustic analysis, it offers advantages of objectivity and quantification. However, it requires special instrumentation that is sometimes difficult to use with young children. The most commonly used aerodynamic measures are intraoral air pressure for oral consonants, airflow for sustained vowels, and glottal (laryngeal resistance). Kinematic analysis is focused on movements. It attempts to record the positions, velocities, and accelerations of individual articulators, as well as the relative timing of different movements performed by two or more articulators. Kinematic data are obtained from specialized equipment, and most methods provide information on only

the most accessible articulators, especially the lips and jaw. Occasionally, kinematic studies are accompanied by electromyography so that movements can be interpreted relative to data on muscle contraction.

In the following discussion, acoustic and physiological methods are grouped together in the section titled 'Instrumental findings.'

Speech Development in Infancy (0–12 Months)

This period covers the progression from cries and vegetative sounds to the onset of the first words, usually at approximately 12 months. A major point to be made about this early period is that it involves

Figure 2 Schematic representation of major speech-related developmental milestones occurring between 12 and 24 months of age. Note that ages and age ranges are approximate and are meant to provide a simplified illustration of the co-occurrence of developmental events.

a significant anatomic remodeling of the speech production system. As mentioned previously, humans start out with a vocal tract like that of nonhuman primates. The human vocal tract emerges developmentally through adjustments that include a descent of the larynx, formation of a right-angled tube in which the oral portion is perpendicular to the pharyngeal portion, and the separation of velum and epiglottis. Some of the changes would seem to contribute importantly to speech maturation, for example, the ability to make reliable oral versus nasal resonance contrasts (e.g., the initial contrast in the words 'buy' vs. 'my'). The anatomic differences are sufficiently great that some writers have asserted that speech production needs at least two theories – one for infants and another for adults. The first year of life typically begins with the birth cry and ends with a child's first words. The intervening vocalizations have been described mostly by perceptual methods, and the resulting data point to both universal and language-specific factors in sound patterns.

Perceptual Findings

Studies of early speech development using perceptual methods are problematic from several perspectives, but especially because of the inevitable tendency for

Figure 4 Schematic representation of major speech-related developmental milestones occurring between 6 and 14 years of age. Note that ages and age ranges are approximate and are meant to provide a simplified illustration of the co-occurrence of developmental events.

adult listeners to describe infant vocalizations in terms of their own linguistic experience. Nonetheless, considerable research has focused on describing pre-speech vocal behavior of infants using perceptual approaches, and these data have been fundamental to proposals of stages in vocal development. Although there are some differences among staging taxonomies identified by different researchers, there is substantial overlap in the behaviors described at different ages during the first year of life.

Generally, research suggests that from birth to 2 months, vocalizations consist primarily of crying and vegetative-type sounds with little or no articulation. Between the ages of 2 and 6 months,

infants begin to produce cooing sounds and laughter. In addition, they begin to make some simple articulatory movements during vocalization, including production of nasalized consonants, glottal and velar consonants, trills and raspberries, and vowel-like productions (primarily front and neutral vowels). Vowel and consonant sounds may be produced in vocal play-type contexts in which there is increasing control of phonation (evidenced in pitch variation during sustained vowel-type productions). Also appearing at this time is marginal babbling, a precursor to true babbling, that involves alternating opening and closing of the vocal tract during phonation.

Between 7 and 12 months of age, children begin canonical babbling, or true babbling. Canonical babbling consists of rapid adult-like alternation between consonant and vowel elements that are often reduplicated (e.g., ba-ba-ba). At approximately the same period, children begin to produce variegated babbling, which incorporates production of different consonant + vowel syllables in succession (e.g., ba-di-ga). Importantly, during this period children begin to produce a greater number of consonant-like sounds, with labial and alveolar sounds predominating the repertoire. By the end of this period, most children begin to produce their first words or word approximations, usually consisting of the same types of consonants and vowels that are present in babbling. One of the guidelines recommended for parents and pediatricians is to follow carefully any child who is not babbling, pointing, or using other gestures by 12 months.

The relationship between babbling and early word production is a much discussed topic of speech development. The discontinuity hypothesis (also known as the babbling independence hypothesis) holds that babbling has little or no connection with early speech development. In contrast, the continuity hypothesis (also known as the babbling drift hypothesis) maintains that there is substantial continuity between sound patterns in babbling and those in early word production. Studies favoring the continuity hypothesis have demonstrated the ability of adult listeners to classify babbling by ambient language, shown acoustic similarities between babbling and speech in adults, and described adaptation of infants' phonetic inventories to those in the ambient language. However, it should be noted that some studies have reported that listeners were unable to make a reliable auditory classification of babbling by identifying the ambient (parental) language of the child.

A common view is that biological factors exert a primary influence on phonetic patterns in the first year of life, and perhaps even into the second year, until language factors eventually begin to mold sound patterns. The primacy of biological factors is demonstrated in the fact that infants from diverse language backgrounds tend to produce the same kinds of sounds in babbling. Specifically, there is a predominance of bilabial and alveolar consonants (e.g., sounds resembling those that begin the words 'ball' and 'doll').

Continuity in vocal development does not necessarily mean progressive unidirectionality in developmental processes of speech. In making the transition from babbling to first words, some infants show a labial regression in which labial sounds are preferred in early words even though their babbling may have shown a growing predominance of alveolar sounds. Also, the pattern of intonation development has been described as U-shaped, meaning that the developmental path includes a phase of apparent regression.

At approximately 1 year of age, plus or minus 2 months, most children utter their first words. At approximately the same age, typically slightly earlier, infants also produce phonetically consistent forms (or vocables). These utterances have a sound–meaning relationship and they are produced with a fairly repeatable sound pattern that allows adults to recognize them. They are not based on words in the adult language, but they may signal an infant's readiness to produce words.

Instrumental Findings

Infants in the first year of life have small vocal folds and a short vocal tract, and both of these help to explain major acoustic properties of infant vocalizations. The infantile vocal folds are associated with a relatively high fundamental frequency of vocalization, with a mean value of approximately 400 Hz, compared to 225 Hz for an adult female and 125 Hz for an adult male. Because the vocal tract of an infant is only approximately one-third to one-half as long as that of an adult, it is expected from standard acoustic theory that infants will have much higher resonance frequencies. Indeed, acoustic studies show that vowel-like sounds have much higher formant frequencies than perceptually similar vowels produced by adults. Similarly, the noise spectra in infant fricatives have energy that extends to much higher frequencies than those seen for adults. Therefore, it is physically impossible for infants to produce vocal sounds that have exactly the same physical attributes of adult sounds. These differences prompt the need for normalization algorithms that minimize cross-talker differences. Most of these algorithms are based on logarithms or ratios.

Acoustic data have been reported on several aspects of vocalization during the first year of life, beginning with the birth cry and continuing to

babbling and first words at the end of this period. Acoustic patterns of the birth cry have been shown to have diagnostic value in that certain acoustic features may indicate developmental problems. Canonical babbling appears to be produced with syllables that prefigure adult syllables with respect to their major acoustic characteristics.

Acoustic analysis may be more sensitive than perceptuophonetic studies for some aspects of sound production. For example, acoustic studies have shown that occasionally young children will make differences among sounds that are not discriminated by adults, even those with phonetic training. As another example, language-specific vowel production in babbling has been demonstrated by showing that acoustic properties of vowel production in infants from different language environments mirrored the acoustic properties in the corresponding adults' models. This conclusion indicates that even before infants begin to produce recognizable words, they may have adapted their vocalizations to properties of the ambient language. As a related point, the babbling of deaf infants differs from that of normally hearing infants, especially in the age period of approximately 7–10 months. It appears that infants connect the perceptual and motor aspects of babbling during this period. The auditory–motor associations may be groundwork for later speech development.

Due to the difficulties of obtaining kinematic data from infants, only a few studies of speech movements have been published for this developmental period. It has been reported that breathing behavior varies considerably across four types of vocalization (cries, whimpers, grunts, and syllable utterances) and there is no consistent pattern of breathing by vocalization type. The major conclusion is that infants have numerous degrees of freedom in controlling the respiratory system to produce sounds.

Speech Development in Toddlers (12–24 Months)

Perceptual Findings

Although most typically developing children begin to produce words during this period, they also continue to engage in babbling behavior. Indeed, the phonetic inventory of toddlers stays relatively consistent until approximately 18 months of age. During this time, children produce approximately two or three times more consonants than vowels and have approximately six consonants in their repertoire (usually stops, nasals, and glides). In addition, the inventory of phones produced in the initial position of words tends to be larger than the inventory of phones produced in the final position of words. Phones produced in the initial position of words tend to involve the anterior portion of the mouth and tend to be voiced. Phones produced in the final position of words tend to be alveolar and voiceless.

Between 18 and 24 months, phonetic inventory size increases to approximately 10–20 consonants, and the inventory of consonants used in the syllable initial position increases more rapidly than the inventory for syllable final position. Although individual differences are present in the acquisition of speech sounds, the pattern of emergence of different sounds and sound classes tends to be relatively consistent.

One important question that has not been comprehensively studied relates to intelligibility of children's speech. In other words, how understandable are children at different periods during speech development? Clinical phoneticians and phonologists have tended to use a phone-and/or a phoneme-based approach to addressing this issue. One widely used metric is percentage of consonants correct (PCC). This measure provides information about how many consonants produced by a child match the adult form of the same consonants. However, it does not provide information about the information-bearing capacity of the speech signal produced by the child. Nonetheless, studies suggest that by the age of 2 years, children have an average PCC of approximately 70%. Although children at this age have a reduced repertoire of sounds relative to the adult, they seem to favor words that are within their phonetic repertoire and are on the path to achieving adult-like mastery.

Instrumental Findings

Studies converge on the general conclusion that children of this age have an increasing ability to produce contrasts in intonation and the phonetic properties of speech sounds. Rate of speech is quite slow compared to that in older children and adults, and air pressures and airflows used to produce speech sounds tend to be higher. As observed for infants in the first year of life, breathing behavior is highly variable and there is little consistency by vocalization type. In other words, speech breathing is not closely matched to the properties of utterances.

Speech Development in Preschoolers (2–6 Years)

Perceptual Findings

Children make important progress in their ability to produce a variety of speech sounds that are approaching adult-like between the ages of 2 and 6 years. There are considerable normative data on phonetic

and phonologic development during this period. By approximately 5 or 6 years of age, most children have all the speech sounds in the English language within their productive repertoire, although they likely have not 'mastered' production of all sounds. Studies suggest that among children between the ages of 3 and 11 years, approximately 92.5% develop articulation 'normally,' such that any developmental speech sound errors resolve spontaneously without the need for speech therapy. Although studies are limited, research also suggests that children between the ages of approximately 4 and 5 years produce continuous speech that is highly intelligible. It is during this period that many childhood disorders of communication can be identified. These include developmental stuttering and disorders of articulation and language.

Instrumental Findings

One of the fundamental questions about speech development pertains to the relationship between speech and feeding behaviors, which, after all, use much of the same biology. One line of thought is that movements for speech are derived from those for the ingestive behaviors of chewing and swallowing. This hypothesis is challenged by evidence of task specificity in infants' movements observed in speech, chewing, and lip protrusion. One of the main differences is that production of true words, as opposed to chewing or lip protrusion, is associated with a stronger coupling among all mandibular muscles. The implication of these kinematic studies is that speechlike movements and nonspeech movements are distinct at the earliest stages of word production. However, more research is needed to show to what degree speech and feeding draw from the same sensorimotor capabilities. This is a pivotal issue in understanding speech development, and it holds implications for theory and clinical application.

Vocal fundamental frequency declines between the ages of 12 months and 3 years so that by the age of 6 years, the mean in both males and females is approximately 250 Hz. Acoustic and physiologic studies generally agree in showing that speech production during this period becomes faster and more precise (less variable across repetitions of the same utterance).

Speech Development in Older Children (6+ Years)

Perceptual Findings

During this period, children are primarily making qualitative refinements in their phonetic development. By the age of approximately 6 years, typically developing children have all phonemes in the English language within their productive repertoire and can produce all consonant singletons accurately in more than 51% of occurrences. Children reach 90% 'mastery' of all consonant singletons by the age of approximately 8 years. Consonant clusters continue to undergo refinements toward adult mastery levels through 9 years of age. For all practical purposes, children have attained adult-like phonetic ability before the age of 10 years. If children begin to learn a second language before the age of 10 years, they have a much greater likelihood of attaining native-like proficiency (absence of accent) than if they begin at a later age. This is one kind of evidence that is used to support the critical period hypothesis for language.

Instrumental Findings

As noted previously, by perceptual standards, speech development can be regarded as complete (adult-like) in early childhood. However, instrumental studies lead to a somewhat different conclusion. Acoustic measurements of segment durations and spectral properties indicate that adult-like precision is not reached until the age of approximately 12 years. Physiological studies show that motor refinements for speech continue even longer – until approximately 16 years of age in both boys and girls. This protracted development of speech matches the development of language, which also has a long period of maturation.

During this period, boys and girls begin to differ slightly in the acoustic characteristics of speech. Sex-related differences emerge for fundamental frequency at 5–8 years and for vowel formant frequencies (i.e., resonance frequencies of the vocal tract) at approximately 8–10 years. However, the most conspicuous differences between boys and girls appear during puberty. Between the ages of 12 and 15 years, boys' vocal fundamental frequency drops markedly (approximately 80%). This voice change, or mutation, is related to a substantial growth of the larynx and its associated tissues.

Conclusions

When speech development is analyzed with respect to its component processes and systems, it is seen to be both complicated and protracted. The biology of speech encompasses variegated tissues and organs of the respiratory, laryngeal, and articulatory systems. These components have different schedules of growth and maturation, and putting them into a coherent framework is a basic challenge of research. Moreover, the control of these systems is linked to the requirements of language, and it appears that

maturation of speech as a motor behavior is in some ways tied to the maturation of language. However, some of the most dramatic advances are seen in infancy and early childhood as the basic capability for speech emerges from earlier coos and babbles. Cross-linguistic studies show that babbling has universal properties, and these are taken to reflect biological predispositions. Eventually, infant vocalizations show adaptations to the ambient language, with the first of these appearing at approximately 6–9 months. Phonetic mastery is achieved by the age of 8 years, but continuing refinement of speech motor control is evident until the age of approximately 16 years.

Spike-Timing-Dependent Plasticity (STDP)

D V Buonomano and T P Carvalho, University of California, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Spike-timing-dependent plasticity (STDP) refers to a form of associative synaptic plasticity in which the temporal order of the presynaptic and postsynaptic action potentials determines the direction of plasticity, that is, whether synaptic depression or potentiation is induced. In the most common form of STDP, long-term potentiation (LTP) is induced if the presynaptic spike precedes the postsynaptic spike (pre→post). In contrast, if the postsynaptic spike happens before the presynaptic spike (post→pre), then long-term depression (LTD) is induced. In addition to the order of the pre- and postsynaptic spike, STDP is sensitive to the interspike interval (ISI), the time elapsed between the two spikes. In general, short intervals produce maximal plasticity, while longer intervals produce little or no change in synaptic strength.

STDP represents an important form of synaptic plasticity for both experimental and computational reasons. Experimentally, LTP and LTD have often been induced by distinct protocols, and the relationship between these protocols as well as their physiological relevance has not always been clear. STDP formalizes the conditions for the induction of both LTP and LTD into a single learning rule. STDP is attractive as a computational learning rule because the direction of synaptic plasticity reflects the causal relationship between pre- and postsynaptic activity. If the presynaptic spike consistently precedes a postsynaptic spike, it is likely that the former contributes in eliciting the latter, and this contribution will be 'reinforced' through potentiation. In contrast, if the presynaptic spike consistently fires after the postsynaptic spike, no causal relationship between pre- and postsynaptic activity is present, and depression will ensue.

STDP and Hebbian Plasticity

The psychologist Donald Hebb postulated that if a presynaptic neuron "repeatedly or persistently takes part in firing" a postsynaptic neuron the synapse between them would be potentiated. This form of plasticity has come to be known as Hebbian or associative synaptic plasticity. However, Hebb's original postulate left two important issues unaddressed. First, what is the learning rule that underlies 'decreases' in synaptic strength? Second, what is the effective time window between pre- and postsynaptic activity that will result in potentiation? STDP addresses both these issues by establishing the specific conditions and temporal requirements for the induction of both LTP and LTD.

In a typical protocol, a single presynaptic spike is repetitively (e.g., every 1 s for 1 min) elicited 0–25 ms before or after a postsynaptic action potential. Here, intervals consisting of pre→post pairings will be defined as 'positive' ISIs, while post→pre pairings will be referred to as 'negative' ISIs. By examining the direction and magnitude of plasticity over a range of ISIs, we can plot the so-called 'STDP function' (change in synaptic strength vs. ISI), schematized in Figure 1. The STDP function characterizes plasticity at a given synapse, and represents the 'time windows' for the induction of both LTP (green) and LTD (red). Because both LTP and LTD are maximal for short intervals, differences of only a few milliseconds result in a sharp discontinuity at ~0 ms. In addition to the amplitude and duration of both time windows, another important feature of the STDP function is their ratio. For example, under the simplified assumption that pre- and postsynaptic spikes occur in isolation and randomly at all possible ISIs, one can see that if the LTP and LTD windows are equal in area there will be no net change in the overall synaptic strength. However, if the LTD area is larger than its LTP counterpart, random pre- and postsynaptic events will lead to a decrease in synaptic strength toward zero. Conversely, synaptic strength will saturate if the LTP area is larger. While not all the experimental data are in agreement, it is clear that in some cases the STDP functions do exhibit larger LTD windows, and thus are consistent with a potential role of STDP in synaptic competition (see below).

STDP functions similar to the one schematized in Figure 1 have been characterized in a number of different preparations including excitatory neocortical synapses, the retinotectal projection in *Xenopus*, and dissociated hippocampal cell cultures. Nevertheless, STDP is not universally observed, and thus the following points should be noted.

1. Not all synapses seem to undergo STDP in response to the pairing of single pre- and postsynaptic action potentials. For example, most evidence suggests that pairing of single pre- and postsynaptic spikes in the Schaffer-collateral→CA1 synapse in hippocampal slices does not result in synaptic changes that follow a function similar to the one depicted in Figure 1. At these synapses, the induction of LTP seems to require a burst of postsynaptic spikes.

Figure 1 (a) A hypothetical STDP function is depicted. Positive or negative interstimulus intervals give rise to LTP or LTD, respectively. No appreciable plasticity is induced at the synapse for large ISIs. Note the sharp discontinuity at 0, and that a longer-lasting LTD window is depicted. (b) A positive ISI is defined as the time interval between an initial presynaptic spike and a consecutive postsynaptic spike, which will lead to LTP. For negative ISIs, the postsynaptic cell fires before the presynaptic, and LTD will ensue.

2. The shape of the STDP function is highly variable. The peak or total area of the LTP and LTD windows are dependent not only on the types of synapses being examined, but on the exact induction protocol, pre- and postsynaptic cell type, and even on the position of the synapse along the dendritic arbor.
3. The standard STDP function is based on isolated single pre- and postsynaptic spikes, and does not necessarily describe synaptic plasticity in response to more complex patterns of activity.

Linearity of STDP

What would happen if the presynaptic spike consistently preceded and followed the postsynaptic spike by ISIs that individually would contribute with the same, but opposite, amount of LTP and LTD? If the result of such an experiment yielded no change in the synaptic strength, it would be said that individual ISIs were independent and that the contributions of each of the intervals summate linearly. In contrast, if, for instance, LTP was observed, STDP would be nonlinear and LTP would be dominant. Under experimental conditions, it is possible to constrain the spike patterns to single isolated spikes; however, *in vivo* data show that bursts of spikes or complex ongoing temporal patterns of spikes are commonly elicited in response to a given stimuli. Thus, in order to understand the computational role of STDP *in vivo*, it is necessary to address the issue of linearity or nonlinearity of STDP, and define the rules governing plasticity in response to complex patterns of pre- and postsynaptic activity.

Experimental studies have examined the issue of linearity by using protocols with spike triplets (e.g., pre→post→pre or post→pre→post) or quadruplets. It is clear that STDP is not strictly linear; however, the precise nature of the interaction of complex spike patterns on the LTP and LTD components of STDP is still emerging. Empirically determining the higher-order features of STDP is a challenging task, because the potential arrangements of spike patterns undergo a combinatorial explosion. Thus, a detailed understanding of the higher-order properties of STDP will likely rely on the elucidation of the underlying mechanisms. Specifically, if the critical cellular, synaptic, and biochemical mechanisms governing STDP can be quantitatively characterized, it should be possible to accurately predict the direction and magnitude of synaptic plasticity in response to any arbitrary patterns of pre- and postsynaptic spikes.

Mechanisms

Over the past decades, considerable emphasis has been placed on elucidating the mechanisms underlying LTP and LTD; similar efforts are currently focused on understanding the mechanisms underlying STDP. Two critical features of STDP must be accounted for at the mechanistic level:

1. *Order*. How can a synapse detect differences of a few milliseconds regarding the temporal order of presynaptic and postsynaptic spikes, and account for the sharp discontinuity observed at approximately 0 ms ISIs?
2. *Interval*. Independently of the issue of temporal order, what are the mechanisms that allow synapses to be sensitive to the pre→post and post→pre intervals? Specifically, why does a long positive (or negative) ISI produce little LTP (or LTD), while a short interval produce stronger LTP (or LTD)?

The mechanisms responsible for the interval sensitivity of the LTP component of STDP are generally accepted as being the same as those underlying associative LTP. Specifically, the *N*-methyl-D-aspartate (NMDA) receptors function as coincidence detectors of pre- and postsynaptic activity. A presynaptic spike

results in the release of glutamate, which binds to the NMDA receptor. Subsequent depolarization caused by a postsynaptic spike produces a voltage-dependent extrusion of the Mg^{2+} ion that impedes Ca^{2+} influx at rest. Only when both of these events occur in close temporal proximity will the NMDA channels allow the critical influx of Ca^{2+}. Since glutamate can remain bound to the NMDA receptor for at least tens of milliseconds, if the postsynaptic spike occurs shortly after the presynaptic event, glutamate will still be bound and Ca^{2+} influx will ensue. Thus, it appears that the binding kinetics of the NMDA receptor can account for the timing of the LTP window of STDP. Specifically, at large positive ISIs, little or no glutamate will remain bound to the postsynaptic NMDA receptor resulting in little or no LTP; however, at short intervals, maximal glutamate will be bound, and high levels of Ca^{2+} influx will be achieved, thus inducing maximal LTP. Consistently, there is robust experimental data showing that the blockade of NMDA receptors blocks the LTP component of STDP. For these reasons, the properties of the NMDA receptor likely underlie both the order and interval sensitivity components of STDP potentiation.

It is not immediately clear how the NMDA receptors could account for both the interval and order sensitivity of the LTD window of STDP. If the postsynaptic neuron fires before the presynaptic one, the membrane of the postsynaptic cell should have returned to close to its resting potential before glutamate is released from the presynaptic terminal (particularly for long negative ISIs); thus, the released glutamate should be ineffective in leading to Ca^{2+} influx. It could be argued that a small degree of Ca^{2+} influx occurs in response to a presynaptic action potential even when it occurs after a postsynaptic spike, and that this is sufficient for the induction of LTD. This argument, however, leads to a scenario in which presynaptic stimulation by itself could induce LTD (which is generally not the case).

Conflicting results have been reported regarding the ability of NMDA antagonists to block the LTD component of STDP; however, at least in some preparations, it seems clear that postsynaptic NMDA receptors are not involved in the induction of LTD in response to post→pre pairings. If NMDA receptors are not necessary for detecting the order and interval of negative ISIs, a second coincidence detector would be required, that is, the presence of a postsynaptic followed by a presynaptic spike must be detected by another biochemical pathway that triggers the induction of LTD. This two-coincidence detector model of STDP assumes the presence of a second biochemical locus that is capable of detecting the order and interval of post→pre spikes. One candidate mechanism for the second coincidence detector is the metabotropic glutamate receptor pathway. In this model, post→pre spiking leads to a low-level Ca^{2+} rise entering through voltage-dependent Ca^{2+} channels (VDCCs) that would prime the activation of the G-protein-mediated cascade, which would in turn be triggered by the presynaptic action potential via metabotropic glutamate receptors.

Computational Relevance and Correlates of STDP *In Vivo*

Competition

In general, computational models of cortical plasticity require two critical components: (1) an associative form of synaptic plasticity that allows correlated inputs to be strengthened and (2) competition, which is required to prevent neurons from responding to multiple sets of correlated patterns (stimuli). In contrast to other models, it has been proposed that STDP may be able to satisfy both these conditions with a single learning rule.

In its simplest sense, in STDP, competition arises between synapses that fire before and after a postsynaptic spike. Synapses from presynaptic neurons that fire before the postsynaptic action potential will be strengthened and take control of the postsynaptic behavior, while the synapses from neurons that fire later will be weakened. A competitive role for STDP predicts that the area of the LTD window should be larger than that of LTP. As mentioned above, this insures that in response to random background activity the net synaptic change is negative. While STDP can clearly implement competition between synapses, it should be stressed that the competition is dependent on the temporal relationship between the stimuli, that is, for different sets of correlated inputs to compete they must occur in close temporal proximity. If the two stimuli are separated by an intervals well outside the STDP window, there can be no interaction (and thus no competition) between stimuli over these time frames (note that LTD produced by spontaneous activity would be common to both stimuli). Thus, while STDP does provide a potential mechanism for competition, it does not by itself provide a universal one.

Computational Relevance and Neural Correlates of STDP *In Vivo*

In vitro STDP is generally studied by directly eliciting action potentials in the pre- and postsynaptic neurons. However, a number of studies have examined the putative *in vivo* correlates of STDP in the context of external stimuli. The order sensitivity of STDP

predicts that if two stimuli, A and B, are reliably presented in the order A→B and in close temporal proximity, a receptive field asymmetry should develop. Specifically, responses to A should increase and those to B decrease. Indeed, several experimental studies have measured stimulus-induced shifts in receptive fields in response to exposure to ordered stimuli. These include experiments in which the stimuli A and B corresponded to orientation of bars of light, visual position, or spatial receptive (i.e., the receptive fields of hippocampal place cells). Taken together, these results support the notion that STDP operates *in vivo*, and plays an important role in shaping neural responses.

While STDP likely contributes to the order-sensitive shifts in receptive field properties, it does not generate order selectivity. In the above example, consistent pairing of stimuli A→B results in strengthening of synapses driven by stimulus A and weakening of those from B, but nevertheless the neuronal response to A→B should be approximately equal to the response to B→A. Thus, the order sensitivity of STDP does not by itself generate order-selective neuronal responses.

Experience-dependent changes in the receptive fields of cortical neurons have also been interpreted in the context of STDP. For example, plasticity can be induced by cutting all but one whisker of the mystacial pad of a rat. In the barrel of a cut whisker, two changes are observed: a decreased response to the normally dominant whisker and an increased response to the spared whisker. It has been proposed that STDP can contribute to this phenomenon. Specifically, the decreased response of layer II/III pyramidal neurons to the previously dominant whisker appears to be due to LTD of synapses from layer IV. It has been shown that this LTD is consistent with STDP and the order of activation of these neurons. Specifically, in the deprived barrel, L-II/III pyramidal neurons may fire before the L-IV neurons, resulting in LTD.

Timing

STDP is highly sensitive to the interval between the pre- and postsynaptic spikes; however, the role of STDP in generating timed responses remains unclear. If a presynaptic spike consistently occurs 25 ms before the postsynaptic spike, the synaptic strength between the two neurons will increase. Assuming that this potentiation can influence cell firing, the postsynaptic neuron will spike at progressively shorter latencies, until the synaptic strength saturates or the interval decreases toward the monosynaptic delay latency. Thus, the original temporal interval used in the training is not effectively reproduced. As a result, STDP maintains the order of activation and favors early responses, but the patterns produced after STDP do not capture the temporal structure of the training stimuli. Nevertheless, STDP could take part in setting up specific spatiotemporal patterns of network activity that could play a role in temporal processing.

Spike-Timing-Dependent Plasticity Models

Introduction

Activity in a neuronal network is spatiotemporal. That is, it changes in space all over the network and in time for each specific neuron separately. How, then, can a network learn such detailed activity? Furthermore, what precisely does learning mean? In this article we focus on spiking neurons so that spatiotemporal activity for a network of size N means a collection of spike times t_i^f, where f indicates the spikes of neuron i and $1 \leq i \leq N$ labels the neurons. Learning then means that, as a result of and starting with a specific set of initial states, the network repeats the same spatiotemporal activity pattern as time proceeds. Of course, we implicitly assume *ceteris paribus* (the other things and thus all inputs from outside being equal).

To understand learning, two fundamental principles are important. First, where does learning take place? The kind of learning we are studying here depends on the arrival of spikes and is strictly local, meaning that events that merely occur at or near a synapse where learning happens are important to the change of the synaptic strength (or efficacy). If this depends only on pre- and postsynaptic spikes, it is called Hebbian.

Second, learning is, in general, slow with respect to the neuronal timescale (milliseconds); for instance, learning associated with sensory modalities takes days, weeks, or even longer. That is (to express it sloppily), most learning relies on repetition: practice makes perfect. The organism repeats the very same or similar patterns or sequences of patterns several times and, in so doing, trains the synapses. Hence, it is bound to be slow. Furthermore, for sensory systems this suggests that interesting phenomena in map formation also happen slowly. We define a map to be a neuronal representation of the outside sensory world. If learning is slow, then long-time correlations are picked up but short-time ones, such as white or light-colored noise, are averaged out.

As for locality of learning, Donald Hebb's classic *The Organization of Behavior* (1949, p. 62), contains the now famous neurophysiological postulate: "When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased". (Hebb, 1949:62)

We are then left wondering where the 'metabolic change' might take place, but Hebb already postulated explicitly that all this happens in synapses connecting the pre- and postsynaptic neurons. So, we focus here on pre- and postsynaptic spikes.

Learning a Spatiotemporal Pattern as Simply as Possible

To make our argument as clear as possible, we simplify it for the moment as much as we can and discretize time by units $\Delta t = 1$ ms, with the idea that a spike generically lasts 1 ms. Furthermore, we also discretize the states of our neurons $i, 1 \leq i \leq N$, through a state variable S_i, assuming two values: $S_i = 1$ if a neuron fires a spike at a certain time and $S_i = -1$ if it does not (the negative sign signaling that nothing happens). This type of neuron is a classic one, described in 1943 by McCulloch and Pitts, and equipped with universal computational capabilities.

To remember a pattern to come, given the network state at time t, we need the network's past – the more of it the better – so as to predict the future state at time $t + \Delta t$. How, then, can the network look backward in time to sample these data? That is both easy and natural – through delays. A neuronal network has lots of delays, most prominently the axonal ones. This is one of the key ideas behind the argument presented here. Interestingly, this idea is historical as well, and we therefore follow this line of thought for a while.

We focus on an excitatory synapse connecting the presynaptic neuron j to the postsynaptic neuron i. Its strength is denoted by J_{ij}. The axonal delay it takes a spike fired by j to arrive at a synapse on neuron i is $\Delta_{ij}^{\mathrm{ax}}$. Imprinting on the network a sequence of states $S(t) = \{S_i(t), 1 \leq i \leq N\}$ during a period $1 \leq t \leq T_l$, where T_l will soon be specified, our synapse should contribute to the learning process in an appropriate way. We can now state without further ado (and then verify that this makes sense) that the simplest possible way for a synaptic change ΔJ_{ij} is given by

$$\Delta J_{ij} = \eta_{ij} \frac{1}{T_l} \sum_{t=1}^{T_l} S_i(t + \Delta t)[S_j(t - \Delta_{ij}^{\mathrm{ax}}) + 1] \qquad [1]$$

This expression is to be added to the already existing synaptic efficacy J_{ij} of a synapse connecting neuron j to neuron i.

What does eqn [1] mean? At time t, a spike arrives at a synapse on neuron i, if at time $t - \Delta_{ij}^{\mathrm{ax}}$ neuron

j has fired. If it has not, then $[S_j(t\text{-}\Delta_{ij}^{ax})+1]=0$, in agreement with the fact that neuronal networks are characterized by low activity so that what is not active should not count. Only if a spike arrives does the synapse change by $\pm 2\eta_{ij}$ according to the postsynaptic activity $S_i(t+\Delta t)$ at the time $t+\Delta t$ following the arrival of the presynaptic spike at time t. Because learning is slow, the factor η_{ij} is to be small, meaning in suitable units $0<\eta_{ij}\ll 1$.

Now comes the key point. We focus on an excitatory synapse where a spike arrives at time t. The argument of the sum in eqn [1] tells us that the synapse is to be strengthened by $2\eta_{ij}$ if neuron i fires at time $t+\Delta t$, whereas it is to be weakened by $-2\eta_{ij}$ if neuron i does not fire. That is, if as an excitatory synapse it does its job, telling i to fire and thus causing the postsynaptic neuron to fire at time $t+\Delta t$, then the synapse is to be strengthened. If, on the other hand, at time $t+\Delta t$ the postsynaptic neuron does not fire, then the synapse does not do its job properly and it is to be weakened. "Those that come too late shall be punished." As for the rationale, it all fits.

Furthermore, we average over a time T_l, meaning we sum up, divide by T_l, and are done. How big or small, then, should T_l be? It is here that the adiabatic hypothesis $0<\eta_{ij}\ll 1$ works to advantage – to great advantage, even. Because in real life learning is slow, which is equivalent to saying $0<\eta_{ij}\ll 1$, we can choose, on the one hand, a T_l much bigger than all neuronal timescales (which are of the order of milliseconds) and, on the other hand, we can choose a T_l much smaller than the time needed to learn a specific task (which takes days or weeks). A gerbil needs 2 days and a barn owl needs 2 weeks to learn azimuthal sound localization – and for most humans learning to playing a piece by Chopin on the piano in 2 weeks is an optimistic estimate. Hence, we can imagine T_l to separate microscopic neuronal timescales (in milliseconds) from macroscopic learning times (in days and longer).

Finally, why does eqn [1] work as an algorithm to store a spatiotemporal pattern? **Figure 1** shows that it does work, but why does it? The key to understanding this is that the synapses use the very same pattern in conjunction with the very same wetware, that is, with the very same neuronal hardware, such as axons and synapses, and hence with the very same axonal delays Δ_{ij}^{ax}, both for learning and later on for replay. A closer look at **Figure 1** readily reveals that the total pattern consists of the disjoint union of parts occurring at subsequent times. Both eqn [1] and the upshot of the physiological learning process are the sum of subsequent parts. If these, or different subsequent patterns, are strongly correlated – roughly speaking, strongly resembling one another – there is a correlation problem needing an outside solution that is also outside the present context (e.g., through unlearning).

Figure 1 Motion of a 'phase boundary', a string of active neurons (black pixels), through a 20 × 20 storage layer. The system starts with a single point in the upper left-hand corner, and the string develops as time proceeds (top to bottom; first left, then right). During the motion, the number of black pixels varies between 1 and 20. From van Hemmen JL, Gerstner W, Herz AVM, Kühn R, and Vaas M (1990) Encoding and decoding of patterns which are correlated in space and time. In: Dorffner G (ed.) *Konnektionismus in Artificial Intelligence and Kognitionsforschung*, pp. 153–162. Berlin: Springer.

Spike-Timing-Dependent Plasticity

The inputs provided by many synapses decide what a neuron does, but, once it has fired, a local synaptic algorithm determines whether each of the synaptic efficacies increases or decreases. Also, without time discretization and when a synapse can remember more than the very last time step (i.e., over a period of time lasting longer than the time span Δt), there is a suitable generalization – the synaptic learning window, to which we now turn. This is a generalization of what we see in eqn [1], called (for good reason, as we will see) spike-timing-dependent plasticity (STDP). Each of the terms in eqn [2], below, has a

neurobiological origin. We designate the process they describe infinitesimal learning because the synaptic increments and decrements are small and, consequently, it takes quite a while before the organism builds up a noticeable effect.

For the sake of definiteness, we now study the waxing and waning of synaptic strengths associated with a single neuron, which therefore need not carry a label (**Figure 2**). The $1 \le i \le N$ synapses stemming from the neurons that we originally labeled j but now relabel i provide their input at times t_i^f. The firing times of the postsynaptic neuron are denoted by t^n, where n is a label like f. Given the firing times, the change $\Delta J_i(t) := J_i(t) - J_i(t - T_l)$ of the efficacy of synapse i (synaptic strength) during a learning session of duration T_l and ending at time t is governed by several factors:

$$\Delta J_i(t) = \eta \left[\sum_{t-T_l \le t_i^f < t} w^{\text{in}} + \sum_{t-T_l \le t^n < t} w^{\text{out}} + \sum_{t-T_l \le t_i^f, t^n < t} W(t_i^f - t^n) \right] \quad [2]$$

which exhibit STDP in the literal sense of the words. Here the firing times t^n of the postsynaptic neuron may, and in general will, depend on J_i; more precisely, they depend on all the J_i with $1 \le i \le N$.

We now focus on the individual terms of eqn [2] and treat them in turn. The prefactor $0 < \eta \ll 1$ reminds us explicitly that learning is slow on a neuronal time scale. Throughout what follows, we refer to this condition as the 'adiabatic hypothesis'. This holds in numerous biological situations and has been a mainstay of computational neuroscience ever since it was proposed. It may also play a beneficial role in an applied context. If the adiabatic hypothesis does not hold and η is not small, a numerical implementation of the learning rule (eqn [2]) is straightforward but an analytical treatment is not. Furthermore, each incoming spike and each action potential of the postsynaptic neuron change the synaptic efficacy in eqn [2] by ηw^{in} and ηw^{out}, respectively.

Figure 2 Single neuron. We study the development of synaptic weights J_i (small filled circles, $1 \le i \le N$) of a single neuron (large circle). The neuron receives input spike trains, denoted by S_i^{in}, and produces output spikes denoted by S^{out}.

The last term in eqn [2] represents the 'learning window' $W(s)$, which indicates the synaptic change in dependence on the time difference $s = t^f - t^n$ between an incoming spike t_i^f and an outgoing spike t^n. When the former precedes the latter, we have $s < 0 \Leftrightarrow t_i^f < t^n$, and the result is $W(s) > 0$, implying potentiation. This seems reasonable because N-methyl-D-aspartate (NMDA) receptors, which are important for long-term potentiation (LTP), need a strongly positive membrane voltage to become accessible by losing the Mg^{2+} ions that block their gate. A postsynaptic action potential induces a fast retrograde spike doing exactly this. Because the presynaptic spike arrived slightly earlier, the neurotransmitter is waiting to gain access, which is allowed after the Mg^{2+} ions are gone. The result is Ca^{2+} influx. On the other hand, if the incoming spike comes too late, then $s > 0$ and $W(s) < 0$, implying depression – which is in agreement with the rule "Those that come too late shall be punished". In neurobiological terms, there is no neurotransmitter waiting to be admitted. The learning rule (eqn [2]) is a direct extension of eqn [1], its time-discrete predecessor. There is, meanwhile, extensive neurobiological evidence in favor of this time-resolved Hebbian learning. An illustration of what a learning window does is given in **Figure 3** below.

Once new (infinitesimal) learning algorithms have been discovered, we can simply adapt W accordingly. For instance, for inhibitory synapses infinitesimal growth processes have been found that can be described qualitatively by putting $W := -W$ in **Figure 4**, which figure and eqn [3] show a typical learning window for an excitatory synapse:

$$W(s) = \eta \begin{cases} \exp(s/\tau^{\text{syn}})[A_+(1 - s/\tilde{\tau}_+) + A_-(1 - s/\tilde{\tau}_-)] & \text{for } s \le 0 \\ A_+ \exp(-s/\tau_+) + A_- \exp(-s/\tau_-) & \text{for } s > 0 \end{cases} \quad [3]$$

Here, as before, $s = t_i^f - t^n$ is the time difference between the arrival of the presynaptic spike and the postsynaptic firing, η is our small learning parameter, $\tilde{\tau}_+ := \tau^{\text{syn}}\tau_+/(\tau^{\text{syn}} + \tau_+)$, and $\tilde{\tau}_- := \tau^{\text{syn}}\tau_-/(\tau^{\text{syn}} + \tau_-)$. Typical parameter values used in numerical simulations are $\eta = 10^{-5}$, $A_+ = 1$, $A_- = -1$, $\tau^{\text{syn}} = 5$ ms, $\tau_+ = 1$ ms, and $\tau_- = 20$ ms.

The philosophy behind eqn [3] and **Figure 4** is straightforward. Neuronal spike generation happens at the axon hillock, where synaptic input is perceived through a postsynaptic potential of finite temporal width. Once a presynaptic spike has arrived at an excitatory synapse at time s, when $W(s)$ is

approximately maximal, then the synapse's influence is felt optimally at time $s = 0$, when the postsynaptic neuron fires. This makes the finite width of W readily understandable.

Figure 3 Schematic of Hebbian learning and spiking neurons. Shown in the bottom graph is the time course of the synaptic weight $J_i(t)$, evoked through input and output spikes (upper graphs, vertical bars). An output spike (e.g., at time t^1) induces the weight J_i to change by an amount w^{out}, which is negative here. To show the effect of correlations between input and output spikes, the learning window $W(s)$ (middle graphs) has been indicated around each output spike; $s = 0$ matches the output spike times (vertical dashed lines). The three input spikes at times $t_i^f = t_i^1, t_i^2$, and t_i^3 (vertical dotted lines) increase J_i by an amount w^{in} each. There are no correlations between these input spikes and the output spike at time t^1. This becomes clear once we look at them through the learning window W, centered at t^1; the input spikes are too far away in time. The next output spike at t^2, however, is close enough to the previous input spike at t_i^3. The weight J_i is changed by $w^{out} < 0$ plus the contribution $W(t_i^3 - t^2) > 0$, the sum of which is positive (arrowheads). Similarly, the input spike at time t_i^4 leads to a change $w^{in} + W(t_i^4 - t^2) < 0$. From Kempter R, Gerstner W, and van Hemmen JL (1999) Hebbian learning and spiking neurons. *Physical Review E* 59: 4498–4514.

On the basis of minimal assumptions in conjunction with the adiabatic hypothesis ($0 < \eta \ll 1$), we can now derive a general learning equation:

$$\frac{\mathrm{d}}{\mathrm{d}t} J_i = \eta \left[w^{in} \nu_i^{in} + w^{out} \nu^{out} + \int_{-\infty}^{\infty} \mathrm{d}s\, W(s) C_i(s,t) \right] \quad [4]$$

In this form the learning equation is easy to remember – the input rate ν_i^{in} modifies the synaptic efficacy through w^{in}, the output rate ν^{out} does so through w^{out}, and the Hebbian correlation function C_i favors or disfavors it through the learning window W. In eqn [4] the correlation function C_i is defined through

$$C_i(s,t) := \frac{1}{T_l} \int_{t-T_l}^{t} \mathrm{d}t' \langle S_i^{in}(t'+s) S^{out}(t') \rangle \quad [5]$$

where S_i^{in} is the input spike train (a flow of delta functions), S^{out} is its analog for the output spike train (cf. Figure 2), and the angle brackets denote an average over stochasticity in the neuronal dynamics with short-range correlations of the order of milliseconds.

We now turn to two applications of STDP that show clearly why and how conjugate pre- and postsynaptic timing can together tune a collection of synapses on a neuron such as that in Figure 2.

Barn Owl's Laminar Nucleus

Our first example illustrates how STDP sampling singles out the right synapses. It is, in fact, what STDP had been made for. Azimuthal sound localization is based on phase locking, a correlated neuronal

Figure 4 A. The learning window W: (a) in units of the learning parameter η as a function of the delay $s = t_i^f - t^n$ between the presynaptic spike arrival at synapse i at time t_i^f and the postsynaptic firing at time t^n; (b) experimentally obtained learning window of a cell in the rat hippocampus with EPSC as excitatory postsynaptic current. In (a), if $W(s)$ is positive (negative) for some s, the synaptic efficacy J_i is increased (decreased). The increase of J_i is most efficient if a presynaptic spike arrives a few milliseconds before the postsynaptic neuron starts firing (vertical dashed line at $s = s^*$). For $|s| \to \infty$ we have $W(s) \to 0$. The form of the learning window and parameter values are as described in eqn [3]. The similarity between (b) and (a) is evident. It is important to realize that the width of the learning window must be in agreement with the other neuronal time constants. In the auditory system, for instance, these are nearly two orders of magnitude smaller, so the learning window's width scales accordingly. (b) From Zhang LI, Tao HW, Holt CE, Harris WA, and Poo M (1998) A critical window for cooperation and competition among developing retinotectal synapses. *Nature* 395: 37–44.

response to cochlear input. In the barn owl, this happens up to 8 kHz. The animal's laminar nucleus is the first place where signals from both ears come together, but the response is completely smeared out because the axonal delays from left and right ears have a broad distribution, approximately 1 ms wide (Figure 5(a)). This is the situation 3 weeks after hatching, when the head of the young barn owl is adult but the owl cannot perform sound localization yet.

Two weeks later, the owl reaches a microsecond precision through an STDP tuning. The result of this is shown in Figures 5(b) and 5(c) for 2 and 5 kHz, respectively. Every axonal delay line preceding a synapse and equipped with the right delay is strengthened; the others are – so to speak – weeded out. Delay lines differing by one or several periods (here 500 or 200 μs) are effectively the same.

Figure 5 Modeling the selection of synapses connected to axonal delay lines during synaptic pattern formation of the synaptic connectivity on an integrate-and-fire neuron as in Figure 2: (a) 3 weeks after hatching a young barn owl's head is adult but the animal cannot perform azimuthal sound localization yet; in view of the broad (here Gaussian) distribution of delays, with a standard derivation of 0.5 ms, this is not surprising. The input through 300 axons from the left and 300 axons from the right ear is taken to be a periodic, inhomogeneous Poissonian input with frequency $\nu = 1/T$, where ν is the best frequency stemming from the cochlea and $T = \nu^{-1}$ is the corresponding period. After 2 more weeks the barn owl is able to localize a sound source and the resulting delay, i.e., synaptic distribution, is shown in (b) and (c) for best frequencies 2 and 5 kHz, respectively. We have obtained, so to speak, survival-of-the-fittest synapses with delays within in a narrow temporal domain or with corresponding delays shifted by one or more periods, which are identical as far as oscillations by period T are concerned. The rest are less fit and have been eliminated, a striking consequence of spike-*timing*-dependent plasticity. From Gerstner W, Kempter R, van Hemmen JL, and Wagner H (1996) A neuronal learning rule for sub-millisecond temporal coding. *Nature* 383: 76–78.

The key mechanism involved in STDP is correlating incoming presynaptic and outgoing postsynaptic spikes. If the postsynaptic neuron fires, we often get a backpropagating spike guaranteeing a fast message telling the synapse, so to speak, that the neuron it is on has fired. In the auditory system, neurons are even more compact than usual, so synapses practically directly feel that their postsynaptic neuron has fired.

Let us now imagine a laminar neuron, as in Figure 2. We start with a collection of synaptic efficacies with a uniform value and with an axonal delay line connected to each synapse providing it with spikes coming from the left or right ear; the wide delay distribution is shown in Figure 5(a). Independent of the other delay lines, each delay line is fed with an inhomogeneous periodic Poisson process with frequency ν and angular frequency $\omega = 2\pi\nu$ as input, that is, a point process with rate function $\lambda(t) = c + \sin(\omega t)$ and $c \geq 1$, a constant. If $\lambda(t)$ is small, the probability of getting an input spike is small, if it is large, the probability is large (although always $\lambda \leq c + 1$), and cochlear input is always noisy. As we see from Figures 5(b) and 5(c), during a training period under the influence of external auditory input only few delay lines survive through a collective coupling of postsynaptic firing and well-timed arrival of presynaptic spikes. (In passing, we note that for the sake of convenience the asymptotic saturation of the synaptic efficacies was built in.)

Place Cells in the Rat's Hippocampus

A completely analogous argument to the one for the barn owl auditory system may well hold for hippocampal place cells too. There is, however, a neat difference. The typical time constant in the auditory system is 0.1 ms; on the other hand, it is 10 ms in the hippocampus, that is, roughly two orders of magnitude more. We may therefore expect that the temporal width of the learning window W depends on the physiological structures it lives in. That is, the width of W in the hippocampus is, indeed, 50–100 ms.

Conclusion

From a theoretical point of view, STDP is extremely appealing. Depending on the arrival time of a presynaptic spike at a synapse on the postsynaptic neuron, the synapse is strengthened or weakened depending on the firing time of the postsynaptic neuron. If the postsynaptic neuron fires at $t = 0$ and the synapse is excitatory, then it is strengthened if it receives a presynaptic spike at a time $t < 0$ and thus tells the

neuron to fire before the latter actually fires. That is, it is doing its job properly, and thus its synaptic strength increases.

If, on the other hand, the presynaptic spike arrives at $t > 0$, then it is too late because the postsynaptic neuron has already fired. "Those that come too late shall be punished," and, hence, the synaptic strength decreases. All this is taken care of by the function W, the learning window in Figure 4. Clearly, if the arrival time of the presynaptic spike and the firing time of the postsynaptic neuron are too far apart, then nothing happens.

What we have analyzed in this article is STDP as a stand-alone phenomenon, that is, in its full simplicity. Neurobiological reality is both more complicated and more fascinating than this, in that STDP automatically normalizes synaptic strengths and gives rise to a whole field of applications such as map formation. Let us now briefly consider these phenomena in turn.

The arguments presented so far hold for a single pair of spikes, a presynaptic one and a postsynaptic one. It has turned out experimentally that synaptic modification may also depend on the spiking pattern, that is, on the interspike intervals within each neuron. In addition, the precise position of a synapse on the dendritic tree may play a role as well.

Furthermore, STDP gives rise to a normalization of the synaptic efficacies so that they do not diverge as time proceeds. Finally, STDP allows for a comprehensive explanation of neuronal map formation, one of the most intricate, yet manageable problems in today's neuroscience. As we have seen, a map is a neuronal representation of the outside sensory world. Although STDP itself is local, map formation can be explained in detail by means of STDP in conjunction with more globally operating mechanisms.

In short, because the very same neuronal wetware with the very same delays is used both for learning and for replay, a reproduction (replay) of what is to be learned is possible. Because STDP is local, it cannot handle global correlations. In spite of that, STDP is a very potent mechanism for storing time-resolved spike data at a scale finer than a millisecond and in this way can explain a huge diversity of neuronal phenomena. As such, it exhibits the mathematical universality to explain neurobiological diversity.

Introduction: Spikes and the Question of Neural Coding

Neurons communicate with each other by electrical pulses, called action potentials or spikes. Whether the exact timing of action potentials or only the mean firing rate plays a role in neuronal communication is a question of intense debate, often referred to as the problem of neural coding. The question is further complicated by the fact that neuronal firing rates can be defined in at least three different ways: (1) the mean firing rate of a single neuron in a single trial, defined as a temporal average over a sufficiently long time (e.g., number of spikes in a time window of 500 ms, divided by 500 ms); (2) the firing density of a single neuron averaged across several repetitions of the same stimulus, typically defined via the amplitude of a peristimulus-time-histogram as a function of time; and (3) the population rate in a group of neurons with similar properties, defined as an average across the group. From reaction time experiments, it is clear that the first definition of a rate (average across time) cannot be the code used by the neurons. Averaging across several repetitions, as in the second definition, is a useful experimental method but cannot be the strategy of an animal which has to respond to a new stimulus. Finally, while the concept of averaging over groups of equivalent neurons is theoretically appealing, it is hard to see how such groups could be defined in a living brain since the organization into groups might change from one moment to the next, depending on task and stimulus demands.

If rates are such a difficult concept, does that imply that the exact timing of individual spikes matters? Not necessarily. A typical cortical neuron receives input from thousands of other neurons. What matters is probably the number (and spatial distribution across the dendrite) of spike arrivals averaged over an interval of one or a few milliseconds. However, if one spike arrival at an excitatory synapse were removed and replaced by a spike arrival at a different excitatory synapse at a similar dendritic location, the response of the neuron would hardly change. Since the question of coding and of the relevance of exact spike timings for neuronal response is still an open issue, researchers in theoretical neuroscience often use models that take the pulsed (i.e., 'spiking') nature of neuronal signals into account. These are so-called spiking neuron models, as opposed to rate models, in which the activity of neurons is described only in terms of firing rates.

Rate Models in Theoretical Neuroscience

In the field of artificial neural networks, the traditional way of describing neuronal activity has been by means of rate models. In this framework, each unit in a neuronal network is characterized by its rate $r(t)$, which depends nonlinearly on the total stimulation I it received immediately before. In a standard model in discrete time, the rate $r_i(t)$ of a neuron i is given by

$$r_i(t) = g(I_i(t - \mathrm{d}t)) \qquad [1]$$

where $\mathrm{d}t$ is the time step of the simulation and g the nonlinear gain function. Typically, the function g takes a value of zero for a stimulation I below some threshold value and saturates at a maximum value $r^{\max}$ for very strong stimulation. The total stimulation I_i of neuron i has two contributions, that is, the sum over all inputs converging onto neuron i plus potentially some external input I^{ext}:

$$I_i(t) = \sum_k w_{ik} r_k(t) + I^{\mathrm{ext}}(t) \qquad [2]$$

where r_k are the firing rates of other neurons k. In continuous time, eqn [1] is often replaced by a differential equation:

$$\tau \frac{\mathrm{d}r_i}{\mathrm{d}t} = -r_i + g(I_i) \qquad [3]$$

with some time constant τ that describes the response time of the unit to a change in stimulation.

While artificial neural networks using rate models have been successfully used in tasks describing cortex development or memory retrieval, the biological interpretation of the network units is unclear. Each unit i and k in eqn [2] could be interpreted as a single neuron and its rate as a temporally averaged firing rate. In view of the limitations of the firing rate concept discussed above, it must then be concluded that such a single-neuron rate model cannot be used to describe the fast neuronal dynamics during, for example, the rapid reaction of an organism to a new stimulus. Alternatively, each unit could be interpreted as a population of cells and its activity as the population rate. However, in that case the connectivity matrix w_{ij} would refer to the connectivity between populations rather than neurons, and the relevance of model results for electrophysiological measurements is questionable.

Detailed Models of a Spiking Neuron

The classical model of a spiking neuron is the mathematical description of Hodgkin and Huxley of action potential generation in the giant axon of the squid. Generation of spikes in the model arises through the interplay of four nonlinear differential equations. The first equation summarizes the current conservation on a small piece of membrane. A current I^{ext} injected onto the membrane can either charge the capacity C of the membrane or pass through one of the ion channels. With three different ion channel types (one for sodium, one for potassium, and one for all remaining 'leak' components), the change of the voltage is given by

$$C\frac{\mathrm{d}u}{\mathrm{d}t} = I^{\text{ext}} - g_{\text{Na}}m^3h(u - E_{\text{Na}}) - g_{\text{K}}n^4(u - E_{\text{K}}) - g_L(u - E_{\text{L}}) \qquad [4]$$

where g_{Na} and g_{K} are the maximum conductance of the sodium and potassium channel, respectively; E_{Na} and E_{L} are their reversal potentials; and m, h, and n are additional 'gating' variables that describe the state of the channel as a function of time. Each of the three variables m, n, and h follows an equation of the form

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -\frac{x - x_0(u)}{\tau(u)} \qquad [5]$$

with empirical function $x_0(u)$ and $\tau(u)$ derived from the experiments (and different for m, n, and h).

Computer simulations as well as mathematical analysis of the system of four nonlinear differential equations shows that action potentials are generated only if the total stimulation I^{ext} reaches a critical value. To a first degree of approximation, one may therefore conclude that action potential generation is an all-or-none process. However, a closer examination of the behavior shows that there is neither a strict voltage threshold nor a strict current threshold. In particular, for time-dependent inputs (e.g., current steps and ramps or randomly fluctuating current as input), not only the momentary voltage or current amplitude matters, but the stimulation history as well.

Formal Spiking Neuron Models

Although neither the Hodgkin–Huxley model nor real neurons have a strict firing threshold, in practice the process of neuronal action potential generation can often be well approximated as a threshold process. The simplest model in the class of formal spiking neuron models is the leaky integrate-and-fire model. In this model, spikes are triggered whenever the membrane potential u reaches a given threshold θ. Below threshold, the membrane potential is described by its capacity C and input resistance R. Current conservation gives the linear differential equation.

$$C\frac{\mathrm{d}u}{\mathrm{d}t} = -\frac{u}{R} + I^{\text{ext}} \qquad [6]$$

If u reaches the threshold θ, the spike time t^f is noted and the membrane potential reset to a fixed value u_{reset}, before integration of eqn [6] is resumed. The essence of the leaky integrate-and-fire model is a clear separation between a completely linear (passive) subthreshold regime and a strict firing threshold. The leaky integrate-and-fire model is today the standard neuron model in many simulation studies concerning the dynamics of large neuronal networks or the question of neural coding.

Generalizations of the leaky integrate-and-fire model have been proposed in several directions. First, since some neurons exhibit in the subthreshold regime a damped oscillatory response to changes in the input (as opposed to a simple exponential decay), the voltage eqn [6] can be coupled with a second equation. As long as this second equation is linear, the subthreshold behavior of the neuron is still completely linear, that is, doubling the amplitude of an input generates a subthreshold response which is twice as large. Second, refractory effects (i.e., reduced responsiveness of a neuron immediately after firing) have been included. The combination of refractory effects with a linear subthreshold behavior leads to the spike response model with a membrane potential

$$u(t) = \eta(t - \hat{t}) + \int \kappa(t - \hat{t}, s)I^{\text{ext}}(t - s)\mathrm{d}s \qquad [7]$$

where $\hat{t}$ is the firing time of the last spike of the neuron, η describes the form of the action potential and its spike after-potential, and κ the linear response to an input pulse. The next spike occurs if the membrane potential u hits a threshold θ from below, in which case $\hat{t}$ is updated. Hence the main characteristics of the Spike Response Model are identical to those of the leaky integrate-and-fire model, that is, a linear subthreshold regime in combination with a strict firing threshold. However, the spike response model allows refractory effects to be included (since the functions η and κ depend on the time since the last firing) as well as subthreshold oscillations (expressed through an appropriate shape of η and κ).

A third generalization of the standard leaky integrate-and-fire model concerns adaptation. By introduction of a second equation that summarizes processes on a slower timescale, it is possible to describe the slow adaptation of the neuron after a step in the stimulating current.

Fourth, the spike triggered by a strict threshold process at the soma can be combined with one or several additional equations describing the (passive) properties of the dendrite. Finally, the strict threshold can be replaced by a smooth threshold process if eqn [6] is turned into a nonlinear equation:

$$C\frac{\mathrm{d}u}{\mathrm{d}t} = -f(u) + I^{\mathrm{ext}} \qquad [8]$$

where $f(u)$ describes the nonlinearities of the membrane in the vicinity of the firing threshold. Two standard choices of $f(u)$ are the quadratic integrate-and-fire model $f(u) = a\ (u-u_1)\ (u-u_2)$ and the exponential integrate-and-fire model $f(u) = -(u/R) + b\ \exp[(u-\theta)/\Delta]$. Both models have free parameters, that is, a, u_1, and u_2 for the quadratic and b, θ, Δ, and R for the exponential integrate-and-fire model, that can be used to adapt the model and put it into a desired firing regime.

Limitations of Formal Spiking Neuron Models

Formal spiking neuron models approximate the electrical properties of neurons by one or a few equations that summarize basic features of normal neuronal behavior with a small number of phenomenological parameters. Formal spiking neurons are therefore not suitable for predicting electrophysiological experiments under nonstandard stimulation conditions. In particular, since all electrical properties of a neuron are summarized in one or two phenomenological equations, these models cannot be used to predict changes of behavior caused by, for example, pharmacological blockage of specific ion channels. Moreover, since the spatial structure of real neurons is not represented in detail, all nonlinear dendritic effects cannot be incorporated into formal spiking neuron models (passive properties, however, can be). Similarly, since the model summarizes neuronal behavior under some reference condition, slow changes in neuronal behavior, caused by slow current ramps or accumulation of intracellular calcium or a simple fatigue of the neuron, for example, cannot be captured.

However, under some stimulation conditions, formal spiking neurons perform surprisingly well. A direct comparison of the spike response model with the Hodgkin–Huxley model during stimulation with random current shows that up to 90% of spike times of the Hodgkin–Huxley model are correctly predicted by the spike response model with a temporal precision of 2 ms. Moreover, a spike response model with a second equation describing adaptation has also been used to predict spike times of layer-V pyramidal neurons in rat cortex under random current injection. The same time-dependent input $I^{\mathrm{ext}}(t)$ was given to both a model neuron and a pyramidal neuron. If the fluctuating current had large amplitude, the neuron itself generated spikes reliably with the same timing across several repetitions of the experiments, but less so if the fluctuation amplitude was reduced. Similarly, the model neuron was able to correctly predict the spike times of the pyramidal neuron (up to 70%) if the fluctuation amplitude of the current was high, but much less well if it was low. Thus, under random current injection, formal spiking neurons describe action potential generation in pyramidal neurons to a high degree of accuracy.

Spiking Neurons in Large Networks

A major advantage of formal spiking neurons such as the leaky integrate-and-fire model is their simplicity, which has two important consequences. First, it is possible to simulate neural networks with a large number of neurons at a reasonable numerical cost. Second, network properties such as the mean firing rate of neurons in a network of randomly connected integrate-and-fire units can be studied analytically with tools from mathematical probability theory, statistical physics, and bifurcation theory.

One important insight that has arisen from studies with formal spiking neurons is the importance of the subthreshold regime for cortical activity. In order to have large networks of interacting spiking neurons working in a state in which individual neurons show irregular firing with broad interspike interval distributions, it turns out to be necessary that the total drive from thousands of excitatory inputs is approximately balanced by inhibition. If this is the case, the neuronal membrane potential hovers normally in the subthreshold regime but stays close to the threshold so that neurons are very responsive to small changes in the input.

Furthermore, studies with networks of spiking neurons have been used repeatedly to elucidate the potential of different neural codes. For example, the stability and reproducibility of spatiotemporal spike patterns in networks of integrate-and-fire neurons have been studied in the context of synfire chains, a potential coding mechanism relying on precise spike times. Similarly, it can be understood why and under what conditions a population of spiking neurons responds instantaneously to changes in the input, that is, much faster than the membrane time constant that characterizes the passive response of the membrane. Finally, formal spiking neurons have been used for studying the functional consequences of spike timing-dependent plasticity.

The example of oscillatory activity allows one to see how formal spiking neurons can be used to predict by a purely mathematical argument the firing activity in large networks. For the sake of simplicity, we suppose that the network consists of N neurons with identical properties and that every neuron is connected to all other neurons by synapses of the same strength. Since we are interested in oscillatory activity, we assume that all neurons in the network fire at the same time, except one that lags behind by a small amount. Will this neuron eventually join the group of the others? To answer this question, we calculate the total synaptic input to this specific neuron, generated by the action potentials in the group of synchronous neurons. Knowing the input, we can derive from eqn [6] or eqn [7] the time course of its membrane potential, and from the time course, we can predict its firing time, that is, the moment when the membrane potential hits the threshold. An analogous calculation is repeated to predict the firing time of the group of synchronous neurons and hence the timing difference between the activity of the single neuron and that of the group. The one neuron lagging behind will eventually join the group of synchronous neurons (i.e., the oscillation is stable) if the timing difference is reduced from one firing cycle to the next. This is just a simple example, but similar mathematical arguments can be used to predict the population activity in large networks and answer questions such as: What is the mean firing activity of neurons in the network? Do neurons fire asynchronously, or do the firing times tend to cluster? Does the network activity show spontaneous oscillations? Will the network switch to a different state on a new input? If yes, could this explain short-term memory in neural networks?

To summarize, formal spiking neuron models are a highly simplified and compressed way of describing action potential generation in real neurons. While such an approach has obvious limitations and cannot be used to study detailed properties of isolated neurons (such as active dendrites or effects of pharmacological blockage of specific channels), the models have been useful in the past to elucidate the essence of spike generation in single neurons as well as principles of neuronal coding in large neuronal networks, and they will probably remain important tools for modeling studies in the future.

Spinal Cord Injuries

A Gorio, G Marfia, D Bottai, and A M Di Giulio, University of Milan, Milan, Italy

Introduction

Throughout the ages spinal cord injury (SCI) has been known as a devastating affliction, with little hope of any treatment's resulting in a meaningful recovery. The unknown Egyptian author of the Edwin Smith Surgical Papyrus accurately described the symptoms of a complete cervical myelopathy. The hopelessness of treatment of SCI was already known 5000 years ago, with the author advising that it was "an ailment not to be treated." Hippocrates advocated the closed reduction of spinal deformities by traction on an extension bench, a method used by physicians throughout the centuries. The first surgical procedure for SCI was performed in the seventh century by Paul of Aegina, who was also considered the originator of the decompressive laminectomy. Sommering discussed the surgical treatment for trauma to the spinal cord in 1793. The advances in surgery in the nineteenth century, such as antisepsis, had little effect on the dismal fate of those suffering from SCI. As reported by Guttman, Cushing reported that during World War I, 80% of the spinal cord-injured died within the first week of injury.

The advent of antibiotic therapy and the availability of whole blood greatly reduced the acute mortality rate for SCI to approximately 20% during World War II. Furthermore, this war provided the impetus for the development of a center for comprehensive treatment, rehabilitation, and research of the spinal cord-injured. This pioneering facility, the Spinal Cord Injuries Centre of the Stoke Mandeville Hospital in Aylesbury, England, was headed by Sir Ludwig Guttmann. Many physicians who trained in this facility subsequently developed similar centers throughout the international medical community. In recent decades, the battle against SCI has been waged in all phases of health care. Prevention of injuries due to trauma has been a major public health concern. This is evident in public awareness programs such as those attempting to prevent drunk driving and diving accidents, as well as safety equipment improvements in motor vehicles. Unfortunately, these efforts have not satisfactorily reached the right target since the number of motor vehicle accidents has greatly increased in very recent years. Such accidents represent more than 70% of the causes of SCI. More than 60% of the affected people are between 15 and 30 years of age. Estimates of SCI prevalence range from 721 to 906 cases per million. These estimates correspond to between 36 000 and 40 000 spinal cord-injured persons alive in Italy. Currently, the mortality rate within 1 year after SCI is approximately 6%. Critical factors in this improved prognosis of SCI have been the advent of emergency medical services and improvements in the acute management of the spinal cord-injured, as well as of the multiple trauma patient.

Although uncommon, SCI is tragic since it completely alters the lives of many of the most productive members of society. Although SCI poses a significant health problem, social ills are linked directly and indirectly to its etiology. The economic cost of SCI is staggering. Despite continuously decreasing lengths of stay for initial hospitalization, mean total hospital charges are increasing. The following figures refer to the United States. In 1986 the mean initial hospital charge was estimated to be $91 400. Latest estimates of individual health care and living expenses attributable to SCI are $198 000 for the first year postinjury and $24 100 each subsequent year, with costs increasing with severity of injury. Based on the current estimates of incidence and prevalence, the annual direct cost of SCI to the United States is $8 billion. If indirect costs such as lost wages and productivity are added, the annual national cost of SCI is nearly $19 billion.

The need for effective acute intervention, both to limit the number of permanently impaired patients and to give real hope to the newly injured, has never been greater. Within the past 2 decades, the intense research into traumatic SCI has yielded only a controversial pharmacological treatment, high-dose methylprednisolone administered acutely after injury. Glucocorticoid therapy seems useful only when administered within 8–9 h of injury. The mechanisms by which glucocorticoids exert their moderately beneficial effects remain unclear, although the anti-inflammatory action of the steroids have been proposed. Yet despite the fundamental inadequacy of high-dose glucocorticoid treatment, it has remained the only available and mandatory therapy for SCI.

With significantly improved mortality rates after SCI, current research is focused on reducing the devastating morbidity after SCI, in both the acute and the chronic phases following injury. Cord injury caused by penetrating forces is usually circumscribed around an area of severe damage that corresponds to the level of the penetrating force. Damage to the spine is quite variable and generally less severe than that to the cord. The injuries due to blunt forces are generated by more complex mechanisms. The force affects the vertebral column and is modified by this impact

before it is transmitted to the cord. Thoracic cord injuries have the highest proportion of complete injuries when compared with cervical or thoracolumbar segments. Primary injury is that which is an immediate result of direct action of mechanical force on the spinal cord. Secondary injury consists of all pathological events initiated by the original mechanical insult. Research has flourished in the field of secondary injury involving both the brain and the spinal cord, and many mechanisms and their potential treatments are common to both organs. The secondary injury following SCI is fundamentally the result of a stroke-like ischemic insult; it is associated with dysregulated arterial flow, venous stasis, edema, and vasospasm, all of which serve to lower spinal arterial perfusion to critically low levels. The biochemical and metabolic events associated with vascular dysregulation are numerous and lead to the progressive degeneration of white and grey matter that may greatly exceed the early mechanical damage. Three major hypotheses have been proposed to account for such damage, namely, disturbances in cellular calcium, free radical production, and excitotoxic amino acid release. A disturbance in intracellular calcium homeostasis is widely acknowledged as being a critical element in the initiation of neuronal injury. Calcium is involved in the regulation of numerous cellular functions, including neurotransmitter release, neuronal excitability, and second messenger and cellular enzyme action. Ischemic insult rapidly results in energy failure, depolarization, and blockade of energy-dependent ionic pumps that normally control intracellular concentrations of sodium and calcium ions. The increased intracellular sodium ion concentration is thought to induce a reversal of calcium ion extrusion through a Na^+/Ca^{2+} antiporter, causing a further increase in intracellular Ca ions. The energy depletion and elevated intracellular Ca ions cause a massive release of excitatory amino acids (e.g., glutamate) that results in excitotoxic neuronal death. The formation of destructive reactive oxygen species (ROS) is strongly associated with damage derived from ischemic and traumatic injuries. These highly reactive radicals, which can cause the peroxidation of membrane phospholipids, cellular proteins, and nucleic acids, attack both neuronal and glial cell membranes as well as the spinal cord vasculature. The spinal cord appears to be particularly vulnerable to such oxidative injury. It contains relatively high concentrations of readily peroxidable fatty acids and is relatively poorly endowed with protective antioxidant enzymes and endogenous antioxidant compounds. Levels of arachidonic acid, generated as a result of membrane calcium-dependent lipolysis (including calcium activation of phospholipase 2), rises quickly during ischemia. Arachidonic acid can then be metabolized by either cyclo-oxygenases or lipo-oxygenases to produce a variety of vasoactive substances: prostaglandins, prostacyclins, thromboxanes, leukotrienes, and ROS. At site of injury, neutrophils are considered to be one of the primary sources of ROS. A complicated interplay of proinflammatory molecules, anti-inflammatory molecules, and migratory cells also mediates the pathophysiology of the spinal cord following injury. Within the first 12 h, neutrophils first appear, with lymphocytes and microglia then mobilized to the injury site within 24–48 h. Much interest has been focused on proinflammatory cytokines, specifically MIP-2, tumor necrosis factor-α (TNFα), interleukin (IL)-1β, and IL-6, which are key mediators of inflammation following CNS lesions. Overproduction of MIP-2 into injured spinal cord was associated with neutrophil infiltration, indicating a key role played by this mediator in inflammatory cell recruitment induced by SCI. In keeping with this suggestion, reparixin (a blocker of IL-8 receptor) treatment has been found to completely prevent neutrophil and ED-1-positive cell infiltration into injured spinal cord. The complex summation of primary and secondary degeneration events determines the extent of tissue damage, normally extending much farther than the limits of the mechanical impact. The attenuation of cellular and molecular abnormalities underlying the secondary injury may result, then, in a dramatic improvement of recovery from SCI-derived disability.

Neutrophils, and perhaps microglia, responding to tissue injury, may inappropriately destroy adjacent tissues, resulting in extension of the infarct. Neutrophils in high concentrations have been observed to accumulate in CNS regions with low blood flow during the early postischemic reperfusion phase, further contributing to delayed hypoperfusion. Soon after the traumatic injury, a marked increase of IL-8 at the lesion site begins and reaches its peak in 24 h, then subsides in 48 h. IL-8 is likely the most important chemokine leading to migration and accumulation of neutrophils in the affected area. The effect of microglia/macrophage activation in the injured spinal cord remains controversial. Suppression or depletion of microglia/macrophages improves tissue integrity and functional recovery after traumatic SCI. However, intraspinal injection of preactivated microglia or blood monocytes increases axon growth at the injury site and may promote improved locomotor function. Because the activation and migration of macrophages/microglia precedes most inflammatory events within the injured CNS, these cells may direct the overall magnitude, kinetics, and effects of downstream inflammatory processes, secondary degeneration, and endogenous mechanisms of spinal cord repair. Specifically, activated microglia has been linked

with regions of increased blood–spinal cord barrier permeability, axonal degeneration, and increased production of inflammatory neurotoxins, chemokines, and cytokines following traumatic CNS injury. Species comparisons have shown that the phagocytic capacity and release of cytokines and eicosanoids are greater in rats than in mice. Expression of CD4 and CD8 molecules on microglia and macrophages in the injured spinal cord of rats could contribute to species-specific differences in lesion pathology. Historically, CD4 and CD8 antigens define T-helper and cytotoxic T cell subsets, respectively. These molecules are essential for major histocompatibility complex (MHC)-restricted antigen recognition by T cells and T cell activation. In the CNS, these molecules are also expressed constitutively on a subset of rat microglia and are upregulated on some activated microglia/macrophages in models of peripheral nerve injury, cerebral ischemia, and multiple sclerosis (i.e., experimental autoimmune encephalomyelitis). Recently, CD8 was localized to hematogenous macrophages infiltrating the brain during the first week following an ischemic insult. Hematogenous macrophages are recruited to the rat spinal cord after contusion injury, and these cells contribute to the acute secondary pathology associated with SCI. Subsets of these macrophages express CD8. The demonstration that ligation of macrophage CD8 can trigger the release of proinflammatory cytokines such as IL-1, TNFα, and nitric oxide provides a mechanism whereby microglia/macrophages could contribute to secondary injury and cavitation in spinal injury. A complicated interplay of proinflammatory and anti-inflammatory molecules and migratory cells also mediates the pathophysiology of the spinal cord following injury. Within the first 12 h, neutrophils first appear, with lymphocytes and microglia then mobilized to the injury site within 24–48 h. Among proinflammatory cytokines, much interest has focused on MIP-2, TNFα, IL-1β, and IL-6, which are key mediators of inflammation following CNS lesions. Glial cells are a primary target of cytokines and are activated in response to many cytokines, including TNFα and IL-1. This activation can trigger further release of cytokines that might affect local inflammatory responses and neuronal survival. It was suggested that IL-1 might promote neurotoxin release from glia and that TNFα could induce apoptosis directly through the activation of Fas receptors. MIP-2 is a primary chemotactic and activating factor for neutrophil. Overproduction of MIP-2 into injured spinal cord was associated with neutrophil infiltration, indicating a key role played by this mediator in inflammatory cell recruitment induced by SCI. In keeping with this suggestion, reparixin treatment completely prevented neutrophil infiltration into injured spinal cord. Similarly, reparixin administration strongly reduced ED-1-positive cell invasion, suggesting that neutrophil infiltration induced by SCI could play an important role in subsequent mononuclear cell recruitment. In agreement with this hypothesis, the phagocytic activity of neutrophils plays an important role in damaged tissue, but activated neutrophils are also known to produce an array of inflammatory mediators including cytokines and chemokines and to regulate the cascade of events leading to TNFα production. In addition, the increase of proinflammatory cytokines occurring after traumatic SCI has been successfully counteracted by 7 days' reparixin treatment, a novel CXCR2 receptor blocker. The inhibitory effect of reparixin on IL-1β and IL-6 was already observed at day 1 after SCI, further sustaining a key role of infiltrated neutrophils in the production of cytokines observed after traumatic SCI. On the other hand, reparixin treatment reduced MIP-2 and TNFα production starting from day 2 after SCI, indicating that resident cells and infiltrated mononuclear cells could be the main source of these factors. Thus neuroinflammation is an important component of SCI, and drugs capable of modifying this picture may prove useful for the development of a much needed pharmacological control of the early degenerative events following traumatic injury of the cord.

The complex summation of primary and secondary degeneration events determines the extent of tissue damage, normally extending much farther than the limits of the mechanical impact. The degenerated tissues are enclosed in a cavity surrounded by reactive glia. Such a scar represents both a safe border for undamaged spinal cord tissue and a powerful limitation to axonal regeneration across the lesion site. The attenuation of cellular and molecular abnormalities underlying the secondary injury may result, then, in a dramatic improvement of recovery from SCI-derived disability. It is well known that more than 90% of the traumatic injuries to the cord are not complete and a portion of spinal axons are spared. Unfortunately, they are unable to conduct electric impulses. Limiting the progression of secondary injury should make it possible to preserve the excitability of spared axons and reduce the extent of cavity formation. The current commonly used standard therapy consists of the administration of methylprednisolone sodium succinate (MPSS) to attenuate SCI damage by reducing lipid peroxidation, free radical formation, and edema occurring during the posttraumatic ischemia and reperfusion. However, in spite of initial clinical data suggesting that treatment using MPSS within 8 h of injury was beneficial, the current consensus is that MPSS offers at best very limited benefit and may actually cause harm. The potential explanation of this recent outcome may be that MPSS treatment

of SCI may produce beneficial effects by reducing proinflammatory cytokines that are likely involved in the process of secondary injury, but detrimental effects by suppressing trophic factors such as nerve growth factor and glial-derived neurotrophic factor.

Erythropoietin and SCI

The cytokine erythropoietin (EPO), long known for its hormonal effects on bone marrow that sustain an adequate circulating red cell mass, has recently been recognized to function as a markedly potent and widespread endogenous molecule protective of multiple injuries in many tissues and mammalian species. Study has demonstrated robust protection of the spinal cord from ischemia, as well as mechanical injury in the rabbit, rat and mouse. EPO mediates protection via multiple, overlapping pathways, including reducing apoptotic cell death and secondary increases in proinflammatory cytokines, mobilizing endothelial progenitor cells to promote angiogenesis. An impressively broad therapeutic time window exists for a nonerythropoietic analogue administered in a multiple dosage regimen following compressive SCI and for a single dose of EPO administered intravenously at 5000 U per kg of bodyweight. With SCI produced by contusion, there is a temporal window for a single dose of EPO. Although an initial improvement is noted for animals treated with rhEPO with a delay of 24–48 h, this improvement is not maintained; the curve flattens, resulting in a final motor score no different from that following administration of saline. This observation suggests that a critical process occurs in the early phase following SCI which is not effected by subcutaneous EPO ultimately leads to a diminished motor function no different from that of saline-treated animals. Using a rat model of contusive injury, researchers determined the effect of EPO (500–5000 U per kg of bodyweight) administered by different routes and timing with respect to injury and of MPSS (30 mg per kg of bodyweight) for neurological outcome, proinflammatory cytokine production, and histological damage of the spinal cord. EPO (5000 U per kg of bodyweight) given intravenously, intraperitoneally, or subcutaneously reached equivalent serum levels only by 15 h, yet was equally effective when administered immediately following injury. This is consistent with a broad therapeutic time window. Although high-dose EPO and MPSS both suppressed the proinflammatory cytokines TNF, IL-1β, MIP-2, and IL-6 within the spinal cord, only EPO administration provided long-lasting neurological improvement; and suppression of inflammatory cytokines does not prevent the development of secondary injury. Surprisingly, MPSS antagonized the protective effects of EPO. This did not depend on reduced EPO receptor (EPOR) expression as EPOR was upregulated following injury whether or not MPSS was present. MPSS may suppress an EPO-mediated growth factor. These data suggest that MPSS should not be administered with EPO in clinical trials for SCI. EPO treatment also improved preservation of ventral white matter compared with saline-treated rats, and this is associated with a significantly increased number of oligodendrocyte precursors (OPCs), identified by NG2 expression. These findings are in line with previous observations that systemic delivery of rhEPO in an experimental model of autoimmune encephalomyelitis decreases demyelination and increases NG2-positive OPCs. Moreover, it has been shown that rhEPO promotes the formation of oligodendrocyte processes and increases the expression of myelin basic protein. Since OPCs are able to differentiate in myelinating oligodendrocytes both *in vitro* and *in vivo*, their enhanced proliferation likely contributes, together with reduction of apoptosis, to the restoration of oligodendrocyte and myelin density. The expression of Nogo-A, a myelin-associated protein containing domains with strong inhibitory activity of neurite growth that in adult CNS is mainly expressed in oligodendrocyte cell bodies and in the myelin membranes, is also affected by EPO in the injured cord. Nogo-A is concentrated at paranodes of myelinated fibers and contributes to the organization of the axolemmal-glial apparatus and to the segregation of potassium channels in juxtaparanodal regions. The remarkable reduction of Nogo-A labeling levels caused by injury reflects the severe structural alterations of myelinated fibers, while the better preservation of the ventral white matter in the rhEPO group is indicated by Nogo-A labeling levels comparable to those of sham-operated rats. In addition, rhEPO treatment not only attenuates astrogliosis but influences the expression of AQP4, an effect that may be beneficial for the resolution of the edema in SCI.

Stem Cell Administration to Spinal Cord Injuries

One of the main targets of research efforts on traumatic SCI is the transplantation of stem cells with the aim of supplying a favorable environment for the stabilization of the early pharmacological effects obtained with EPO, and possibly for axonal regeneration across the lesion, as some recent reports based on the use of chondroitinase ABC and anti-Nogo antibodies suggest. In most cases of CNS trauma and disease, both neurons and glia are lost. Cell replacement might be a vital step in CNS lesions, in which spared systems cannot supplant the function of lost cells. An excellent example is the loss of motor neurons in the case of injury to the

cervical spine. No matter how well the lesion is bridged or reinnervated, the target motor neurons that project to the muscles are irrevocably lost. Recognizing the need for cell replacement, several laboratories have taken advantage of fetal tissue grafts to replace cells after a variety of CNS insults. Somatic stem cells can be derived from fetal or adult stage in animal life and are tissue specific. The prevailing hypothesis on their physiological role is that they may constitute a reservoir of multipotent cells available for substituting aged or injured cells of the same tissue. Such a result has been shown in some instances, such as the cases of satellite cells in the regeneration of striated muscle, keratinocytes in skin growth, and bone marrow precursors in the generation of blood cells. Somatic stem cells are capable of active and powerful proliferative activity during an unlimited time. In this way, a constant number of progenitor stem cells is maintained throughout life and constantly employed, such as in the physiological replacement of skin and blood cells, or for a sudden need, as in the case of tissue repair. Thus some stem cells will proliferate and maintain the existing pool while others will undergo differentiation. It is still unclear what factors influence such a physiological choice of fate by stem cells lying in the same tissue, but several *in vitro* studies have suggested that the process might be regulated by both local and circulating factors. In the brain, transplanted bone marrow cells contributed to the population of cerebellar Purkinje neurons. These observations have disarmed long-held beliefs in lineage-restricted stem cells with a finite specialization repertoire. These lineage changes have been named 'cellular transdifferentiation' and represent a new life for the clinical interest in stem cell application. Work is under way to clarify whether transdifferentiation of stem cells occurs and is useful when these cells are applied to injured cord.

Neural Stem Cells

It is well known since Ramon y Cajal's pioneering work that injured neurons regrow the degenerated processes (axons and dendrites) rather than dividing into a new neural cell, as happens in other organs, such as liver. Thus the discovery that stem cells are present and proliferate under appropriate conditions in some brain areas represented a major scientific breakthrough. Once purified, neural stem cells (NSCs) show a high rate of cellular division and high proliferative activity. This type of cell has also been isolated and cloned using human brain as a source.

Skin-Derived Stem Cells

Skin-derived stem cells were transplanted into the cord of traumatic SCI-lesioned rats. The advantage of using skin-derived stem cells is that they represent a readily accessible source of neural progenitor cells that can be obtained without invasive procedures. These cells grow in a medium enriched with epidermal growth factor and acidic fibroblast growth factor (nonpermissive (NP) medium), and after 7 days form spheres that can be dissociated into single cells that gradually reform other spheres. The expression of nestin marker was maintained over 15 passages of spheres in NP medium. Single cells after adhesion on a laminin-coated dish have an asymmetric shape; 12% are positive for nestin, neurofilaments, and tubulin III; and more than 80% are positive for glial fibrillary acidic protein (GFAP). Cells dissociated from spheres grown in NP medium were injected into the gracilis and cuneatus fascicle 3 mm caudal or rostral or both to the impact site, performed at T9. Cells were transplanted within 30' of the impact or a week later. Within 3 days most of the transplanted cells migrated into the lesion site and were located at the most outer portion of the cavity, just in contact with the lesion scar. The early transplanted cells reversed their *in vitro* differentiation and became mac-1 positive cells with a macrophage-like cell shape (50% of total cells) within 1 week after transplantation, and at 90 days massive apoptosis was observed, as expected. The late transplanted cells differentiated into cells positive for GFAP (30%), neurofilament (18%), and platelet/endothelial cell adhesion molecule (PECAM; 2%). When immediately after transplantation animals were treated with EPO, the number of PECAM-positive cells increased to 14%, and several of them, as in the picture shown above, were, in continuity with nonexogenous endothelial cells, forming capillaries in the white matter and in the cavity at the site of injury. Whereas early transplants were totally ineffective on locomotor recovery as assessed with the Basso–Beattie–Bresnahan (BBB) scale, the late ones showed a small improvement that became significant 40 days after transplantation. When EPO was used with transplants, there was an immediate improvement of locomotion recovery that was significant as early as 4–7 days after transplantation and maintained thereafter.

Mouse NSCs were supplied within 24 h to the injured cord of mice by direct injection into the cord or via intravenous administration. The lesion was performed as described above for the rat, but the force was smaller, 40 g. The evaluation of the hind limb recovery of function was performed according to the BBB Ohio Scale for mice. Following the traumatic lesion, mice's ability of free locomotion by means of the hind limbs was temporarily lost; 4 days later a slow and gradual recovery began in saline-treated rats. In these animals the maximal extent of recovery (8 points on the BBB Scale) was achieved in 16–20 days. The intraspinal

injection of NSCs promoted a much faster recovery: a significant improvement (12 points BBB Scale) in 2 weeks. However when NSCs were supplied intravenously, the effect was earlier and greater. It must be born in mind that the intraspinal injection of NSCs is a second lesion. Cellular preservation was optimal, and none of the administered NSCs were GFAP-positive, even after 2–3 months of their application. The intravenous route of NSCs administration yielded a better recovery than the intraspinal one. About 2% of total intravenously administered NSCs homed in on the SCI site and survived almost undifferentiated; thus the positive effect of NSC treatment cannot be ascribed to damaged tissue substitution. The NSCs homing in on the injury site triggered within 48 h a local tremendous increase in the expression of neurotrophic factors and chemokines. These cells still maintained the ability to produce neurospheres 1 week after transplantation, when they were recovered from the lesion site and grown *in vitro*. Most NSCs were phagocytated by macrophages at a later time. The environmental modification of lesion site and the augmented expression of neurotrophic factors and chemokines by live NSCs may be the basis of the enhanced recovery of function. More recently, a new population of NSCs has been isolated that migrates to the site of SCI and transdifferentiates into cholinergic neurons bearing axonal and dendritic processes. These processes form throughout the lesion area a rich neuropile that constitutes a favorable environment for axonal regeneration, as shown by the abundant number of TH- and 5-HT-positive axons crossing the injury gap. This new achievement increases hopes of finding a proper cellular therapy for SCI.

Conclusions

Acute SCI-induced paraplegia may be prevented in experimental animals by administration of rhEPO within the 24 h, and the effect is secondary to the attenuation of secondary degeneration and improved myelination. The potential of somatic stem cells to transdifferentiate *in vivo* and to promote recovery when applied after traumatic injury of the spinal cord promises to revolutionize the treatment for such a terrible condition, one that is also extremely costly for public and family budgets. On the other hand, little is known about the mechanisms that regulate stem cell proliferation and differentiation, and a deeper knowledge of their physiological role is needed.

Spinal Cord Pain Systems

Initial Processing of Pain Signals by Nociceptors

Nociceptors

Neural responses that lead to the perception of pain commonly begin with the activation of nociceptors, which are sensory receptors that respond to stimuli that cause or threaten to cause tissue damage (Figure 1). Essentially all peripheral tissues, including skin, muscles, joints, and visceral organs, are innervated by nociceptors. Nociceptive primary afferents are generally supplied by unmyelinated or finely myelinated axons, although a few have Aβ fibers. Noxious stimuli can be mechanical, thermal, or chemical in nature or combinations of these. Transduction of noxious stimuli depends on the activation of protein molecules located in the cell membranes of nociceptors. Examples of such transducer proteins include several transient receptor potential molecules, such as TRPV1s, which respond to noxious heat, lowered pH, and certain chemicals (notably capsaicin), but not to mechanical stimuli, and TRPV2s, which respond to higher temperatures than do TRPV1 receptors but which do not respond to capsaicin or reduced pH. Other transducer proteins encode noxious cold, noxious mechanical stimuli, reduced pH, or a variety of noxious chemicals.

It should be noted that not all pain responses are triggered by the direct activation of nociceptive afferent neurons. Pain can also result more indirectly following damage to nervous tissue. Peripheral neuropathic pain may develop following damage to peripheral nerve, and central neuropathic pain from damage to any of several central nervous system structures, including the spinal cord, the brain stem, and the somatosensory portions of the thalamus or cerebral cortex. The mechanisms underlying neuropathic pain are still unclear but are under intense scrutiny.

Nociceptive Neurons in Dorsal Root and Cranial Nerve Ganglia

The cell bodies of nociceptive primary afferent neurons reside in peripheral sensory ganglia, including the dorsal root ganglia and some cranial nerve ganglia, such as the trigeminal ganglion. The cell bodies of nociceptors tend to be small or medium in size, and their surface membranes contain a variety of active proteins, including neurotransmitter receptor molecules that are also present on the terminals of the neurons in the central nervous system or in the periphery. Activity in the peripheral branch of the axon of a nociceptor will propagate into the appropriate ganglion and may invade the cell body. More important, the action potential will reach synaptic terminals within the central nervous system by way of the central branch of the ganglion cell. This results in the release of excitatory transmitters (such as glutamate, substance P, and calcitonin gene-related peptide) in the dorsal horn of the spinal cord (or medulla) that activate central nociceptive neurons, some of which project to the thalamus or other rostral brain areas and initiate higher-level processing of pain signals.

Nociceptive Neurons in the Spinal Cord and Brain Stem

Nociceptive Interneurons

Recordings from interneurons in the dorsal horn of the spinal cord (or in the pars caudalis of the spinal nucleus of the trigeminal nerve, often designated the medullary dorsal horn) can be used to demonstrate their responses to various types of peripheral stimuli applied to their receptive fields. Often, the interneurons selected have cutaneous receptive fields, favoring the application of well-controlled stimuli. However, in some studies, they are activated by less well-controlled stimuli applied to other tissues, such as a muscle, joint, or visceral structure.

Many dorsal horn interneurons receive a convergent input from different types of receptors supplying the same tissue and/or from several different tissues. In general, workers in the field of somatosensory physiology have classified dorsal horn interneurons on the basis of their responses to graded intensities of mechanical stimuli applied to the skin. Thus, some dorsal horn neurons respond just to input from low-threshold cutaneous mechanoreceptors. Such neurons are classified as 'low threshold (LT)' neurons. Other interneurons can be activated to some extent by low threshold mechanoreceptors but even more effectively by nociceptors. These have been termed 'wide dynamic range (WDR)' neurons. Still other interneurons are excited exclusively (or nearly exclusively) by nociceptors. These are called 'nociceptive-specific (NS)' or 'high threshold (HT)' neurons (Figure 2(a)).

Despite its widespread use, this classification scheme is deficient in several ways. One problem is that the actions of thermoreceptors are ignored. For example, there are neurons in the superficial dorsal

Figure 1 Sensory responses of a human and action potential responses of an unmyelinated C cutaneous nociceptor in a monkey to graded intensities of heat stimuli. In (a) are shown the time course of the pain ratings of the human to a series of heat stimuli. The skin temperature in degrees Celsius is plotted on the *y*-axis and time in seconds on the *x*-axis. The arrows indicate the times of onset and termination of the stimuli. The lower graph was recorded when the skin was normal and the upper graph after a mild burn (50 °C for 100 s). In (b) are peristimulus time histograms showing the responses of a C polymodal receptor that innervated the skin of a monkey subjected to the same stimulus regimen, including the mild burn. Note that the skin damage lowered the threshold and enhanced the responses of the nociceptor; that is, it caused peripheral sensitization of the afferent. The damage altered the pain ratings in a comparable way, resulting in primary hyperalgesia. CMH is C mechanoheat and CS is conditioning stimulus. Reproduced from LaMotte RH, Thalhammer JG, and Robinson CJ (1983) Peripheral neural correlates of magnitude of cutaneous pain and hyperalgesia: A comparison of neural events in monkey with sensory judgments in human. *Journal of Neurophysiology* 50: 1–26, used with permission from The American Physiological Society.

horn that respond to specific thermoreceptors (cold or warm receptors). These neurons are either left out of this classification scheme, or if the neurons have a convergent input from mechanoreceptors or mechanical nociceptors, they are classified on the basis of their responses to mechanical, but not to thermal, stimuli. However, their function may relate more to thermal than to mechanical sensation. Another defect in this classification system is that many nociceptive neurons are activated by stimulation not only of the skin but also of other structures, such as muscle, joints, or viscera.

Another approach to the classification of dorsal horn neurons is by application of cluster analysis. This involves the use of a cluster analysis technique, such as k-means cluster analysis, to separate the responses of a set of neurons according to their similarities to each other and to their differences from the responses of other sets of neurons (Figure 2(b)). The use of different intensities of mechanical stimuli applied to the skin leads to the demonstration of several clusters that resemble the sets of LT, WDR, and HT neurons already mentioned. It would theoretically be feasible to include also the responses of the neurons to other stimuli, such as thermal stimuli or stimuli applied to deep structures, to yield a more refined analysis. However, to do this, the mathematics becomes much more complex.

Nociceptive Spinal Reflex Circuits

Nociceptive spinal cord interneurons may participate either in motor circuits whose activity leads to spinal reflexes or in sensory circuits that signal pain by way of axonal projections that ascend to the brain.

The class of spinal reflex that is activated by nociceptive spinal interneurons is the flexor withdrawal reflex or flexion reflex. When a noxious stimulus is applied to the skin, as for example when a person steps on a tack, the limb directly affected by the noxious stimulus is flexed so that the limb is withdrawn from the stimulus. At the same time, the extensor muscles of the contralateral lower extremity contract in a crossed extension reflex, which functions to provide the increased postural support needed to prevent the individual from falling while the other lower extremity is flexed. Details of the pattern of reflex activity depend on the site of noxious stimulation, a phenomenon known as 'local sign.' The interneurons that participate

Figure 2 The classification scheme used for spinal cord neurons is based on the responses to graded intensities of mechanical stimulation. The stimuli were brushing (BR) with a camel hair artist brush, compression of the skin with arterial clips having two levels of grip force, the weaker causing a sensation of pressure (PR) when applied to human skin and the stronger (PI) causing overt pain but no visible damage. The final, most intense stimulus was squeezing (SQ) the skin with serrated forceps, a damaging stimulus. The three representative neurons whose responses are shown in the peristimulus time histograms in (a) were classified as low threshold (LT), wide dynamic range (WDR), and high threshold (HT) on the basis of their responses to the series of four mechanical stimuli (applied during the times indicated by the horizontal bars). The bar graphs in (b) show the response profiles of five classes of interneurons in the cervical spinal cord dorsal horn as determined by k-means cluster analysis, using the responses of these interneurons to the same four mechanical stimuli as in (a). The peristimulus time histograms at the bottom show the responses of representative interneurons that belonged to each cell class. From Sorkin LS, Ferrington DG, and Willis WD (1986) Somatotopic organization and response characteristics of dorsal horn neurons in the cervical spinal cord of the cat. *Somatosensory Research* 3: 323–338.

in the flexor withdrawal reflex are thought to include those activated by afferents known as the 'flexion reflex afferents.'

The flexion reflex is commonly used as a means of assessing responses to painful stimuli, either in the awake or in a lightly anesthetized state. However, since the flexion reflex occurs below a complete spinal cord transaction, it is clearly not a direct measure of pain sensation.

Projection Neurons

Spinal cord nociceptive neurons include not only interneurons but also neurons that project to a variety of targets in the brain (Figure 3). Several of these ascending spinal cord tracts have an important nociceptive component. These projection neurons are also generally classified as LT, WDR, or HT neurons, but in addition they can often be identified according to their projection targets. This can be accomplished in anatomical experiments by retrogradely labeling the neurons with a tracer substance that is injected into a site in the brain that receives synaptic terminals from the spinal projection neurons of interest, followed by retrograde axonal transport of the marker and its identification at the spinal cord level by an immunohistochemical staining procedure or by fluorescence microscopy.

Alternatively, the target of the axon of a projection neuron can be identified in physiological experiments by antidromic activation. This involves electrical stimulation of the axon terminals within the target structure and the recording of antidromically propagated action potentials from the vicinity of the cell body of the projection neuron. Antidromic activation is verified by several criteria: (1) the antidromic action potential occurs at a constant latency following repetitive stimulation; (2) antidromic action potentials can follow high frequencies of stimuli, unlike action potentials produced by orthodromic activation; and (3) orthodromic action potentials collide with antidromic action potentials over a predicted range of intervals.

Spinothalamic Tract

Clinical observations have suggested a prominent role for the spinothalamic tract (STT) in pain and in thermal sensations. There is also evidence of a role

Figure 3 Sensory projection systems that ascend from the spinal cord to the brain (ascending input) are indicated on the left side of the illustration. Primary afferent input involving Aβ mechanoreceptors (yellow arrows at the bottom right) ends in the dorsal horn and also projects by way of collaterals through the dorsal column to the dorsal column nuclei in the caudal medulla. The dorsal column nuclei then project contralaterally to the ventral posterior lateral thalamic nucleus (light orange arrow), and this nucleus in turn projects to the somatosensory cortex (orange arrows). Aδ and C afferents (shown by the maroon arrow at the bottom right) synapse in the dorsal horn. Projections to the brain (red arrows at the left) are to the brain stem reticular formation, thalamus, hypothalamus, and amygdala. Descending control systems (green arrows on the right) include the corticospinal tracts, forebrain projections to the periaqueductal gray (PAG) and rostral ventral medulla (RVM), as well as projections of the PAG, locus coeruelus and RVM to the spinal cord dorsal horn. From Willis WD and Westlund KN (2004) Pain system. In: Paxinos G and Mai JK (eds.) *The Human Nervous System*, 2nd edn., Amsterdam: Elsevier/Academic Press.

of the STT in tactile sensation. On the basis of the effectiveness of cordotomies placed in slightly different parts of the anterolateral quadrant of the spinal cord in producing a loss of cutaneous pain and temperature sensations, it has been suggested that the component of the STT that mediates thermal sensation ascends in the lateral funiculus just dorsal to that which mediates pain.

Neurons that give rise to the STT are concentrated in Rexed's laminae I and IV–VI, although some are also found in other laminae, such as lamina VII (the intermediate region) and IX (which is in the ventral horn; Figure 4).

There is a special, numerous set of STT neurons in the upper cervical segments. However, the receptive fields of these are very large and often bilateral, and so they are unlikely to signal the location of a discrete somatosensory stimulus. Similarly, a population of STT neurons in the intermediate region and ventral horn of the spinal cord that projects to the central lateral intralaminar nucleus of the thalamus have large receptive fields and are more likely to be involved in arousal and in attentional mechanisms than in the sensory discrimination of pain. By contrast, many of the STT neurons in the dorsal horn have relatively discrete receptive fields (sometimes as small as those of the mechanoreceptive neurons found in the dorsal column nuclei) and so could contribute to the localization of a painful stimulus applied to the body surface, such as a pin-prick. Although a number of laboratories have reported that neurons in lamina I of the spinal cord are generally of the HT variety, studies in our laboratory on the monkey spinal cord indicate that primate lamina I STT cells are usually of the WDR type. Furthermore, many WDR STT cells with cell bodies located in the deeper layers of the dorsal horn have dorsally extending dendrites that may reach laminae I and II (Figure 5(c)). Other deeply positioned STT cells are of the HT type (Figure 5(a)). Rarely, an STT cell is classified as an LT cell (Figure 5(b)).

Craig and his colleagues have observed that some lamina I STT cells can be activated by weak thermal stimuli, suggesting that these play a role in thermal

Figure 4 Projections of neurons of the spinothalamic tract and of the spinal nucleus of the trigeminal to the ventral posterior lateral and medial thalamic nuclei in a monkey. The site of injection of the retrograde tracer, cholera toxin subunit B, into the ventrobasal complex is shown in (a). Retrogradely labeled neurons concentrated in lamina I and in the deep dorsal horn are plotted in drawings of the trigeminal spinal nucleus (b) and of the cervical (C) and lumbosacral (L) enlargements ((c) and (d)). sensation. The axons of these lamina I STT cells ascend in the lateral funiculus of the spinal cord white matter in a position that is consistent with the location of the thermosensitive spinal projection to the thalamus.

The STT provides a prominent input to the ventral posterior lateral nucleus, and there are also terminations of spinal cord projections in the ventral posterior inferior nucleus, the posterior complex, and the intralaminar complex, particularly in the central lateral nucleus. There is a recent controversy about the thalamic nuclei in which lamina I STT cells terminate. Craig and colleagues suggest that most or all lamina I STT cells terminate in a newly defined nucleus termed by them the VMpo nucleus (posterior part of the ventral medial nucleus). However, several other groups, including ours, have been able to stimulate the axons of lamina 1 STT cells antidromically and to label such neurons retrogradely from the ventral posterior lateral nucleus (Figure 4), and thus we do not believe that the claims of the Craig group reveal a balanced picture of the spinothalamic input to the thalamus. Other reservations about the proposed VMpo nucleus by the laboratory of Edward Jones are based on anatomical considerations.

Postsynaptic Dorsal Column Pathway

The postsynaptic dorsal column pathway originates from neurons of the dorsal horn located in laminae IV–VI and to a lesser extent from neurons in the area near the central canal. The axons of these neurons enter the dorsal column (and also the dorsal part of the lateral funiculus) and ascend to terminate in the dorsal column nuclei (n. gracilis or cuneatus, depending on whether the cell of origin is below or above the midthoracic level, respectively).

Postsynaptic dorsal column neurons in cats or monkeys are generally classified as WDR neurons, and rarely as LT or HT neurons. However, in addition to mechanical stimulation of the skin, these neurons can often be activated by stimulation of visceral organs. For example, many postsynaptic dorsal column neurons in the lumbosacral spinal cord can be excited by noxious colorectal distention. Similar responses can be recorded from neurons in the nucleus gracilis and in the ventral posterior lateral thalamic nucleus, and these responses are nearly eliminated following transection of the fasciculus gracilis (Figure 6). This arrangement appears to be the

Figure 5 Primate spinothalamic tract (STT) neurons were injected intracellularly with horseradish peroxidase and later reconstructed histologically. Drawings of the soma, dendrites, and axons of three such STT cells are shown in (a)–(c), along with peristimulus time histograms of the responses of these neurons to graded intensities of mechanical stimuli. The receptive field of each is also shown on a drawing of the leg. The STT cells in (a), (b), and (c) were classified as high threshold, low threshold (LT), and wide dynamic range, respectively. The LT STT cell was one of very few recorded in our studies. Reproduced from Surmeier DJ, Honda CN, and Willis WD (1988) Natural groupings of primate spinothalamic neurons based on cutaneous stimulation: Physiological and anatomical features. *Journal of Neurophysiology* 59: 833–860, used with permission from The American Physiological Society.

explanation for the success of midline myelotomies at T10 in eliminating pelvic cancer pain in human patients, as described by Hirshberg, Nauta, and their colleagues.

Spinoreticular and Spinomesencephalic Tracts

There are abundant projections of spinal cord neurons to various parts of the brain stem reticular formation, including the medullary, pontine, and midbrain reticular formation (Figure 3). Particular nuclei in which these projections terminate in the medulla and pons include the dorsal reticular nucleus and the central nucleus of the medulla, the nucleus reticularis gigantocellularis and nucleus paragigantocellularis, and the nucleus pontis caudalis. The spinomesencephalic tract ends in several midbrain nuclei, including the nucleus cuneiformis, the periaqueductal gray, the parabrachial nuclei, and the superior colliculus.

Figure 6 The postsynaptic dorsal column pathway transmits visceral pain signals, and interruption of the dorsal columns can relieve pelvic cancer pain. The drawings of transverse sections of the spinal cord in (a)–(c) show the locations of midline myelotomies that interrupted the medial part of the dorsal column in three patients. The patient whose spinal cord section at T10 is shown in (a) experienced complete relief from colon cancer pain during a 3-month survival period. The patient whose lesion at T7 is shown in (b) had lung cancer and had incomplete pain relief, perhaps because the lesion did not extend sufficiently far bilaterally or was not rostral enough. The patient whose lesion is shown in (c) had several years of relief of pelvic cancer pain. On the left in (d) is a drawing of one surgical technique for midline myelinotomy. At the right is a drawing of the postsynaptic dorsal column pathway, including a primary visceral afferent nociceptor, an interneuronal connection in the spinal cord, a projection from a postsynaptic dorsal column neuron to the nucleus gracilis, and projection from the nucleus gracilis to the contralateral ventral posterior lateral (VPL) thalamic nucleus. From Willis WD and Westlund KN (1997) Neuroanatomy of the pain system and of the pathways that modulate pain. *Journal of Clinical Neurophysiology* 14: 2–31.

Recordings have been made from spinoreticular neurons identified by antidromic activation from the reticular formation, and such neurons have also been retrogradely labeled following injections of tracers into particular parts of the reticular formation. In general, spinoreticular neurons that end in the pontomedullary reticular formation are located in deep layers of the dorsal horn or in the intermediate region and medial ventral horn. Spinomesencephalic neurons are often located in the dorsal horn in positions similar to those of STT cells that project to the lateral thalamus.

Spinoreticular neurons may have restricted cutaneous or deep receptive fields or large, complex receptive fields. They are generally nociceptive, either WDR or HT neurons, but there are some LT spinoreticular

neurons as well. Similarly, neurons of the spinomesencephalic tract are usually WDR or HT neurons, often with complex receptive fields.

It has been suggested that neurons of the reticular formation that are excited by pathways ascending from the spinal cord can in turn activate thalamic neurons that contribute to arousal and to mechanisms of attention. However, the significance of such spino-reticulo-thalamo-cortical pathways has been questioned.

Spinolimbic Pathways

Several pathways ascend from the spinal cord to terminate in brain structures that belong to the limbic system, including the hypothalamus and the amygdala (Figure 3). The spinohypothalamic tract has two components that ascend either laterally or medially through the brain stem. The origin of these projections is neurons located in the superficial and deep laminae of the dorsal horn, as well as in lamina X. Terminals are found bilaterally. It is interesting to note that the axons cross the midline in the hypothalamus and descend into the posterior thalamus and then caudally throughout the entire longitudinal extent of the brain stem. Most of the spinohypothalamic neurons from which recordings have been made were nociceptive, either WDR or HT neurons, but a small fraction were LT cells. Other spinolimbic pathways include a continuation of the spinoparabrachial pathway to the amygdala (the spino-parabrachio-amygdalar pathway), as well as a direct spinoamygdalar pathway and several other projections from the spinal cord to the septal nuclei, the nucleus accumbens, and other limbic structures. Presumably these spinolimbic pathways participate in the motivational-affective components of pain responses.

Plastic Changes in Pain Responses

Peripheral and Central Sensitization

Strong noxious stimuli can alter the responsiveness of peripheral and central nociceptive neurons. For example, damage or inflammation can cause nociceptive primary afferent neurons to develop an enhanced responsiveness (Figure 1). This change is known as peripheral sensitization. Nociceptive neurons in the spinal cord dorsal horn can also develop increased responsiveness following a strong noxious stimulus. This process is called central sensitization.

Peripheral sensitization can involve the activation of transducer proteins, such as TRPV1, by the action of sensitizing agents, including inflammatory mediators such as bradykinin, prostaglandins, monoamines, neurokinins, and growth factors, on signal transduction cascades. Central sensitization is triggered by the synaptic release of neurotransmitters such as glutamate, substance P, and calcitonin gene-related peptide onto dorsal horn neurons. An increase in intracellular sodium concentration results both from the influx of sodium ions through the surface membrane by way of *N*-methyl-D-aspartate (NMDA) receptor channels and voltage-gated sodium channels, as well as by release of sodium from intracellular stores following the activation of metabotropic receptors. The increased sodium concentration activates signaling molecules, including nitric oxide synthase (NOS) and sodium/calmodulin activated protein kinase II (CaMKII). A downstream consequence is the phosphorylation of various proteins, including subunits of NMDA (Figure 7) and alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors.

This leads to stronger excitation of the affected central neurons by several mechanisms, including (1) increased responsiveness of NMDA (Figure 8(a)) and AMPA glutamate receptors; (2) reduced effectiveness of γ-aminobutyric acid and glycine actions

Figure 7 After an intradermal injection of capsaicin (CAP) into the rat foot, there is an increase in the amount of phosphorylated NR1 subunit protein of *N*-methyl-D-aspartate receptors in the lumbosacral spinal cord, as shown by Western blots. In (a) are immunoblots showing NR1 and phospho-NR1 protein 1/2 h after a vehicle injection (right lanes) in comparison with these proteins 1/2 h after CAP injection (left lanes). The bar graph in (b) shows the relative densities of the proteins. Note that phospho-NR1 increased significantly, but NR1 did not, following CAP injection. From Zou X, Lin Q, and Willis WD (2000) Enhanced phosphorylation of NMDA receptor NR1 subunits in spinal cord dorsal horn and spinothalamic tract neurons following intradermal injection of capsaicin in rats. *Journal of Neuroscience* 20: 6989–6997.

Figure 8 The responses of primate spinothalamic tract (STT) cells to iontophoretically released amino acid neurotransmitters are shown before (left column) and after (right column) the intradermal injection of capsaicin into the skin of the receptive field. The peristimulus time histograms in (a) show the responses of an STT cell to glutamate (GLUT) and to *N*-methyl-D-aspartate (NMDA). From Dougherty PM and Willis WD (1992) Enhanced responses of spinothalamic tract neurons to excitatory amino acids accompany capsaicin-induced sensitization in the monkey. *Journal of Neuroscience* 12: 883–894. The current monitors below each histogram indicate the current doses. The records in (b) are the effects of iontophoretically applied glycine and γ-aminobutyric acid (GABA) before and after capsaicin. Reproduced from Lin Q, Peng YB, and Willis WD (1996) Inhibition of primate spinothalamic tract neurons by spinal glycine and GABA is reduced during central sensitization. *Journal of Neurophysiology*. 76: 1005–1014, used with permission from The American Physiological Society.

on inhibitory amino acid receptors (Figure 8(b)); and (3) increased trafficking of AMPA receptors into the postsynaptic membrane. Central sensitization in the spinal cord can be compared to long-term potentiation in such brain structures as the hippocampal formation.

Behavioral Consequences of Sensitization

Peripheral sensitization is thought to account for the development of primary hyperalgesia following a strong noxious stimulus (see Figure 1). Central sensitization has been proposed to help account for secondary mechanical allodynia and hyperalgesia. These sensory changes have been well described in humans (Figure 9). Alterations in the excitability of primary afferent nociceptors have been demonstrated in both human and animal experiments, and changes in the responses of central nociceptive neurons to peripheral stimulation, including the responses of primate spinothalamic neurons, have been observed in animal

Figure 9 The spread of secondary hyperalgesia across the skin following application of a strong but localized noxious stimulus (such as a small burn or injection of capsaicin). The pain produced by this stimulus is transmitted to the contralateral side of the brain by nociceptive projection neurons that are activated by the stimulus. However, nociceptive circuits within the ipsilateral dorsal horn also transmit the signal to projection neurons at other levels of the spinal cord. These neurons undergo central sensitization, making them more responsive to inputs from normal skin. For example, application of a tactile stimulus in an area of skin several centimeters from the damaged area will now result in pain (tactile mechanical allodynia), and intense mechanical stimulation will now result in hyperalgesia. From Hardy JD, Wolff HG, and Goodell H (1967) *Pain Sensations and Reactions*. New York: Hafner.

experiments. Parallel changes in the behavioral responses of rats have also been reported. Secondary mechanical allodynia is of particular interest since this term describes a process by which touch becomes painful. Patients afflicted with this condition feel pain in response to contact with clothing or bedding. One mechanism by which a tactile stimulus can become painful would be an increase in the responses of WDR neurons to innocuous mechanical stimuli, with a resultant increase in action potential generation, leading to the transmission of pain signals to the brain.

Spinal Cord Regeneration after Injury: Bridging by Schwann Cells and Bioimplants

J W Fawcett, Cambridge University Center for Brain Repair, Cambridge, UK

© 2009 Elsevier Ltd. All rights reserved.

Why Are Bridges Needed?

Where a spinal cord injury completely transects the cord, the two stumps form a new glia limitans at their ends with a glial scar underneath it, and they then retract apart. With time after injury the cord distal to the injury atrophies, and the distance between the stumps gets larger. In the gap between the two stumps is cerebrospinal fluid with meningeal and other fibroblastic tissue. It is clearly impossible for axons from either stump to regenerate through this environment and into the other stump, which in human spinal cord injuries may be more than 1 cm away. In order for any axon regeneration to occur, a bridge of a material that can promote axon growth will have to be placed across the gap. Most spinal cord injuries are incomplete, which means that there is some spinal cord tissue running across the injury site. The nature and quantity of this tissue varies greatly depending on the injury. Most commonly, fracture dislocations of the cord are associated with injuries in which the gray matter in the center of the cord is lost but there is some white matter sparing around the outside. In other forms of penetrating injury, some gray matter remains and the outer white matter is damaged. In all cases, there is a lesion cavity. In cases of incomplete injury, axon regeneration could in principle occur through the remaining gray or white matter. However, in human cord injuries in which the injury may be 1 cm or more, to expect axons to regenerate for this distance through the scar tissue that is found on the perimeter of the lesion and then on down the cord may be unrealistic. Providing a bridge of axon growth-permissive material across the lesion core or cavity may provide a better chance of regeneration. The more complete the lesion, the more likely it is that it will need to be bridged if there is to be any chance of significant axon regeneration.

Bridge Principles: The On-Ramp, the Off-Ramp, and the Bridge

A bridge that promotes axon regeneration across a spinal cord injury has three zones. The bridge itself is the material that carries regenerating axons across the lesion site. At either end, the bridge interfaces with the damaged spinal cord. Here, the growing axons have to enter the bridge from central nervous system (CNS) tissue or exit the bridge to re-enter CNS tissue; these are known as the on-ramp and the off-ramp, respectively. It is useful to think of bridges in this way, but in reality motor axons enter the bridge from rostral and exit it caudally, whereas sensory axons need to regenerate in the other direction. The two ends of the graft therefore function as both an on-ramp and an off-ramp for different sets of axons. What properties do these three regions of the bridge require?

The bridge must support the long-distance growth of axons and guide those axons toward the off-ramp. After the axons have grown, it must allow the axons to be myelinated where appropriate and provide sufficient trophic support to allow the axons to survive. In order to perform these functions, it needs to either contain myelinating glia or promote their entry after axons have grown.

The on-ramp must attract sprouting axons to leave the environment CNS tissue adjoining the bridge and guide them into the bridge. It is therefore necessary that an inhibitory scar barrier is not induced between bridge and spinal cord. It is also desirable that there be some form of locally active molecule that will attract axons toward the bridge, such as a trophic factor.

The off-ramp is the most problematic part of bridge design. At this point, axons must leave the bridge environment, which is generally attractive to axons, and pass into the more inhibitory CNS environment, passing through the reactive glial environment that may have formed at the interface between bridge and spinal cord. In order to achieve this, it may be necessary to arrange for molecules, such as trophic factors, that attract axons to be present in the spinal cord just beyond the bridge.

What Properties Should a Bridge Have?

The properties desirable for a spinal cord injury bridge must satisfy the requirements described previously. The bridge must integrate into the spinal cord tissue on either side. If axons are to pass between the graft and the spinal cord over the on- and off-ramps, it is not desirable to have a scarlike boundary between the graft and spinal cord tissue. Different glial cell types often do not intermix, leaving a boundary of reactive tissue, as occurs to some extent when Schwann cells and astrocytes interface with one

another. A graft material that integrates seamlessly into the spinal cord stumps allowing axons to cross is preferred. The central part of the bridge must promote long-distance axon growth, provide trophic support, and should either contain myelinating glia or promote their entry from the stumps at either end. At the on-ramp end of the graft, it is necessary that axons are attracted toward the bridge. This can be accomplished if the bridge secretes trophic factors or other growth-promoting molecules. At the off-ramp end of the graft, it is necessary for axons to leave the usually very attractive environment of the graft and pass into the rather inhibitory environment of the injured spinal cord. This can be facilitated in cellular bridges if the bridge cells migrate from the bridge into the spinal cord through scar tissue, bringing axons with them. Providing an attractive cue such as a source of trophic factors in the spinal cord just beyond the bridge is helpful. Treatment of the boundary between bridge and spinal cord to break down scar tissue (e.g., by digestion with chondroitinase) or with cells that ease axons across the interface (e.g., olfactory glia) has enabled axons to grow out of bridges and back into spinal cord.

Schwann Cell/Peripheral Nerve Bridges

The idea of using peripheral nerve grafts to repair injuries to the CNS dates back to the pioneering experiments of Tello and Cajal. The rationale is that axons regenerate well after peripheral nerve injury, and transplanting this obviously permissive environment into the CNS might promote regeneration there. This concept was revived in the 1980s when Albert Aguayo, Peter Richardson, and Sam David used modern axon tracing methods to examine axon regeneration through peripheral nerve bridges transplanted into spinal cord injuries. They observed that many axons grew through the bridges. However, very few axons were able to cross the off-ramp to re-enter CNS tissue. Moreover, almost all the neurons whose axons had grown into the grafts had their cell bodies very close to the graft interface. These findings demonstrate the main problems with the technique. First, CNS axons usually show a substantial regeneration response only when cut close to their cell body. Second, regenerating axons will preferentially grow in the most permissive and attractive environment, and they will therefore not leave the attractive environment of a peripheral nerve graft to enter the inhibitory CNS environment found on the other side of the off-ramp. There have been many subsequent experiments in which peripheral nerve grafts or grafts containing purified Schwann cells have been transplanted. These experiments demonstrate a third problem: Schwann cells do not migrate out of grafts to mix with the astrocytic environment of the spinal cord but, rather, remain in a circumscribed area, with a sharp interface between themselves and reactive hypertrophic astrocytes. The interface between Schwann cell bridges and the spinal cord is therefore not unlike the interface between Schwann cells and astrocytes at the peripheral root entry zones, and these are also a barrier for axon growth from peripheral to central nervous system territory. Schwann cell grafts have been prepared in a number of ways. In many experiments, a cell suspension is injected into the injury site. This is the method usually used to introduce the cells into impactor lesions. For repair of a complete transection, the Bunge laboratory, which has provided much of the recent literature on Schwann cell transplantation, incorporates Schwann cells into a matrigel support and then inserts this into polyacrylonitrile/polyvinylchloride copolymer tubes into which the ends of the cord are inserted. There is some uncertainty about the survival of transplanted Schwann cells. After Schwann cell transplants, there are many Schwann cells in the treated area even months after implantation. However, it appears that many of these cells may be host Schwann cells which have been recruited in some way due to the transplant of exogenous cells.

Olfactory Glia Bridges

In order to overcome some of the previously described problems with Schwann cell bridges for spinal injury repair, several groups have investigated the use of olfactory glia as an alternative. The rationale for the use of these cells is that in the normal adult CNS new axons are constantly growing from the olfactory epithelium into the CNS at the olfactory bulb. The cells over which the axons grow and which carry them into the CNS environment are olfactory ensheathing cells. These cells share many characteristics with Schwann cells, including their ability to promote axon regeneration. However, they appear to integrate better with astrocytes and may have some ability to migrate in the adult CNS environment. Several laboratories have implanted these cells into spinal cord injuries with variable results. The cells are derived either from the olfactory bulb or from the olfactory epithelium. The most positive results come from Raisman's laboratory. They transplant the cells from semipurified cultures, scraped off the dish with their own matrix and then implanted. Long-distance regeneration of the corticospinal and other tracts with dramatic functional recovery is

reported in rodent models. Ramon-Cueto also showed that olfactory glial transplants could promote recovery in a complete transection model. In other laboratories, the results have been less positive, with limited cell migration and little axon regeneration. In all cases, the cells have been implanted into partial lesions of the cord, usually as a cell suspension. The reasons for the different outcomes are not clear. As with Schwann cell transplants, host Schwann cells are recruited to olfactory glial transplants.

Two groups implant olfactory cells into human patients as experimental therapies. Huang's group in Beijing implants cells derived from the olfactory region of midstage human embryos, whereas Lima's group in Lisbon implants adult olfactory epithelium. In neither case are there control groups, and it is not possible to make judgments about the efficacy of the treatments. A small controlled phase I safety trial of olfactory glial transplantation into human spinal cord injuries has been conducted in Brisbane. Initial results suggest that the transplants are safe.

Stem Cell Bridges

As it became possible to grow neural stem cells *in vitro*, and to direct their differentiation to some extent toward neurons or glia, experiments were performed grafting these cells into spinal cord injuries. The expectation that the cells would differentiate to replace the lost spinal cord tissue has not been fulfilled. However, in several cases the transplants have shown protective ability, with the lesions being smaller than in controls. Some axon growth into the grafts has been seen, but this has been fairly modest unless the cells have been modified to secrete neurotrophins. Some progenitor transplants have led to remyelination of axons, many of which are demylinated by spinal cord injuries. This approach has been followed by Keirstead's laboratory and developed with industry support, and clinical trials of the treatment are planned.

Noncellular Bridges

There has been considerable interest in designing bridges for spinal injury repair produced from bioengineered polymers. Degradable biomaterials have included collagen, fibronectin mats, alginates, and poly (glycolic acid)/poly (lactic acid) implants. Nondegradable materials have included PHEMA, PHPMA, polyacrylonitrile/polyvinylchloride copolymer, and carbon nanotubes. These materials have been variously seeded with growth-promoting cells such as Schwann cells and with cells secreting trophic factors.

Combinatorial Treatments to Make Bridges More Effective

The previous discussion shows that there are several problems that need to be solved before transplantation strategies for spinal injury will work. It is necessary to attract axons into the grafts, particularly those whose cell bodies are far away from the site of injury, to promote the growth of axons through grafts and particularly to encourage axons to leave the grafts over the off-ramp to re-enter the spinal cord tissue.

Neurotrophins have been used to encourage axons to grow into grafts and also to help them leave the grafts. The axons entering Schwann cell grafts tend to be mainly those belonging to neurons close to the injury site. Tetzlaff et al. enabled regeneration of axons cut farther from the cell body into a nerve graft by infusing brain-derived neurotrophic factor (BDNF) around rubrospinal neurons, showing that they could then regenerate their axons into a nerve graft placed far from the neuronal cell bodies. Cells grafted into spinal cord injuries have also been genetically modified to secrete trophic factors. Fibroblasts or bone marrow stromal cells secreting BDNF or NT-3 grafted into the cord attract large numbers of host Schwann cells and regenerating axons. Neurotrophin infusion has been used to partially overcome the problem of persuading axons to exit bridges and re-enter the spinal cord across the off-ramp region, with the infusion being made on the spinal cord side of the off-ramp. Implants of NT-3 secreting fibroblasts below spinal cord injuries have been successful in promoting the growth of axons through injuries. However, axons tend to grow into the attractive region of high neurotrophin concentration and not beyond it. A trail of implants placed at intervals down the cord is a possible strategy for inducing longer distance regeneration.

The bacterial enzyme chondroitinase digests the glycosaminoglycan chains of chondroitin sulfate proteoglycans. These proteoglycans are a major inhibitory factor in glial scar_tissue, and the glycosaminoglycan chains are responsible for much of their activity. Because there is intense glial reactivity in spinal cord injuries, and at the ends of peripheral nerve and Schwann cell grafts, the enzyme has been infused on the rationale that it would aid the growth of axons into grafts and their growth back into spinal cord tissue. Fouad et al. showed increased axon growth into and through Schwann cell grafts, and Houle et al. showed much increased regeneration of axons through peripheral nerve grafts and back into spinal cord tissue following chondroitinase treatment, in both cases with increased behavioral recovery.

Olfactory glia have been implanted at the interface between Schwann cell grafts and spinal cord tissue. The cells allowed larger quantities of axons to grow out of the grafts into the spinal cord.

Various signaling pathways are involved in promoting axon growth and regeneration. A number of experiments have shown that elevation of the cAMP level in neurons can increase the ability of their axons to regenerate in the spinal cord. This strategy was also used as an adjunct to Schwann cell transplantation, resulting in improved axon growth, sparing of spinal cord tissue, and greater functional recovery.

Future Perspectives

Repair of human spinal cord injuries will require bridging strategies. Successful bridges will probably combine cellular therapies with bioengineered substrates designed to orient and position the cells. Attention will also have to be given to trophic support of the axons, promoting myelination, and enabling axons to enter and leave the bridges. The result will be complex combinatorial implants. However, for the first clinical trials, simpler designs will be used. It is hoped that a matrix containing Schwann cells or olfactory glia, possibly combined with a strategy to help axons enter and exit the grafts, will be sufficient to produce measurable benefit.

Spinal Cord Regeneration and Functional Recovery: Strategies

Overall Strategies for Spinal Cord Repair

Spinal cord injury (SCI) disconnects the cord distal to the injury from descending motor inputs, and prevents ascending sensory information from reaching the brain. Lesions above the thorax also block sympathetic outflow, and the sacral parasympathetic output is affected in most patients. In addition, the local damage at the region of injury affects motor neurons and other spinal circuits at that level. Most spinal injuries are incomplete, so in the majority of patients some function in some of these modalities remains. The aim of spinal cord repair is to replace the functions that have been lost, and by doing so to allow the patient to regain as much useful function as possible. The patients' own priorities for return of function depend on their level of the injury. For patients with high cervical injuries affecting the diaphragm, the priority is to regain sufficient motor ability to get off the ventilator, while for patients with slightly lower C4–C5 injuries the priority is to regain some voluntary arm movement. For patients with thoracic injuries, who have normal arm and hand control, the priorities are very different, with sexual function and bowel and bladder control heading the list. There is no treatment at present that comes close to promoting complete repair of the damaged spinal cord. However, there are various interventions currently under development that will probably bring back some useful function to patients. The rationale for these interventions is described in this section, then more detail is provided later.

The earliest stage of intervention after SCI is to attempt to protect the cord from further damage. Considerable additional damage can be caused by unskilled handling of patients by emergency teams, but the standard of training and equipment is now excellent in most countries. Following injury, there is an extended period of lesion extension, with death of neurons and glia caused by excitotoxic, inflammatory, and other mechanisms. There has been a long search for effective neuroprotective treatments, but none is yet proven to be effective in human patients. The National Acute Spinal Cord Injury Studies (NASCIS) trial suggested that high-dose methyl prednisolone, if given within 8 h of injury, had some protective action. However, recent studies suggest that the benefits and adverse effects of this treatment are evenly balanced, and it is not used in many countries.

Axon regeneration is a major target for spinal cord repair. The potential benefits of promoting axon regeneration through and beyond spinal cord injuries are obvious. In current animal experiments axon regeneration has been seen for a maximum of about 4 cm. This could produce a useful motor improvement over three or four spinal segments below the injury. However, there is also a possibility that motor axons regenerating through an injury might connect to intraspinal circuits, leading to a relay of their influence further down the cord. The extent to which these intraspinal relay circuits are functional in the human cord is at present uncertain. For sensory axon regeneration, it is unlikely using present technology that axons can be made to regenerate as far as the sensory nuclei of the medulla. However, as with motor circuits, many sensory axons do not connect directly to the medulla, but make their first synapse close to the level at which they enter the cord, making it possible that information from regenerating sensory axons could be relayed to the brain.

Plasticity is an important target for spinal cord repair. Most spinal injuries are incomplete, leaving some axons passing through the lesion. Promotion of plasticity may therefore allow the remaining connections to have greater effects. Some indication of the potential of this form of treatment can be inferred by studying spontaneous recovery after spinal cord injury in young children. The spinal cord, as with most parts of the nervous system, has a period of great plasticity after birth, which becomes much reduced with maturation. Young children show much greater recovery after equivalent SCI than adults do, demonstrating the potential effects of greater plasticity on spinal cord injury.

In addition to biological treatments to enhance regeneration and plasticity, there will be a considerable part to play for prosthetic devices. Biological treatments are likely to have their greatest effect on the spinal levels just below the injury, so enhancing functions further below these levels may require prosthetic devices.

Protecting the Cord from Further Damage

The mechanisms that increase the size of spinal injuries over time are probably similar to those that expand the size of strokes and other injuries. Excitotoxicity, inflammation, mitochondrial damage, and

other mechanisms are involved. In parallel with attempts to develop neuroprotective strategies for stroke, treatments have been applied to spinal injury models. Following encouraging animal data, high-dose methylprednisolone entered trials with the NASCIS consortium. Some benefit was shown in those patients that received the treatment 3–8 h after injury. In some countries this became the standard of care, but in recent years adverse effects from the treatment have emerged, and in most countries the treatment is now not routinely given. Good preclinical data promoted a clinical trial of the *N*-methyl-D-aspartate (NMDA) receptor blocker gacyclidine, but this did not show clinical benefit. Potential anti-inflammatory and other treatments are undergoing preclinical development, but currently there is no treatment that is generally accepted to be useful for neuroprotection after SCI.

Axon Regeneration Strategies

After lesions in the spinal cord or elsewhere in the central nervous system (CNS) there is no long-distance axon regeneration, unlike in the peripheral nervous system (PNS), where axons can regenerate over long distances. At the site of injury a glial scar forms, and the abortive axon growth terminates in this structure.

Why Does Axon Regeneration Fail in the Damaged Spinal Cord?

Myelin inhibitory molecules Where the spinal cord is damaged, myelin is disrupted, and degenerating axons beyond the lesion also generate myelin debris. This debris is cleared very slowly compared with myelin clearance in the damaged PNS, and remains for months after the injury. This and other differences between PNS Schwann cells (which promote axon regeneration) and oligodendrocytes led to studies examining the effects of CNS myelin on axon regeneration. Myelin from several mammalian species is very inhibitory to axon growth, and removal of oligodendrocytes from the region around a spinal cord injury promotes some axon regeneration. Four types of inhibitory molecules have now been identified. Nogo-A is a member of the reticulon family and is found in oligodendrocytes and some axons. It acts on the Nogo-66 receptor and also on a currently unidentified second receptor. Myelin-associated glycoprotein (MAG) is one of the most plentiful myelin proteins and also has inhibitory effects via the Nogo-66 receptor and via gangliosides. Oligodendrocyte myelin glycoprotein (OMgp), a third myelin molecule, also produces inhibitory effects via the Nogo-66 receptor. The Nogo receptor associates in *cis* with p75, LINGO-1, and TROY to produce inhibitory signaling, much of it via the small guanine triphosphate hydrolase (GTPase) Rho. In addition ephrin-B3 is expressed on oligodendrocytes, inhibiting growth through interactions with Eph receptors on axons. There is therefore a plethora of inhibitory molecules on oligodendrocytes. Many experiments have modified inhibition from just one of these molecules and shown some axon regeneration, but the effects of multiple treatments are not yet established.

The glial scar Wherever the CNS is damaged a glial scar forms, first evident within hours of injury and developing over a period of weeks. Initially microglia, oligodendrocyte precursors, and astrocytes hypertrophy and multiply. Later meningeal cells from the surface or from major blood vessels enter to form a fibroblastic lesion core, which also contains vascular endothelial cells and inflammatory cells. Within this structure there are several inhibitory influences. In the glial tissue surrounding the lesion core several inhibitory chondroitin sulfate proteoglycans (CSPGs) are upregulated, produced by astrocytes and oligodendrocyte precursors. This, together with upregulation of tenascin, leads to a highly inhibitory extracellular matrix through which axons would have to regenerate. Astrocytes also upregulate inhibitory ephrin-B2 and EphA4. In the lesion core the meningeal cells express high levels of members of the semaphorin 3 family, and also slit proteins.

Axon growth ability Axon growth cone activity is influenced by the integration of many signaling pathways. Many of the inhibitory molecules act via the small GTPase Rho, which in turn has effects on the axonal cytoskeleton through the control of actin polymerization and depolymerization. However, there are also positive effects on axon growth which can come from neurotrophins, integrins, adhesion molecules, and other sources. To some extent inhibitory influences from the previously discussed molecules can be counteracted by growth-promoting effects of adhesion molecules and tropic molecules and vice versa. In the damaged CNS the environment surrounding axons is overwhelmingly inhibitory, with the various inhibitory influences overwhelming any growth-promoting effects. In addition, axons vary greatly in their ability to regenerate, with adult CNS axons exhibiting lower growth ability than embryonic axons. Also, some CNS axons regenerate better than others. For instance, in the spinal cord the central branches of sensory axons generally regenerate more vigorously than do other damaged axons.

Treatments to Promote Spinal Cord Axon Regeneration

Neutralizing myelin inhibitory molecules Historically, Nogo-A was the first inhibitory molecule to be discovered in the CNS, and treatments based on its neutralization are therefore well advanced. Many experiments have shown that administration of antibodies able to block the inhibitory effects of Nogo-A can promote the regeneration of axons in the damaged spinal cord, and can promote functional recovery. Only a small proportion of the cut axons have been seen to regenerate, and only for distances of between 1 and 2 cm, but this has been associated with substantial functional recovery. The most recent experiments have used two monoclonal antibodies that bind to the middle section of the molecule, which does not interact with the Nogo-66 receptor. These have been applied to macaque partial cervical injuries and have produced considerable functional recovery. Other Nogo-related treatments have focused on the Nogo-66 receptor and the part of the Nogo-A molecule that interacts with it. Thus a soluble form of the receptor and a peptide that competes with Nogo-A for binding to it both promote axon regeneration after spinal cord injuries. Signaling from the Nogo-66 receptor involves p75, TROY, and LINGO-1. Therapies based on these molecules have not yet been tested in spinal cord injuries.

Overcoming inhibition in the glial scar Much of the inhibition of axon regeneration in the glial scar comes from the various CSPG molecules that are upregulated after injury. The inhibitory properties of these molecules depend largely on the sulfated sugar glycosaminoglycan chains attached to the core proteins. Bacterial enzymes called chondroitinases digest these glycosaminoglycans into disaccharides, and this removes much of the inhibitory activity from the CSPGs. This strategy has been applied to rodent spinal cord injuries, resulting in a degree of axon regeneration comparable to that seen after anti-Nogo-A antibody treatments, with good return of function. Mice lacking expression of EphA4 exhibit enhanced axon regeneration after injury, but there are at present no reagents that can be applied to the injured spinal cord to neutralize Eph/ephrin mechanisms or semaphorin 3 inhibition.

Treatments affecting the regenerative ability of axons Many of the inhibitory mechanisms discussed in the preceding sections converge on a small number of signaling pathways, which in turn affect the activity of axon growth cones via controls on cytoskeletal motility mechanisms. There have therefore been attempts to affect axon regeneration by manipulating these signaling processes. Many of the inhibitory molecules signal through Rho, and blocking Rho from its effector kinase can therefore block inhibitory influences on axon growth. Rho kinase inhibitors and the bacterial Rho ribosylation enzyme C3 have been used for this purpose. The C3 enzyme has been attached to a cell-permeant peptide, allowing it to enter cells, and this compound, named Cethrin, has recently started clinical trials. During development the regenerative vigor of axons declines, and this is associated with a decrease in cAMP levels. Treatments that increase neuronal cAMP have enhanced axon regeneration in tissue culture models and in the damaged rodent spinal cord. Other signaling pathways in which intervention has led to axon regeneration in animal spinal injury models are conventional forms of protein kinase C and the epidermal growth factor (EGF) receptor, and the target of inosine, serine–threonine kinase (N-kinase). In addition to treatments affecting signaling pathways, axon regeneration has been promoted by the application of neurotrophins, which stimulate axon regeneration. Neurotrophins applied at the injury site or beyond it have increased the number of regenerating axons and have acted as chemotropic attractants, bringing axons through the injury site. Neurotrophins have effects both on axons and at the level of the cell body, where they induce expression of regeneration-promoting genes. Brain-derived neurotrophic factor (BDNF) applied to the cell bodies of descending spinal cord tracts has prevented neuronal atrophy and promoted axon regeneration.

Transplantation of permissive cells Axons regenerate over long distances after peripheral nerve damage in association with Schwann cells. This observation led to experiments in which peripheral nerve tissue and Schwann cells were implanted into the CNS, with the result that many CNS axons are stimulated to regenerate in this Schwann cell environment over long distances. Regeneration into these Schwann cell grafts has been considerably enhanced by increasing cyclic adenosine monophosphate (cAMP) levels. However, a problem is that these axons are unwilling to cross the sharp boundary that forms between the implanted Schwann cells and the CNS astrocytes, and to leave the Schwann cell environment and reenter the CNS. To some extent this problem has been solved by using olfactory ensheathing cells, which are similar to Schwann cells and promote CNS axon growth. These cells have some ability to mix with astrocytes and migrate from the transplant site into the host CNS. Regenerating axons are able to cross these transplants and continue on into the host CNS, in some cases with good return of neurological functions. A third strategy has been to transplant embryonic CNS tissue

into spinal cord lesions, on the rationale that axons grow in this environment during development. These transplants have promoted regeneration of various classes of CNS axon, again with return of function. This form of transplant has an added dimension, which is that the neurons in the transplant can receive inputs from regenerating host axons and grow their own axons into the host tissue, thereby acting as relays.

Bridging the gap Human spinal cord injuries can be large, with damaged tissue extending over more than one spinal level. Even the most common injuries due to fracture dislocation produce damage over 1 cm or so. In most human injuries the cord lesion is incomplete, with some remaining spinal cord tissue continuing across the lesion. Experience from animal studies shows that regenerating axons generally grow through this remaining tissue rather than through the fibroblastic lesion core. However, for all lesions, and necessarily for complete lesions, it may be necessary to provide a bridge of permissive material to carry axons across the lesion area. Schwann cells or olfactory ensheathing cells are the obvious candidates for this permissive bridging material. However, given the size and disorganization of the lesion it will probably be necessary to implant them in some form of matrix. Discussion of potential designs is beyond the scope of this article, but progress has been made with oriented fibronectin fibers and with self-aggregating peptide fibrils.

Promoting CNS Plasticity

Most spinal cord injuries are incomplete, leaving some axons passing through the lesion site. In over half of patients these carry some useful function. A potential form of treatment is to enhance the natural plasticity of the spinal cord so that these remaining connections increase their efficacy. A possible problem with this concept is that remaining axons induced to sprout might make inappropriate connections and produce maladaptive changes. As described in the following sections, the general finding is that this has not been a problem and that the spinal cord is able to make good use of the new connections, and function is improved. However, sprouting of small sensory axons induced by nerve growth factor (NGF) has been shown to produce enhanced pain sensitivity.

Decline in Plasticity with Age

A general feature of the CNS is that there is a period of great plasticity immediately after birth, known as the critical period. These critical periods terminate in rats at around 35 days after birth, and in humans around 5 years, depending on the brain area. During these critical periods the compensation for injury and functional recovery from various forms of CNS damage, including SCI, is considerably greater than in later life. It is therefore a reasonable treatment objective to attempt to return to the adult CNS the degree of plasticity that was present in the young. The factors that terminate critical periods are not well understood, and much of what is known comes from investigations into ocular dominance plasticity in the visual cortex. It is generally accepted that increased inhibitory influences from GABAergic inhibitory interneurons plays a part, but removing this inhibition results in epileptic attacks and so is not a practicable treatment option. Recently two other mechanisms have been discovered. At the time that plasticity terminates many neurons become surrounded by condensed extracellular matrix coats known as perineuronal nets (PNNs), which contain several inhibitory CSPGs together with tenascin and hyaluronan. Removal of these structures by digestion with chondroitinase or prevention of their formation results in enhanced plasticity. There is also evidence for an involvement of Nogo-A in plasticity, because anti-Nogo antibodies have been shown to promote spinal cord plasticity, and animals lacking the Nogo-66 receptor display prolonged ocular dominance plasticity.

Treatments That Enhance Plasticity

The adult CNS displays a degree of plasticity which allows some functional recovery after damage. Recently three interventions have been developed that enhance this process: chondroitinase, anti-Nogo-A antibodies, and inosine. Chondroitinase digests the glycosaminoglycan chains on CSPGs and also has activity against hyaluronan. Following chondroitinase treatment of the brain or spinal cord, many of the PNN molecules are removed. This treatment has been shown to return plasticity both to the visual cortex and the spinal cord. Following spinal cord injury, chondroitinase treatment led to a rapid improvement in sensory–motor performance, at least some of which must have been due to promotion of plasticity, and the treatment has promoted recovery in a model in which plasticity must have been the mechanism after peripheral nerve repair with inaccurate connection of the motor and sensory axons. Chondroitinase also promotes sprouting of sensory axons, but without producing hyperalgesia. Anti-Nogo-A was applied to animals with lesions of one corticospinal tract, leading to sprouting of the remaining tract across the midline. The antibody

also produced rearrangement of topography in the motor cortex and recovery of function in stroke models, presumably by promoting plasticity. Manipulation of the Nogo-66 receptor has also promoted sprouting, and prolonged visual cortex plasticity is seen in mice lacking the Nogo-66 receptor. Inosine, whose action is thought to be via N-kinase, was given to rats with partial spinal injuries and promoted both axon regeneration and sprouting, and recovery of function in a stroke model.

Rehabilitation Treatments and Plasticity

As with other conditions in which there is physical damage to the CNS, rehabilitation therapy can improve the abilities of patients. After spinal cord injury, patients usually receive intensive physiotherapy to maximize useful functions. There is also extensive experience of the beneficial effects of physical therapy in other CNS disorders such as stroke. These treatments probably work in part by stimulating and guiding plasticity in the CNS, allowing intact parts of the CNS to take over lost functions. Constraint therapy, in which strapping of the unaffected limb is used to improve function in a disabled arm after stroke, has this aim. It is probable that the effectiveness and speed of action of physical therapy could be improved by treatments, as described previously, that promote plasticity. There is direct evidence for this from the use of cortical stimulation to promote plasticity in stroke models coupled with rehabilitative therapy.

Prostheses and Other Devices

Regeneration and plasticity therapies of the type described in the preceding sections are starting to enter clinical trials, and will eventually become an accepted part of the treatment for spinal injury. However, it seems probable that they will have their maximum effect in the spinal levels immediately below the lesion. Moreover, there is currently no treatment under development that promises to induce a complete repair of a spinal cord injury. Patients will therefore continue to suffer from disabilities for which they require treatment. Alongside advances in regeneration and plasticity treatments have been advances in prosthetic devices designed to aid bladder, bowel, arm, and hand function and devices to aid with standing and walking. Discussion of these approaches is

Figure 1 Summary of the classes of treatment that have been developed to promote axon regeneration in the damaged spinal cord. Some treatments, such as bridge grafts and treatments affecting the glial scar, must be applied to the site of injury. Myelin inhibitors are found throughout the central nervous system as well as at the injury site, and need to be applied both to the injury and more distally. Neurotrophins exert a major part of their effect through changes in gene expression in the neuronal cell body, and have been most effective applied here as well as at the injury site.

beyond the scope of this article. However, advances in the field are being made, as are improved methods for interfacing microelectronics with the nervous system. It is probable that in the foreseeable future spinal injury treatment will involve both regenerative treatments and prosthetic devices.

Clinical Trials

Of the treatments that have been successful at promoting recovery of function after spinal cord injury in animal models, two have now begun clinical trials, the Rho inhibitor Cephrin and a humanized anti-Nogo-A monoclonal antibody. Other treatments are in late preclinical development. The development of new regeneration and plasticity-inducing treatments, which have been effective in animal models of spinal cord injury, has necessitated the urgent development of methods for conducting clinical trials. Because of the unpredictability of outcome soon after injury, the limited number of patients available, and the difficulties in assessment, the development of trial protocols is challenging. This area is beyond the scope of this article, and readers are referred to the report by Steeves, Fawcett, and Tuszynski of the first international meeting on clinical trial design in SCI that was held in 2004 in Vancouver, Canada.

Future Prospects

For many years there have been progressive advances in the basic science of axon regeneration and plasticity. These have now led to several treatments that have promoted functional recovery in animal models of SCI, and the first of these treatments have now entered phase I clinical trials. Over the coming years more treatments will reach this point, and information on efficacy will come from phase II and phase III trials, the methodology for which is currently under development. It is probable that some of these treatments will show efficacy and will become part of the standard treatment for the condition. A condition of the complexity of SCI will require more than one intervention for optimum treatment, and it will be necessary to find out how best to combine therapies. These efforts will be preceded by animal experiments on combination treatments. Alongside this will go advances in physical therapy, probably aided by treatments to promote plasticity, and the development of new prostheses.

Spinal Motor Neurons: Properties

H Hultborn, University of Copenhagen, Copenhagen, Denmark

The Motor Neuron

Spinal motor neurons are located in the ventral horn along the whole spinal cord, as well as in cranial motor nuclei. The large alpha (α-)motor neurons innervate skeletal muscle fibers (extrafusal fibers), whereas the smaller gamma (γ-)motor neurons (around 30% of the total number of motor neurons) innervate the intrafusal muscle fibers of the muscle spindles. Several of the large motor neurons innervating the extrafusal muscle fibers have now been shown to also innervate intrafusal muscle fibers. They are often referred to as β-motor neurons, although their properties are otherwise identical to the α-motor neurons. The dendritic tree of the α-motor neurons may extend for several millimeters, as can be visualized following the injection of markers through a recording microelectrode and subsequent reconstruction. The diameter of the soma region is only 50–100 μm. The spinal segments controlling the musculature of the limbs are thicker because of the many motor neurons and interneurons, as well as the extensive sensory information entering the segments from the limbs. The motor neurons innervating a given muscle are clustered in a motor nucleus, which can be seen as a specific area in a transverse section and as a cigar-shaped column along the rostro-caudal axis.

The Motor Unit

In the beginning of the twentieth century, Sherrington defined the motor unit as the "motorneurone axon and its adjunct muscle-fibres" and also described the idea of an orderly recruitment of such motor units in the control of a graded muscle contraction. The motor unit is, thus, composed of a motor neuron and the innervated muscle, as sketched in Figure 1(a). Each muscle cell is innervated by only a single motor axon in the adult animal, but each motor neuron innervates from as few as ten up to about 1000 muscle cells, depending on the muscle size and whether it is used in fine or coarse motor activities. Mammalian muscle cells are divided into slow- and fast-twitch muscle fibers. Indeed, they are usually divided into three classes: S (slow), FR (fast resistant), and FF (fast fatigue). Slow and fast refer to the contraction speed of the innervated muscle units; resistant and fatigable describe how the muscle unit contractility is sustained during prolonged activation. Based on the histochemical profiles and biochemical features of the muscle fibers, these three types are often referred to as slow oxidative (or type I), fast oxidative glycolytic (or type IIA), and fast glycolytic (or type IIB), respectively. All muscle fibers in a muscle unit are of the same type. It has been established that many parameters of the muscle unit depend on the innervation pattern by the motor neuron. Low-frequency discharges during prolonged periods of activity causes the muscle twitch to be slow and the muscle fibers to become resistant to fatigue when tested with long bursts of activity. Conversely, infrequent bursts of high firing frequency causes the motor units to become fast contracting and fatigue sensitive. This has been established by externally applying stimulus patterns to peripheral nerves and has been supported by experiments with cross-reinnervation of fast and slow muscles. It is thus established that motor neurons of different types (slow or fast) strongly influence the innervated muscle fibers with regard to their contractile properties (speed and endurance) and their associated biochemical profile. The degree to which a reinnervating motor neuron can reset the properties of all reinnervated muscle fibers can vary. Therefore, it may be more accurate to speak of an adaptive range of muscle properties which are susceptible to modification by the motor neuron. Some experiments also suggest that the good match between properties of the motor neuron and the reinnervated muscle fibers requires that the muscle fibers talk back to the innervating motor neuron to specify their intrinsic properties, influencing the motor neuron firing pattern. Thus, there is a mutual interdependency between the neuronal and muscular components in the motor unit.

Motor Neuronal Control of Muscle Force: Recruitment and Frequency Modulation

The output of the motor neuron is simple – all-or-none action potentials that are conducted to the end-plate region. Here the synaptic connection, with acetylcholine as the transmitter, is strong enough to ensure that each action potential in the motor neuron is causing one action potential in every connected muscle fiber (thus, the whole muscle unit) and thereby elicit a muscle twitch. The strength of muscle contraction therefore depends on how many motor neurons are activated (summation of muscle unit twitches) and the frequency of discharge (the higher the frequency, the more efficient the summation of the twitches within individual muscle units;

Figure 1 Drawings of the motor unit properties: (a) the motor neuron and its innervated muscle fibers (inset shows the summation of tension as the activation frequency increases); (b) motor unit properties for slow units; (c) motor unit properties for fast resistant units; (d) motor unit properties for fast fatigue units. In (b)–(d) the upper panels show that the size of the motor neurons is larger for fast than for slow units; the axons also have correspondingly a larger diameter for fast than for slow units. The profile of various enzymes is different for slow and fast fibers, as indicated by intensity of immunohistochemical staining of the muscle fibers (black > gray > white) for myofibrillar ATPase histochemistry (with alkaline preincubation, M-ATPase, related to fast contraction; with acid preincubation, Ac-ATPase, slow fibers are strongly stained; fast fatigue fibers are intermediately stained), oxidative enzymes (oxidative capacity, Ox), glycolytic enzymes (anaerobic capacity, Glycol). In (b–d) the middle panels show recordings of single twitches. Note the differences in peak amplitude as well as twitch time course. In (b–d) the lower panels show force maintenance with repetitive activation of the motor unit 0.33 s bursts of 40 Hz once per s for up to 1 h. ATP, adenosine triphosphate; EPSP, excitatory postsynaptic potential.

see Figure 1(a)). The recruitment order of motor neurons depends both on the intrinsic properties of the motor neurons as well as the distribution of the synaptic excitation projecting to them. The frequency of repetitive firing depends on the strength of synaptic excitation and on the intrinsic properties that convert the net excitation to a frequency code. The basic understanding that the muscle force depends on both the number of recruited motor units and their firing frequency goes back to the initial investigations by Adrian and Bronk in the 1920s.

Spike Threshold – Recruitment of the Motor Neuron

If an excitatory postsynaptic potential (EPSP) produced in the motor neuron is small, the movement of K^+ ions through leak channels is sufficient to restore the resting membrane potential; so the EPSP is seen to decay and no action potential is elicited. However, if the EPSP is larger, the K^+ ion leak cannot prevent the activation of voltage-dependent Na^+ channels. The Na^+ entry causes depolarization and activation of neighboring voltage-dependent Na^+ channels and forms a rapid positive feedback system underlying an explosive increase in Na^+ conductance. This transient Na^+ conductance underlies the all-or-none action potential and thereby causes the recruitment of the motor neuron into the motor output. The spike threshold (V_{th}) is therefore the membrane potential at which the inward Na^+ current (from Na^+ channels opened by the depolarization) just outweighs the outward currents (mainly the K^+ leak current) trying to stabilize the membrane potential by bringing it back to the resting membrane potential. If the concentration of Na^+ channels is high, only a smaller percentage need to open to reach the

point of balance between the inward and outward currents; thus, the V_{th} is lower when the number of Na^+ channels is high. Therefore, the part of the motor neuron with the highest density of Na^+ channels has the lowest threshold and is the location for spike initiation under physiological circumstances. Motor neurons have the highest Na^+-channel density within the initial segment (i.e., axon hillock). Therefore, even though the amplitude of the EPSPs are larger at the dendritic level, close to the synapse, the much lower threshold at the initial segment ensures that the spike is initiated at this place independent of the location of the excitatory synapses. When considering integration, this has the strategic advantage that it is a weighted sum of all synaptic input that determines whether the threshold will be passed and cause the recruitment of the motor unit.

It is obvious that the spike threshold is an important variable in deciding when a motor neuron is recruited into a motor task. The threshold depends on several parameters, including the speed at which the depolarization occurs. If the depolarization is slow and ramplike, it causes the Na^+ channels to open, but the opened channels also have time to inactivate. This accommodation causes an increased V_{th} (i.e., threshold is at a more depolarized membrane potential). It has been demonstrated that different motor neurons have different spike thresholds. Thus, the V_{th} is lower for motor neurons supplying slow muscle fibers than for those innervating fast muscle units (Table 1), which facilitates the recruitment of small slow units before large fast ones. For many years, aside from accommodation already described, the spike threshold was considered to be a fixed parameter for a given motor neuron. Therefore, it came as a surprise when it was discovered that V_{th} could be lowered in a state-dependent manner, as illustrated in Figure 2. In this example, V_{th} moved from −46 mV at rest to −55 mV during fictive locomotion elicited by the stimulation of the mesencephalic locomotor center (MLR) *in vivo*. This finding has subsequently been confirmed during motor activity in brain stem-attached *in vitro* preparations. It was determined that the lowering of V_{th} can be induced through a neuromodulatory action of monoamines, most likely accomplished by hyperpolarizing the voltage dependency of fast Na^+ channels.

Table 1 Properties of motor neurons

	S	*FR*	*FF*
Muscle unit properties			
Twitch contraction time	+++	+	+
Fatigue resistance	+++	++	+
Aerobic capacity	+++	++	+
Anaerobic capacity	+	++	++
Isometric force (twitch)	+	++	+++
Motor neuron properties			
Membrane area	+	++	+++
Conduction velocity	+	++	+++
Membrane resistivity, R_M	+++	+	+
Voltage threshold, V_{th}	+	++	+++
Rheobase current	+	++	+++
AHP duration	+++	+	+
Synaptic input			
Monosynaptic Ia EPSP	+++	++	+
Cutaneous and red nucleus EPSP	+	++	++
Cutaneous and red nucleus IPSP	+++	+	+

AHP, afterhyperpolarization; EPSP, excitatory postsynaptic potential; FF, fast fatigue; FR, fast resistant; IPSP, inhibitory postsynaptic potential; S, slow.

Firing Frequency Is Controlled by Summed Synaptic Input and the Postspike Afterhyperpolarization

Following recruitment, the motor neuron can respond to suprathreshold excitation with a train of action potentials. As discussed earlier, the frequency of the resulting firing can encode the strength of the synaptic excitation, and an increased frequency enhances the summation of the force produced by repetitive twitches (Figure 1). The postspike afterhyperpolarization (AHP) has a key function in transducing the summed result of processed synaptic input into a variable spike frequency. In the case of sensory axons, Adrian and Zotterman concluded as early as 1926 that the "... regular rhythm could be explained as the natural consequence of the refractory period and the subsequent return of excitability." It was known even then that stronger excitation of a sensory neuron overcomes its refractoriness and results in a higher spike frequency. In 1929, Adrian and Bronk extended the observations to motor axons and wrote, "... The likeness between the impulse discharge from a sense organ and that from a motor nerve cell suggests that both are due to some property common to axon or dendritic terminations in general." The direct demonstration of refractoriness in motor neurons did not occur until many years later, when it was uncovered by intracellular recording as the postspike AHP by Eccles and co-workers in the early 1950s (Figure 3(a)). They also compared the duration of the AHP in different types of motor units (slow and fast) and suggested that "... since it seems likely that the frequency of repetitive discharge from motor neurons is controlled by the AHP, durations of the AHPs are matched to the twitch durations of muscle." To further advance the understanding of the transduction process in the motor neurons, Granit, Kernell, and co-workers used current injections through the recording microelectrode to mimic synaptic currents (Figures 3(b) and 3(c)).

Figure 2 Lowering of voltage threshold for the production of action potentials during locomotion: (a) trial for a hip extensor motor neuron (bars labeled *b* and *c* denote the time periods expanded in panels (b) and (c)); (b) voltage threshold for the production of action potentials (V_{th}) before fictive locomotion; (c) voltage threshold for the production of action potentials (V_{th}) during fictive locomotion. Firing was elicited in lumbar motor neurons by intracellular current injection, prior to and during fictive locomotion evoked by stimulation of the mesencephalic locomotor region. In the trial in (a), a 50 nA ramp of current was injected, after which the brain stem stimulation was started (indicated by the bar under the ENG trace). Fictive locomotion was evident as rhythmic activity that alternated between extensor and flexor electroneurograms (ENGs, flexor not illustrated). Discontinuous current clamp recording allowed accurate measurement of the membrane potential during simultaneous current injection. As shown in (c), during fictive locomotion, less current was required to fire the neuron (compare current at the pluses (+) in (a)) and the V_{th} was hyperpolarized compared to (b). Note that the neuron fired at 29 Hz before locomotion and at 59 Hz at the same membrane potential during locomotion (see bracketed areas). ENG, electroneurogram; MLR stim, mesencephalic locomotor center stimulation. From Krawitz S, Fedirchuk B, Dai Y, Jordan LM, and McCrea DA (2001) State-dependent hyperpolarization of voltage threshold enhances motoneuron excitability during fictive locomotion in the cat. *Journal of Physiology* 532: 271–281.

Figure 3 The postspike afterhyperpolarization and relation between injected current and firing frequency: (a) a single action potential with the subsequent afterhyperpolarization; (b) repetitive firing in a motor neuron with intracellular current pulses of increasing amplitude; (c) relation between injected current and firing frequency.

The relation between injected current (I) and the resulting firing frequency (f) typically had a slope of 1–2 imp/s/nA for a relatively long linear segment, which was subsequently named the primary range. In some cases, large current injections reached a level where a steeper linear slope was seen; this was called the secondary range. It was typically seen when the spike frequency reached ~50 imp s^{-1}.

The AHP is caused by a K^+ current ($I_{K,Ca(SK)}$) that is elicited by Ca^{2+} entry during the action potential. The time course and properties of the AHP seen after individual action potentials can explain much of the I–f relation, especially for the primary range. Accordingly, when the AHP amplitude is reduced by pharmacological means or by applying neuromodulators, the f/I slope becomes steeper. With the stronger depolarizing currents needed to reach the secondary range, persistent inward currents are activated. They effectively boost the current injected through the recording microelectrode and therefore contribute to the steeper f/I slope of the secondary range.

The minimum rate for a repetitive discharge is lower for slow motor units than for fast ones, and this is directly related to the longer duration of the AHP in slow motor neurons. There is no real difference in the f/I slopes between slow and fast motor neurons, although the rheobase is much lower for the slow units which are recruited before the fast units. With long-lasting constant current pulses, there is an evident adaptation of the firing frequency; that is, the frequency is highest in the beginning (especially for the first interspike interval) and gradually decreases during the train. The explanation for this early adaptation is mainly an enhancement of AHPs which delays following spikes. However, a progressive increase in the spike threshold (V_{th}) caused by partial Na^+ conductance inactivation may also contribute to the adaptation. Following longer-lasting repetitive discharges, a late adaptation is seen. There is evidence that an electrogenic Na^+–K^+ pump causing a hyperpolarization may contribute to this late adaptation.

The Influence of Dendrites on Synaptic Excitation and Inhibition

The dendritic tree of an α-motor neuron may extend for several millimeters, whereas the diameter of the soma region is only 50–100 μm (Figure 4(a)). The number of synaptic boutons is estimated to around 100 000, probably originating from around 10 000–20 000 presynaptic neurons. The dendritic membrane area accounts for around 97% of the total area, and the dendrites receive synapses over their entire length. Thus, the dendrites have large effects on the electrical properties of the motor neuron and influence the synaptic potentials as they spread from the dendritic synaptic sites to the initial segment where the action potentials are elicited (see the section titled 'Spike threshold – recruitment of the motor neuron'). The influence of the dendrites was first addressed by Rall in the 1950s. He found that the change in membrane potential resulting from a current pulse injected into the soma (through the recording microelectrode) did not follow a single exponential, as would be expected by a simple model of the membrane having a resistance and capacitance in parallel (an RC network). He demonstrated that the faster transients could be explained if the cable properties of dendrites were taken into account. He subsequently studied the effects of dendritic cable properties on synaptic potentials and synaptic integration. As illustrated in

Figure 4 Dendtritic tree and models of nerves: (a) motor neuron visualizing the extensive dendritic tree; (b) diagram of the simple circuit model of a nerve membrane (insert: the RC circuit) and the Rall model of the dendritic tree mathematically transformed into an equivalent cylinder of five or ten equal compartments; (c) simulated EPSP shapes (as seen from the soma) as the same excitatory conductance transients were applied to different dendritic compartments. EPSP, excitatory postsynaptic potential; RC, resistance and capacitance. (b,c) From Rall W (1964) Theoretical significance of dendritic tree for input–output relation. In: Reiss RF (ed.) *Neural Theory and Modeling,* pp. 73–97. Stanford: Stanford University Press.

Figures 4(b) and 4(c), the depolarization seen at the soma was not only smaller but also slower when the same conductance was simulated at increasing distances from the soma. The attenuation may be smaller than expected because the membrane resistivity (R_m) is likely to be much higher at the distal dendrites than at the soma. Furthermore, the attenuation illustrated in Figure 4(c) was calculated for passive dendrites. However, as we describe in the next section, motor neurons contain voltage-dependent noninactivating inward currents that can amplify the summed net depolarization in the dendrites and therefore boost the passive spread from the dendrites to the soma/initial segment.

The Role of Persistent Inward Currents in Amplifying Synaptic Inputs

The classic view of the mammalian motor neurons, which emerged from the laboratories of Eccles and Granit in the 1950s and 1960s, was that the membrane was essentially passive in its areas of synaptic contact (i.e., largely in the dendrites). As a result, the relation between a motor neuron's synaptic excitation and its firing frequency was initially thought to be determined solely by the cell's postspike AHP. When Schwindt and Crill discovered in the late 1970s that motor neurons could display prolonged plateau potentials and self-sustained firing, it certainly opened new horizons in the exploration of motor neuron function. They demonstrated that plateau potentials were due to voltage-dependent, noninactivating Ca^{2+} currents. Compared to steady-state outward currents, the persistent inward currents were large enough to produce a maintained shift in the membrane potential (i.e., the plateau potential). In their experiments, penicillin and tetraethylammonium were used to block outward Cl^- and K^+ currents, respectively, thereby uncovering the inward Ca^{2+} current. A few years later, the Copenhagen group (Hultborn, Hounsgaard, Kiehn, and co-workers) continued the analysis of self-sustained discharge, including its mechanisms and function. The phenomenon, its dependence on physiological transmitters (monoamines), and its cellular mechanisms were unraveled in a series of experiments conducted initially in *in vivo* cat preparations and, subsequently, using an *in vitro* preparation of the turtle spinal cord. In addition, it is now established that a persistent Na^+ current also contributes to plateau potentials in mammalian motor neurons and that not only monoamines but a number of physiological transmitters can facilitate the appearance of plateau properties. Such neuromodulation may be accomplished by reducing outward currents and/or augmenting the persistent inward Ca^{2+} and Na^+ currents. Figure 5 illustrates how the persistent inward current manifests itself in current-clamp mode when activated by current injection through the recording microelectrode. Short depolarizing current pulses (Figure 5(a)) may trigger repetitive firing that outlasts the stimulating current pulse (i.e., self-sustained firing). Alternatively, persistent inward current can cause a sudden acceleration of the firing frequency seen during a linearly increasing ramp of current injection. When the threshold for the persistent inward current is reached (arrows in Figures 5(b) and 5(c)), there is a noticeable jump in the firing frequency. With triangular current pulses sufficient to activate the persistent inward current (Figure 5(b)), the firing frequency remains higher during the downslope of the current injection because the frequency is supported by the additional persistent inward current. This phenomenon is apparent as a counterclockwise hysteresis of the *f*/*I* relation (Figure 5(c)). When action potentials are blocked, the persistent inward current manifests itself as a sustained membrane depolarization (i.e., the plateau potential; Figure 5(d)) and a counterclockwise hysteresis of the *V*/*I* relation produced by a triangular current pulse (Figures 5(e) and 5(f)). Voltage-clamp recording *in vivo* and *in vitro* have greatly enhanced the analysis of the voltage dependency and the dynamics of the persistent inward currents. It has also yielded better evidence for the localization of these currents over the soma-dendritic membrane. Several lines of evidence suggest that the main origin of the persistent inward currents is dendritic. Therefore, dendritic synaptic inputs have a more direct access to the voltage-sensitive noninactivating Ca^{2+} and Na^+ channels underlying the persistent inward current than the current injected through a microelectrode located in the soma. Thus, synaptic current is more effective in turning the persistent inward current on and off than are currents injected experimentally into the soma through the recording microelectrode. It is likely that in normal conditions the persistent inward current is not an all-or-nothing phenomenon but rather might be activated regionally in the dendrites in a graded fashion determined by the local depolarization in the vicinity of the active synapses. That would optimize the conditions in which this persistent current can act as an amplifier for synaptic inputs.

Recruitment Order Is Controlled by Intrinsic Motor Neuron Properties and Synaptic Organization

As was first described by Denny-Brown in the late 1920s, small (slow-twitch) motor units are recruited before large (fast-twitch) ones. In the 1960s, Henneman and collaborators confirmed these observations in a large number of studies and also demonstrated

Figure 5 Signs of plateau potentials recorded in spinal motor neurons; sustained shifts in excitability triggered by depolarizing and hyperpolarizing currents injected intracellularly into cat spinal motor neurons in a decerebrate, unanesthetized preparation: (a) sustained repetitive firing in a motor neuron, which was initiated by a short depolarizing current pulse and terminated by a short hyperpolarizing pulse; (b) firing pattern and membrane potentials during injection of triangular current pulses (spike activity in a motor neuron (upper trace) and triangular profile of its injected current (second trace)); (c) graph of (b); (d) sustained repetitive firing in a motor neuron following an injection of QX 314 to block Na^+ channels; (e) firing pattern and membrane potentials during injection of triangular current pulses (showing the membrane potential without spikes); (f) graph of (e). In (a,b) and (d,e), the upper traces are intracellular recordings and the lower traces indicate the amount and timing of the injected current. In (b) the interrupted vertical lines point to the difference in firing frequency at similar current intensities during the ascending and descending phase; the interrupted horizontal line shows the zero level for injected current. In the graph in (c), the thin lines approximate the *f/I* slopes for Kernell's primary and secondary ranges of firing. Note the counterclockwise hysteresis. Modified from Hounsgaard J, Hultborn H, Jespersen B, and Kiehn O (1988) Bistability of alpha-motoneurons in the decerebrate cat and in the acute spinal cat after intravenous 5-hydroxytryptophan. *Journal of Physiology* 405: 345–367; Bennett DJ, Hultborn H, Fedirchuk B, and Gorassini M (1998) Synaptic activation of plateaus in hindlimb motoneurons of decerebrate cats. *Journal of Neurophysiology* 80: 2023–2037.

that derecruitment proceeds in the reverse order. As small (slow-twitch) motor units also have smaller-size motor neurons than large (fast-twitch) ones, they described the small-to-large recruitment order as a consequence of motor neuronal size, now known as the size principle. Inherent in this concept was the idea that somehow the anatomical size of motor neurons reflected their excitability. Indeed, less current is needed to bring the small S motor neurons to discharge (lower rheobase). However, if synaptic density and distribution over the membrane are the same for small and large motor neurons, size *per se* could not explain orderly recruitment. But size seems to correlate with other parameters of direct influence on excitability. For instance, the membrane resistivity, R_M, seems to be higher in type S than in types FR and FF motor neurons (Table 1). In addition, the absolute voltage threshold for the action potential seems to be lower in type S than in types FR and FF motor neurons (see Table 1). These built-in features in the motor neuron pool could account for motor units being recruited in a force-related manner (from small type S to large type FR and, finally, type FF) even under conditions of equal synaptic density and efficacy across the motor neuron types.

These findings do not exclude the possibility that variation in the distribution of synaptic inputs among the different motor neuron types of a given pool play an additional role for the orderly recruitment. Indeed, the evidence favors that the preferential projection from (for example) the monosynaptic Ia excitation from muscle spindles fortifies the recruitment order from type S to FR and FF. Exceptions to the normal recruitment order have been described, for example, a selective recruitment of fast motor units during the extremely fast movements seen with paw shake (activated in the cat when the paw is wetted). Synaptic inputs to motor neurons from skin afferents and the rubrospinal tract produce inhibition in motor neurons supplying slow-twitch motor units

and excitation to those innervating fast-twitch ones. The use of such pathways may explain the reversed recruitment order. There has been much discussion concerning to what extent this deviant projection pattern might change orderly motor-unit recruitment. Such a differential distribution of synaptic inputs not only changes the recruitment order but – perhaps more important – also the ease of graded recruitment (i.e., the recruitment gain in a motor neuronal pool). This argument is further illustrated in Figure 6. A motor neuron may be said to have an intrinsic excitability, here operationally defined as the amount of injected current required to discharge the motor neuron in the absence of background synaptic activity. At any given moment, the ability of a motor neuron to generate an action potential depends on both its intrinsic excitability and the sum of its synaptic inputs. If the distribution of some synaptic inputs deviate (pool bias) from the common drive (pool drive), the pool bias might expand or compress the range of functional thresholds among the motor neurons. This changes the ease with which a uniformly distributed excitatory system (pool drive in Figures 6(a)–6(c)) activates the pool. More precisely, the term recruitment gain has been used to indicate the relation between the intensity of the synaptic input (drive) to a motor neuron pool and the output from that pool (i.e., the number of active cells). It predicts that a biasing input (with the distributions to low- and high-threshold motor units different from that of the drive input) will indeed change this gain (Figure 6(d)). There is some experimental evidence, both in the cat and in humans, supporting this reasoning.

Intrinsic Motor Neuron Properties Are Controlled by Neuromodulators

Specific control of the timing of motor neuronal activity in relation to execution of movement is relying on fast ionotropic receptors at excitatory (mainly glutamate as the transmitter) and inhibitory (mainly glycine and γ-aminobutyric acid (GABA) as transmitters) synapses. However, more long-lasting and general control of motor neuronal excitability in relation to the sleep–wake cycle, exercise level, and affective state is mediated mainly by metabotropic receptors (mainly amines and peptides). These modulatory actions are mainly exerted by acting on intrinsic mechanisms, thereby indirectly changing the overall behavior of the motor neuron. In the preceding sections, we describe a number of functions that depend on specific voltage-dependent ionic channels, which build up the intrinsic response properties of the motor neurons. They include (1) the transient Na^+ channels ($I_{Na,t}$), responsible for the voltage threshold and the depolarizing phase of the action potential; (2) K^+ channels ($I_{K,Ca(SK)}$), causing the postspike AHP and thus controlling the relation between net synaptic excitation and firing frequency; and (3) persistent voltage-dependent noninactivating inward currents (Ca^{2+}, $Ca_v1.3$, and Na^+ channels), underlying the plateau potentials and serving to amplify synaptic inputs. These are only a few examples; there are many more. Here we briefly mention the following:

1. The leak currents I_{leak} (mainly K^+ currents) that stabilize the resting membrane potential at rest.

Figure 6 Testing the recruitment gain hypothesis, which concerns changes in recruitment gain produced by conditioning volleys with a non-uniform distribution to the pool (pool bias), which differs from the orderly distribution of the test volley (pool drive): (a) diagram showing inputs (pool drive and pool bias) to a motor neuron pool (with early- and late-recruited motor neurons shown as small and large, respectively); (b) recruiting of the motor neurons by the test volley in the normal orderly manner, from slow (low-threshold) to fast (high-threshold) units; (c) the addition of a conditioning volley (pool bias) that inhibits slow motor units and facilitates fast ones; (d) diagram illustrating the relation between the test volley and the number of recruited motor neurons in the control situation (as in (b)) vs. sural nerve stimulation (i.e., a pool bias-conditioning stimulus, as in (c)). As shown in (c), when a conditioning volley is added, the test volley still recruits motor neurons in the same order but within a smaller range of the test volley. This is seen as a compression of the excitability spectrum. The recruitment gain is increased because a smaller increment of the test volley is needed to recruit successive motor neurons. Modified from Hultborn H, Brownstone R, Toth TI, and Gossard JP (2004) Key mechanisms for setting the input-output gain across the motoneuron pool. *Progress in Brain Research* 143: 77–95; unpublished material by JB Nielsen, H Hultborn, and J-P Gossard.

2. A number of K^+ channels activated by depolarization that contribute to the rapid repolarization of the action potential.
3. A K^+ current (I_{Kir}) activated by hyperpolarization and referred to as an inward rectifier.
4. A mixed Na^+ and K^+ current (I_h) activated by hyperpolarization that produces a slow depolarization of importance for rhythmic behavior (i.e., a pacemaker potential).

All these voltage-dependent ion channels seem to be controlled by neuromodulators. The serotonergic system, in particular, is important for two reasons: much is known about the mechanisms underlying the actions of serotonin at motor neuronal level, and there is an emerging knowledge on the relation between the activity of the serotonergic system and motor behavior.

Serotonin increases motor neuronal excitability by decreasing the leak current, by lowering the spike threshold, by reducing the AHP, and by enhancing plateau properties (i.e., facilitating the persistent inward currents). All the serotonergic projections originate for the raphe nuclei in the brain stem, with the neurons located in the raphe pallidum and obscurus nuclei projecting to the spinal motor nuclei. Chronic recording from the raphe neurons in these nuclei in freely moving animals (cats) showed a strong correlation in their activity to the motor activity level. They have a low discharge rate at sleep, and during rapid eye movement (REM) sleep with muscular atonia they become almost silent. During waking, their frequency increases and correlate well to the level of motor activity (standing < walking < running on a treadmill). During forced running on a treadmill, the frequency started out very high but then slowly decreased as the animal became more tired. At exhaustion (i.e., the cat did not manage to follow the pace), the raphe neurons' firing frequency dropped dramatically until they became virtually silent as the animal stopped running, and their activity recovered during rest (up to 1 h). These observations have triggered discussions on the involvement of the raphe-spinal projection in central fatigue.

Motor Neuronal Plasticity Following Training or Disuse

Do α-motor neurons, like muscle fibers, adapt to long-lasting increases or decreases in activity? There is much evidence to support the idea that motor activity and motor learning indeed involve neuronal plasticity at both the spinal and supraspinal levels of the central nervous system. However, it is only during the last several years that changes in the properties of α-motor neuron themselves in response to altered levels of physical activity have been directly assessed. The present evidence originates from experiments in which rats were subjected to forced endurance training or spontaneous running in exercise wheels to increase the motor activity or were subjected to body-weight support (i.e., suspension of the hindlimbs) for a couple of weeks to reduce the motor activity. Only a few examples of the described changes are mentioned here. With increased motor activity, the slow motor neurons showed more negative resting membrane potential as well as firing threshold. It was proposed that these changes may prevent depolarization, accommodation, and firing adaptation during prolonged activity. During inactivity, the resting membrane potential and firing threshold became more depolarized. The motor neurons become less excitable and more prone to accommodation and frequency adaptation. The signals mediating the adaptation of these (and other) motor neuron properties are not known at this time. However, it has been proposed that increased levels of neurotrophins originating from the exercised muscle, or other neurotrophic factors released by afferent activity, may induce appropriate changes in motor neuronal gene expression.

Motor Neuronal Plasticity Following Chronic Spinal Lesions

Chronic spinal transection has also been used as a model of reduced activity, although it obviously involves much more than inactivity. For example, the partial denervation and secondary changes resulting from the degeneration of descending axons affect the environment of the motor neurons. Several studies reported that complete or partial spinal lesion may cause a small but significant reduction in the number of motor neurons caudal to the lesion, as well as morphological changes, such as changes in soma diameter and dendritic size and branching, in the surviving population. Electrophysiological examination of motor neuron properties revealed that the resting membrane potential and voltage threshold became depolarized and that the excitability for repetitive firing was reduced. These changes were reduced by passive exercise of the hindlimbs or transplantation of fetal spinal cord tissue.

As already described, the persistent inward currents underlying the plateau properties need descending monoaminergic facilitation for optimal function. Previous studies in cats showed that, following acute spinal transaction, plateau properties are lost but could be restored by the administration of precursors or agonists of monoamines. It was, therefore, surprising to find that plateau potentials, which were

Figure 7 Tonic stretch reflexes and plateau potentials in motor neurons in the chronic spinal cat (recorded in a cat 3 weeks following a complete spinal transection at low thoracic level): (a) tonic stretch reflex in the triceps surae (upper) and raw EMG (recorded with surface electrodes) during a manual flexion of the ankle joint (lower); (b) ankle angle and EMG for (a); (c) responses of an extensor motor neuron to injection of rectangular current pulses; (d) responses of an extensor motor neuron to injection of triangular current pulses; (e) graph of (d). The upper traces in (c) and (d) illustrate intracellular recordings, and the lower traces indicate the injected current. Note in (c) the accelerating firing frequency during the rectangular current pulse and the afterdischarge following the termination of the current pulse. In (e) the instantaneous frequency measured in the record in (d) is plotted against current. The direction of arrows indicated the ascending (○) and descending (●) phase of the triangular waveform. The frequency–current relation shows a counterclockwise hysteresis. EMG, electromyogram. Modified from Eken T, Hultborn H, and Kiehn O (1989) Possible functions of transmitter-controlled plateau potentials in alpha motoneurones. *Progress in Brain Research* 80: 257–267.

lost in the acute spinal state, reappeared 2–3 weeks after spinalization without the addition of monoaminergic precursors or agonists. Based on this observation, it was suggested that reemerging plateau properties following spinal injury may play a role in re-adapting the overall excitability of the spinal network below the lesion and may be a contributor to the pathophysiology of spasticity. These chronic-spinal experiments were originally performed in cats with spinal transection at a low thoracic level (Figure 7). Bennett and colleagues later developed a rat preparation in which a very caudal chronic spinal lesion causes pronounced hyperreflexia of the tail without interfering with the normal hindlimb or bladder function. This caudal part of the spinal cord is also so thin that it can be investigated under *in vitro* conditions. This model has recently been used for studying the cellular mechanisms behind the development of spasticity and hyperreflexia following a chronic lesion.

Summarizing Remarks

In many respects, motor neurons resemble other neurons in the central nervous system. However, their output has to match the properties of the muscle fibers that they innervate and to deliver spike trains that are appropriate to cause the muscle forces necessary for the normal motor behavior. This requires relatively lower firing frequencies than most other central nervous system neurons, and therefore many intrinsic properties of motor neurons are geared to obtain that result. Accordingly, there are systematic differences between motor neurons innervating slow muscle units compared with those innervating fast muscle units. The underlying mechanisms for this match seem to depend on a mutual interdependence between the motor neurons and the muscle fibers they innervate. The recruitment of the motor neuron and the relation between the synaptic input and the firing frequency are set by the spike threshold, the postspike AHP, and the amplification of the net synaptic excitation at dendritic level. All these intrinsic properties of the motor neurons are under the control from a number of neuromodulatory control systems, typically using monoamines and neuropeptides as transmitters. In the case of the serotonergic system, we now know much about the behavioral situations in which it is activated, as well as its mechanisms of

action at motor neuronal level. These neuromodulatory systems govern a short-term, state-dependent plasticity of motor neuron function to match normal variations of environmental demands. Long-term changes in motor neuron properties in response to long-lasting increases of motor activity (exercise) or decreased activity (disuse and spinal lesions) have also been established, but the signals underlying this plasticity are still mainly unknown.

Spine Plasticity

W-B Gan, N Kasthuri, and G Yang, New York University School of Medicine, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

In 1888, Ramon y Cajal, one of the greatest neuroanatomists, described a series of small protrusions extending from the dendrites of neurons. These protrusions, termed 'dendritic spines,' have since been found on both excitatory and inhibitory neurons throughout the central nervous system of diverse species (Figure 1). Electron microscopic studies indicate that the vast majority of dendritic spines (~98%) are associated with synaptic contacts between neurons. Because spines are excellent indicators of synaptic connections and can be visualized using light microscopy, their structure and function have been extensively studied. It is now well established that dendritic spines are specialized structural, biochemical, and electrical compartments in which neurons communicate with each other. Despite the fundamental role of dendritic spines in the nervous system, key aspects of their development and plasticity in living animals still remain unclear. For example, how do spines form? How long does a spine last in an animal? How does experience of the external world change the development and life time of spines? What are the roles of abnormal spine plasticity in various brain diseases? With the development of new molecular and cell biology tools, neuroscientists have recently begun to glimpse the answers to these questions.

The Development of Spines

Dendritic spines appear early during development soon after dendritic processes are extended from neurons. Time-lapse imaging of spine formation in neuronal cultures, brain slices, and living animals has shown that spines either form directly from dendritic shafts or are transformed from dendritic 'filopodia' – long and thin protrusions without bulbous heads (Figure 2). At early stages of development, synaptic contacts already exist between spines and presynaptic axons, suggesting that the process of spine formation is intimately associated with the process of contact formation between neurons. An important question about spine development is related to the temporal sequence of 'spinogenesis' and 'synaptogenesis': Do neurons make synaptic contact (synaptogenesis) before dendrites produce spines (spinogenesis), or is it the other way around? The answer to this question is important for understanding whether spinogenesis reflects intrinsic properties of postsynaptic dendrites or is governed by extrinsic factors associated with presynaptic axonal terminals.

There are several alternative ways in which spinogenesis and synaptogenesis might occur during development. In the first, dendrites produce long and thin dendritic filopodia that 'sample' some of the potential axonal contacts in nearby regions. Capturing and choosing the appropriate presynaptic axon eventually result in the maturation of the filopodia into the spines. Consistent with this view, dendritic filopodia are abundant in the young developing brain during the period of extensive spinogenesis. Electron microscopic (EM) studies indicate that some filopodia make several synaptic contacts with axons, whereas others do not have any synaptic contacts. Furthermore, time-lapse imaging of filopodia has shown that the vast majority of filopodia undergoes rapid extension and retraction within minutes to hours, consistent with their 'sampling' of the local 'synaptic neighborhood.' Importantly, studies both *in vitro* and *in vivo* have shown that a small percentage of filopodia are transformed into the more stable thin- or mushroom-like anatomy of dendritic spines, providing direct evidence for filopodia as spine precursors. The fact that most filopodia do not result in spines suggests perhaps the highly selective nature of finding appropriate axonal partners.

Although the theory in which dynamic filopodia find their partners and mature into spines seems to describe an important rule of spine development, other modes of spinogenesis may also occur. For example, presynaptic axons can find/recognize the shafts of dendrites and induce the postsynaptic cell to make a dendritic spine directly below that axonal terminal. In support of such a scenario, other EM studies have shown that the formation of shaft synapses often precedes the formation of spine synapses at early developmental stages. Furthermore, time-lapse imaging studies have also found that spines can occasionally form directly from dendritic shafts rather than from filopodia. This latter observation is compatible with an alternative model in which spines first emerge independently of synaptic contact and then axonal terminals find/recognize these pre-formed spines on dendrites to make specific contacts. Also consistent with this model, spinogenesis can occur in the absence of synaptogenesis under certain conditions, such as deafferentation in some parts of the brain. Thus, although there is a strong correlation between the production of postsynaptic dendritic spines and the establishment of connections with presynaptic axonal partners, the actual relationship between these two

Figure 1 Dendritic spines as the primary contact sites of excitatory synapses are highly abundant in the brain. In this image, a few cortical neurons and their dendrites are labeled in different colors with lipophilic dyes from a mouse cortex at the age of postnatal day 20. A large number of dendritic spines can be seen along individual dendritic branches, demonstrating both the complexity of neuronal connections and the importance of dendritic spines as fundamental structural units in the brain. Scale bar = 25 μm. Adapted from Gan W-B, Grutzendler J, Wong W-T, Wong Rol, and Lichtman JW (2000) multicolor 'DiOlistic' labeling of neuronal circuits using lipophilic dye combinations. *Neuron* 27: 219–225, with permission.

phenomena may vary with different systems and under different conditions.

The definitive answer of when synaptogenesis occurs in relation to when spines develop requires simultaneous monitoring of pre- and postsynaptic cells as they are making contacts and subsequently identifying whether such contacts are synaptic in nature using EM. Although technically challenging, such experiments are now possible. Regardless of how spinogenesis correlates with synaptogenesis, a key aspect of spine development is that most of the newly formed spines are eliminated soon after they are formed, suggesting a highly selective process in the formation of stable spines. As described later, such a selective process goes well beyond the peak of spinogenesis and represents a prominent feature in the maturation of the developing brain.

Substantial Net Loss of Spines during Late Postnatal Development

Soon after Cajal described dendritic spines, he inferred that as the number of spines per unit length of a dendrite decreased with late postnatal development of the nervous system, neuronal circuits were probably rewiring by removing spines and hence the connections between neurons. This prophetic prediction, as many of Cajal's predictions, was subsequently confirmed by more quantitative analyses of the number of synapses and spines in fixed brains from different species at varying developmental ages. In the cerebral cortex of humans and other mammals, rapid synaptogenesis during early postnatal life is followed by a substantial (~50%) loss of synapses/spines that extends through adolescence. In adulthood, the number of spines appears relatively constant until the late stages of life. These studies allowed neuroscientists to infer, like Cajal, that indeed the number of spines seemed to decrease during late postnatal development and stabilize in adulthood.

However, evidence from the analysis of fixed postmortem tissue could not determine the dynamic behavior of spines and the nature of spine loss. For example, because spines are appearing and disappearing, the decrease in spine number could be due to more elimination of existing spines or to slower addition of new spines. The answer to this question would require the confluence of techniques in molecular biology and optical imaging, more than a century after the initial discovery of spine loss. The advent of transgenic mice expressing green fluorescent protein and its spectral variants in a subset of neurons and the use of two-photon microscopy to image spines in the living brains of these transgenic mice allowed neuroscientists for the first time to record the dynamic behavior of spines. It was found that in layer 5 pyramidal cells of different cortical regions, the number of dendritic filopodia is progressively reduced as development proceeds. Consistent with the role of filopodia in spinogenesis, the rate of spine formation is also reduced over the same interval. Importantly, in the first few postnatal months, the rate of spine removal was significantly higher than the rate of spine addition, leading to the net loss of spines observed in diverse regions of the cortex.

These *in vivo* imaging studies confirm Cajal's initial inference: The major rewiring of the cortex during late postnatal life is the elimination of connections between neurons. Because a substantial loss of synapses occurs across different regions of the developing brain in monkeys and humans, it is possible that spines of many cell types and cortical layers undergo a similar pruning process via similar mechanisms. The substantial loss of spines before adulthood correlates with

Figure 2 *In vivo* time-lapse imaging of dendritic spine formation and elimination in the mouse cortex. (a–d) Repeated imaging of two dendritic branches from 4 to 6 weeks of age reveals spine elimination (arrowheads) and formation (large arrows) as well as filopodium turnover (small arrows) in control (a and b) and sensory-deprived mouse barrel cortex (c and d). Long-term sensory deprivation via whisker trimming reduces spine elimination in young adolescent mouse barrel cortex from 4 to 6 weeks of age. (e and f) *In vivo* imaging of cortical dendrites and axons (green) near an amyloid deposit (red) in cortical layer 1 of a mouse model of Alzheimer's disease at 6 months of age. Although the majority of spines (arrowheads) and axonal varicosities (asterisks) were stable over 2 days, some structural changes (e.g., spine loss (arrows) and varicosity formation (double arrows)) occurred near the deposits. Scale bars = 2 μm (a–d) and 5 μm (e, f). Adapted from Zuo Y, Yang G, Kwon E, Gan WB (2005) Long-term sensory deprivation prevents dendritic spine loss in primary somatosensory cortex. *Nature* 436: 261–265, and Tsai J, Grutzendler J, Duff K, and Gan W-B (2004) Fibrillar amyloid deposition leads to local synaptic abnormalities and breaking of neuronal branches. *Nature Neuroscience* 7: 1181–1183, with permission.

the development of many cortical functions, suggesting that sculpting early established synaptic connections is a fundamental process in the developing brain.

Spine Stability in Mature Animals

Although many of the initial investigations into spine plasticity focused on development, a time when animals are undergoing remarkable changes in shape and behavior, little was understood about the degree of spine plasticity in adulthood until recently. The adult mammalian brain possesses remarkable plasticity essential for learning and equally remarkable stability for maintaining memory. Although it is generally believed that changes in synaptic strength and number underlie various forms of learning and plasticity in the brain, it is unknown whether or not synaptic connections are stable enough to serve as a structural basis for long-term memory. One way to address this question is to directly observe the degree of stability of synaptic connections in the mature brain. For example, if the majority of adult synapses remains throughout life, this would suggest that memory and basic cortical functions can be stably maintained by synaptic connections that are established during development. On the other hand, if adult synapses are highly dynamic and turn over multiple times within the lifetime of an animal, this would suggest that long-term information might instead be stored in a dynamic manner within highly plastic neuronal circuits.

As described previously, by actually observing the same dendritic spine over time, investigators can measure the dynamic nature of spines in living mouse cortex. By repeatedly imaging the adult mouse cortex over time, it was found that adult spines are remarkably stable on the apical dendrites of layer 5 pyramidal neurons in many regions of the cerebral cortex.

Only 4 or 5% of spines disappear or appear over 1 month in sensory, motor, and frontal cortices. In the somatosensory cortex, >70% of spines are present over a 19-month interval. Assuming that all the spines have a similar turnover rate, the average lifetime of an individual adult spine would be approximately 63 months. Because the average life span of a mouse is approximately 3 years, these results suggest that the majority of adult spines in the cerebral cortex can last throughout the life span of an animal. This cortical-wide spine stability could therefore provide a structural basis for lifelong information storage. Interestingly, whereas the vast majority of spines are stable in adulthood, spine morphology changes both during development and in adulthood. Because spine size correlates with synaptic strength, changes in spine morphology indicate that synaptic strength and, consequently, neuronal function might be readily modified without synapse turnover. Such alterations in the strength of previously established connections could be important for rapid adult plasticity seen in short-term learning. Over an extended period of time, changes in synaptic efficacy may ultimately result in a limited degree of spine turnover and circuit rewiring.

The results mentioned previously mirror studies on the peripheral nervous system in which mouse neuromuscular junctions and submandibular ganglia maintain axonal branching patterns over many months in adulthood. These observations suggest that synaptic stability dominates in the mature nervous system and raise the question of how synaptic connections can be kept largely stable in the presence of lifetime experience. It is important to note that studies so far have examined the dynamics of spines located in cortical layer I; it remains unknown whether the observations of spine stability can be generalized to the entire dendritic tree of layer 5 pyramidal cells or different neuronal types. In addition, whether and to what degree spines can remain stable over the life span in other species such as monkeys and humans require further investigation.

Genetic Control of Spine Formation and Elimination

One of the major goals of research on spine plasticity is to understand how and to what degree spine formation and elimination are regulated by intrinsic genetic programs. By removing or overexpressing individual genes, investigators have identified many genes that are important for regulating the number and size of dendritic spines. These genes encode a wide variety of proteins, including transcription factors, protein kinases, neurotransmitter receptors, adhesion molecules, postsynaptic density proteins, as well as actin cytoskeleton and its regulatory elements. Because spine formation is closely associated with synaptogenesis, genes participating in synapse formation generally have varying effects on the generation of dendritic filopodia and spines. Interestingly, the initial formation of spines can occur in the absence of sensory activity or even more extreme, in the cerebellum, spines of Purkinje neurons can form in the absence axonal terminals. Thus, it appears that some aspects of the ontogenesis of spines are genetically determined and do not rely on synaptic transmission. On the other hand, lack of various subunits of neurotransmitter receptors and ion channels has significant impact on spine density both *in vitro* and *in vivo*. Furthermore, modifying inhibitory neuronal activity either genetically or pharmacologically has profound effects on spine density in excitatory pyramidal neurons. These studies suggest a complicated relationship between gene transcription and neuronal activity in the generation and maintenance of new spines.

One emerging scenario on the genetic control of spine plasticity is that various gene products and patterns of neuronal activity converge to regulate actin polymerization and depolymerization in dendritic spines, leading to spine formation or elimination. Actin filaments form the main cytoskeleton of dendritic spines and are remarkably dynamic. The Rho family of small GTPases, including RhoA, RhoB, and Rac, regulates dynamics of the actin cytoskeleton and is an important contributor to spine formation and elimination. Overexpression or suppression of these molecules as well as their interacting proteins results in changes in the density of dendritic filopodia and spines *in vivo* and *in vitro*. In addition, neuronal activity can induce extensive remodeling of the actin cytoskeleton via calcium influx through glutamate receptors of the *N*-methyl-D-aspartate (NMDA) and the α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) subtypes that are highly concentrated at the postsynaptic spines. Many lines of evidence have shown that NMDA and AMPA receptor activation is essential for spine formation and/or maintenance, and that the effect of these receptors on actin dynamics is at least partly mediated by the calcium/calmodulin-dependent protein kinase II pathway.

Much progress has been made in the past few decades regarding the gene regulation of spine development and plasticity. However, most of the studies so far have focused on the role of individual genes in regulating spine density from a single time point

observation. Due to the dynamic nature of spinogenesis, it is important to combine molecular and time-lapse imaging approaches to determine the role of different genes and signaling pathways in various phases of spine formation and maintenance. Furthermore, gene expression is dynamically regulated *in vivo* and lack of a specific gene is likely to alter not only the function of a particular gene *per se* but also patterns of neuron activity in general, which in turn impact on spine plasticity. Thus, in living animals, better temporal and spatial control of gene expression, in combination with improved *in vivo* imaging and electrophysiology, is necessary to decipher the gene regulation of spine plasticity in the future.

Experience-Dependent Regulation of Spine Plasticity

A fundamental aspect of the nervous system is that the patterns of neuronal connectivity and the animal's behavior are profoundly influenced by experience throughout life. For example, long-term sensory deprivation starting at birth and continuing until young adulthood often reduces the number of synapses, whereas enriched environments increase the extent of dendritic branches and synapse number in sensory cortices. Furthermore, in cultured brain slices, induction of long-term potentiation, a synaptic model for learning and memory, can cause rapid outgrowth of dendritic protrusions as well as the formation of multiple synapses over hours. These results suggest that sensory experience and/or neuronal activity often leads to an increase in spine and synapse formation at early stages of development. Time-lapse imaging has been used to examine the long-term effect of sensory experience on the rates of dendritic spine elimination and formation in mouse barrel cortex, a cortical region in which sensory input can be easily manipulated (Figure 2). The results indicate that during adolescence when the peak of synaptogenesis is over and synapse elimination dominates, sensory deprivation preferentially reduces the rate of spine elimination rather than formation. Furthermore, as spines become stabilized in adulthood, the impact of sensory deprivation on spine elimination is reduced substantially. Therefore, sensory experience appears to have different roles in regulating the number of synapses depending on the animal's developmental stage.

It is well established that anatomical features such as dendrite and axon branching patterns in the visual system of the developing mammals are highly sensitive to changes in the external environment but that this sensitivity decreases into adulthood. The previously described studies indicate that experience-dependent spine plasticity also decreases as an animal's age increases. Specifically, there appears to be a temporal window after birth and before 'adulthood' when spine plasticity progressively diminishes and the malleability of the nervous system decreases. As spines become more stable, the ability of the cortex to rewire and, as a result, the ability of animals to change their behavior secondary to environmental changes become limited. Thus, one important insight from the studies on experience-dependent spine plasticity is that the period of heightened sensitivity to experience, termed the 'critical period' is closely associated with the period of spine plasticity.

Another insight is related to the role of spine pruning in the development of the mammalian brain. It is generally believed that a functional mature nervous system is formed from an initial pool of imprecise synaptic connections by selectively forming some synapses and eliminating others based on experience. Although many lines of evidence have demonstrated the role of experience in promoting spine formation, the dominant feature of spine plasticity during late postnatal development is experience-induced spine loss. These results again resonate with studies of the development of the connections between spinal motor neurons and their muscle targets in the peripheral nervous system. Here, it has been established that initially multiple motor neurons make synaptic contacts with individual muscle cells, and this initial exuberance is pruned by competition mediated by neuronal activity. Thus, experience-dependent sculpting of neuronal connectivity seems vital to the maturation of the brain. The same mechanism may also be important for learning and memory formation throughout life.

It is important to mention that many studies have shown substantial changes in the number of synapses following various learning and injury paradigms even in the mature brain. Soon after brain injury, animals, including humans, show a remarkable ability to relearn behavior, suggesting that the mature brain must retain some capacity to form new synapses and rewire its circuitry. Indeed, work has demonstrated that trauma to the skull in mature animals leads to a substantial increase in the turnover rates of adult spines. Thus, although *in vivo* imaging studies have shown that adult spines can form and retract to a limited degree under normal and sensory-deprived environments, it remains to be determined to what degree spine dynamics can be altered under enriched environment and learning conditions.

Dendritic Spine Pathology in Brain Disorders

A number of psychiatric and neurological diseases are associated with alterations in spine morphology or density. Because spine morphology and number are intimately linked to neuronal function, altered spine structures in disease states are likely to have diverse detrimental effects. For example, higher spine density and more immature, long, and thin dendritic spines have been found in many areas of the brain in fragile X syndrome (FXS), the most frequent form of inherited mental retardation. Patients with Down's syndrome have decreased spine density in the neocortex and hippocampus. Schizophrenic patients also exhibit decreased spine density in neocortical pyramidal neurons. Important progress has been made in the past few decades in identifying the genes responsible for psychiatric diseases and developing mouse models for mechanistic studies. In the case of FXS, it has been shown that the disease can be caused by a mutation of the *fragile mental retardation 1* (*Fmr1*) gene located on the X chromosome. The *Fmr1* gene encodes a protein, the fragile X mental retardation protein (FMRP), which binds to many mRNA ligands and acts as a translational suppressor in different subcellular locations, including dendrites and dendritic spines. Similar alterations in dendritic spine morphology and density, as well as behavioral deficits, have been found in *Fmr1* knockout mice and human patients, suggesting that this mouse model is excellent for studying mechanisms underlying the development of FXS. Emerging evidence suggests that many psychiatric diseases are fundamentally disorders of early development that become progressively worse and eventually manifest in early adulthood. Because of the heightened spine plasticity early in life, it is conceivable that the rates of spine formation and elimination in young developing brains are more sensitive to alterations due to mutations of genes related to psychiatric diseases. Even slight changes in spine plasticity may accumulate over time and lead to a substantial increase or decease in spine density as observed in many psychiatric disorders.

In addition to many hereditary mental illnesses, abnormal spine morphology and number have been found in other brain disorders, such as addiction, anxiety, and depression, that are often linked to environmental factors such as malnutrition, abnormal hormone level, and chronic drug abuse. For example, in animal models, repeated exposure to psychomotor stimulants such as amphetamine and cocaine causes an increase in both the dendritic branching and spine density on apical dendrites of pyramidal cells in the prefrontal cortex as well as on medium spiny neurons of the nucleus accumbens. Such an increase in spine density indicates that synaptic reorganization occurs in these brain regions upon repeated drug exposure. The significant and persistent drug-induced synaptic changes may play an essential role in the development of compulsive patterns of drug-seeking behavior.

Structural changes of dendritic spines also likely play an important role in the pathogenesis of many age-related neurodegenerative diseases. This is especially true in Alzheimer's disease (AD), in which the best correlate of cognitive dysfunction is thought to be the loss of synapses as seen by immunohistochemistry and EM in postmortem tissue. Amyloid peptide deposition and tangle formation, two of the hallmarks of AD, are commonly associated with dystrophic neurites and loss of synapses. By cross-breeding a transgenic mouse model of AD with mice expressing yellow fluorescent proteins in subsets of neurons, the degree and time course of synaptic disruption associated with fibrillar amyloid deposits have been studied *in vivo* with two-photon microcopy (**Figure 2**). Time-lapse imaging over days to weeks revealed extensive formation and elimination of dendritic spines near the periphery of the amyloid plaques, suggesting that amyloid deposition triggers continuous remodeling of nearby neuronal structures. Furthermore, local dendritic and axonal abnormalities associated with amyloid deposits can eventually result in synapse loss and the breakage of dendrites and axons. These studies indicate that the accumulation of fibrillar amyloid leads to large-scale and permanent disruption of synaptic connections, contributing to cognitive decline and memory loss in AD.

As described previously, neurological disorders and neurodegenerative diseases are frequently associated with aberrant spine structure and plasticity in critical brain regions. Because dendritic spines are the major sites of neuronal connections in the brain, it is perhaps not surprising that changes in spine plasticity would have a significant impact on disease pathogenesis and progression. The important issue is to determine whether change in spine plasticity is merely the consequence or the primary cause of the diseases and how abnormal spine plasticity contributes to the disease progression. Abnormal formation and/or pruning of spines during development may compromise the establishment of a functional brain. Because spines are remarkably stable in adults, such developmental defects may have long-lasting effects later in life. Furthermore, the failure of the nervous system to maintain stability of neuronal connections could also lead to cognitive and behavioral deficits in at least some brain diseases. The answers to such questions will undoubtedly provide important insight into the

onset, progression, and treatment of psychiatric and neurological diseases.

Mental Retardation

Mental retardation (MR), defined by global deficiencies in cognitive abilities, affects approximately 2–3% of children and young adults. MR shows a wide range in the severity of cognitive disability and is commonly divided into intelligent quotient (IQ) ranges between 85 and 70 (borderline), 70 and 55 (mild MR), 55 and 40 (moderate MR), 40 and 25 (severe MR), and below 25 (profound MR). In addition, MR is often associated with deficits in adaptive behavior. These include at least two of the following skill areas: communication, self-care, ability to live independently, social and interpersonal skills, decision making, health, and safety. The underlying causes of MR are extremely heterogeneous and include nongenetic factors such as infectious disease, premature birth, and fetal alcohol syndrome, as well as genetic changes that include chromosomal abnormalities and single-gene mutations.

Among mentally handicapped families, an excess of males over females has long been noted. There is now evidence to support that this male bias is largely due to mutations in X-linked genes. X-linked MR (XLMR) has been divided into syndromic and nonsyndromic forms of MR. In syndromic XLMR (MRXS), the cognitive disability is associated with a fixed constellation of other manifestations, such as body and brain malformations. In contrast, nonsyndromic XLMR (MRX) is characterized by reduced cognitive function without any other clinical features. Notably, the boundaries between MRXS and MRX are not always clear. The subclassification of MRX versus MRXS largely relies on the clinical evaluation of the patients. Furthermore, mutations in the same gene have been found to produce both forms of XLMR. For instance, the Aristaless-related Homeobox (ARX) gene was initially identified as a MRXS gene; however, more recently some ARX mutations have also been identified in families with MRX. In this article, we kept the MRX/MRXS subclassification of genes as described in 'Euro–MRX European mental retardation consortium'(see 'Relevant Websites').

The search for genes associated with XLMR has been very active over the past few years. Approximately 50 genes linked to MRXS and 20 genes linked to MRX have been identified so far (for an update, see 'Relevant Websites' ('Greenwood Genetic Center')). For most of the XLMR genes identified, there is as yet little information available as to how mutations in these genes result in cognitive impairment. Moreover, their corresponding proteins seem to display very different functions. However, recent studies have revealed that several of the MRX gene products share in common that they all impinge on the actin cytoskeleton and affect dendritic spine morphogenesis. The dynamic actin-rich nature of dendritic spines pointed to Rho GTPase family members as central contributors because they are key regulators of actin dynamics and organization. Indeed, mutations in regulators and effectors of the Rho GTPases have been found to underlie various forms of MR. In this article, we first discuss briefly the role of Rho GTPases in spine and synapse formation and subsequently describe in more detail some of the Rho GTPase signaling pathways involved in MRX and MRXS, as well as in autosomal MR.

Mental Retardation, Spines, and Rho GTPases

Approximately three decades ago, Golgi staining of postmortem material of children with MR indicated for the first time that MR is associated with abnormalities in dendrites and dendritic spines, which are the main sites of excitatory synapses. Dendritic spines take on various shapes, including stubby, thin, or mushroom; and significantly a strong correlation between the size of the spine head and synaptic strength has been suggested. Studies on children with MRX revealed a reduction in the number of dendritic spines and a predominance of very long and thin spines at the expense of stubby and mushroomlike spines. Given that the long thin spine morphology resembled immature spines, the term spine dysgenesis was introduced. Subsequent studies have demonstrated that several types of MR and cognitive disorders are associated with abnormalities is spine density and/or morphology. For instance, patients with fragile-X syndrome (FRAXA) have an increased proportion of long tortuous thin spines, whereas patients with schizophrenia or Down syndrome more commonly reveal a reduction in spine size and spine density. These findings suggested that abnormal development of dendritic spines within the brain might contribute to or underlie changes in plasticity and cognitive impairment.

Morphology and rapid motility of dendritic spines are widely believed to be dependent on polymerization and/or depolymerization of actin. A number of studies have demonstrated that molecules that either

directly or indirectly modify the actin cytoskeleton, such as Rho GTPase family members, RhoA, Rac1, and Cdc42, influence the number and/or shape of dendritic spines and, ultimately, synaptic function. Rac1 and Cdc42 promote, whereas RhoA inhibits, the growth and/or stability of dendritic spines. Rac1 and RhoA also differentially regulate two different forms of rapid motility that are often observed in spines, namely head morphing and protrusive motility.

An expanding number of positive and negative regulators of the Rho GTPases, including guanine nucleotide exchange factors (GEFs) and GTPase-activating proteins (GAPs), and downstream effectors have been identified and shown to control Rho GTPases postsynaptically and to mediate their actions on spine morphogenesis. Significantly, mutations in several of these regulators and effectors have been associated with various forms of MR; these include MRX, MRXS, and autosomal MR (Figure 1).

Rho-Linked Proteins Involved in Mental Retardation

Nonsyndromic X-Linked Mental Retardation

Among the 20 identified genes that have been associated with MRX, three code for regulators and an effector of Rho GTPases: *oligophrenin-1* (*OPHN1*); *ARHGEF6*, also referred to as *αPIX* or *Cool-2*; and *PAK3*. How mutations in MRX genes result in defects in neuronal signaling and function *in vivo* remains largely unknown. However, recent studies have started to provide insight into the functions of these Rho-linked proteins.

Oligophrenin-1 *Oligophrenin-1 (OPHN1),* the first identified Rho-linked MRX gene, encodes a Rho-GAP protein that negatively regulates RhoA, Rac1, and Cdc42 *in vitro*, in nonneuronal and neuronal cells. The protein is expressed in multiple tissues, although with highest levels in the brain, where it is

Figure 1 Rho-linked mental retardation proteins and effector pathways connecting Rho GTPases to actin dynamics. The proteins encoded by Rho-linked genes involved in different forms of MR are highlighted in red. Aβ, amyloid β; ARHGEF6, a Rho guanine nucleotide exchange factor 6; Arp2/3, actin-related proteins 2 and 3; CREB, cAMP-responsive element-binding protein; CYFIP, cytoplasmic FMR1 interacting protein; FMR1, fragile-X mental retardation-1; FMRP, fragile-X RNA-binding protein; GAP, GTPase-activating protein; LIMK, Lin-11, Isl-1, and Mec-3 kinase; MEGAP, mental disorder-associated GAP protein; mGluR, metabotropic glutamate receptor; MLC, myosin light chain; MLCK, myosin light chain kinase; MLCP, myosin light chain phosphatase; OCRL1, oculo-cerebrorenal syndrome of Lowe; OPHN1, oligophrenin-1; P, phosphorylation; PAK, p21-activated kinases; RhoA, Rac1, and Cdc42, Rho GTPase family members; WASP, Wiskott–Aldrich syndrome protein; WAVE, WASP family verprolin-homologous protein.

found in neurons of all major regions, including the hippocampus and cortex, and is present in axons, dendrites, and spines. Families with mutations in the *OPHN1* gene were initially described as having a MRX phenotype, but on reevaluation the affected males were found to have also cerebellar abnormalities, in particular, cerebellar hypoplasia. Independent reports describing additional families with mutations in *OPHN1* revealed that these individuals, in addition to cognitive impairment, also suffered from epilepsy and ataxia and showed strabismus, macrocephaly, and hypogenitalism.

All *OPHN1* mutations identified to date appear to result in a loss of protein function. A recent study has provided insight into to how mutations in *OPHN1* may impact neuronal function. By using RNA interference (RNAi) and antisense RNA approaches, it was found that the knockdown of *OPHN1* in CA1 pyramidal neurons in hippocampal slices results in a significant decrease in dendritic spine length. This phenotype was mimicked using a constitutive active (CA) RhoA mutant and was rescued by inhibiting a key effector of RhoA, termed Rho-kinase. These findings support a model in which the loss of OPHN1 causes changes in spine morphology during development as a result of changes in the actin cytoskeleton triggered by the elevation of RhoA and Rho-kinase activities.

Interestingly, OPHN1 has also been reported to associate with Homer, a postsynaptic adaptor protein that links glutamate receptors, such as type-1 metabotropic glutamate receptors (mGluRs), to multiple intracellular targets. Moreover, Homer proteins have been shown to influence dendritic spine morphogenesis and synaptic transmission. Although the function of this interaction remains to be established, it raises the intriguing possibility that OPHN1 acts downstream of glutamatergic receptors to regulate RhoA activity in spines and, in turn, spine morphogenesis. Taken together, this study supports the idea that cognitive impairment observed in *OPHN1* patients can be attributed to aberrations in dendritic spine morphology.

PAK3 A second Rho-linked MRX gene, *PAK3*, encodes a member of the larger family of p21-activating kinases (PAKs). PAK proteins function as Rac1 and Cdc42-specific effector molecules that mediate the actions of these GTPases on cytoskeletal remodeling and gene expression. PAK3 is highly expressed in the brain, particularly in postmitotic neurons of the cerebral cortex and the hippocampus, where it shows a diffuse distribution throughout the soma and proximal dendrites. Mutations in the *PAK3* gene have been identified in several MRX pedigrees. These mutations have been associated with either the loss of PAK3 protein or loss of its kinase activity.

Recent studies have provided evidence for a role of PAK3 in spine morphogenesis and synaptic plasticity. Antisense- and RNAi-mediated suppression of PAK3 levels, or the expression of a dominant negative PAK3 mutant carrying the human MRX30 mutation, in rat hippocampal organotypic slice cultures resulted in the formation of abnormally elongated dendritic spines and filopodia-like protrusions and in a decrease in mature spine synapses. These defects were associated with reduced expression of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPAR) at the synapse and defective long-term potentiation (LTP). In a parallel study, it was demonstrated that PAK regulates spine morphogenesis by triggering the phosphorylation of myosin light chain (MLC). Surprisingly, mice lacking the *PAK3* gene showed no obvious deficits in neuronal structures. However, these mice were selectively impaired in late-phase hippocampal LTP, a distinct form of long-term synaptic plasticity involving new gene expression. The mice also showed a dramatic decrease in the levels of the active form of cyclic adenosine-3′,5′-monophosphate (cAMP)-responsive element-binding protein (CREB) in the hippocampus. CREB is a transcription factor required for activity-dependent gene expression and L-LTP. These findings suggest a novel role for PAK3 in the regulation of CREB function and in synaptic plasticity and cognition. They also support a model in which abnormal CREB function may contribute to the cognitive deficits in MR patients. The differences seen with regard to spine morphology between knockout and RNAi studies may potentially reflect differences between a homogeneous and a heterogeneous cell population, respectively.

Interestingly, defects in PAK signaling not only result in MRX, but recently have also been associated with Alzheimer's disease (AD). This may not be that surprising considering the analogy between AD and MR. Both conditions share in common spine loss or spine alterations. AD is the most common form of degenerative dementia of the human central nervous system. It is defined clinically as a progressive loss of cognitive function with the onset of a slowly progressive impairment of memory during mid-to-late adult life. The neuropathologic hallmarks of this disease include amyloid deposits (Aβ), neurofibrillary tangles, and reductions in the number of neurons and synapses in many areas of the brain, but especially in the cerebral cortex and the hippocampus. Loss of postsynaptic proteins, such as PSD95 and drebrin, are also observed in neurons affected by AD. PAK1 and 3 protein levels and their activities were found to be markedly reduced in brains of AD patients.

The latter was accompanied by a prominent cofilin pathology and loss of the spine actin-regulatory protein drebrin, which cofilin removes from actin. Drebrin is localized at spines in adult brains and is required for active clustering and synaptic targeting of PSD95. Interestingly, the Aβ oligomers implicated in AD were shown to cause PAK signaling defects resulting in a loss of drebrin from the spines. The expression of active PAK could prevent the effects induced by Aβ oligomers, and significantly, pharmacological PAK inhibition in adult mice was sufficient to cause drebrin loss and memory impairment. These findings demonstrate that the loss of PAK3 and/or PAK1 is involved in both developmental-dependent and age-dependent cognitive deficits, such as observed in AD.

ARHGEF6 The *ARHGEF6* gene, also known as *αPIX* or *Cool-2*, codes for a Cdc42/Rac1 exchange factor, which was initially isolated as a PAK-interacting protein. More recent studies have unraveled the complex nature of its GEF activity toward Rac1 and Cdc42. In its dimeric form, αPIX/Cool-2 functions as a Rac1-specific GEF, whereas in its monomeric form, αPIX/Cool-2 can act as a GEF for Rac1 and Cdc42 but only on the binding of PAK or Cbl to its SH3 domain. An intriguing feature of αPIX/Cool-2 is its ability to interact with activated mutant forms of Rac1 and Cdc42, which is unusual for a GEF. Activated Cdc42 was found to enhance the GEF activity of dimeric αPIX/Cool-2 toward Rac1, whereas activated Cdc42 inhibited the GEF activity of monomeric αPIX/Cool-2.

The first mutation in *ARHGEF6* associated with MR was identified in a male carrying a reciprocal X;21 translocation breakpoint located between exons 10 and 11 of the *ARHGEF6* gene. Subsequently, mutations have been identified in the first intron of this gene. These mutations result in preferential skipping of exon 2 and a predicted protein product that lacks the first 28 amino acids in affected males of a large MRX family (MRX46). How mutations in *ARHGEF6* affect neuronal morphology and/or function and how they contribute to MRX remain unknown. However, recent studies examining the closely related family member of αPIX/Cool-2, namely βPix/Cool-1, have provided some clues to the function of ARHGEF6/αPIX/Cool-2 in neurons. It has been shown that the G-protein-coupled receptor kinase-interacting protein 1 (GIT1), an adaptor protein that is enriched at synapses of cultured hippocampal neurons, functions to localize βPIX to dendritic spines and to locally activate Rac1 and its downstream effector, PAK. Mislocalization of GIT1 leads to alterations in spine morphogenesis and synapse formation. Moreover, the GEF activity of βPIX toward Rac1 was found to be necessary for spine morphogenesis and synapse formation. Based on these observations, it was suggested that a signaling complex consisting of βPix, GIT1, Rac1, and PAK plays an essential role in spine and synapse formation.

Interestingly, the truncated ARHGEF6/αPIX/Cool-2 mutant found in MRX46 family members lacks the GIT1-binding domain. It is, therefore, tempting to speculate that this mutant protein is mislocalized and thereby causes aberrations in spine morphology. Consistent with a potential role for PIX family members in the formation and stabilization of synapse-bearing spines, the *Drosophila* homolog, dPIX, has been shown to play a major role in regulating postsynaptic structures and protein localization at the glutamatergic neuromuscular junction. In the future it will be of interest to investigate whether mutations in αPIX/Cool-2 affect spine morphology and postsynaptic signaling and whether this protein acts in a common pathway with PAK3 underlying cognitive function.

Syndromic X-Linked Mental Retardation

Rho-linked genes are also associated with syndromic forms of XLMR. These include FRAXA and Lowe syndrome.

FMR1/CYFIP/Rac FRAXA is the most common monogenic form of inherited MR (estimated prevalence of 1/4000 males and 1/8000 females). The manifestations include (in addition to cognitive deficits) poor eye contact, approach–avoidance behavior, tactile defensiveness, impulsivity, elongated facial features, and machroorchidism. Many patients also manifest attention-deficit hyperactivity disorder and autistic-like behavior. FRAXA is typically caused by an unstable expansion of the CGG trinucleotide repeat and hypermethylation of CpG dinucleotides in the 5′ untranslated region of the fragile-X mental retardation-1 gene (*FMR1*), which results in transcriptional silencing of *FMR1*. *FMR1* encodes an RNA-binding protein (FMRP) that is present at synapses, and evidence has been presented that it acts as a translational regulator. It binds to specific mRNAs through an RNA G-quartet structure.

As mentioned earlier, the shape and density of dendritic spines are altered in patients and in *FMR1*-deficient mice brains. These findings led to the postulation that a defect in maturation and/or function of synapses could be the basis of MR. A major challenge has been to define the mechanism(s) underlying the *FMR1*-associated abnormal spine morphology. A few reports suggested that FMRP could affect spine morphogenesis through the regulation of cargo mRNAs,

such as Map1B and profilin mRNAs. Recent studies, mainly performed in *Drosophila*, have linked FMRP's effect on spine morphology to the Rac1 GTPase signaling pathway. One group demonstrated that the mRNA encoding Rac1 is present in Fmr1-messenger ribonucleoprotein complexes *in vivo*. Moreover, evidence was provided that *Fmr1* and *Rac1* genetically interact and that Rac1 mediates, at least in part, the effects of Fmr1 (*Drosophila* fragile X-related protein) on dendritic branching. An independent study demonstrated a biochemical association between the Fmr1-interacting protein CYFIP and Rac1. The same study also provided data showing that Rac1 negatively regulates CYFIP, which in turn negatively regulates Fmr1, implying that Rac1 indirectly activates Fmr1. Together with the previous findings, these data suggest that there is a feedback loop between Rac1 and Fmr1 functions *in vivo*.

Interestingly, the mammalian homologs of *Drosophila* CYPIP, CYFIP1 and CYPIP2, have also been shown to interact with FMRP. In mammals, CYFIP1 (also known as p140/Sra-1) was initially identified as a target of Rac1, whereas CYFIP2 (also termed PIR121) was found to be part of the Wiskott–Aldrich syndrome protein family Verprolin-homologous protein (WAVE) complex, which mediates actin nucleation by Rac. In its inactive state, this complex contains WAVE and four other proteins: HSPC300, Nap125, Abi2, and PIR121. When active Rac1 is added, the complex dissociates, freeing WAVE and HSPC300, thereby allowing WAVE to activate the actin-related protein 2/3 (Arp2/3) complex to induce actin polymerization. In analogy to the mechanism of WAVE activation, a model was proposed in which CYFIP dissociates from FMRP/Fmr1 on interaction with activated Rac1, allowing released FMRP/Fmr1 to regulate local protein translation.

Taken together, these observations suggest a model in which Rac1, CYFIP, and FMRP act together in a dynamic signaling complex to regulate actin dynamics and control local protein translation, processes that are key to neuronal morphogenesis and connectivity.

OCRL1 Lowe oculocerebrorenal syndrome (OCRL) or Lowe syndrome is a rare X-linked developmental disorder characterized by a pleiotropic phenotype, including congenital cataracts, muscular hypotonia, MR, and renal Fanconi syndrome. The gene responsible for OCRL was identified by positional cloning of X chromosome breakpoints and encodes a protein termed OCRL1. The protein contains a central inositol polyphosphate-5-phosphatase domain and a Rho-GAP homology domain in its C-terminus. OCRL1 was found predominantly in the *trans*-Golgi network and functions as an active phosphatase with phosphatidylinositol 4,5-bisphosphate ($PI(4,5)P_2$) as its preferred substrate. The GAP domain of OCRL1 has been shown to interact with Rac1 and to possess weak GAP activity toward Rac1.

Mutations that cause Lowe syndrome have been mapped exclusively to the *OCRL1* gene. The observed mutations include premature stop codons, frameshift mutations, in-frame deletions, genomic or exon deletions, and missense mutations that yield single amino acid changes. It was observed that *OCRL1*-deficient fibroblasts derived from Lowe syndrome patients have increased $PI(4,5)P_2$ levels, alterations in the actin cytoskeleton, an increased sensitivity to actin depolymerizing agents, and mislocalization of the actin-binding proteins α-actinin and gelsolin. These findings suggest that increased $PI(4,5)P_2$ levels and abnormal cytoskeleton may contribute to the disease process. Whether $PI(4,5)P_2$ affects the cytoskeleton in a Rho GTPase-dependent or -independent manner remains to be established. The potential involvement of the Rho-GAP domain is of particular interest given that several mutations of *OCRL1* in Lowe syndrome patients have been found in the Rho-GAP domain. Surprisingly, *OCRL1* knockout mice do not develop Lowe syndrome. A potential explanation for this observation is that in mice the OCRL1 loss of function is compensated by the phosphatase, Inpp5b, which shares high homology with OCRL1. Notably, Inpp5b is expressed at significantly higher levels in mice than in humans, especially in the tissues affected by Lowe syndrome.

Autosomal Mental Retardation

Mutations in Rho-linked genes that give rise to MR are not only found on the X chromosome, but have also been identified on autosomes. These include the *MEGAP/WRP/srGAP3* gene, which encodes a Rho-GAP, and the *LIMK1* gene, which codes for a downstream effector of Rac1 and RhoA. Mutations in the *MEGAP* gene are associated with $3p^-$ syndrome, whereas the loss of *LIMK1*, along with several other genes, is associated with Williams syndrome.

MEGAP The *MEGAP* gene was identified as a gene that is disrupted in patients suffering from $3p^-$ syndrome. These patients exhibit (in addition to MR) microcephaly, growth failure, heart and renal defects, hypotonia, and facial abnormalities. Notably, the MEGAP (mental-disorder-associated GAP) gene product had previously been identified as a WAVE-associated protein (WRP) and as a ROBO-interacting protein (srGAP3). The MEGAP/WRP/srGAP3 mRNA

transcript is predominantly expressed in fetal and adult brains and is enriched in the neurons of the hippocampus, cortex, and amygdula.

Biochemical studies showed that this protein strongly enhances intrinsic Rac GTPase activity and, to a lesser extent, Cdc42. Together with the observation that MEGAP/WRP/srGAP3 directly binds to WAVE-1, a model was proposed in which MEGAP/WRP/srGAP3 functions in a negative feedback loop that inactivates Rac1 associated with WAVE-1, thereby controlling actin dynamics and spine morphogenesis. Two independent groups generated and characterized WAVE-1 knockout mice. One of the groups reported that WAVE-1 knockout mice exhibit defects in balance and coordination, reduced anxiety, and deficits in learning and memory. Interestingly, these phenotypes are strikingly similar to those observed in $3p^{-}$ syndrome patients. Together, these findings suggest that signaling through MEGAP/WRP/srGAP3 and WAVE-1 to the actin cytoskeleton is important for normal neuronal function.

LIMK1 Williams syndrome (WS; or Williams–Beuren syndrome) is a rare (1/25 000) genetic disorder characterized by mild MR, cardiovascular problems, distinctive craniofacial features, poor visual-motor integration, attention deficits, and, at times, hyperactivity. The genetic basis for WS has been attributed to a heterozygous deletion of approximately 1.5 Mb at chromosome 7q11.23. This deletion encompasses fewer than 20 genes, including *LIMK1*. The loss of *LIMK1* is believed to be responsible for some of the neurological aspects of WS, particularly the impaired visual-spatial cognition. *LIMK1*, which encodes a neuron-specific LIMK-family member, acts downstream of both Rac1 and RhoA and phosphorylates, and it inactivates the actin depolymerization factor ADF/cofilin, thus controlling actin dynamics.

Studies examining the phenotypes of *LIMK1* knockout mice provided the first insights into how the lack of *LIMK1* may contribute to some symptoms of WS. Mice with a homozygous deletion of *LIMK1* showed abnormal spine morphology: spine head size was dramatically decreased and spine necks were thicker. Moreover, these mice revealed enhanced hippocampal LTP following repeated high-frequency stimulation. Both aberrations in spine morphology and synaptic function were related to perturbations in ADF/cofilin phosphorylation and actin dynamics, thus potentially linking cytoskeletal defects to WS. Significantly, *LIMK1* knockout mice also displayed heightened locomotor activity, impaired spatial learning, and altered fear response. These phenotypes are similar to certain deficits found in human patients with WS.

Interestingly, a brain-specific microRNA, miR-134, has recently been localized to the synaptodendritic compartment of rat hippocampal neurons. This miRNA negatively regulates the size of dendritic spines, and this effect was mediated by miR-134 inhibition of the translation of an mRNA encoding LIMK1. This finding indicates that the level of LIMK1 can be highly regulated in dendritic spines.

Conclusion

The identification and characterization of Rho-linked genes associated with different forms of MR have contributed greatly to our current understanding of how defective cellular signaling can result in abnormal neuronal connectivity, which can give rise to impaired information processing underlying cognitive function. Aberrations in Rho-mediated signaling pathways (by, e.g., mutations in genes encoding regulators of Rho GTPases, including OPHN1, ARHGEF6, MEGAP, and OCRL1, or downstream effectors such as PAK3, LIMK1, and FMRP) lead to a deregulation of dendritic spine formation. Given the association between abnormalities in the size, shape, and number of dendritic spines and changes in LTP end LTD, this strongly supports the idea that structural changes of dendritic spines may underlie the cognitive deficits associated with MR. Taken together, Rho GTPase signaling is critical in the regulation of neuronal structure, which may explain why aberrations in Rho GTPase signaling can result in MR.

Spinocerebellar Atrophy

M Manto and P Jissendi, Université Libre de Bruxelles, Bussels, Belgium

© 2009 Elsevier Ltd. All rights reserved.

Since the discovery of triplet repeat expansions in 1991, more than 13 human disorders sharing an expansion of simple DNA sequences have been identified. These diseases are clinically and genetically heterogeneous, characterized by an elemental feature of repetition of unstable repeats. Autosomal dominant spinocerebellar ataxias (SCAs), fragile X syndrome (*fragile site mental retardation 1* (*FMR1*) gene), and Friedreich ataxia (FA) are among this group of neurological diseases. Patients exhibit various combination of supraspinal and spinal symptoms. The current numbering of SCAs corresponds to the order of gene description (SCA1–SCA8, SCA10–SCA23, SCA25, mutations in the gene encoding fibroblast growth factor (FGF)14, dentatorubral-pallidoluysian atrophy (DRPLA)). The *FMR1* gene is involved in different syndromes, including fragile X syndrome and fragile X-associated tremor/ataxia syndrome (FXTAS). Fragile X syndrome is a childhood disease whose main clinical deficit is mental retardation, whereas FXTAS occurs in adults.

Epidemiology of Triplet Expansion Disorders

The prevalence of SCAs is estimated to be 1–4 per 100 000. However, values can be much higher in some regions of the world due to a founder effect. This is the case for SCA2 in Cuba and SCA3 in the Azores. The SCA10 families originated in Latin America, and DRPLA is observed mainly in Japan. The commonest forms of SCAs are SCA1, SCA2, SCA3, SCA6, and SCA7. SCA3 might be the most prevalent SCA in the world.

FA is the most common form of recessive ataxia. Atypical features are increasingly recognized in individuals with FA. Late-onset Friedreich ataxia (LOFA) and very-late-onset Friedreich ataxia (VLOFA) are characterized by a symptomatic onset after 25 and 40 years of age, respectively. FA is seen in individuals of European, North African, Middle Eastern, and Indian descent, and also in Southeast Asian populations.

Fragile X syndrome is the most common inherited form of mental impairment. Carrier frequencies are approximately 1/800 males and 1/260 females. FXTAS develops in adults over 50 years of age. In men with late-onset cerebellar ataxia, the prevalence of premutation alleles is 13 times greater than expected based on the prevalence in the general population; the estimated prevalence of FXTAS amongst men older than 50 in the general population is about 1/6000. The prevalence of the mutant allele in patients presenting an unexplained gait ataxia starting after 50 years is 1–4%, and the prevalence is approximately 2–3% in patients developing symptoms suggestive of the cerebellar type of multiple system atrophy. Penetrance increases with age, and penetrance among carriers of larger premutation alleles is greater. The age at death is inversely correlated with repeat size.

Anticipation

Genetic anticipation was initially described in myotonic dystrophy, associated with expansions of CTG repeats. The disorder is characterized by earlier onset and increased severity as the mutant gene is transmitted from one generation to the next. Genetic anticipation was subsequently found for Huntington's disease (CAG expansion), FA (GAA expansion), and various autosomal dominant SCAs. The penetrance of mutations increases in successive generations, an observation made initially in fragile X syndrome, in which a progressive intergenerational expansion of CGG repeats located within the 5′ untranslated region (UTR) region of the *FMR1* gene was discovered. This discovery was followed by the demonstration of CAG repeat expansions in spinal and bulbar muscular atrophy (SBMA, also called Kennedy disease), and others findings followed.

Clinical Description

Patients exhibit combinations of a cerebellar syndrome with extracerebellar signs (Table 1). The cerebellar syndrome includes gait ataxia, which is usually the main ataxic deficit; ataxia of stance; dysmetria and/or kinetic tremor in four limbs; oculomotor deficits; and dysarthria. Because the degenerative process is not limited to the cerebellum but extends to the retina, optic nerve, brain stem, basal ganglia, cerebral cortex, spinal cord, and peripheral nervous system, extracerebellar signs are common. It is noticeable that within a genetic subtype the clinical signs may be highly variable. Moreover, phenotypic overlap may be marked. Several clinical scales (such as the International Cooperative Ataxia Rating Scale (ICARS) or Friedreich Ataxia Rating Scale (FARS)) have been developed to quantify clinically the neurological deficits.

Table 1 Clinical spectrum of spinocerebellar ataxias associated with triplet repeats

Pure ataxia					
Pure cerebellar syndrome[a] SCA5*, SCA6*					
Eyes/oculomotor control	*Movement disorders*	Pyramidal signs	*Cortical signs Cognitive impairment behavioral symptoms*	*Seizures*	*Peripheral nervous system*[b]
Cerebellar ataxia plus					
Slow saccades:[c] SCA1, SCA2**, SCA3, SCA7*	Parkinsonism: SCA1, SCA2, SCA3, SCA12, SCA17, SCA21 FXTAS	SCA1, SCA2, SCA3* (spasticity), SCA4, SCA7, SCA8, SCA11,	SCA1, SCA2, SCA3, SCA13, SCA17*, SCA19, SCA21, SCA-FGF14, DRPLA*	SCA10*, SCA17, DRPLA*	SCA1, SCA2, SCA3, SCA4*, SCA6, SCA8, SCA-FGF14, SCA12, SCA17, SCA18*, SCA22, SCA25*
	Dystonia: SCA3, SCA17	SCA12, SCA13, SCA15	FXTAS		FXTAS
Downbeat nystagmus: SCA6*	Tremor: SCA8, SCA12, SCA16 (head + hand), SCA19, SCA20 (palatal)	FA	FA[d] (?)		FA[d]
Ophtalmoplegia: SCA1, SCA2, SCA3	Dyskinesias: FGF14*				
Pigmentary retinopathy: SCA7**	Myoclonus: SCA2, SCA14, SCA17, SCA19, DRPLA Chorea: SCA1, SCA17, DRPLA				

[a]The following SCAs may evolve from a pure cerebellar syndrome into a cerebellar ataxia plus syndrome: SCA8, SCA11, SCA14, SCA15, SCA16, SCA22.
[b]Sensory neuropathy and sensorimotor axonal neuropathy; dying-back axonopathy, and/or neuronopathy.
[c]Maximal saccade velocity influenced by polyglutamine size.
[d]Possible hypertrophic cardiomyopathy and diabetes mellitus.
*indicates clinical signs which are suggestive; ** indicates clinical signs which are highly suggestive and with some specificity in the context of an autosomal dominant progressive cerebellar syndrome. DRPLA, dentatorubral-pallidoluysian atrophy; FA, Friedreich ataxia; FGF, fibroblast growth factor; FXTAS, fragile X tremor ataxia syndrome; SCA, spinocerebellar ataxia.
Adapted from Manto M (2005) The wide spectrum of spinocerebellar ataxias. *Cerebellum* 4: 2–6.

Symptoms of Spinocerebellar Ataxias

Symptoms of SCA1, SCA2, SCA3, SCA7, SCA8, SCA12, SCA13, SCA17, and SCA25 may start in the first decade, whereas ataxia can start after 65 years in SCA6 (Figure 1). As a general rule, there is an inverse correlation between the length of the repeat and the age of onset.

Some correlations between CAG repeat length and phenotypic presentation have been reported. For instance, SCA3 patients may present a syndrome of ataxia plus peripheral neuropathy or a combination of ataxia plus spasticity when the repeats are less than 73 CAG or more than 73 repeats, respectively.

The phenotype of SBMA includes gynecomastia, testicular atrophy, and muscle weakness due to the degeneration of the anterior horns in the spinal cord.

Symptoms of Friedreich Ataxia

Patients with FA exhibit combinations of oculomotor deficits (mainly fixation instability), dysarthria, gait and limb ataxia, loss of vibration sense and impaired joint position sense starting usually in lower limbs, loss of tendon reflexes with spasticity, and Babinski's sign. Spastic paraplegia may be a leading symptom. Preserved reflexes may occur in the Friedreich ataxia with retained reflexes (FARR). Atypical phenotypes are described, especially in compound heterozygosity. Symptoms related to concentric hypertrophic cardiomyopathy and diabetes mellitus may occur. Electrocardiographic repolarization abnormalities are common. Cardiomyopathy is a cause of premature death. Joint deformities are frequent. Approximately 40% of patients show a slight to moderate hearing deficit. Patients with relatively short expansions usually exhibit a clinical course which is more benign. The phenotype in VLOFA is classically milder.

Symptoms of Fragile X-Associated Tremor/Ataxia Syndrome

Fragile X syndrome is the most common cause of inherited mental retardation. The gene, called *FMR1*, codes for the fragile X mental retardation protein (FMRP) protein. Loss of function of *FMR1* is a model for neurodevelopmental and behavioral disorders such as autism (Table 2). Because Fragile X syndrome is an X-linked disorder, the production of FMRP by the normal allele generally results in less severe phenotypes in women. IQ correlates with blood concentrations of FMRP in both sexes. Overexpression of *FMR1* mRNA causes FXTAS in adults older than 50 years. The phenotype of FXTAS combines intention tremor/ataxia and various combinations of parkinsonism, dementia, neuropathy, and autonomic dysfunction. Cognitive symptoms range from mild frontal executive and memory deficits to global dementia. Anxiety, agitation, or depression are frequent psychiatric manifestations. Emotional problems were more common in adult premutation carriers compared to a control group, and their severity might be correlated with the concentrations of *FMR1* mRNA. The age of onset of tremor or ataxia inversely correlates with repeat size.

Figure 1 Age of onset of triplet expansion disorders. Dots on vertical bars indicate mean ages of onset. (Not illustrated: dentatorubral-pallidoluysian atrophy (DRPLA), range of 0–62 years (mean = 30); fibroblast growth factor (FGF)14, range of 27–40 years (mean = 34).) FXTAS, fragile X tremor ataxia syndrome; FA, Friedreich ataxia; SCA, spinocerebellar ataxia. Adapted from Manto M (2005) The wide spectrum of spinocerebellar ataxias. *Cerebellum* 4: 2–6.

Table 2 Phenotypes in full mutation or premutation of FMR1

	Symptoms	*Onset*	*Penetrance*

Radiological Findings

Magnetic resonance imaging (MRI) is considered as the imaging of choice in SCAs. However, the scan may be normal when symptoms start. Four patterns of atrophy are found in SCAs: (1) a pattern of pure cerebellar atrophy (in SCA4, SCA5, SCA6, SCA8, SCA9, SCA10, SCA11, SCA14, SCA15, SCA16, SCA18, SCA21, and SCA22); (2) a pattern of olivopontocerebellar atrophy (in SCA1, SCA2, SCA3, SCA7, and SCA13); (3) a pattern of global cerebral atrophy (in SCA12, SCA17, SCA19, and DRPLA); and (4) an association of brain atrophy with spinal atrophy in upper segments (in SCA1, SCA2, and SCA3). Most of the SCAs start by a cerebellar atrophy which can progress subsequently to extracerebellar structures. **Figures 2–4** illustrate typical MRI findings in SCA1, SCA2, and SCA3, respectively. Volumetric studies have shown putaminal and caudate atrophy in SCA3 but not in SCA1 or SCA2. A notable finding is the presence of calcifications in the cerebellar nuclei in SCA20. White matter lesions may be observed, particularly in DRPLA.

Proton magnetic resonance spectroscopy (H^1-MRS) has been used to evaluate the metabolic counterpart of cerebellar or olivopontocerebellar volume loss in SCAs. In the spectrum at short echo time, *N*-acetylaspartate (NAA) decrease is well correlated with neuroaxonal loss or dysfunction and with clinical disability. Figure 3 illustrates the abnormal spectrum in a patient presenting with SCA2.

Positron emission tomography may show a reduced 18-fluoro-2-deoxyglucose (FDG) signal in the posterior fossa, as well as in the basal ganglia and cerebral cortex. In SCA3, increased glucose metabolism in the temporal and parietal cortices of asymptomatic carriers may correspond to compensation. Widespread hypometabolism may be observed in SCA6, contrasting with the clinical findings of an apparently pure cerebellar syndrome from the clinical point of view.

FA patients usually present with spinal cord atrophy (Figure 5). Slight to moderate cerebellar vermian atrophy is not exceptional. The neuroradiological features of FXTAS include prominent white matter disease. The involvement of middle cerebellar peduncles on T2-weighted images is suggestive but not specific (Figure 6). Global brain atrophy is more pronounced in the frontal and parietal regions, pons, and cerebellum. The degree of brain atrophy is correlated with the CGG repeat size.

Neuropsychological Deficits

Cognitive deficits occur at variable degrees. Executive deficits are a common finding in several SCAs. Poor performance on the Wisconsin Cart Sorting Test (WCST) is found in SCA1, SCA2, SCA3, and SCA6. Patients may develop a dementia, especially with SCA17. Depression and personality disorders may occur in up to 65% and 25% of patients, respectively.

Clinical Neurophysiology

Very mild to marked neuropathy may develop in SCAs. Sensory or sensorimotor neuropathy is found in approximately 50% of patients with SCA1, in 80% of patients with SCA2, and in 75% of patients with SCA3. Approximately half the patients with SCA6 exhibit a mild sensorimotor neuropathy.

An early peripheral sensory axonal neuronopathy, characterized by a reduction of the amplitude of sensory action potential (SNAP), is common in FA. Somatosensory-evoked potentials are markedly abnormal in most cases. There is an inverse correlation

Figure 2 Brain MRI of a patient with SCA1: (a) sagittal T1-weighted image; (b) coronal-T2-weighted image. The images show vermian and cerebellar atrophy characterized by the enlargement of the fissures and the absence of pontine atrophy. Notice the atrophy of the supratentorial structures. MRI, magnetic resonance imaging; SCA, spinocerebellar ataxia.

Figure 3 Brain MRI and H^1-MRS of a patient with SCA2: (a) MR images used to plan the single voxel acquisition; (b) spectrum acquired in the deep left cerebellum of patient; (c) spectrum acquired in the deep left cerebellum of age- and sex-matched control. The images in (a), axial FLAIR, coronal T2-weighted, and sagittal T1-weighted (from left to right), show global atrophy in the posterior fossa, as well as in the supratentorium The spectrum in (b) shows a decrease of the NAA/Cr ratio (1.26) compared to the control (1.53). Cho, choline; Cr, creatine; FLAIR, fluid-attenuated inversion recovery; H^1-MRS, proton magnetic resonance spectroscopy; MRI, magnetic resonance imaging; NAA, *N*-acetylaspartate; TIR/M, T inversion recovery-modular; TITFE/M, T1 turbo-fast echo-modular.

between GAA expansion size and the severity of the electrophysiological deficits. Peripheral motor nerve action potential amplitude, and motor conduction velocities are within the normal range in most patients. Central motor conduction times (CMCTs) are increased and worsen with time.

An electroencephalogram (EEG) may show a predominance of slow disorganized activities in hereditary ataxias. Interictal EEG may be abnormal is patients exhibiting seizures such as SCA10.

Diagnosis and Differential Diagnosis

As a result of the marked phenotypic variability of triplet expansion disorders even within single families, the diagnosis cannot rely solely on clinical evaluation;

Figure 4 Brain MRI of a patient presenting SCA3: (a) sagittal T1-weighted image; (b) axial T2-weighted image. Images show enlargement of the cisterns in the posterior fossa with global cerebellar atrophy; an involvement of the brain stem is visible at the level of the medulla. MRI, magnetic resonance imaging; SCA, spinocerebellar ataxia.

Figure 5 Spinal MRI (cervical segments) of a patient presenting Friedreich ataxia: (a) T2-weighted image; (b) T1-weighted image. Shrinkage of the spinal cord is visible. H, head (cranial direction); F, foot (caudal direction).

Figure 6 Brain MRI in a patient presenting FXTAS: (a) sagittal T1-weighted image; (b) axial FLAIR image; (c) coronal T2-weighted image. The image in (a) shows the vermian atrophy. The images in (b) and (c) show the cerebellar atrophy and suggestive hypersignal abnormalities in the white matter of middle cerebellar peduncles bilaterally; this is more obvious on the right (arrow). Note the atrophy of cerebral sulci in (c). FXTAS, fragile X tremor ataxia syndrome; FLAIR, fluid-attenuated inversion recovery.

a detailed genetic search is necessary. From the phenotypic point of view, several genetic diseases may overlap with triplet expansion disorders.

The following disorders need to be considered in the differential diagnosis, among others: episodic ataxias (EA), hereditary spastic paraplegias (HSP), Huntington's disease (CAG triplet expansion), essential tremor, hereditary sensory–motor neuropathy (HSMN), mitochondrial diseases (Kearns-Sayre syndrome; myoclonus epilepsy associated with ragged-red fibers (MERRF) syndrome; mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke (MELAS) syndrome; neuropathy, ataxia and retinitis pigmentosa (NARP); Leigh syndrome), gluten ataxia, vitamin E deficiency (AVED), ataxia with ocular apraxia (AOA), leukodystrophies, progressive myoclonic epilepsies, multiple system atrophy, parkinsonism, and cerebrovascular diseases. Family history can remain negative in SCAs with late-onset symptoms, such as SCA6; in case of severe anticipation, as in SCA7; in case of reduced penetrance, as in SCA17; in families with marked phenotypic variations among members; and in case of false paternity.

Pathological Findings

Dominant olivopontocerebellar atrophy is a characteristic feature of SCA1, SCA2, and SCA7. Various degrees of Purkinje cell degeneration, ranging from depleted dendritic trees to total loss, are regularly found (Figure 7). A characteristic feature of SCA with cortical cerebellar atrophy is the formation of empty baskets about the atrophic Purkinje cells. The marked involvement of the Purkinje neurons contrasts with the relative sparing of the stellate/basket cells and Golgi neurons. The granular layer of the cerebellar cortex is often relatively preserved. Grumose degeneration of neurons in dentate nuclei – which can occur also in FA – is frequently found in SCA3. Retrograde atrophy of the inferior olivary nuclei occurs in several SCAs and hypertrophic inferior olivary neurons may be found in DRPLA. Unlike in SCA6, which spares the spinal cord, gray and white matter abnormalities are found in the spinal tracts of SCA2 and SCA3 patients. Nigral lesions are common in SCA2 and SCA3.

Immunohistochemical studies show neuronal inclusions positive for antipolyglutamine antibodies (Figure 8). They are considered a pathological hallmark of SCAs. Inclusion bodies are most frequent in the neurons of the basis pontis in SCA1, SCA2, and SCA3.

In FA, pathological changes occur first in the dorsal root ganglia, with the loss of large sensory neurons, followed by axonal degeneration in the posterior

Figure 7 Immunofluorescence with anticalbindin: (a) patient with SCA6; (b) control. Scale bar = 50 μm. The image in (a) shows Purkinje cell atrophy. Reduction in the size of Purkinje cell bodies and simplified dendritic tree are observed in SCA-6. SCA, spinocerebellar ataxia. From Koeppen A (2005) The pathogenesis of spinocerebellar ataxia. *Cerebellum* 4: 62–73.

Figure 8 Inclusion bodies in spinocerebellar ataxias: (a–b) SCA3, anti-ataxin 3 (c) SCA3, anti-ubiquitin; (d) SCA1, antipolyglutamine; (e) SCA2, antipolyglutamine; (f–h) SCA17 (TATA-binding protein), antipolyglutamine; (i–j) SCA6, antipolyglutamine. Image (a) shows multiple small nucleoliform ataxin 3-reactive intranuclear inclusions in neurons of the basis pontis (arrows). Image (b) shows ataxin 3 reaction product (arrow). Image (c) shows co-localizing with ubiquitin (arrow). Image (d) shows positive–contrast reaction product in large intranuclear inclusions (arrows). Image (e) shows that the intranuclear inclusion body (arrow) is relatively small compared to those in SCA1 (d). In image (g), neurons of the basis pontis show pannuclear reaction product. Image (h) shows pannuclear inclusions in basket and stellate cells, and the inset shows an intranuclear inclusion in a surviving Purkinje cell. In image (i), pontine neurons show small intracytoplasmic inclusions (arrows). Image (j) shows Purkinje cell containing multiple cytoplasmic inclusion bodies. Scale bar = 25 μm (a–c, f, h); 10 μm (d, e, g, j, h inset); 15.9 μm (i). SCA, spinocerebellar ataxia. From Koeppen A (2005) The pathogenesis of spinocerebellar ataxia. *Cerebellum* 4: 62–73.

columns and pyramidal and spinocerebellar tracts, as well as atrophy/neuronal loss in Clarke's column. Mild degenerative changes may be found in the medulla, cerebellum, and pons. A biopsy of peripheral sensory nerves reveals an important loss of myelinated fibers, with the complete disappearance of large myelinated fibers, in absence of regenerative process.

A substantial degree of inflammation and a perinuclear accumulation of iron are observed in cases with hypertrophic cardiomyopathy. The analysis of iron and iron-responsive proteins suggests that cardiomyopathy results from iron-catalyzed mitochondrial damage followed by muscle-fiber necrosis and a chronic reactive myocarditis. Although iron accumulation in the heart is now an established feature for

FA, cardiomyopathy differs greatly from cardiac hemochromatosis, in which iron levels rise to much higher concentrations and iron does not accumulate in mitochondria. At the level of the heart, the thickness of interventricular septum and posterior wall and the ventricular mass indices are correlated with the GAA repeat length on the shorter allele.

FXTAS is characterized by the presence of eosinophilic ubiquitin-positive intranuclear inclusions in the neurons and in the astrocytes, both in the brain and spinal cord. Inclusions are τ-negative/α-synuclein-negative and contain *FMR1* mRNA, an argument in favor of the toxic RNA hypothesis. There is a correlation between the repeat size and the frequency of intranuclear inclusions. Spongiosis of the middle cerebellar peduncles and the loss of Purkinje cells are common. Weak, elongated, and immature synapses are found, hence the hypothesis that FMRP is involved in synaptogenesis.

Molecular Basis of Triplet Expansion Disorders

The repeats exert their detrimental effects through different molecular mechanisms, depending on whether they are located in coding or noncoding regions of the gene (Figure 9). On the basis of pathogenic mechanisms, disorders of unstable repeat expansions can be divided in four groups: (1) diseases caused by expansions of coding repeats which result in altered protein function, (2) diseases caused by expansions of noncoding repeats which result in loss of protein function, (3) diseases caused by expansions of noncoding repeats which result in impaired RNA function, and (4) diseases of unknown pathogenesis. The loci of trinucleotide expansions are given in Table 3.

Gain of Function of Proteins

Polyglutamine expansions are associated with transcriptional alterations. For several SCAs (SCA1, SCA2, SCA3, SCA6, SCA7, SCA8, and SCA17), an abnormally long polyglutamine tract has been reported as in Huntington's disease, hence the terminology of polyglutamine expansion disorders. Phenotypic differences among the diseases are determined not only by the repeat length but also by the instrinsic function of the disease-causing protein. Formation of unusual structures by repetitive DNA seems to be a core mechanism of repeat instability which leads to elongated polyglutamine tracts.

Proteins resulting from defective genes aggregate both in the cytoplasm and in the nucleus. They are cleaved before entering the nuclei. Transcriptional deregulation might be a key factor in the pathogenesis of most polyglutamine disorders, polyglutamine tracts interacting closely with well-defined transcriptional regulators such as cAMP responsive element-binding protein (CREB). For instance, the SCA7 gene product, ataxin 7, is part of a transcriptional coactivator complex, called STAGA, which has histone acetyltransferase activity. In SCA17, the CAG repeat expansion occurs in TATA-binding protein (TBP), a transcription factor. SBMA (X-linked) is caused by a polyglutamine expansion in the androgen receptor. Impaired protein conformation leads to protein accumulation and a cascade of aberrant protein–protein interactions, resulting finally in cell death. Chaperones and proteasomes are used to refold or dispose polyglutamine-containing fragments in order to prevent further aggregation. Accumulation of insoluble aggregates occurs in the nuclei for SCA1, SCA7, and SCA17; in the cytoplasm for SCA2 and SCA6; and in both the nuclei and cytoplasm for DRPLA, SBMA, and SCA3. Small aggregates sequester other proteins and protein complexes including proteasomes and transcription factors, leading to inclusion bodies. Formation of inclusions might be a protective mechanism against the toxicity of expanded polyglutamine proteins. A mechanism of impaired Ca^{2+} influx into neurons in SCA6, caused by mutations in the α-1A subunit of the voltage-gated neuronal Ca^{2+} channel, could contribute to the neurological deficits in this relatively pure cerebellar syndrome.

Loss of Protein Function

The decreased expression of molecules involved in translational control as in fragile X syndrome and in mitochondrial function as in FA has widespread pathogenic effects, as expected. Frataxin is a highly conserved nuclear-encoded protein found in prokaryotes and eukaryotes at the inner mitochondrial membrane. Frataxin appears necessary for the efficient regulation of cellular iron homeostasis. GAA trinucleotide repeat expansion in the frataxin gene results in frataxin deficiency, due to the inhibition of transcriptional elongation. Most patients have expansions in both alleles. The longer the repeat, the lower the level of frataxin. All patients carry at least one copy of an intronic GAA triplet-repeat expansion impairing frataxin transcription. Molecular diagnosis of FA is based on the detection of this expansion, which is present in homozygosity for the majority of cases. Some patients are heterozygous for the GAA expansion and show a frataxin point mutation at the other allele (compound heterozygotes). Several roles have been suggested for frataxin: as an iron-binding protein, in the protection

Figure 9 Trinucleotide repeat expansions in coding and noncoding DNA regions. (Not shown: CAG expansion in Huntington's disease (exon 1 of the Huntingtin gene).) DRPLA, dentatorubral-pallidoluysian atrophy; FA, Friedreich ataxia; FGF, fibroblast growth factor; FXS, fragile X syndrome; ORF, open reading frame; SBMA, spinal and bulbar muscular atrophy; SCA, spinocerebellar ataxia; UTR, untranslated region.

Table 3 Loci of triplet expansion disorders

Expansion subtype (*gene product*)	*Locus* (*normal/pathogenic repeat length*)	*Putative function*
Spinocerebellar ataxias		
SCA1 (ataxin 1)	6p23 (6–39/40–82)	Transcription
SCA2 (ataxin 2)	12q24.1 (15–24/32–200)	RNA metabolism
SCA3/Machado-Joseph disease (ataxin 3)[a]	14q24.3–q31 (13–36/61–84)	De-ubiquitylating activity
SCA4	16q22.1	
SCA5	11p12	
SCA6 (CACNA1A)	19p13 (4–20/20–29)	P/Q type α-1A Ca^{2+} channel subunit
SCA7 (ataxin 7)	3p12–13 (4–35/37–306)	Transcription
SCA8	13q21 (16–34/>74)	
SCA9		
SCA10 (ataxin 10)	22q13 (10–20/500–4500)	
SCA11	15q14–21.3	
SCA12 (PPP2R2B)	5q31–33 (7–45/55–78)	Phosphatase regulation
SCA13	19q13.3–q13.4	
SCA14 (PKC-γ)	19q13.4-qter	
SCA15	3p24.2-pter	
SCA16	8q22.1–q24.1	
SCA17 (TATA-box binding protein)	6q27 (25–42/47–63)	Transcription
SCA18	7q22–q32	
SCA19[b]	1p21–q21	
SCA20	11?	
SCA21	7p21.3–p15.1	
SCA22[b]	1p21–q23	
SCA23	20p13–12.3	
FGF14	13q34	
SCA25	2p15–p21	
DRPLA (atrophin 1)	12p13.31 (7–34/49–88)	Transcription
FX		
Fragile X syndrome (FMRP)	Xq27.3 (6–60/>200 full mutation)	Regulation of translation
FXTAS (FMRP)	Xq27.3 (6–60/60–200 premutation)	RNA-mediated
Fragile X syndrome E (FMR2)	Xq28 (4–39/200–900)	Transcription?
Friedreich ataxia (frataxin)		
	9q13–q21.1 (6–32/200–1700)	Iron metabolism in mitochondria

[a]Allelic to Machado-Joseph disease (MJD).
[b]CA19 might be allelic with SCA22.

and synthesis of Fe–S clusters, and as an associate of ferrochelatase for heme metabolism. Tissue from patients is characterized by iron deposits and a generalized decrease in the activity of proteins containing Fe–S clusters. In the nervous system, frataxin is highly expressed in the spinal cord, particularly in the dorsal root ganglia and at lower levels in the cerebellum.

Figure 10 Interactions between *FMR1* gene and mGluR5 receptors. In subjects with a normal allele, mGluR5 stimulates the translation of a pool of *FMR1* mRNA. FMRP, the gene product, represses mRNA translation (FMRP targets the pool of mRNAs at the synapse). In case of full mutation, the translational repression is lost. The mGluR5-dependent long-term depression (LTD) is thus increased. mGluR, metabotropic glutamate receptor. Adapted from Jacquemont S, Hagerman R, Hagerman P, and Leehey M (2007) Fragile-X syndrome and fragile X-associated tremor/ataxia syndrome: Two faces of *FMR1*. *Lancet Neurology* 6: 45–55.

Fragile X syndrome is characterized by transcriptional silencing and loss of the protein product of *FMR1*, FMRP. Tracts with more than 200 CGG repeats cause fragile X syndrome, whereas intermediate alleles of 60–200 repeats (premutation) cause FXTAS. Fragile X syndrome may rarely result from deletions of *FMR1* or its promoter and not from the expansion of CGG repeats. FMRP is enriched in neurons. It associates with polyribosomes as part of a large messenger ribonucleoprotein particle (mRNP). FMRP inhibits translation. FMRP also localizes to the dendritic spines, where an upregulation occurs in response to stimulation by metabotropic glutamate receptors (mGluRs) (Figure 10). FMRP could be involved in translation of specific RNA targets at synapses and might modulate synaptic maturation and pruning (elimination of weak synapses) via a regulatory action of gene products involved in synaptic developments.

Patients with fragile X syndrome E (FRAXE) exhibit variable phenotypes, including learning deficits and mental retardation. Expansion of a CCG repeat of the *FMR2* gene results in transcriptional silencing and hypermethylation of the CpG Island. Deficits in the mitogen-activated protein kinase (MAPK) pathway are associated with X-linked mental retardation syndromes, suggesting that *FMR2* could play a role in these pathways. Both in fragile X syndromes and in FA, there is a correlation between repeat length and disease severity; transcriptional silencing being greater with longer repeats.

Impaired RNA Function

Carriers of premutation alleles (60–200 CGG repeats) in the *FMR1* gene may develop FXTAS. There are several lines of evidence indicating an RNA-mediated pathogenesis, with an RNA toxic gain of function. The elevation of *FMR1* mRNA to levels 2–8 times normal occurs, and the translation efficiency of *FMR1* mRNA is reduced. Inclusions co-localize with components of the protein degradation system. FXTAS shares with the next group the fact that expansion mutations occur in noncoding mRNA.

Unidentified Mechanism

SCA8 is caused by an expansion of CTG triplets in the 3′UTR of an untranslated RNA. The SCA8 transcript might function as an endogenous antisense RNA overlapping with the *KLHL1* gene encoding an actin-binding protein. Toxic effects of the expanded CUG RNA might participate in the pathogenesis.

SCA10 is characterized genetically by a pentanucleotide-repeat expansion in an intron of gene *E46L* (*ATXN10*). ATTCT repeats are unique in the high content of A-T, a feature of DNA sequences that form unpaired structures under torsional stress – called DNA unwinding elements (DUE). The length of expanded ATTCT repeats is variable in different tissues and highly unstable during paternal transmission. SCA10 repeat expansion is one of the largest microsatellite repeat expansions described in the human genome. Here also, the size of the expanded repeat shows an inverse correlation with the age of onset. SCA10 encodes a ATXN10 protein of 475 amino acids with a molecular weight of approximately 53 kDa. Transcriptional silencing of the gene is a plausible hypothesis.

A CAG repeat expansion has also been found in the 5′ region of the *PPP2R2B* gene in SCA12. *PPP2R2B* is a regulator of the protein phosphatase PP2A, modulating dephosphorylation activity for specific substrates such as vimentin or τ. The expansion does not encode a polyglutamine tract.

Experimental Models of Repeat Expansion Disorders

Mouse models have been generated for SCA1, SCA2, SCA3, SCA7, and SCA8. Transgenic mice expressing expanded polyglutamine tracts in a foreign protein develop a phenotype and neuropathological findings reminiscent of polyglutamine disorders. The fact that overexpression of molecular chaperones in fly and mice models reduces toxicity supports the hypothesis that expanded polyglutamines enhance mechanisms acting against protein misfolding. In *Drosophila*, histone deacetylase inhibitors have been shown to reduce toxicity.

Studies in yeast and mice have provided insights into FA pathogenesis. The deletion of the yeast

frataxin homolog YFH1 results in the accumulation of iron in the mitochondria; increased sensitivity to oxidative stress; and reduced activities of aconitase, which contains Fe–S clusters. The inactivation of the FA mouse gene leads to early embryonic lethality, in absence of iron deposits, showing an important role of frataxin in development. Oxidative stress has been pointed to as a main factor in the pathogenesis of FA, although a recent study in a mouse model challenged this hypothesis.

The *Drosophila* model of fragile X syndrome is characterized by a rescue of synaptic plasticity deficits with mGluR antagonists. Data in this model support the importance of the association of FMRP with the RNA interference machinery. FMRP might bind specific RNA ligands; this would recruit RNA-induced silencing complex (RISC) and micro-RNAs, facilitating translational control. *FMR2*−/− mice present with deficits in regulation of nervous system development, sensory perception, and synaptic plasticity. The fragile X premutation CGG repeats generate inclusion formation and progressive degeneration in the eye of *Drosophila melanogaster*. These inclusions are mainly found in the cytoplasm and are ubiquitin and HSP70 positive. Electrophysiological studies reveal an increased mGluR1-dependent long-term depression (LTD) in *FMR1* knockout mice, supporting the hypothesis of an upregulation of the downstream effectors of mGluRs.

Genetic Counseling

Diagnosis of a triplet expansion disorder has consequences for many family members. Therefore, genetic counseling is recommended when a triplet expansion disorder is suspected or demonstrated. Families of carriers of fragile-X alleles illustrate the complexity of counseling.

Therapies

Treatment of SCAs remain an open issue. We are still missing a therapy to prevent neuronal cell death. The benefits of pharmacological treatments remain limited, although some benefits regarding ataxic symptoms have been reported with 5-hydroxytryptophan, buspirone, acetazolamide in SCA6, and deep brain stimulation in patients presenting tremor in SCA2. *N*-methyl-D-aspartate (NMDA) modulators might be helpful in some cases. Amantadine/levodopa/dopamine agonists may improve extracerebellar symptoms in SCA2 and SCA3. Baclofen/tinazidine improves spasticity. Dystonia can be treated with botulinum toxin. However, patients with spinal cord involvement are at risk for developing muscle atrophy. Restless legs and periodic leg movements in sleep usually respond to dopaminergic treatment. Muscle cramps may be disabling, especially in SCA3. Cramps may respond to magnesium, quinine, or mexiletine. Urinary urgency is improved with spasmolytics or adrenergic α-receptor blockers. Depression may improve with antidepressant treatment. Seizures require the administration of antiepileptic drugs according to international guidelines.

Pilot studies with vitamin E, coenzyme Q10, or idebenone have shown the potential effects of antioxidant therapies for FA. Idebenone seems to play a protective effect against cardiomyopathy. If iron chelators are to be used, they must be able to enter in the mitochondria. Larger randomized clinical trials with antioxidants are ongoing. A combination of antioxidants, anti-inflammatory drug, and a chelating drug could be considered. β-Blockers at high doses could provide benefits in patients with heart disease.

mGluR5-coupled pathways are dysregulated in individuals with fragile X syndrome. Whether mGluR5 antagonists (such as derivatives of methylphenylethynylpyridine (MPEP)) could be useful in treating FXTAS needs to be investigated.

Speech rehabilitation and regular physiotherapy/occupational therapy are recommended. Most patients will have some improvements with the use of orthesis, sticks, or strollers. Unfortunately, many patients will become wheelchair-bound during the course of their illness. Swallowing difficulties are common in advanced cases of SCAs. Gastrostomy is usually recommended.

New drugs are currently tested in transgenic models (*Caenorhabditis elegans*, *Drosophila*, and mice). RNAi therapies with the goal of inhibiting polyglutamine-induced neurodegeneration is under evaluation. Transplantation of stem cells is another approach. Prevention of protein misfolding and aggregation by overexpressing chaperones, such as heat shock protein (HSP)70 or DNAJ1, and application of histone deacetylase (HDAC) inhibitors, increasing acetylation at particular residues on histones, are being assessed.

For specific queries about DNA studies, readers are referred to the Genetic Alliance website. Users will have access to supports groups (e.g., National Ataxia Foundation (NAF) and Friedreich Ataxia Research Alliance (FARA)). In Europe, the Eurosca consortium does the analysis; a list of universities performing the studies is on the website.

Split-Brain Patients

M E Roser, University of Plymouth, Plymouth, UK
M S Gazzaniga, University of California at Santa Barbara, Santa Barbara, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Terminology

The term split brain is used to denote a patient in whom the cortical commissures have been severed, for the relief of epilepsy that cannot be controlled by medication, in an operation known as either a commissurotomy or a callosotomy. A commissurotomy involves severing the corpus callosum, the anterior commissure, and the hippocampal commissure. The massa intermedia, if present, is also severed. A callosotomy involves sectioning of the corpus callosum alone, either completely or partially. In a partial callosotomy, either the anterior or the posterior callosum may be cut. Complete callosal disconnection may result from a staged callosotomy in which the anterior and the posterior parts of the callosum are severed in two separate operations.

History

The split-brain operation in humans was first reported in the early 1940s by the neurosurgeons Van Waganen and Herren, who carried out more than 30 such operations as a treatment for intractable epilepsy. Severing the commissures between the hemispheres prevented the interhemispheric propagation of seizures. These patients were later tested by Akelaitis, who reported that the patients showed no marked effects on behavior beyond the reduction in their epileptic symptoms. This negative finding was congruent with earlier studies of callosal infarcts which suggested that the cortical commissures had little functional role, a state of affairs which prompted Karl Lashley to facetiously remark that the purpose of the corpus callosum was to "keep the hemispheres from sagging."

It was not until the systematic experiments carried out on commissurotomized cats and monkeys by Ronald Myers and Roger Sperry that the importance of the cortical commissures for the transmission of information between the hemispheres became strikingly apparent. Cutting the commissures disrupted the transfer of visual and tactile information, and learned associations, from one hemisphere to the other. The animal studies also suggested that division of the hemispheres would have no catastrophic consequences for human patients because the animals displayed normal behavior outside of the testing situation.

Following the publication of these studies, the commissurotomy operation was carried out on a number of human patients in the early 1960s by the neurosurgeons Philip Vogel and Joseph Bogen. These patients are commonly referred to as the California series and include patients W.J., N.G., and A.A. Other extensively tested patients, including P.S. and J.W., were operated on in the 1970s by Donald Wilson and David W Roberts at Dartmouth Medical School. Many of these patients have participated in a large number of experiments over decades.

The divided human brain offered a unique opportunity for each hemisphere to be studied in relative isolation. The initial investigations of hemispheric communication and asymmetry in humans were carried out by Michael Gazzaniga, working in the laboratory of Roger Sperry. These studies demonstrated the striking disconnection syndrome in which each hemisphere remains unaware of the sensory and gnostic properties of stimuli presented to its opposite number.

Testing Split-Brain Patients

In everyday situations, the split-brain patients appear normal. This is due to the freedom with which they can direct their gaze and movements around in the environment, allowing both hemispheres knowledge of their surroundings. Only when patients are tested in strictly controlled circumstances does the disconnection syndrome become apparent. To test each hemisphere individually, stimuli must be presented to only one hemisphere. Tactile shapes, for example, may be palpated by one hand but hidden from view.

Testing with visual stimuli usually involves the presentation of stimuli to each of the visual hemifields for a duration less than 200 ms, brief enough to preclude a saccade toward the stimulus while it is displayed. Each hemifield projects to the contralateral visual cortex, and thus a stimulus in the left hemifield will be seen by the right hemisphere. In order to achieve lateralized presentation of stimuli, patients are required to fixate on a central point on the display. Stimuli are displayed at locations eccentric to the foveated point by several degrees of visual angle. A chin rest is often used to minimize head movements and infrared eye tracking can ensure that the patient's gaze remains on the fixation point. Using the brief-presentation technique, simple pictures, words, shapes, and colors can be lateralized.

For presentations longer than a few hundred milliseconds, necessary for extended viewing of complex stimuli, steps must be taken to ensure the stimulus remains in one visual hemifield. One method is to prevent foveation by employing a stimulus deflector, which tracks eye movements and adjusts the view of the display accordingly so as to ensure that any saccade toward the stimulus is accompanied by a corresponding movement of the stimulus away from fixation. Another method allows for extended viewing in free, monocular, vision but restricts visual input to one hemisphere through the use of a contact lens that occludes one-half of the visual field. Finally, visual information may be presented in full view of the patient, and thus to both hemispheres, with a response required from only one hemisphere.

Responses are typically collected from the hemisphere to which the stimulus was presented, often by using the hand on the same side as the stimulus. Control of the distal effectors, such as fingers, is thought to be predominantly contralateral. Thus, button presses, as a measure of either simple reaction time or of categorical choice, are often used. In some experiments, a hemisphere may be required to respond by reaching for a picture representing the correct choice.

Care must be taken when testing patients that one hemisphere is not able to cross-cue, or tip off, its opposite number as to the nature of a stimulus or the correct response. Patients are seated with their hands and feet apart. Objects are placed on a soft surface so that they do not make identifying noises when moved.

Neuropsychological Profile

Most patients who have participated in multiple studies over several decades have been assessed as showing verbal, memory, and attentional capacities within normal limits, although scores are often below average. Memory, particularly free recall, shows the greatest deficit, and may result from section of both the corpus callosum and the hippocampal commissure.

Drawing conclusions about function in the brain on the basis of results from split-brain patients is complicated by their history of epilepsy and invasive surgery. Because split-brain patients have diverse medical histories, it is desirable to test as many patients as possible. Often, a multiple case study approach is taken because patients cannot be grouped for comparison with a control group. This heterogeneity does, however, increase the impressiveness of obtaining the same result in two or more patients because consistent patterns of asymmetry are unlikely to have resulted from common neurological history.

Although the brains of callosotomy patients differ greatly from intact brains, evidence from both behavioral testing and functional imaging studies suggests that the patterns of functional lateralization observed in the split brain are congruent with those found in neurologically intact participants in many different cognitive domains. It must be remembered, however, that the divided brain is an unusual situation and that cognitive processes may not operate in the same fashion in each isolated hemisphere as they do in the intact brain. Thus, comparison with a control sample is desirable.

The Disconnection Syndrome

One of the earliest findings from split-brain research was the importance of the corpus callosum for the transmission of information between the hemispheres. The relative isolation of each hemisphere is referred to as the disconnection syndrome and is manifested as poor performance at cross-comparisons of stimuli presented to different hemispheres and, for most patients, an inability to verbally name stimuli presented to the right hemisphere.

Split-brained patients often perform at chance level on tests in which they must decide whether patterns or objects in the two visual fields are the same or different. This includes letters, digits, words, colors, shapes, and luminances. The importance of the corpus callosum for the transfer of information between the visual cortices is also apparent using electrophysiological measures. Sensory evoked potentials are not seen over the hemisphere ipsilateral to a visual stimulus in patients in whom the posterior corpus callosum has been severed. Some patients, however, can judge whether lines on each side are aligned or not. These preserved abilities presumably rely on intact subcortical pathways between the hemispheres.

An inability to name stimuli presented to the right hemisphere can be demonstrated by having the split-brain patient fixate on a central point and flashing stimuli to the left visual field. If the patient is asked to verbally name the stimulus presented to his or her left visual field, he or she is unable to do so because the right hemisphere, in most patients, is not able to produce speech and is separated from the linguistically able left hemisphere. The right hemisphere can, however, control the left hand to find a covered object that corresponds to the stimulus presented. The patient is not able to verbally name the object until it is moved into the right visual field or the right hand.

Other evidence for perceptual disconnection comes from presenting, to each visual field, words that can be

combined to form the names of emergent objects. Patients are then asked to draw what they saw. One callosotomy patient, V.P., who has some residual fibers left in her corpus callosum, is able to integrate words presented in the two visual fields (e.g., the words 'head' and 'stone') and draw the emergent object, in this case a headstone. Another subject, J.W., whose corpus callosum was fully cut, did not draw emergent objects when tested but instead drew each object separately. Thus, the perception of complex visual information is divided between the hemispheres of the split brain.

Evidence for the division of attention between the hemispheres is more equivocal. Visual search of an array of objects can be carried out independently by each hemisphere. This was suggested by the observation that the addition of items to the stimulus array impacts to a lesser degree on performance when the objects to be searched are distributed between the two visual hemifields than when the items are all contained within one hemifield. The ability to carry out two independent search processes also leads to a rare advantage in performance for split-brain patients over callosally intact participants.

The ability to divide some attentional processes between the hemispheres does not, however, endow split-brain patients with twice the attentional resources available to neurologically normal individuals. Performance of a demanding task by one hemisphere has been shown to negatively impact upon performance by the other hemisphere, suggesting a finite, shared, pool of attentional resources.

Learned bimanual tasks are not adversely affected by callosotomy, although the acquisition of new skills involving complex bimanual coordination is impaired. Conversely, callosotomy patients can perform some coordination patterns which callosally intact subjects find difficult, such as drawing two different shapes simultaneously, one with each hand. This independence of action following callosotomy suggests that the corpus callosum contributes to the interhemispheric integration of bimanual movement. Some studies suggested that callosal integration is confined to information about movement direction and not timing because temporal coupling of the hands was preserved in callosotomy patients, although recent results have suggested that this only occurs for movements with discrete events.

The divided brain presents an opportunity to study each hemisphere in relative isolation. It can also allow the researcher to obtain double dissociations of cognitive processes if the two processes rely critically on different hemispheres. In one case, seemingly indivisible cognitive processes, such as spoken and written language output, can be separated into lateralized components.

Partial Callosotomy and Callosal Channels

Callosotomy is typically performed in a staged manner, with either the anterior callosum, the genu, or the posterior callosum, the splenium, sectioned first, followed by the remaining fibers if the first operation fails to sufficiently reduce the patient's epilepsy. Because the corpus callosum is organized in a roughly topographic fashion, tests of patients after partial callosotomy can reveal the functional specificity of regions of the corpus callosum. Section of the splenium and midbody disrupts the transmission of visual and somatosensory information between the hemispheres, resulting in poor performance on cross-comparison tasks. Intact anterior pathways are able to support the transfer of semantic information between the hemispheres, allowing patients to perform above chance on tests of naming left visual field stimuli, although performance is often slow and imprecise. Anterior section produces less evidence of disconnection, although the disruption to anterior midbody tracts can affect bimanual coordination for complex motions.

Subcortical Transfer

Each hemisphere of the split brain shows awareness of the presentation of a stimulus to the opposite hemisphere. Simple responses, such as button presses, can be made to stimuli presented in the visual field opposite the response hand. These are known as crossed responses and are subject to a delay, ranging from 30 to 70 ms, relative to uncrossed responses. This delay is thought to index the time taken for transmission of a signal from the hemisphere receiving the stimulus to that making the response, via subcortical channels, and contrasts with 5–15 ms delay for interhemispheric transfer in callosally intact subjects.

The affective content of a stimulus may also be transferred between the hemispheres, as shown by an experiment in which emotive pictorial stimuli were presented to the right hemisphere and were found to affect the judgment of emotionally neutral stimuli, and the patient's current environment, by the left hemisphere.

The complexity of subcortical visual transfer in the split brain is limited to basic spatial information that can support interhemispheric comparisons of stimulus location and alignment. Some experiments suggested that higher order information, such as category or numerical value, could be transferred subcortically and support comparative judgments such as whether a stimulus in one visual field was bigger than

a stimulus in the opposite field or whether two stimuli were both of the same categories. The deterioration in performance of stimulus cross-comparisons with increasing set size suggested, however, that this apparent ability was due not to the transfer of complex information but to the responding hemisphere adopting a response strategy based only on the information presented to it. Thus, care must be taken, when testing subcortical transmission in split-brain patients, to ensure that experimental situations truly require transmission for above-chance performance. The transfer of binary information, such as whether a number is odd or even, coupled with response strategies, seems sufficient to explain most instances of apparent higher order transfer.

Hemispheric Specialization

Testing the split brain can reveal whether each isolated hemisphere is competent at a particular task and the degree to which a process can be supported by a single hemisphere. The term specialization, when applied to one of the hemispheres in the split brain, is sometimes used to imply that one hemisphere bears primary responsibility for a particular perceptual, cognitive, or motor process, usually on the basis of a performance difference between the hemispheres. Asymmetries in behavior are often more stark in the divided brain than in lateralized responses from normal controls. Double dissociations between the performances of the two hemispheres on two tasks are sometimes observed, and most fully justify the interpretation that the different processes are predominantly handled by different hemispheres. This is especially true if each hemisphere performs at chance level on one task. Often, hemispheric differences in performance are relative because both hemispheres are capable of above-chance performance. This result is often interpreted as suggesting that the two hemispheres contribute to performance to different degrees. Findings suggesting different levels of competence in each hemisphere are congruent with studies in neurologically normal subjects that suggest that many hemispheric asymmetries are relative, rather than absolute, and can change as task demands change.

Language

Early testing of the split-brain patients revealed their inability to name stimuli in the left visual hemifield and confirmed the primacy of the left hemisphere for the understanding and production of language. In most patients, only the isolated left hemisphere is able to process complex grammar, although in some patients the right hemisphere is capable of making simple grammaticality judgments. The right hemisphere of most patients can understand simple verbal instructions, although these are often accompanied by visual examples presented in central vision. It can also understand simple phrases which, although they contain several words organized grammatically, may be best characterized as single items in a lexicon.

The right hemisphere is able to understand the meaning of words and can choose a picture that represents the item represented by an auditory or visual word stimulus, but in most patients it is unable to match rhyming words and pictures. This suggests that the right hemisphere does not generate the corresponding phonology for the item represented in the picture. However, several patients have demonstrated the development of the ability to verbally name stimuli presented in the left visual hemifield, in one case approximately 10 years after surgery.

Visual Perception

Both hemispheres in the split brain are capable of a range of visual processes, including object recognition, but the right hemisphere displays superiority for visual processes that include a spatial component. The spatial ability of the isolated right hemisphere was demonstrated early in the history of split-brain testing by requiring patients to replicate a pattern by arranging blocks with each hand. This task was performed better, by most patients tested, when using the left hand and patients were frequently unsuccessful when using their right hand. Similarly, tactile patterns are better recognized by the right hemisphere. In the visual domain, the difference in spatial ability between the hemispheres is apparent on a test of mental rotation, which requires the patient to decide whether two objects are mirror images or identical, but rotated, objects. Additional studies have found right hemisphere superiority for judging spatial relations, such as orientation and alignment, between objects. Comparisons of visual stimuli on nonspatial dimensions, such as luminance, can be performed equally well by the two hemispheres.

Based on observations of visual field differences in normal subjects, several dichotomies have been proposed for how visual processes differ between the two hemispheres. These include specializations for processing high- and low-spatial frequencies, the global and local arrangement of arrays, and categorical and coordinate representations of space. Testing in the split brain has not lent strong support to these hypotheses, with several studies failing to show the predicted hemispheric differences. The most common finding was that both hemispheres were capable of

performing both modes of processing included within each of the dichotomies, with occasional instances of superior performance by one hemisphere, in line with predictions. This finding is congruent with the view that hemispheric specialization is relative, and fluid, rather than absolute.

The right hemisphere has shown superiority over the left hemisphere for some types of perceptual grouping. Both hemispheres, in two callosotomy patients, were able to group visual stimuli and perceive illusory contours, but only the right was able to group stimuli and perceive an amodally completed object, in which the object's illusory boundaries were partly occluded. This finding suggests that simple perceptual grouping processes are supported by each hemisphere, but complex grouping processes are lateralized.

Differences between the hemispheres are also apparent in the processing of the timing of visual events. The left hemisphere of commissurotomy patient L.B. performed better than the right hemisphere at discriminating between simultaneous and successive lights when delays were very short. In contrast, L.B., and two callosotomy patients, showed a right hemispheric advantage for temporal discrimination of delays between the onsets of two visual stimuli when delays were in the range necessary to produce apparent movement. The two callosotomy patients also showed right hemisphere superiority for determining if the motion of a stimulus was caused by the impact of another stimulus. Thus, the right hemisphere seems superior to the left for the perception of interactions between objects in space and time.

Face Processing

Both hemispheres in the divided brain are able to recognize the self from pictures of the patient's face which are morphed with pictures of the faces of others, although different studies have found opposite hemispheric asymmetries in biases toward identifying faces as either self or other. The right hemisphere in several callosotomy patients has shown greater ability than the left hemisphere in matching pictures of similar faces to a sample, although tests of other patients have failed to find a right hemispheric advantage on tests of face perception. The left hemisphere is better able to voluntarily produce facial expressions of different emotions.

Memory

Some commissurotomy and callosotomy patients have shown lowered performance on tests of general memory ability, although others show little deficit. In affected patients, this deficit is greater than that seen in other domains investigated by standard neuropsychological assessment. Poor memory for new information, such as word associations, contrasts with the intactness of previously learned information and memories of events prior to the surgery. This deficit may result from interruption to both the corpus callosum and the hippocampal commissure and fornix. The involvement of the hippocampal commissure is suggested by the lack of memory deficits exhibited by some anterior callosotomy patients, in whom the hippocampal commissure is spared. Evidence from several patients also suggests that recognition memory may not be affected to the same degree as recall.

Relative hemispheric advantage on memory tests can depend on both the nature of the task and the stimuli. For instance, it was found that in several patients the right hemisphere outperformed the left hemisphere in a test of memory for tactile shapes, but the left hemisphere performed better when patients were required to remember sequences of tactile shapes. Material-specific depth-of-processing effects, in the two hemispheres of two callosotomy patients, and the lack of a catastrophic memory deficit suggest that both hemispheres are capable of memory encoding. The finding also suggests that different material, such as faces and words, are encoded preferentially by one of the two hemispheres.

A tendency for the left hemisphere to elaborate on information it receives may underlie its poor performance on tasks that involve distinguishing between previously seen and novel items with semantic content, such as words or pictorial representations of common scenes. The left hemisphere was found to falsely recognize previously unseen items that were semantically congruent with items shown during the encoding phase. The right hemisphere made no such systematic error.

Higher Cognition

Debate on whether the isolated hemispheres each possess consciousness, either complete or impoverished, has persisted since the publication of early observations from split-brain patients. Both hemispheres display a range of positive competencies, but the mounting evidence for, sometimes subtle, hemispheric differences suggests that consciousness is not identical in the two hemispheres.

The isolated right hemisphere performs poorly on many problem-solving tasks, whereas the left hemisphere remains capable of a level of abstract reasoning comparable to the patient's preoperative performance. The right hemisphere in two callosotomy patients was found to be unable to perform a task involving reasoning about causes, despite this

task being solvable by young infants, although the left hemispheres in the same patients performed well.

The left hemispheres of several callosotomy patients have shown a propensity for providing elaborative accounts of their experience and their own behavior, including those initiated by the right hemisphere. If the left hemisphere is challenged to provide an explanation for the behavior of the right hemisphere, patients often reply with interpretation that is consistent with the information presented to the patient's verbally able left hemisphere. The tendency for the left hemisphere to form generalizations about its environment has also been shown in a nonlinguistic test involving the prediction of the location of a forthcoming stimulus. Thus, the interpretive and linguistic processes that allow individuals to make sense of their conscious experience seem to be most fully actualized in the left hemisphere of the split brain.

Spontaneous Patterned Activity in Developing Neural Circuits

P Wenner, Emory University, Atlanta, GA, USA
M B Feller, University of California, at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

How do neuronal circuits become assembled during development? Mechanisms that govern the formation of neural circuits during development traditionally have been divided into activity-independent and activity-dependent categories. In this view, the early organization of the circuits, namely the phenotype, location, and early connections of neurons, is governed by activity-independent mechanisms (e.g., the genetic profile of the cell). Neural activity subsequently acts to refine initially crude connections into the detailed circuits that characterize the adult nervous system. However, in the past few years, challenges to these two basic assumptions have suggested the model may be oversimplified. First, there is growing evidence that environmental cues, mediated by chemical and electrical activity within the cell, influence the earliest stages of development. Second, immature circuits generate highly correlated activity patterns before the onset of sensory experience, raising the possibility that this activity can drive early developmental events. This article is devoted to describing spontaneous correlated activity in developing neural circuits and the cellular mechanisms that underlie this activity.

The Depolarizing Nature of GABA

One common feature of developing neural circuits is that in immature neurons, activation of γ-aminobutyric acid $(GABA)_A$ receptors is excitatory. The depolarizing action of GABA is due to the complement of chloride cotransporters that exist early in development. High levels of NKCC1, a Na–K–Cl cotransporter which move chloride ions into cells, and low levels of the cotransporter KCC2 which exports chloride, results in elevated intracellular chloride levels. Hence, the reversal potential for GABA is more depolarized than the resting membrane potential. Thus, when $GABA_A$ receptors are opened, chloride leaves the cell, producing a depolarization. Later in development, as KCC2 becomes the predominant cotransporter, intracellular chloride is lowered and GABA becomes hyperpolarizing, as in the adult. In the developing spinal cord and hippocampus, the depolarizing, excitatory nature of GABA is crucial to the existence of the spontaneously correlated activity.

Spinal Cord

Spontaneous network activity (SNA) has been studied in developing spinal networks in the embryonic chick, mouse, and rat. Extensive study in the chick embryo has provided the best understanding of the underlying mechanisms and functions of SNA and is therefore the main focus of this discussion; however, the same principles are likely to apply for SNA in most species. SNA begins at a stage corresponding to when the first synapses are formed (~embryonic day 4.5; E4.5), and continues into late embryonic development (E16), when chloride conductances are no longer excitatory. Through these stages limb motoneurons have innervated their targets, interneuronal and sensory circuits have formed, motor and sensory neuron cell death begins and ends, and significant descending input arrives in the lumbosacral cord.

SNA is experienced in many spinal neurons synchronously. Cells have 20–30 mV depolarizations upon which are superimposed bursts of spiking activity. SNA lasts for multiple seconds followed by periods of many minutes of inactivity (**Figure 1(a)**). A vast majority of spinal neurons are recruited into the bursts or episodes, including motoneurons, which drive embryonic limb movements. In the chick embryo, within a single episode of SNA there are cycles of depolarizations and associated bursting, the period of which becomes longer toward the end of the episode. The pattern of activity within a cycle is dependent on the kind of motoneuron and can alternate between antagonist motoneurons. Although the mechanism is unknown, it has been suggested that a fast depression and recovery may underlie the generation of the cycling. When the cord is no longer able to generate the next cycle the episode ends.

Episodes of spontaneous network activity occur as a result of a highly excitable, synaptically coupled circuit, where GABA, acting through $GABA_A$ receptors, is depolarizing and therefore excitatory. Thus, the network is hyperexcitable because both excitatory and what will become inhibitory neurons promote the activation of the cells to which they project. The recruitment sequence is as follows. Motoneurons begin to fire in the interval between episodes, and progressively fire more vigorously as the interval extends. Surprisingly, spinal interneurons do not appear to discharge in the interepisode interval. Rather, motoneuron discharge eventually intensifies

Figure 1 Spontaneous network activity in the spinal cord and its onset. (a) An example of two episodes of spontaneous network activity is shown via extracellular muscle nerve recordings. Episodes are associated with large depolarizations and spiking, and are followed by an interepisode interval consisting of a ramp depolarization and associated motoneuron discharge toward the end of the interval. (b) Schematic demonstrating the connectivity of motoneurons (MN), GABAergic R-interneurons (R-int), and other GABAergic and glutamatergic spinal interneurons. Numbers indicate the order in which each population is recruited at episode onset. (c) Recruitment order at episode onset is shown by imaging the cut face of the spinal cord with many spinal interneurons labeled with a calcium-sensitive dye. In panel 1, unlabeled MNs are active as determined by simultaneous muscle nerve recordings (not shown). In panel 2, cells in the location of R-interneurons become active, followed by other interneurons (panel 3), and finally the entire network of labeled interneurons (panel 4). Adapted from Wenner P and O'Donovan MJ (2001) Mechanisms that initiate spontaneous network activity in the developing chick spinal cord. *Journal of Neurophysiology* 86: 1481–1498, used with permission from the American Physiological Society.

to the point where it recruits GABAergic interneurons that receive direct input from the motoneuron recurrent collaterals. The excitatory GABAergic projections of these interneurons then excite other interneurons, eventually recruiting the entire network. As a result, spiking activity at episode onset is first observed in motoneurons, then recurrently activated interneurons, and finally all spinal neurons (Figures 1(b) and 1(c)).

During the episode, the spinal circuits become progressively depressed until they can no longer sustain the activity. Following an episode, several features of excitability of the cord are depressed. Spinal neurons are hyperpolarized relative to the period just before the episode, and then gradually experience a ramp depolarization in the interepisode interval (Figure 1(a)). Motoneurons no longer fire action potentials after an episode and only begin to fire minutes into the interval as the resting potential begins to recover to pre-episode levels. In addition, synaptic strength of many of the connections is weakened following the episode. Reflex synaptic responses, as well as miniature postsynaptic potentials thought to represent responses to a single vesicle of transmitter, are reduced in amplitude following the episode. As the cord recovers from the previous episode and the resting membrane potential depolarizes and synaptic strength increases, the spinal networks are once again competent to generate another episode.

Glutamatergic, nicotinic, glycinergic, and GABAergic transmitters all contribute to the drive underlying the episodes, and if any one of these transmitters is blocked the other transmitters will compensate for the loss. Very early in development (E4.5) nicotinic transmission and, to a lesser degree, GABAergic transmission, are most important for generating SNA. From E8 on, however, GABA appears to be the dominant transmitter in setting the frequency of episode occurrence. Why is GABAergic transmission so important to episode frequency? This is due to the modulatory nature of chloride-mediated $GABA_A$ currents, which significantly contribute to

the episode-induced depression and recovery of spinal excitability. During an episode of activity $GABA_A$ channels open and allow chloride ions to flow out of the cell to the extent that the reversal potential is altered and the driving force for chloride-mediated conductances is reduced. This is why evoked and miniature synaptic currents are smaller following an episode. Synaptic strength then recovers in the interepisode interval because chloride pumps (presumably NKCC1) progressively restore the higher intracellular chloride concentration, and therefore restore driving force for the GABAergic currents. Intracellular chloride modulation may also contribute to the hyperpolarization and recovery of the membrane potential following an episode, because this process is mediated by a tonic $GABA_A$ current. However, chloride regulation cannot completely account for the ramp depolarization because the tonic GABAergic current is completely abolished following the episode, even though $GABA_A$ agonists puffed on the cord after an episode produce a significant depolarization. This suggests that extracellular GABA builds up in the interval and then is cleared during the episode. Therefore GABA is critically important in the periodicity of SNA because it contributes significantly to the episode-induced depression and recovery of spinal excitability, through the ramp depolarization and chloride-mediated synaptic strengthening during the interepisode interval.

The embryonic movements driven by SNA are known to be important in bone, muscle, and joint development. Further, motoneuron pathfinding into the limb is dependent on normal levels of SNA and the development of locomotor circuits within the cord is thought to be dependent on nicotinic transmission associated with SNA. In addition, recent work has shown that SNA regulates the strength of both excitatory and soon-to-be inhibitory synapses. SNA is thought to provide the activity that allows the network to assess the synaptic strength of its excitatory and inhibitory components and thus adjust the gain of these synapses in order to maintain the activity at appropriate levels. In this way spontaneous activity can act to coordinately mature glutamatergic and GABAergic synaptic strength.

Retina

Immature retinal ganglion cells (RGCs) spontaneously fire bursts of action potentials. The spontaneous activity propagates across the ganglion cell layer, a pattern referred to as 'retinal waves.' Retinal waves have been detected in a broad range of vertebrate species, including chicks, turtles, mice, rats, rabbits, ferrets, cats, and primates. Though extensive studies have been conducted in most of these species, the focus here is on the mechanisms described for mammals, wherein retinal waves are detected during an extended period prior to the onset of light responses. That said, the spatial and temporal properties of retinal waves, and the synaptic circuits, are remarkably similar across all species.

Retinal waves initiate in random locations and propagate from one cell to another, correlating the firing of hundreds of cells (Figure 2). Though individual retinal waves have complex propagation properties, the firing properties of individual retinal ganglion cells is fairly stereotyped, with each cell firing a 1 to 2 s burst of action potentials that are separated by 1–2 min of silence. Retinal waves propagate with a speed of 100–200 $\mu m\, s^{-1}$. Following a retinal wave, a local region of the retina will go into a refractory period, during which retinal waves cannot be initiated. This refractoriness, a robust feature of the network, lasts 30–45 s and contributes to the complex geometry of the progression of the wave front.

Retinal waves persist for a long period of time perinatally in rodents and rabbits, first detected a few days before birth and lasting 2–3 weeks. During this time, the retina is rapidly developing, with dramatic changes in functional synaptic circuits. When retinal waves are first detected, an immature inner retina, containing synaptically connected RGCs and amacrine cells, has formed, but the ventricular zone still comprises most of the retina. By eye-opening (P14), all of the cell layers are fully developed and light responses are robust.

The maturation of retinal circuitry is reflected in the changing synaptic mechanisms that mediate waves. Retinal waves are divided into three distinct stages based upon the mechanisms that generate them (Figure 2). Stage I retinal waves are mediated before the formation of synaptic connections and these waves end at birth in mice, when amacrine cells and RGCs are synaptically connected, as determined by electron microscopy and electrophysiology. The mechanisms underlying stage II retinal waves are the most extensively studied. Stage II retinal waves are blocked by nicotinic acetylcholine receptors (nAChRs) antagonists. RGCs receive both cholinergic and GABAergic synaptic input during retinal waves. Only one class of cell in the retina, the starburst amacrine cell, releases acetylcholine (ACh). Very recent experiments in rabbit retina indicate that the properties of starburst amacrine cells and the starburst amacrine cell network are sufficient to explain most characteristics of stage II retinal waves. Starburst amacrine cells undergo spontaneous depolarizations, neighboring starburst amacrine cells monosynaptically release both ACh and GABA onto one another, and each starburst amacrine

Figure 2 (a) Retinal waves. Current clamp recording from starburst amacrine cell (SAC), showing rhythmic compound bursts associated with retinal waves. (b) Schematic of wave-generating circuitry. Left: During stage II retinal waves, the cholinergic starburst amacrine cells (SAC) synapse onto one another and onto retinal ganglion cells (RGC). Not pictured are photoreceptors and bipolar cells, which are not yet connected to RGCs. RGCs and SACs receive excitatory synaptic inputs through nicotinic acetylcholine receptors (nAChRs) and γ-aminobutyric acid $(GABA)_A$ receptors. SACs release both ACh and GABA. Right: During stage III retinal waves, the retina's vertical circuit is complete. Calcium transients in RGCs are blocked by ionotropic glutamate receptor antagonists and are made more frequent by $GABA_A$ and glycine receptor antagonists. Bipolar cells (BC) synapse onto RGCs; inhibitory amacrine cells (AC) synapse onto RGCs and bipolar cells (PR, photoreceptor). (c) Time evolution of two retinal waves occurring in the same region 30 s apart. Dark areas indicate decreases in fura-2 fluorescence associated with the increased calcium evoked by waves. Images were acquired with a silicon intensifier target (SIT) camera. An initial background frame was acquired and was subtracted on a pixel-by-pixel basis from all subsequent frames to create a difference image. Each frame is 1.2×1.2 mm. cell receives input from around 20 other starburst amacrine cells. (Starburst cells are one of a few neurons that secrete two neurotransmitters. GABA and ACh are not thought to be released from the same vesicles, or even the same location on starburst amacrine cell processes, but their release mechanisms have not yet been elucidated.) This connectivity among starburst amacrine cells may provide the substrate for wave propagation. Starburst amacrine cells also synapse onto RGCs, such that waves of depolarization propagating through the starburst amacrine cell network also activate nAChRs and $GABA_A$ receptors on RGCs, causing them to fire correlated bursts of action potentials. Though these findings have yet to be reproduced in other species, it is likely to be generalized and therefore is the best current model of retinal wave generation.

There are still many aspects of stage II retinal waves that are the focus of ongoing research efforts. During stage II retinal waves, activation of $GABA_A$ receptors

on retinal ganglion cells is depolarizing. However, $GABA_A$ receptor antagonists modulate but do not block retinal waves. Hence it has been hypothesized that GABA contributes to the depolarization of retinal ganglion cells, but not the propagation of activity through the starburst amacrine cell network. In addition, in many species, retinal waves are blocked by either gap junction receptor or adenosine receptor antagonists. Last, the spatiotemporal properties of retinal waves are strongly modulated by drugs that modulate the cyclic adenosine monophosphate/protein kinase A (cAMP/PKA) second messenger pathway by mechanisms that are not yet understood.

The circuits mediating stage III waves are also a topic of ongoing research. Stage III waves emerge when glutamatergic synapses between bipolar cells and retinal ganglion cells are first formed. The circuitry underlying stage III waves is known to be distinct from that mediating stage II waves. Ionotropic glutamate receptor antagonists but not nAChR antagonists block stage III retinal waves. In rabbits, during stage III waves, starburst amacrine cells no longer undergo spontaneous depolarizations and nAChRs are downregulated in starburst amacrine cells, indicating the starburst network is not the source of wave initiation or propagation. The observation that stage III waves are blocked by ionotropic glutamate receptor antagonists indicates that synaptic release from bipolar cells, the primary source of glutamatergic input to retinal ganglion cells, is a critical component of the network mediating stage III waves. However, bipolar cells are not directly coupled to each other and it is not known whether they function as pacemakers at this stage of development. Hence, many details regarding the mechanisms underlying stage III waves remain to be discovered.

Retinal waves are required for normal establishment of circuits with in the visual system. Many of the highly ordered connections in the visual system are refined at an early stage of development, prior to normal visual experience. For example, upon initial growth to the superior colliculus, retinal projections are broadly distributed. Subsequently, retinocollicular projections refine to form retinotopic maps. Similarly, upon initial growth to the lateral geniculate nucleus of visual thalamus, retinal projections from the two eyes significantly overlap. Subsequently, retinogeniculate axons refine into eye-specific regions. Blockade of retinal activity blocks the normal refinement process, and transgenic mice that do not have normal patterns of spontaneous activity do not undergo the normal refinement process. Though these findings indicate a role for spontaneous retinal activity, it remains a controversial question as to which of the unique spatiotemporal properties of retinal waves are required for driving refinement. Similar experimental paradigms indicate that early retinal activity may also be important for driving the establishment of adult circuitry in primary visual cortex as well. Hence, retinal waves have become a primary model for understanding how early neural activity drives the formation of adult circuitry before the onset of sensory experience.

Hippocampus

Spontaneous periodic network events are also a characteristic feature of the developing hippocampus. In the immature hippocampus, these events are referred to as giant depolarizing potentials (GDPs). GDPs have been recorded *in vivo* and extensively in *in vitro* hippocampal slices. GDPs invade all subfields of the hippocampus and cause correlated depolarization of both pyramidal cells as well as depolarizing inhibitory interneurons.

GDPs initiate in the CA3 subregion, with some recent evidence suggesting that they are initiated by intrinsic pacemaker activity of pyramidal cells. Activity in the CA3 region is propagated through the hippocampus via immature GABAergic and glutamatergic synapses. The pattern of spontaneous firing is more frequent than that previously described for spinal cord and retina. Both *in vivo*, and *in vitro*, GDPs last 0.5–3 s and occur every 2–10 s. There is no neuronal firing in between these population events, as observed in spinal cord and retina, but in sharp contrast to the adult hippocampus.

The generation of GDPs is due to synergistic interactions between immature $GABA_A$ and *N*-methyl-D-aspartate (NMDA) receptors. Blockade of either type of receptor prevents GDPs. Transmission through immature $GABA_A$ receptors is excitatory. Glutamate synapses are also immature during the developmental period when GDPs are expressed. In the mature hippocampus, glutamatergic synapses contain a mixture of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and NMDA receptors. However, during development, there is a large percentage of NMDA-only synapses with this level, decreasing during the first postnatal week. NMDA receptors are considered 'coincidence detectors' because activation of these receptors requires both glutamate binding and depolarization of the membrane. It has been postulated that depolarization via $GABA_A$ receptors acts to relieve the Mg^{2+} block of NMDA receptors. Hence, excitatory GABAergic synapses from interneurons and glutamatergic inputs from pyramidal cells contribute to the generation of GDPs.

The immature pattern of $GABA_B$ receptors is also important in shaping GDPs. $GABA_B$ receptors are

G-protein-coupled receptors that activate potassium channels and therefore hyperpolarize membranes. $GABA_B$ receptors are absent on postsynaptic membranes during the first postnatal week, adding to the excitability of the networks. However, presynaptic $GABA_B$ receptors are mature, and therefore control the release of GABA and glutamate. Hence, blocking $GABA_B$ receptors dramatically changes the structure of GDPs such that they look more like seizure events.

Several functions for GDPs in the development of mature excitatory and inhibitory transmission have been postulated and are the focus of current research efforts. Some studies indicate that GDPs are critical for the normal maturation of glutamatergic and GABAergic synapses in at least three ways. First, GDPs are likely important in determining the timing of pre- and postsynaptic activity, which appears to be important in mediating the developmental switch for $GABA_A$ receptors as they transition from excitatory to inhibitory. Second, depolarization via $GABA_A$ receptors leads to the phosphorylation of certain transcription factors, which may be critical for development. Third, the activation of NMDAR-only synapses through the synergistic actions of $GABA_A$ and NMDA may provide that critical signaling necessary to drive the transport of AMPA receptor subunits. This 'AMPA-fication' of glutamatergic synapses is a critical step in the formation of adult hippocampal circuitry.

Conclusions

Following the formation of the first synaptic connections, developing networks express a spontaneous correlated activity that shares many characteristics in very different networks, while each also expresses its own unique features. We now consider the similarities and differences in the three networks discussed.

In spinal cord, retina, and hippocampal tissues, episodes of activity lasts seconds and are followed by long episodes of quiescence. During the episodes of activity, many cells experience depolarizations and increases in intracellular calcium, known to be important in several aspects of development. Depolarizing GABAergic transmission is critical for the generation of episodes of activity, especially in the spinal and hippocampal networks. Following the activity, the network is reduced in its excitability, though the source of this network depression may be different in the different circuits.

The existence of the spontaneous activity in multiple species and the similarities in the activity in different parts of the nervous system suggest a general importance of the activity toward some common functions. There is growing evidence for a role for spontaneous activity in the developing nervous system, by refining the connectivity of projection neurons, the development of local circuitry, or the activation of second messenger cascades that drive long-lasting transcriptional events. In the spinal cord, SNAs have been implicated in both how motoneurons select targets and in the balance of excitatory and inhibitory synaptic strength in local circuits. Retinal waves have a well-established role in influencing projections of retinal ganglion cells, but a role for the activity in the retina itself has not yet been elucidated. Hippocampal GDPs also have been implicated in the development of local circuitry and may be critical for establishing the synaptic relationships between the different subregions of the hippocampus.

One of the remaining controversies is whether spontaneous activity is 'instructive' or 'permissive' during these developmental events. An instructive role indicates that all of the relevant information driving a particular development process is contained in the firing pattern. For example, do SNAs influence targeting of motoneurons by ensuring that neighboring motoneurons are more correlated in their firing than are motoneurons in a different segment (an instructive signal)? Or do SNAs exert their actions by maintaining a certain average firing rate that allows different molecular interactions between motoneurons and their targets to take place (a permissive signal)? There are some clear examples where at least some features of the spontaneous firing patterns matter. For example, changing the frequency of SNAs influences the expression of different molecules. In another example, in transgenic mice that disrupt the endogenous pattern of retinal waves to disrupt nearest-neighbor correlations but maintain similar average firing rates, both retinotopic and eye-specific refinements are inhibited. Experiments with targeted manipulations that alter specific features of spontaneous activity patterns will determine what features of this early network activity are critical for the normal development of adult neural circuits. Hence, understanding the cellular basis of the different features of spontaneous activity patterns will be critical for designing these future studies.

Sporadic Degenerative Ataxias and the Dominantly Inherited Spinocerebellar Ataxias

T Klockgether, University of Bonn, Bonn, Germany

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The sporadic degenerative ataxias, formerly named sporadic olivopontocerebellar atrophies, and the autosomal dominantly inherited spinocerebellar ataxias (SCAs) are adult-onset progressive diseases in which ataxia is the prominent clinical manifestation. In most of these diseases, ataxia is the consequence of degeneration of the cerebellar cortex and its afferent or efferent fiber connections. Additional pathology may be found in other parts of the nervous system, specifically in the brain stem, basal ganglia, spinal cord, and the peripheral nervous system. While the sporadic degenerative ataxias are diseases of unknown etiology, the SCAs are caused by dominant mutations of single genes, many of which have been identified. Both groups of diseases are distinct from the acquired ataxias, in which ataxia is due to a defined exogenous or endogenous nongenetic cause.

Patients with sporadic degenerative ataxia fall into two groups. In one group, the underlying pathology is that of multiple system atrophy (MSA), involving widespread degeneration in the central nervous system with presence of glial cytoplasmic inclusions (GCIs). In another group of patients, pathology and clinical manifestations remain largely confined to the cerebellum. At present, it is not known whether the latter manifestations represent a disease entity or rather are a collection of phenotypically similar syndromes. We use the name 'sporadic adult-onset ataxia of unknown etiology' (SAOA), while others prefer the older term 'idiopathic late-onset cerebellar ataxia' (IDLOCA).

Pathogenesis of MSA

MSA is a sporadic, adult-onset neurodegenerative disease that encompasses the former disease categories sporadic olivopontocerebellar atrophy, striatonigral degeneration, and Shy–Drager syndrome. Reasons to combine these diverse categories under the heading of MSA were the large clinical overlap between these disorders and the discovery that the brains of individuals affected by any of them contained GCIs, which are now considered as a highly specific marker of MSA (Figure 1). According to the clinical presentation, a cerebellar (MSA-C) and a parkinsonian (MSA-P) type of MSA are distinguished.

MSA is characterized by widespread degeneration in the central nervous system, with a particularly strong involvement of the cerebellar cortex, dentate nucleus, pontine nuclei, inferior olive, putamen, caudate nucleus, pallidum, substantia nigra, subthalamic nucleus, thalamus, pyramidal tract, preganglionic sympathetic neurons of the intermediolateral cell columns of the spinal cord, anterior horn, and Onuf's nucleus. GCIs are mainly found in oligodendroglial cells of the motor cortex, white matter underlying the cortex, corpus callosum, pyramidal tract, basal ganglia, pons, cerebellar white matter, cerebellar peduncles, and spinal cord. GCIs are accumulations of fibrils that are predominantly formed by polymerized α-synuclein (Figure 1). Although less prominent, there are also α-synuclein-positive inclusions in the cytoplasm and nuclei of neurons.

Although the etiology of MSA remains unknown, recent experimental work has provided new insights into the molecular pathogenesis. Overexpression of human α-synuclein under a myelin basic protein promoter in mice led to the formation of α-synuclein-positive inclusions in oligodendrocytes, astrogliosis of white matter tracts, and neurodegenerative changes in the basal ganglia and neocortex. In another mouse model, overexpression of α-synuclein in oligodendrocytes led to glial inclusions, neuronal cell loss, and progressive motor impairment. Both animal models support the view that accumulation of α-synuclein in oligodendrocytes contributes to the neurodegeneration in MSA. Together, the available autopsy findings and the observations in transgenic animal models suggest that the neurodegeneration of MSA is due to a profound disturbance of the microenvironment formed by oligodendroglia, axons, and neurons, with α-synuclein as a key player in the interaction between these cellular elements.

Clinical Features of MSA

MSA is a rare disorder, with an estimated prevalence of 4.4 in 100 000. Clinically, MSA patients present with various combinations of parkinsonism, cerebellar ataxia, pyramidal tract dysfunction, and autonomic failure. In a large series of European MSA cases, 87% had parkinsonism, 74% had autonomic failure, 54% had cerebellar ataxia, and 49% had pyramidal tract dysfunction. In 58%, the disease

Figure 1 GCIs in cerebellar white matter of a MSA patient.

started with parkinsonism, while cerebellar ataxia was the first symptom in 29%. Interestingly, cerebellar ataxia is more prevalent among Japanese MSA patients. In a recent clinical study of 230 Japanese MSA patients, 67% were classified as MSA-C.

Most MSA patients with parkinsonism have an akinetic–rigid syndrome. When present, tremor is often irregular with myoclonic jerks. The ataxic syndrome in MSA points to a diffuse involvement of the cerebellum, with ataxia of gait and stance, ataxia of limb movements, action tremor, ataxic speech, and cerebellar oculomotor disturbances. This syndrome is undistinguishable from that in other degenerative disease of the cerebellum. Pyramidal involvement is usually manifested by increased muscle reflexes and extensor plantar responses. Proper spasticity is rarely encountered.

Orthostatic hypotension and urinary incontinency are the major manifestations of autonomic failure in MSA. Orthostatic hypotension is due to degeneration of preganglionic sympathetic neurons in the intermediolateral cell columns of the spinal cord, which results in an impairment of the baroreflex. A drop of systolic blood pressure of more than 20 mmHg is considered pathological. Symptoms of orthostatic hypotension may range from dizziness to syncope, with loss of consciousness, and are often precipitated by heavy meals. Orthostatic hypotension in MSA may be associated with increased blood pressure in supine position. Neurogenic bladder dysfunction is frequent in MSA and present in almost all patients in advanced disease stages. In male, it is always combined with erectile dysfunction. Typical clinical manifestation of neurogenic bladder dysfunction is urinary incontinence due to disturbed sphincter function caused by degeneration of preganglionic sympathetic neurons of the spinal cord and Onuf's nucleus. Many patients have additional urinary retention which is caused by parasympathetic dysfunction. MSA starts between 50 and 60 years of age and takes an unrelentlessly progressive course. After 5 to 6 years most MSA patients require a wheelchair. Median survival is 9 years. Death typically occurs due to bronchopneumonia.

Magnetic resonance imaging (MRI) has been extensively used to study the brain morphology of MSA patients *in vivo*. MRI abnormalities occurring in MSA include progressive atrophy of infra- and supratentorial brain structures as well as signal abnormalities. Morphometric studies reveal volume loss of the cerebellum, brain stem, putamen, and cortical areas, in particular the insular cortex. The signal changes typical for MSA are best seen on T_2-weighted images obtained by MRI scanners with high-field strength. They include increased signal in the middle cerebellar peduncles and the pons, decreased signal in the putamen, and a rimlike hyperintensity lateral to the putamen (Figure 2). These abnormalities have high specificity, but low sensitivity for the diagnosis of MSA. The apparent diffusion coefficient is increased in the putamina of MSA patients, suggesting neuronal loss with enlargement of the extracellular space. Positron emission tomography (PET) studies showed reduced metabolic activity in the basal ganglia, brain stem, and cerebellum.

Figure 2 MRI in MSA. (a) T_1-weighted images with severe atrophy of the cerebellum and brain stem in an MSA-C patient. (b) Signal abnormalities in the basal ganglia on T_2-weighted images in MSA. Left upper panel: Normal. Right upper panel: Slight hypointensity of the putamina in a case of beginning MSA. Left lower panel: Mild atrophy of the basal ganglia and marked hypointensity of the putamina in an MSA-P patient. Right lower panel: Marked atrophy of the basal ganglia, marked hypointensity of the putamina, and unilateral rimlike hyperintensity lateral to the basal ganglia in a patient with advanced MSA.

There is no curative or preventive treatment for MSA. Parkinsonian symptoms may respond to levodopa, but the response is often transient and usually less robust than in idiopathic Parkinson's disease. Autonomic symptoms are treated in standard manner. There is no effective symptomatic treatment for ataxia.

Sporadic Adult-Onset Ataxia of Unknown Etiology

SAOA is a sporadic adult-onset ataxia disorder. It is clinically distinguished from MSA by the lasting absence of parkinsonism and severe autonomic failure. Epidemiological studies and clinical case series suggest that SAOA occurs with twice the frequency of MSA. An epidemiological survey in Wales found a prevalence of 8.4 in 100 000.

The etiology and pathogenesis of SAOA are unknown, and there is only limited knowledge of the neuropathology of this disorder. The few available autopsy studies suggest that the degeneration mainly affects the cerebellar cortex with or without involvement of the inferior olives. This degeneration pattern was previously designated as late cerebellar cortical atrophy. GCIs are not found in SAOA brains.

SAOA begins around the age of 50 years and affects men more frequently than women. Clinical presentation is characterized by progressive cerebellar ataxia accompanied by signs of peripheral neuropathy and pyramidal tract dysfunction in half of the patients. At first presentation, the differentiation between MSA-C and SAOA is often impossible. However, the more benign course and the absence of severe autonomic failure and parkinsonism allow differentiation of SAOA from MSA. The majority of SAOA patients are still ambulant 10 years after onset of ataxia. Median survival ranges from 20 to 25 years, resulting in an almost normal life expectancy. On MRI, SAOA patients usually have isolated cerebellar atrophy with little or no involvement of the brain stem. Currently, there are no treatment options for SAOA.

Genetics and Pathogenesis of SCAs

The SCAs are a genetically and clinically heterogeneous group of autosomal dominantly inherited progressive ataxia diseases. To date, almost 30 different gene loci have been found (Table 1). Of the mutations that have been identified, SCA1, SCA2, SCA3, SCA6, SCA7, and SCA17 are translated CAG repeat expansions coding for an elongated polyglutamine tract within the respective proteins. These diseases belong to a larger group of polyglutamine disorders that also include Huntington's disease, dentatorubro-pallidoluysian atrophy, and spinobulbar muscular atrophy. Three SCAs, SCA8, SCA10, and SCA12, are caused by untranslated repeat expansions in noncoding regions of the respective genes. In SCA5 (gene name: *spectrin, beta, non-erythrocytic 2*; *SPTBN2*), SCA13 (*potassium voltage-gated channel*; *KCNC3*), SCA14 (*protein kinase C, gamma*; *PRKCG*), SCA27 (*fibroblast growth factor 14*; *FGF14*), and 16q22-linked autosomal dominant cerebellar ataxia (*pleckstrin homology domain containing, family G*, or *puratrophin-1*; *PLEKHG4*), point mutations have been found in the respective genes. In all other SCAs, the affected genes and mutations have not yet been identified.

The genetic heterogeneity of the SCAs implies an even greater heterogeneity of the molecular pathogenesis. There has been some recent progress in the understanding of the pathogenesis of the polyglutamine disorders, while there is still very limited knowledge of the mechanisms that underlie the SCAs due to untranslated repeat expansions and to point mutations.

All polyglutamine diseases share common pathogenetic pathways which involve the deleterious actions of the expanded polyglutamine tracts. On the other hand, it is increasingly recognized that the actions of the respective disease proteins and their specific alterations due to mutations significantly contribute to the development of the disease phenotype. This dual pathogenetic model explains the common features shared by all polyglutamine diseases as well as the unique features of each particular disease.

That expanded polyglutamine tracts exert powerful neurotoxic actions has been convincingly shown in transgenic models in which overexpression of expanded polyglutamines in arbitrary proteins in neurons caused neurodegeneration. Several observations suggest that cleavage of the disease proteins and formation of smaller polyglutamine-containing protein fragments are prerequisites for polyglutamine-mediated neurodegeneration. However, the enzymes mediating protein cleavage have not yet been fully identified. In most polyglutamine diseases, a nuclear localization of the disease protein is required for its deleterious action.

Elongated polyglutamines have a strong tendency to misfold and aggregate. According to current view, oligomeric intermediates originating from the aggregation process are responsible for the pathogenesis, while the visible (via the light microscope) neuronal inclusions found in neurons of SCA brains are thought to be inert or even protective. Oligomeric intermediates exert their deleterious action by abnormally interacting with other cellular proteins. Potential interaction partners are transcription factors, which contain polyglutamine tracts. As a result,

Table 1 SCAs: molecular genetics and clinical phenotype

Disorder	*Mutation*	*Gene product*	*Clinical phenotype*
SCA1	Translated CAG repeat expansion	Ataxin-1	Ataxia, pyramidal signs, neuropathy, dysphagia, restless leg syndrome
SCA2	Translated CAG repeat expansion	Ataxin-2	Ataxia, slow saccades, neuropathy, restless leg syndrome
SCA3 (Machado–Joseph disease)	Translated CAG repeat expansion	Ataxin-3	Ataxia, pyramidal signs, ophthalmoplegia, neuropathy, dystonia, restless legs syndrome
SCA4	Unknown	Unknown	Ataxia, sensory neuropathy
SCA5	Point mutation	Beta-III spectrin (SPTBN2)	Almost purely cerebellar ataxia
SCA6	Translated CAG repeat expansion	Calcium channel subunit (CACNA1A)	Almost purely cerebellar ataxia
SCA7	Translated CAG repeat expansion	Ataxin-7	Ataxia, ophthalmoplegia, visual loss
SCA8	3′-Untranslated CTG repeat expansion	Ataxin-8	Ataxia, sensory neuropathy, spasticity
SCA10	Intronic ATTCT repeat expansion	Ataxin-10	Ataxia, epilepsy
SCA11	Unknown	Unknown	Almost purely cerebellar ataxia
SCA12	5′-Untranslated CAG repeat expansion	Phosphatase subunit (PP2A-PR55β)	Ataxia, tremor
SCA13	Point mutation	Potassium channel (KCNC3)	Ataxia, mental retardation
SCA14	Point mutation	Protein kinase Cγ (PKCγ)	Ataxia, myoclonus, dystonia, sensory loss
SCA15	Unknown	Unknown	Almost purely cerebellar ataxia
SCA16	Unknown	Unknown	Almost purely cerebellar ataxia
SCA17	Translated CAG repeat expansion	TATA-binding protein (TBP)	Ataxia, dystonia, chorea, dementia, psychiatric abnormalities
SCA18	Unknown	Unknown	Ataxia, sensory neuropathy, neurogenic muscle atrophy
SCA19	Unknown	Unknown	Ataxia, myoclonus, cognitive impairment
SCA20	Unknown	Unknown	Ataxia, dysphonia
SCA21	Unknown	Unknown	Ataxia, parkinsonism
SCA23	Unknown	Unknown	Ataxia, sensory neuropathy, pyramidal signs
SCA25	Unknown	Unknown	Ataxia, sensory neuropathy
SCA26	Unknown	Unknown	Almost purely cerebellar ataxia
SCA27	Point mutation	Fibroblast growth factor 14 (FGF14)	Ataxia, tremor, mental retardation
SCA28	Unknown	Unknown	Ataxia, ophthalmoparesis, pyramidal signs
16q22-linked ADCA	Point mutation	Puratrophin	Almost purely cerebellar ataxia

a general suppression of gene transcription has been found in models of polyglutamine diseases. The important role of transcriptional dysregulation in the pathogenesis of polyglutamine disorders is underlined by the discovery that SCA17 is caused by a CAG repeat expansion in the gene of an essential transcription factor, TATA-binding protein (TBP).

With the exception of SCA6 (*calcium channel, voltage-dependent, P/Q type, α 1A subunit*; *CACNA1A*) and SCA17 (*TATA box binding protein*; *TBP*), the functions of disease proteins of all SCAs of the polyglutamine group were completely unknown when the respective gene mutations were discovered. The physiological roles of these proteins, which have been named ataxins, are currently under intense investigation. In SCA1, the polyglutamine expansion stabilizes ataxin-1 and leads to its accumulation. Ataxin-1 interacts in a polyglutamine-independent way with the mammalian transcription factor senseless/Gfi-1, which is expressed in cerebellar Purkinje neurons. Loss of Gfi-1 leads to degeneration of cerebellar Purkinje neurons, suggesting that ataxin-1/Gfi-1 interaction contributes to the neurodegeneration in SCA1.

Ataxin-3, the disease protein of SCA3, binds polyubiquitin chains and acts as an ubiquitin protease. In addition, ataxin-3 has been shown to bind to DNA and form a transcriptional repressor complex. The transcriptional repressor function is lost in mutated ataxin-3. Overexpression of normal ataxin-3 prevents polyglutamine-induced neurodegeneration, raising the question whether a loss of the physiological function of ataxin-3 amplifies the polyglutamine-mediated toxicity in SCA3.

In SCA6, the polyglutamine expansion in the α_{1A} voltage-dependent calcium channel subunit impairs the physiological function of Ca^{2+} channels, resulting in reduced Ca^{2+} influx. As a consequence, cells overexpressing mutant Ca^{2+} channels are more susceptible

to cell death. The molecular mechanisms underlying the SCAs that are caused by untranslated repeat expansions, SCA8, SCA10, and SCA12, are poorly understood. Based on observations in a transgenic mouse model it has recently been suggested that SCA8 pathogenesis involves toxic gain-of-function mechanisms at both the protein and RNA levels.

It is generally thought that the pathogenesis of the SCAs caused by point mutations is more closely related to the physiological function of the affected proteins than is that of the SCAs which are due to repeat mutations. An example for this assumption is SCA5. SCA5 is caused by mutations of the *SPTBN2* gene, which is highly expressed in cerebellar Purkinje neurons. The *SPTBN2* protein, beta-III spectrin, acts as a stabilizer of the glutamate transporter EAAT4. Mutations might thus result in abnormal glutamate signaling and excitotoxicity. On the other hand, point mutations of the *PRKCG* gene in SCA14 have been shown to lead to the formation of intracytoplasmic aggregates, suggesting a disease mechanism resembling that in polyglutamine disorders.

Given the large genetic heterogeneity of SCAs it is not surprising that autopsy findings are extremely variable. Even within one genotype, neuropathology is not uniform. SCA1, SCA2, and SCA7 are prototypes of a degeneration pattern that was previously designated as olivopontocerebellar atrophy with degeneration of the cerebellar cortex, pontine nuclei, and inferior olives. In SCA2 brains there is almost always severe loss of dopaminergic neurons of the substantia nigra. The autopsy findings in these disorders may closely resemble those in MSA-C. However, GCIs are absent or present in only small numbers. Instead, in some polyglutamine disorders, particularly in SCA1, SCA3, SCA7, and SCA17, characteristic nuclear inclusions are found in neurons. These inclusions are formed by aggregated disease proteins encoded by the mutated genes. In addition, these inclusions contain additional proteins, such as chaperones, proteasomal subunits, and transcription factors.

In other SCAs, such as SCA6, the degeneration is largely confined to cerebellar Purkinje neurons without major involvement of other parts of the brains. For many of the less frequently occurring SCAs, systematic autopsy studies are lacking.

Clinical Features of SCAs

SCAs are rare disorders. Epidemiological studies conducted in different European regions have found prevalence rates ranging from 0.9–3.0 in 100 000. Due to founder effects, the prevalence is much higher in some geographically isolated areas. One example is the province of Holguin in Cuba, where SCA2 has an estimated prevalence of 43 in 100 000. Worldwide, SCA1, SCA2, SCA3, and SCA6 are the most common SCAs. Depending on the respective geographical region these mutations account for up to 75% of all SCA families. Although ataxia is the prominent symptom of all SCAs, clinical presentation is diverse. Ataxia is usually of cerebellar type, but there are also SCAs with predominantly sensory ataxia, such as SCA4, or with a strong sensory component, such as SCA3.

To account for the clinical heterogeneity of the dominantly inherited ataxias, a simple clinical classification was introduced by Harding. Although this classification has been replaced by the genetic SCA classification, the Harding classification is still useful for clinical purposes. Harding distinguished between dominant ataxias with a complex phenotype in which ataxia is accompanied by varying nonataxia symptoms, which she named autosomal dominant cerebellar ataxia type I (ADCA-I); a less frequent phenotype with a purely cerebellar syndrome, ADCA-III; and a rare phenotype in which ataxia is accompanied by progressive visual loss, ADCA-II. The majority of SCA disorders, including the most prevalent disorders, SCA1, SCA2, and SCA3, fall into the ADCA-I category. SCA6 is the prototype of the ADCA-III category, but other disorders, such as SCA5 and SCA11, are also purely cerebellar disorders. The ADCA-II phenotype is almost exclusively found in SCA7. Some SCA disorders have unusual phenotypes that cannot be readily classified with the Harding classification. These include SCA4, with prominent sensory neuropathy, and SCA10, with epilepsy.

SCA1 patients suffer from a progressive cerebellar syndrome with ataxia of gait and stance, ataxia of limb movements, dysarthria, and cerebellar oculomotor abnormalities. The oculomotor abnormalities include gaze-evoked nystagmus, saccade hypermetria, broken up smooth pursuit, reduced optokinetic nystagmus, and impaired suppression of vestibulo-ocular reflex by fixation. In the majority of patients, there are additional noncerebellar symptoms. About half of the patients have supranuclear gaze paresis and/or saccade slowing. Pyramidal tract signs with spasticity, extensor plantar responses, and hyperreflexia are found in more than 50% of SCA1 patients. Decreased vibration sense is found in up to 80% of the SCA1 patients. Dysphagia is a frequent complaint of SCA1 patients and is a particular clinical problem in late disease stages. Disturbances of sphincter control, mainly bladder dysfunction, occur less frequently, and are encountered in about 20% of the patients. Basal ganglia symptoms with parkinsonism

or dystonia are observed only occasionally. Mental disturbances are encountered in less than 10% of SCA1 patients.

SCA2 patients suffer from a progressive cerebellar syndrome with ataxia of gait and stance, ataxia of limb movements, and dysarthria. Saccade slowing is a highly characteristic feature that is observed in the majority of SCA2 patients. About half of the patients have vertical or horizontal gaze palsy. Cerebellar oculomotor abnormalities are rarely found in SCA2. Typically, tendon reflexes are absent or decreased. Pyramidal tract signs are present in less than 20% of the patients. Vibration sense is decreased in most patients, while sensation is otherwise normal. Atypical SCA2 phenotypes with prominent dementia, an amyotrophic lateral sclerosis (ALS)-like presentation, and levodopa-responsive parkinsonism are also encountered. Often, these patients have shorter expansions than the do more frequent ataxic SCA2 patients.

The clinical picture of SCA3 is characterized by a wide range of clinical manifestations, the precise nature of which partly depends on repeat length. All SCA3 patients suffer from a progressive syndrome with ataxia of gait and stance, ataxia of limb movements, and dysarthria. Vertical or horizontal gaze palsy is a frequent additional finding which occurs independently of age of onset. At least 40% of SCA3 patients have a levodopa-responsive restless leg syndrome. Saccade velocity is usually normal. Patients with a repeat length of more than 74 have an early disease onset and clinical features of pyramidal tract and basal ganglia involvement. Most of these patients have increased tendon reflexes, extensor plantar responses, spasticity, and dystonia. Patients with an intermediate repeat length of 71–74 units have a disease onset in middle age and show mainly ataxia and gaze palsy. Patients with a repeat length of less than 71 have a later disease onset and show signs of peripheral neuropathy with loss of tendon reflexes, amyotrophy, and decreased vibration sense. However, the boundaries between these clinical syndromes are vague, and the clinical phenotype of an individual may change with progression of the disease.

SCA6 patients suffer from a progressive cerebellar syndrome with ataxia of gait and stance, ataxia of limb movements, and dysarthria. Horizontal gaze-evoked nystagmus is almost universally present, and downbeat nystagmus is found in more than half of SCA6 patients. Other cerebellar oculomotor findings are also common, such as impaired smooth pursuit and dysmetric saccades. With disease progression, some SCA6 patients have clinical evidence of non-cerebellar involvement, including pyramidal signs and mild sensory disturbances.

SCA7 is clinically characterized by the combination of ataxia and visual loss. In patients with late disease onset, after the age of 40 years, cerebellar ataxia is the first symptom, followed by progressive loss of vision. In about half of the patients with late disease onset, there is no evidence of retinal degeneration or optic atrophy, suggesting that retinopathy only affects the macula. All patients with earlier disease onset, before the age of 40 years, have visual problems, starting either prior to or at the same time as cerebellar ataxia. A majority of these patients have retinal degeneration; some of them also have optic atrophy. Tendon reflexes are usually brisk. There are a number of additional symptoms that occur in less than half of the patients, and that tend occur more frequently in patients with long disease duration. These symptoms include gaze palsy, dysphagia, hearing loss, and muscle weakness.

Age of onset is highly variable in the various SCA disorders. Even within the same family the age at which ataxia is first noticed may range from childhood to late adulthood. In the polyglutamine disorders, SCA1, SCA2, SCA3, SCA6, SCA7, and SCA17, a part of this variability is explained the CAG repeat length. Patients with shorter alleles have a later disease onset, while the disease in those with longer alleles starts earlier. As the repeat length may increase from generation to generation, there is often a tendency to earlier disease onset in subsequent generations. This phenomenon is termed 'anticipation.' On average, SCA1 and SCA2 start between the ages of 30 and 40 years, SCA3 around 40 years, and SCA6 between 50 and 60 years. All SCA disorders take an unrelentlessly progressive course. On average, patients become wheelchair bound after 15 years and die 20 to 25 years after onset of ataxia.

Like the underlying neuropathology, MRI findings are heterogeneous. The most consistent finding is cerebellar atrophy, but in some SCA disorders with a strong sensory component of ataxia, such as SCA3 and SCA4, cerebellar atrophy may be absent or mild despite severe ataxia. In SCA1, SCA2, and SCA7, there is usually combined cerebellar and brain stem atrophy, resulting in a pattern of infratentorial atrophy similar to that in MSA (**Figure 3**). In contrast, SCA6 is the prototype of a SCA disorder with an isolated cerebellar atrophy on MRI (**Figure 4**). Morphometric MRI studies show additional shrinkage of the cervical spinal cord and volume loss of basal ganglia nuclei.

At present, there are no treatment options for the SCAs. Accompanying symptoms, such as restless legs syndrome, are treated in standard manner.

Startle Response

J R Fetcho and D L McLean, Cornell University, Ithaca, NY, USA

Startle Behavior

When a door unexpectedly slams, people are usually startled. In humans, the movements produced during this response include a rapid closing of the eyes and a hunching of the body as a result of a large contraction of the muscles in the neck and body (Figure 1). Such startle responses are nearly universal among animals and they occur in response to a strong, abrupt, and unexpected stimulus, such as a loud sound, an unexpected touch, or the sudden appearance of another animal or person. These startle responses are found widely among both invertebrates, including animals such as flies and crustaceans, and most vertebrates, including fish, amphibians, and mammals. The movements that occur during the response vary among different animals. In flies and in some mammals, the response can include a jumping movement. In crayfish and in fish, a flip of the tail moves the animal quickly through the water (Figure 2).

Behavioral Role of the Startle Response

Despite the varying forms of the movement during the startle response, its behavioral role is similar among the different species. The response serves a protective function that can move an animal rapidly out of the way of an attacking predator or protect vital parts of the body, such as the eyes, from injury that might be associated with an unexpected event. In many nonmammalian species, the startle response is referred to as an escape response because it often occurs in conjunction with a predatory attack.

Shared Features of Neuronal Circuits for Startle Responses

An appropriately timed, rapid, and powerful startle response can mean the difference between life and death for an animal. As a consequence, the neuronal networks underlying the startle response are well designed for both a rapid response and a powerful activation of muscle. The ways in which fast, powerful neuronal circuits are built are similar in different species, so the design of startle networks is similar in very diverse animals (Figure 3).

Startle responses are remarkably fast. In a larval zebra fish, which bends away from the location of a startling stimulus, the response can occur within approximately 5 ms of the onset of the stimulus. During the startle, the fish bends so that the head touches the tail in approximately 15 ms and the fish has moved several body lengths away from its starting location in 100 ms. Humans are slower but still remarkably fast, with the shortest muscle response latencies as little as 14 ms. The speed of response is accomplished by a very short and fast conducting pathway from the sensory input that triggers the response to the motor neurons that lead to the movement. The pathways typically include few neurons from input to output, which minimizes the delay introduced by synaptic connections. In fish, for example, the shortest pathway for an escape in response to an acoustic input involves only four neurons – the hair cells in the ear that connect to eighth nerve fibers which in turn connect to a neuron called the Mauthner cell (Figure 3), which directly connects to motor neurons in spinal cord to activate the startle response. The speed of the pathways is further optimized by the presence of electrical synapses, which allow direct current flow between one neuron and the next and reduce the delays associated with chemical neurotransmission. Finally, the startle circuits contain large, relatively fast conducting neurons in the pathways. These so-called giant neurons have relatively very large axons and, often, large cell bodies as well.

In invertebrates, fish, and amphibians, there are very few of these giant neurons, which can be present as a bilateral pair and are individually identifiable from animal to animal. The individual neurons receive input from many different sensory modalities, including the visual, auditory, and somatosensory systems, as well as more specialized senses such as the lateral line system, which senses water flow in fish. The presence of these large, multimodal interneurons has made the startle system especially good for electrophysiological studies because the large size allows relatively easy recording from the neurons.

A strong response during startle is ensured by the powerful connections of startle pathways to motor neurons that excite large numbers of very fast contracting muscle fibers. The motor neurons excited by the giant neurons in startle pathways are typically the largest motor neurons in the animal, with each motor neuron innervating many muscle fibers. This activates the fibers in the muscles nearly simultaneously to produce a powerful pulse of motor output that initiates the response.

The timing of startle responses can be critical. The response is typically initiated by a strong sensory input. The electrical properties of the giant neurons,

Figure 1 Human startle response. During the startle response the eyes and mouth close, the body is hunched, and the muscles of the neck and torso contract. These act to protect vital parts of the body from potential injury associated with the loud sounds or abrupt visual stimuli that might indicate a falling or flying object.

Figure 2 Escape response in a fish. Overlapping images of a fish doing a startle response after an abrupt touch of the body. The fish bends quickly to one side (in approximately 10 ms) and moves rapidly away from the stimulus.

which initiate the response, along with a powerful inhibition of these nerve cells at weak stimulus strengths give the neurons a high threshold for firing action potentials. This high threshold makes functional sense because the startle response is such a dramatic, energetically demanding movement that it would be detrimental to an animal to be constantly startling to every weak sensory stimulus in the environment. The relatively high threshold also helps to time the initiation of a startle response in a way that might maximize the ability of an animal to evade a predatory attack. For example, when a bird attacks a fish, if the fish performs the startle tail flip response too soon it might be possible for the bird to adjust its attack to the new location of the fish. The high threshold may help ensure that the startle does not occur until after the bird is committed to strike at a particular location, with the startle moving the fish out of that location at the last possible moment.

Important Observations Made Using Startle Circuits

Cellular and Synaptic

The remarkably large size of the neurons and their axons in startle circuits has made them a favorite preparation for basic studies of the physiology of nervous systems because of the ease of recording from the neurons. As a result, studies using startle neurons have provided a number of critical insights into the basic function of neurons and their synaptic connections. The most prominent of these is the

Figure 3 Similarities between startle neuronal circuits in fish and mammals. Inputs from the hair cells in the ear excite neurons in the brain stem that project to the spinal cord, where they directly excite motor neurons to cause the muscle contraction typical of the response. M-cell, Mauthner cell.

Nobel Prize-winning work of Hodgkin and Huxley, which described the ionic basis of the action potential by using a giant axon involved in the startle response of squid. The large size of the axon allowed them to thread a wire along inside it and control the membrane potential. This ability to properly clamp the transmembrane voltage and measure the currents required to do so during an action potential led to the discovery of the contribution of changes in membrane conductance to potassium and sodium to the generation of the action potential.

Other key contributions from studies of startle neurons include the first description of electrotonic transmission in a vertebrate nervous system. This was possible because the large size of the Mauthner neuron that generates the startle response in goldfish, along with some unique electrical properties of the cell, allowed for some of the earliest intracellular recordings from a neuron and its synaptic inputs in an intact brain. This ability to record reliably from a particular neuron in fish also led to the first description of field effect inhibition in the nervous system. This inhibition occurs not by a conventional synaptic interaction but, rather, as a result of current flows induced by the activated neurons, along with special morphological features that constraint the pathways along which the current can flow. Finally, studies of synaptic contacts onto the giant Mauthner neuron also provided striking evidence that each active zone in a presynaptic terminal releases at most one vesicle of neurotransmitter when the presynaptic neuron fires one action potential. These and other fundamental discoveries can all be attributed to the specializations of startle circuits that made them very accessible for even the earliest electrophysiological studies.

Network Level

One of the main challenges of neuroscience is to link neurons to the behavior they produce. Neurons in startle networks were some of the first to be shown to be active in a particular behavioral context. Once again, this was possible because the large size of the neurons allowed recording of the firing with extracellular electrodes even in freely moving animals. Such work showed a tight relationship between the firing of a giant neuron and the production of a rapid escape response, suggesting a causal role. Later studies in which the startle neurons were selectively deleted by using strong current injections or a laser confirmed a role for the giant neurons in the startle behavior.

Variability of the Startle Response

Although the startle response is often considered an almost reflexive response, there is evidence for variability in the behavior as a function of the sensory stimulus that elicits it. In crayfish, for example, a rostral stimulus activates one type of giant neuron (the medial giant interneuron) to produce a tail flip that moves the animal backward, away from the stimulus. A caudal stimulus, in contrast, activates another giant neuron (the lateral giant) that produces a different tail flip that directs the animal forward, away from the stimulus. Changes in the set of active neurons are also documented for the escape behavior in fish, where variation in the location of the sensory stimulus leads to activation of different large reticulospinal neurons and the production of different movements, all of which act to direct the fish away from a potential threat. Thus, there is considerable sophistication to the sensorimotor response, even though the network is relatively simple.

Plasticity of the Startle Response

A further level of sophistication in the response is evident in documented plasticity in synaptic connections in the circuits. There is evidence that both excitatory and inhibitory synapses in the circuits can undergo changes in strength depending on the pattern of activity in the network. This makes behavioral sense because the network must adjust to changes in the sensory environment. A fish in an environment that has considerable auditory noise (e.g., near a waterfall) might have an advantage if it reduced the efficacy of an auditory stimulus in producing an escape while maintaining the response to other sensory modalities. Otherwise, the fish would constantly be producing escapes to irrelevant stimuli. The ability of the escape behavior to show behavioral plasticity such as habituation is consistent with the importance of matching even this relatively simple behavior to the sensory environment.

Neuromodulatory systems such as those using dopamine and serotonin are intimately associated with neurons in startle networks, where they may plays roles in altering excitability and synaptic function to produce response plasticity. Neuromodulatory systems are often disrupted in neuropsychiatric diseases, which are also associated with alterations of the startle response.

Evolution of the Startle Response

The startle networks in invertebrates and aquatic vertebrates tend to involve few neurons, with at most only a handful of the giant neurons, which are critical for the response. In contrast, the network in mammals, although almost identical to that in fish

with regard to the number of synapses from auditory input to motor neuron, includes many more neurons at each step of the pathway (Figure 3). As in fish, the main giant neurons initiating the startle in mammals are located in the reticular formation (in the caudal pontine reticular nucleus) and their axons extend down the spinal cord to excite motor neurons. The evolution of the startle response thus appears to involve expansion of the number of neurons at each step in the pathway in more complex animals without much change in the number of steps, which might compromise the speed of response.

Pathology of the Startle Response

The startle response also plays an important role in studies of neuropsychiatric diseases of humans because disruptions in startle are often symptomatic of broader neurological problems. The startle response shows a well-known phenomenon called prepulse inhibition that is affected in a number of neurological disorders such as schizophrenia, Huntington's disease, and obsessive–compulsive disorder. In normal prepulse inhibition, when a weak sensory stimulus that does not elicit a startle is followed within less than approximately 0.5 s by a strong stimulus that would normally elicit a startle, the weak stimulus suppresses the response to the strong one. This phenomenon occurs in both invertebrates and vertebrates, including humans, and is thought to block later inputs to allow time for processing of the initial weak stimulus. This would seem counterproductive in a startle situation, but nonetheless prepulse inhibition does exist in startle circuits and is very important clinically because it is altered (often reduced) in diseases such as schizophrenia. The ease of testing for prepulse inhibition of startle in humans can provide an indication of a potential disease state. More important, the efficacy of various drugs in reducing deficits in prepulse inhibition might offer some indication of the effectiveness of the drug for treatment of the disease states. The effects on prepulse inhibition may well result from alteration of transmitter systems during disease, including inhibitory pathways known to be important for gating the flow of sensory information as well as changes in the neuromodulatory serotonergic and dopaminergic systems that are important both in startle responses and in many neurological diseases.

One indication of the critical role of inhibitory pathways in startle is an identified genetic disease of startle circuits called hyperekplexia, or familial startle disease. This is characterized by exaggerated startle responses and a reduction of habituation. The disease results from a mutation in the α subunit of the glycine receptor that alters the strength of inhibition. A balance between inhibition and excitation regulates the threshold of startle responses and a shift of this balance toward excitation by the mutation may explain the enhancement of startle in the disease.

Conclusion

The startle response is a fast, protective, fundamental sensorimotor response in animals that is often used to avoid predators. The circuits are simple and fast, with large neurons, which has allowed studies of neurons in startle networks to provide fundamental insights into the cellular and synaptic biology of the nervous system. The plasticity of the startle response and its disruption in disease states with broad neuropsychiatric consequences have made it a model system for studies of the neuronal generation of behavior and its disruption and treatment during disease.

Decoding a Code

If given the code *1-A-B-2-A-B-3-D-4-C-D-5-E-F-6-E-F*, 'cracking' it requires reducing the search space to a manageable size. The only way to achieve this reduction is to assume the nature of the information that code represents. Consider hieroglyphics. Although a code used by the Ancient Egyptians for 3500 years, it remained untranslatable for approximately 1500 years, even though much was known about the code and its history. Even when the 'Rosetta Stone' discovered by Napoleon's troops found its way to the University of Cambridge (by not altogether scrupulous means), Thomas Young – the father of modern color vision research – only managed to translate some of the text, particularly the proper nouns, even though the same decree on the stone was also inscribed in Greek and Demotic. Most of the hieroglyphic text was undecipherable because Young assumed – like most before him – that hieroglyphs were used to symbolize only objects and events in the natural and social world of the Egyptians. When Jean Francois Champollion put forward a new framework for thinking about hieroglyphs, namely that hieroglyphs had phonetic value as well as symbolic meaning and thus served as spoken language, he was able to translate the remaining text in 1821, thus initiating the modern field of Egyptology. The point, then, is that to fully understand hieroglyphics, one needed to describe not only its structures and organizations but also the information that it represented. This truism for hieroglyphs is true for any code, including the codes used in neural processing.

The spatial and temporal patterns of activity in the human visual brain are codes that ultimately transform the light that falls onto the eye into the sensations of color, space motion, form, etc. that guide our behavior. The aim of vision research, then, is to decipher this code. Fundamental to this aim is describing its underlying anatomy, physiology, and biochemistry. Of equal importance, however, is to deduce the nature of the information represented in that description. For many years, those in vision research assumed (usually implicitly) that visual encoding was a complex algorithm (e.g., sequence of filters) for accurately reconstructing the qualities of real-world objects (their reflectance, illumination, size, location, etc.) from elemental features of retinal images. In other words, the assumption was that the brain evolved to reconstruct and represent in perception the world as it is. Despite the intuitive appeal of this representationalist framework, exemplified in the important work of David Marr and colleagues in the 1970s and 1980s, it is beginning to lose ground – although not in all areas of investigation (e.g., some continue to argue that reflectance, illumination, and transmittance are represented explicitly as layers in visual processing). Replacing this perspective is a new framework, grounded in decades of computational, physiological, and behavioral studies on human and nonhuman visual processing, which suggests that vision encodes not the physical world as such but, rather, the statistics of its ecological influence on human observers.

Encoding Statistics

Why encode statistics? There are at least two reasons: energy resources for animals are limited, and the behavioral significance of visual information is ambiguous.

Energy Conservation

The survival of a visual animal requires generating useful behavior from stimulus information that falls onto its light sensors. One problem in doing this successfully is that neural processing is expensive. If more energy is spent on vision than is obtained through visually guided behavior, an animal's probability of survival decreases; spend less energy and the probability of survival increases. It is therefore reasonable to assume that a significant constraint in the evolution of vision has been the need to conserve the amount of energy an animal uses to process visual information.

One way to save energy is to see with as few cells as possible since each cell in the visual system uses energy to grow and be maintained. The smaller the visual network, the less energy the network requires. However, all things being equal, the fewer the cells, the less information the network can process. Thus, maintaining information capacity requires a commensurate increase in the amount of information encoded by each cell in a smaller network. This means smaller networks must work harder, fire more often and in more complex temporal patterns, and thus multiplex their functions. However, the cost of signaling with noisy synapses is nonlinearly related to signaling rate. The more often a cell 'fires,' the more expensive each response becomes. Thus, although there is pressure to evolve a system made up of fewer, frequently active cells, there is also selection

pressure to do just the opposite: spread visual processing across a larger network of infrequently firing cells – called 'sparse coding.'

From this we can hypothesize that visual processing evolved to maximize its information capacity while minimizing cell number and signaling frequency. How can it do all three? The answer is presumably computational efficiency achieved by eliminating redundancy in the code. There are two sources of redundancy in visual processing. The first is neuronal. If two cells fire simultaneously in response to the same sensory information, then their responses are correlated. Correlated signals are duplicate codes and therefore redundant. The costs associated with coding redundancy are the necessary increase in cell number and cell signaling. Thus, decorrelating responses early in visual processing by reducing the overlap in the information encoded by each cell can save energy by encoding the same information more efficiently.

The second source of redundancy is the natural image. To understand why, consider all the possible images the visual system could experience on a standard computer monitor set to a resolution of 1280×1024 pixels. Given 1.3 million pixels and a 32-bit color depth, the size of this theoretical image database is $10^{6\,619\,700\,000\,000}$. With the number of atoms in the universe being only 10^{21}, this is very large indeed (even larger if one were to equate the number of pixels of the monitor with the number of retinal receptors). Most of these images, however, would be fairly uninteresting, made up of random white noise (like 'snow' on television late at night) where each pixel is statistically independent from the quality of all other pixels in space and time. Images of natural scenes, on the other hand, are far more interesting, occupying a unique and relatively small part of the landscape of all possible images. What is interesting about natural images is that they have 'structure,' where pixel intensity at each point is correlated with the intensity of the neighboring pixels in space and time. The reason for these correlations is that surfaces and illuminants in the natural world are extended in space, and motion is continuous in time. Encoding information about individual pixels, therefore, would be highly inefficient since the relationship between pixels would lead to correlated (and thus redundant) neural responses. Instead, the visual system can increase the sparseness of its code by decorrelating its neural responses to images, which is achieved by taking advantage of the statistical relationships between pixels at multiple spatial and temporal scales.

Thus, assuming the visual system actually needs to re-encode the patterns of light that fall onto the retinae as efficiently and accurately as possible in its post-receptor processing, then clearly encoding the inherent spatial/temporal statistics of images is advantageous since it conserves energy.

Behavioral Robustness

It is important to ask why vision should re-encode the retinal image in the first place. After all, since all the information about an image is available in the pattern of retinal activation, then no matter how efficient and faithful its subsequent representation, the re-encoded information is redundant with the original retinal representation. There are several possible answers to this question. One is that the mammalian retina must send information about the activity of its 130 million receptors down an optic nerve that for whatever reason is constrained to only 1.2 million axons. Given this massive convergence of wiring, and assuming most visual processing of color, form, motion, etc. begins in the primary visual cortex (which is questionable, given the complexity of retinal and thalamic processing), coding efficiency may be a necessary step for maximizing image information en route to the cortex. Note, of course, that the seeming 'bottleneck' of the optical nerve may actually be a manifestation of efficient coding. On the other hand, the insect visual system does not suffer the same retina-to-brain wiring bottleneck, and yet much of the direct evidence for coding efficiency has been substantiated in insects. Thus, another possibility is that re-encoding the spatial and temporal patterns of activation across the retina enables information about the visual image to be mapped at minimal cost to multiple 'channels' (or modules) for independent parallel processing, thereby gaining the advantages that parallel processing confers on complexity of behavior.

Finally, and most critically, it is important to emphasize that an image of the world is just that – an image. Although real-world 'scenes' (defined in terms of the statistics of objects, illuminations, and three-dimensional distances) and their 'images' (defined in terms of lower and higher-order correlations between pixels) are frequently used interchangeably in the literature, the two are very different indeed. Thus, although research on statistics and/or entropy of images has been important for validating the ecological basis of vision, the analysis does not actually deal with the real challenge of visual ecology, which is not to 'see' the image that falls onto the eye (efficiently or otherwise) but, rather, to behave toward objects in the world that generated the image. It is therefore essential that vision research also explores directly the role that the behavioral significance of image information has played in visual

a

b

Figure 1 Continued

evolution and development. Evidence that it does play a role, even at the lowest level of visual processing, is indicated by the spectral sensitivity of retinal receptors. For instance, bees have three broadband receptors tuned to approximately 350, 450, and 550 nm. Computational analysis has shown that this combination of receptors is ideal for detecting stimulus information arising specifically from flowers (it is of course also possible – if not likely – that flowers evolved their reflectance characteristics according to the bee's spectral sensitivity). Similarly, the sensitivities of the 'red' and 'green' cones in the human eye are well matched to behaviorally relevant stimulus information arising from their historical environment. More generally, the relationship between the behavioral value of stimuli and receptor sensitivity has been thoroughly described in natural systems and quantitatively modeled in robotic and artificial life systems. Thus, the behavioral significance of images at the very least constrains the window through which the animal sees its world by determining what stimulus information to detect and what to ignore. However, it also does a good deal more. It actually shapes the way the visual system subsequently processes that information.

The reason is that there is not intrinsic significance for any image since each of its attributes is derived simultaneously from multiple attributes of the world (reflectance and illumination in the case of the spectral quality of a stimulus and size and distance in the case of its projected angle; **Figure 1**). Thus, if an animal is to survive, it must overcome the fact that the only direct information it has about the world is inherently ambiguous vis-à-vis its generative source. Little is known about how vision resolves this challenge. What is clear is that the only way to do so effectively is by encoding the statistical relationship between images, scenes, and behaviors in past experience. Originating with the work of Helmholtz and then Gibson, this empirical/ecological view of vision has been usefully explored quantitatively using Bayesian decision theory.

Work on visual illusions demonstrates the validity of this probabilistic framework particularly well. For instance, in **Figure 2** the two red crosses on the right and left faces of the cube appear to have different brightness, with the one in 'shadow' seemingly brighter than the one in 'light.' Despite their appearance, the crosses are in fact physically identical in that they reflect the same amount of light to the eye (**Figure 2(b)**); also note that all the small 'black' tiles in depicted light are physically the same as all the small 'white' tiles in depicted shadow). This perception of different colors in response to identical stimuli is an 'illusion' (like many others published previously): what is seen is not what is really there. Note, however, that had the identical stimuli originated from a real cube in light and shadow, then in the past experience of the animal the behavioral significance of the identical stimulus elements would have turned out to be differently reflective surfaces, with the one in shadow being a more reflective surface than the one in bright light. If vision evolved to see the world not as it is but, rather, with reference to statistical information about what an image turned out to be in the past (shown didactically in **Figure 1**), then the perception of the crosses in **Figure 2** should represent this experience and the crosses should appear to have different brightness, as indeed they do. Thus, these observations (and many similar observations) indicate that vision uses statistics not only to conserve energy but also to generate behaviors from image information that is inherently meaningless.

A corollary of this view is that a more complete understanding of vision will require quantitative descriptions of the probabilistic relationship between natural images, the patterns of activation in the relevant network generated by those images, and subsequent motor behavior, as well as the 'cost' to the animal/agent of generating that behavior, which can be modeled explicitly using Bayesian decision theory and/or empirical ranking theory. Although most of this information is unknown, if not unknowable, for human vision, in exploring the general biological and computational principles of vision it is not necessary to focus exclusively on primates (or even mammals for that matter) since simpler systems (e.g., insects) also evolved to overcome the same ecological challenges of vision. Also, since simple systems (both natural and artificial) are far more tractable,

Figure 1 Physical interactions in the generation of spectral stimuli. (a) Diagram illustrating the inevitable conflation of illumination, reflectance, and transmittance in the generation of spectral returns that elicit color sensations. (b) The typical consequences of the interaction of reflectance, illumination, and transmittance in this process. In this example, a 'surface' with a given reflectance efficiency function (illustrated here as a simple sine wave) is 'illuminated' by equiluminant spectra whose configuration, relative to that of the surface's reflectance, is the same (1), the opposite (2), or shifted toward long (3) or short (4) wavelengths. For comparison, the dashed line represents a 'white' light illuminant comprising a uniform distribution of wavelengths. For the sake of simplicity, transmittance is assumed to be uniform (although usually minor, the effects of atmospheric transmittance are neither negligible nor uniform). Note that the spectral returns given by the product of the reflectance efficiency functions and the illuminants vary systematically relative to the return generated by the same surface under white light.

Figure 2 (a) A cube in light and shadow. Although the red crosses on the two sides of the cube appear to have different brightness, they are in fact physically identical, which is shown in the key (b). The illusion of brightness in a suggests that the human visual system encodes the statistical relationship between the patterns of light that fall on the retina and the surfaces and illuminants that generated those patterns in the past.

they provide an essential platform for rationalizing 'empirical' vision in quantitative terms – in parallel with the important work on humans and other primates.

Conclusion

There is nothing red about 'r-e-d'; 'l-o-n-g' is shorter than 's-h-o-r-t'; there is no '2-ness' in the letter string 't-w-o'; and there is nothing singular about 'o-n-e.' English is an emergent, social, and biological phenomenon, understandable only within its social and biological context. Information about syntactic structure, if divorced from the information encoded in the system, describes the code but does not explain it. Adaptive networks, like the visual brain, are also frequently described as codes that translate image information into behavior. As with all codes, understanding vision requires not only a clear description of its functional structure but also a clear understanding of (or at least coherent assumption about) the nature of the information encoded by vision. Answering the latter question, which is a key aim of theoretical and computational neuroscience, requires taking into account the challenges that are actually faced by vision in its evolution and development when interacting with the world. There are at least two: energy is limited and visual processing expensive, and image information is ambiguous and robust behavior essential for survival. Both issues have been the focus of much research on primates, insects, and synthetic visual systems, although usually pursued along parallel (i.e., noninteracting) lines of investigation. Nonetheless, both constraints may be resolved by the same process of encoding the statistics of images and the probabilistic relationship between images and their behavioral significance in an animal's ontogeny and phylogeny. This view, which is frequently prosecuted by a combination of information theory, Bayesian decision theory, and coding theory, provides a clear framework for rationalizing perception and processing based on explicit assumptions about the nature of the information encoded in the visual system.

Statistical Learning of Language

J S F Hay, University of Wisconsin–Madison, Madison, WI, USA

The Problem of Language Acquisition

Learning language is a complex endeavor, both for infants learning their first language and adults learning their second, third, or fourth languages. What makes learning language so complex is that language itself is so complex. Elements in natural language, like sounds, words, and phrases, can be combined and recombined to form an infinite number of unique sentences. It is the task of language learners to figure out what the basic elements are and then to learn which combinations of these elements are permitted in their particular language.

How does this problem relate to learning the sounds (phonetics) and sound patterns (phonotactics) in language? In this case, finding the basic elements means figuring out which differences between speech sounds in a language environment matter within the language and which differences can or should be ignored. More than 800 speech sounds are found across the world's languages. Determining how a language breaks up the auditory space is not a simple task. Some languages use as few as 11 consonants and vowels, whereas others use as many as 141. It is the language learners' task to discover the relevant sounds in their native language. Learners then need to discover which sounds are allowed to go together, when they should go together, and in which order. For example, the sounds /t/ and /s/ are allowed to occur together at the beginning of words in Japanese, as in 'tsunami,' but in English they are allowed to occur together only in borrowed words. Because parents cannot directly communicate to their infants which sounds are important or which sounds go together, infants need to have a way to learn this through experience.

Infants are faced with a similar problem during word discovery. How can infants pick words out of continuous speech before they know any words? Similarly, they have to discover how words relate to things in their environment and how words themselves combine together to make phrases. Again, infants do not receive explicit instruction to help them solve these problems. To make matters even more challenging, the linguistic environment is noisy and imperfect. Although there is an essentially infinite number of possible combinations of sounds, words, and phrases, language learners can be exposed only to the subset of possible combinations permitted in their language. In addition, there is no explicit negative evidence provided in linguistic input to tell children that certain combinations are not allowed. How do children learn which combinations are permitted and which are not allowed from this seemingly impoverished input? Part of the answer lies in the fact that language is rich with regularities that language learners are well equipped to track.

What Is Statistical Learning?

Statistical learning is a process by which an individual can discover and make use of experienced regularities. Broadly defined, it involves detecting structure in the environment by tracking patterns in the input. Natural language contains myriad statistical information that can be captured by listeners. The majority of research on statistical learning has focused on how human adults, infants, and even nonhuman animals track regularities during phonetic acquisition, speech segmentation, and the learning of simple grammatical structures. Each of these areas is reviewed in the following sections.

Finding the Elements: Distributional Learning and Phonetic Acquisition

Statistical learning mechanisms have recently been invoked to explain how infants acquire their native-language distinctions between speech sounds. Newborn infants can detect sound contrasts found across the world's languages, often responding more to differences between sounds that are different consonants or vowels than to equivalent differences between instances of the same consonant or vowel. It is fairly straightforward to assess infants' responsiveness to different contrasts. When infants are presented with a sound that they find interesting, they tend to look in the direction that the sound is coming from. If the sound is played repeatedly, infants will become bored, and the amount of time they spend looking in the direction of the sound decreases. If the sound is changed and infants notice and find the change interesting, they will reorient toward the sound. If infants do not notice the change or do not find the change interesting, they will continue to pay little attention to the new sound. In this way infants' responsiveness to different sound contrasts can be measured. Over time, infants' perceptual abilities become tailored to their native language, and by 10 to 12 months of age, they show greater responsiveness

to native-language contrasts than to nonnative contrasts. For example, young infants can discriminate between English productions of /r/ and /l/, irrespective of their linguistic environment. Infants in an English-speaking environment maintain the ability to discriminate the /r/–/l/ contrast. However, by their first birthday, infants who are raised in Japanese-speaking environments, where there is a single consonant that is similar to both English /r/ and /l/, no longer show differential responding to this contrast. How do infants progress from possessing language-general perceptual systems to being native-language listeners?

This focusing of perceptual skills may be partially explained by all perceptual systems' propensity to develop according to the structure of the experienced environment. Specific sound inventories employed by different languages vary greatly. Within each language, speech sounds have substantial regularities, however, and it is these regularities that may help infants during acquisition of native-language consonants and vowels. To use the /r/–/l/ example, in English these two sounds are distributed bimodally in the multidimensional space that differentiates /r/ from /l/. This means that the majority of English speakers' productions of /r/ cluster around average acoustic values for /r/, and their productions of /l/ cluster around average acoustic values for /l/. There are productions of both /r/ and /l/ that are distributed further from average productions, but they occur with a lower frequency. If infants can track the distribution of sounds in their environment, English-learning infants should learn to attend to the differences between /r/ and /l/ because they conform to a bimodal distribution. In Japanese, there is a consonant that falls in the acoustic region between English /r/ and /l/. The majority of productions of this Japanese consonant cluster around the average acoustic value for it, and a smaller number of productions fall on either side of this cluster, overlapping some English productions of /r/ and /l/. Infants growing up in Japanese-speaking environments learn to ignore the difference between English /r/ and /l/ as both sounds fall within a single Japanese consonant category. Thus, distributional information could, in principle, provide the necessary information for phonetic acquisition.

Infants' ability to discover visual distributional and correlational information has been well demonstrated experimentally. Infants' ability to track distributional information for the purpose of learning native-language consonants and vowels has been suggested in only a small number of studies, however. The ability to track distributional information is not specific to humans; for example, it has also been shown in a rodent population. Responding to change depending on distributional information – a skill that may be a precursor to phonetic acquisition – is present across species.

Finding the Elements: Statistical Learning and Speech Segmentation

Imagine that you are in a foreign country and you hear the following sentence: *lalangueparleénecontientpasdesignauxphysiquesmarquantledébutetlafind'unmot* (spoken language does not contain physical signals that mark the beginning and end of a word). Unlike written language, in which words are separated by blank spaces, spoken language unfolds continuously, with few obvious cues to word boundaries. If you do not already know French, you probably would find that the sentence sounded as if it was spoken very quickly, and you would have no idea how many words were in the sentence. Preverbal infants are faced with a similar situation when first learning their native language. Parents do not generally speak to their children in single-word utterances. Although speech to infants tends to be acoustically exaggerated, compared to adult-directed speech, it also does not contain many discrete cues to word boundaries. How can infants learn the words in their language, given that there are few acoustic cues to word boundaries?

Part of the answer likely involves prosodic and rhythmic information, as well as intraphrase pauses. These cues, however, are not always present when infants are initially finding words in continuous speech. Fortunately, spoken language contains rich statistical information about words and their boundaries. Transitional probability (TP), also termed conditional probability, is the probability of one event given the occurrence of another event. This statistic refers to more than the frequency with which one element follows another because it adjusts for the base rate of the first event or element. The TP of Y given X is represented by the following equation:

$$\mathrm{P}(Y|X) = \text{frequency of pair } XY/\text{frequency of } X$$

TP between syllables provides a reliable cue to word boundaries in that within a word, the probability that a given syllable will be followed by another particular syllable is relatively high, whereas between words, the probability of one syllable following another is relatively low. Take, for example, the following series of likely two-word phrases that an infant might hear: pretty baby, happy baby, cute baby, pretty kitty, pretty doggy, pretty horsey. In this microcorpus, every time an infant hears *ba*, it is followed by *by*. Therefore, within the word 'baby,' the

syllable sequence has a high TP (TP = 1.0), and infants should treat 'baby' as a good word candidate. So although the syllable *ba* predicts the syllable *by*, hearing *ty* (from 'pretty') does not necessarily predict *ba* (from 'baby'). The TP between syllable sequences *ty* and *ba* is 0.25, and therefore '*tyba*' is a less good word candidate in English than 'baby.' Until recently it was unknown whether humans could track these regularities.

In the mid-1990s, Saffran, Aslin, and Newport developed a paradigm to test whether infants could track TPs. They created a language that contained four three-syllable nonsense words (i.e., tupiro, golabu, bidaku, and padoti), hereafter called 'words,' which were concatenated together in a quasi-random order (e.g., *bidakupadotigolabubidakutupiru* . . .). Words were defined by their high internal TP (TP = 1.0): each syllable within a word perfectly predicted the occurrence of the next syllable. The TP between syllables spanning word boundaries was much lower (TP = 0.33). The language was synthetically produced with no other markers to word boundaries. The researchers familiarized 8-month-old infants with 2 min of this artificial language, with the hypothesis that infants who can track TP should treat words from the language differently from nonwords (sequences of familiar syllables in a novel order, with a TP of zero). Using a head-turn preference procedure, they assessed the infants' preference for words from the language versus nonwords. Infants preferred listening to the nonwords (new sound sequences) from the artificial language. In a more stringent test of infants' abilities to track TP, the researchers presented a second group of infants with words and part-words (sequences made from combining the second two syllables from a word with the first syllable from another word in the language; part-words had a TP of 1.0 between the first and second syllables and a TP of 0.33 between the first and second syllables and a TP of 1.0 between the second and third syllables). They found that 8-month-old infants preferred listening to the part-words from the artificial language, suggesting that the infants had correctly segmented words from the language and now found the sequences with lower TPs more novel and hence more interesting.

These results have been replicated numerous times. With longer exposure to the artificial languages, older children and adults can also track TPs in more-complex artificial languages and use that information for speech segmentation.

The ability to track TPs is not specific to speech, sound, or even humans. Saffran and colleagues have found that human infants and adults are successful at segmenting tone 'words' – tone sequences with high internal TPs – from a continuous stream of tones, suggesting that this type of statistical learning is not tied to speech or language. Researchers have also found that cotton-top tamarins can segment trisyllabic words from an artificial language on the basis on TPs alone. Following 20 min of exposure to an artificial language, tamarins were more likely to orient in the direction of a concealed speaker if they were presented with a either a nonword or a part-word than if they were presented with a word from the artificial language. This finding suggests that the ability to track and segment speech on the basis of TPs is not special to humans and that the ability probably did not evolve specifically for language. Rats are also able to segment words from continuous speech on the basis of TP. Finally, both human infants and adults are successful at extracting sequences of visual shapes on the basis of their TPs. This type of statistical learning is not constrained to the auditory domain.

Given that the ability to track TP is so ubiquitous across perceptual domains and across species, how likely is it that the abilities demonstrated in these laboratory speech segmentation tasks are actually applicable to real-world speech segmentation and word learning? In a study designed to address this question, 17-month-old infants were familiarized with an artificial language that contained no acoustic cues to word boundaries and then tested for the ability to treat words from the language as labels for objects. Infants learned object–label associations only when the label was a statistical word from the previously familiarized artificial language. Infants failed to learn the object–label association if the label was either a part-word or a nonword. Thus, statistical words do, in fact, make good word candidates. Statistical learning is likely to be one of the learning strategies employed by infants during language acquisition.

The Transition from Language-General Statistical Cues to Language-Specific Linguistic Cues in Speech Segmentation

The ability to track purely statistical regularities (e.g., distributional shape and TPs) in the linguistic environment is essential for the initial stages of language acquisition. Once infants have discovered some basic linguistic elements, such as words, they can then use this information to bootstrap into discovering more linguistic regularities, such as phonotactic and rhythmic patterns. This bootstrapping also involves statistical learning. For example, infants raised in an English-speaking environment learn that some sound clusters, such as 'dl,' are not permitted at the beginning

of words in English but that they can be heard at word boundaries, as in the phrase 'good luck.' Once infants have learned the types of sounds that are allowed to occur together at the beginning of words, hearing an illegal sound cluster (such as dl) provides a good cue to word boundaries. Given a novel sequence such as 'murdlarn,' English-learning infants are more likely to segment it as murd + larn than as mur + dlarn because dl is an illegal initial sound cluster in English.

Stress can also provide a cue to word boundaries. In English, the majority of two-syllable words have stress on the first syllable (e.g., BAby, KItty, BOttle, TAble). In Spanish, the second to last syllable of a word is usually stressed (e.g., meSEta, gaTIto, caBAllo), and in French the final syllable of the phrase is stressed (e.g., petit beBE, grand chaTON, pain doRE). Once infants learn the association between stressed syllables and words, they can use stress as a cue to find words in speech. There is evidence that 9-month-old infants from English-speaking homes will use stress instead of TP to segment continuous speech when the two cues are in conflict, missegmenting statistical words in favor of extracting words that have a trochaic (strong–weak) stress pattern. In contrast, younger infants rely heavily on TP for speech segmentation, ignoring stress as a marker for word boundaries. When familiarized with a series of strong–weak nonsense words, however, even younger infants will switch to a stress-based segmentation strategy. Linguistic experience seems to be necessary for infants to violate purely statistical regularities in favor of more language-specific segmentation strategies.

Why would infants switch from using purely statistical cues, such as TP, to using more language-specific cues when the two cues are in conflict? One possibility is that using language-specific cues is ultimately easier. Tracking statistical regularities requires the learner to be able to perceive and retain information across instances and then perform computations on that information. As might be expected, statistical regularities and language-specific cues are rarely in conflict in natural languages. If a cue provides a good indicator to word boundaries, it does so precisely because its presence maps onto differences in TPs between and within words. It is the consistency of this mapping, and the redundancy it provides, that directs its usefulness for segmentation. If stress pattern (e.g., a strong–weak pattern in English or a weak–strong pattern in French) and syllable TP were uncorrelated, stress would likely not be used as a cue to word boundaries. These linguistic cues likely function in conjunction with purely statistical cues and provide a rich system of regularities for the language user to absorb.

Finding the Structure: Statistical Learning, Grammatical Structure, and Predictive Dependencies

Phonetic distribution shape and syllable TP provide only some of the statistical information necessary for infants to acquire language. Infants must also gather information about grammar and syntax. Since the 1960s, the orthodox view has been that infants are born with innate linguistic knowledge of a universal system of grammar (or universal grammar). According to the strong version of the theory, initially proposed by Chomsky, aspects of language that are learned, are learned through neural mechanisms that have evolved specifically for language. This neural mechanism is sometimes referred to as a language acquisition device. Research on statistical learning has suggested that, like phonetic acquisition and speech segmentation, learning at least some aspects of grammatical structure can be accomplished through general statistical learning mechanisms.

Tracking grammatical structure is substantially more complex than tracking distributional shape or TP. Learners must be able to abstract form classes (like determiners, adjectives, nouns, and verbs), have a rudimentary understanding of how form classes relate to how phrases are structured, and then be able to combine smaller phrasal units to form larger units – all within the structure allowed by a given language. Results from computational modeling suggest that word co-occurrence information available in large language corpora is sufficient for determining abstract form classes, such as parts of speech and the phrases in which they occur. Grammatical systems are also rife with predictive dependencies, such that the presence of one type of form class will predict the presence of another form class. For example, in English the presence of a determiner (e.g., 'a' or 'the') predicts the occurrence of a noun later in the sentence. The reverse relationship does not exist. Nouns often occur without determiners.

Saffran created an artificial language to investigate whether adults and children could learn rules about how phrases are structured based on the types of predictive dependencies found in natural languages. In Saffran's artificial language, sentences were made up of required and optional phrases. Each phrase was also made up of required and optional words. For example, in the language, A-words (i.e., biff, hep, mib, and rud) could occur with or without a following D-word (i.e., klor and pell), but a D-word was always preceded by an A-word. Saffran predicted that this type of statistical relationship should help learners discover phrase structure. Following exposure to

the artificial language, adult learners judged new sentences that followed the rules of the language to be more grammatical than new sentences that violated one of the rules. Predictive dependency was one of the primary factors that affected grammaticality judgments. That is, novel sentences that violated the predictive dependencies found in the artificial language were judged to be ungrammatical. Although there were a number of irrelevant surface features over which participants could have calculated statistical regularities, doing so would not have resulted in accurate grammaticality judgments. Success on the task demonstrates that human learners can use predictive dependencies in the service of acquiring simple phrase structure.

Infants and tamarins can also use predictive dependencies to discover structure in strings of words. After listening to a simplified artificial language, where predictive dependencies exist between individual words instead of between word classes, both infants and tamarins listened longer to an ungrammatical string of familiar words than to a different string made up of the same words that preserved the predictive dependency relations of the artificial language. When these two groups were presented with the more complex artificial language, in which the predictive dependencies were between word classes instead of individual words, only the human infants were capable of using dependencies among classes of words to acquire structured phrases.

Using a similar paradigm, it has been demonstrated that 12-month-old infants are able to learn novel grammatical structure following a short exposure (2 min) and that they can generalize the learned grammatical structure to new vocabulary. For example, if infants were exposed to a string such as FIM-SOG-FIM-FIM-TUP (with structure A X A A Y), they were able to abstract the learned grammar to the string PEL-TAM-PEL-PEL-JIG. In this experiment the TP of the test stimuli was zero because the vocabulary was new. This suggests that 12-month-old infants abstract beyond first-order word dependencies, even when the dependencies are only probabilistic in nature, to learn grammatical structure.

Constraints on Statistical Learning

It is evident that both human and nonhuman animal listeners are good at extracting regularities in the linguistic environment and that these abilities are relevant to the task of language learning. Natural languages contain statistical information that powerful statistical learning mechanisms could track but that would be irrelevant for the human language learner. For example, the distribution of syllables in English is such that it would be possible to track which words follow words whose second syllable begins with *th* (e.g., tether *ball*, mother *dearest*, lathered *up*) or which words are presented third in sentences (e.g., Once upon *a* . . . , The very *next* . . . , The white *snow* . . .), but such information is irrelevant to the task of language acquisition. The problem faced by the language learner remains essentially the same as discussed in the first section; there are infinitely many generalizations that are consistent with a given linguistic corpus over which the learner must compute the relevant statistics. Statistical learning must therefore be constrained or biased in order to reduce the acquisition problem.

Fortunately, language learners are biased to extract regularities that are relevant to natural languages. Artificial languages that have grammatical structures found in natural languages, like predictive dependencies, are easier to learn than artificial languages that do not have these naturally occurring structures or dependencies. These findings are true for adults, children, and infants. This suggests that natural languages might be structured in the way they are because predictability facilitates the discovery of underlying structure. There are additional types of constraints that may inform statistical learning and might also help structure language. For example, there are auditory constraints that make certain sounds easier to discriminate and easier to learn, and languages exploit such constraints when selecting their sound inventories. The study of constraints on statistical learning is even newer than the young field of statistical learning. It does, however, suggest that the constraints on learning may actually help structure language itself.

Introduction

Functional neuroimaging has become a popular method for investigating functional brain anatomy. As various neuroimaging techniques have developed, there has been a commensurate increase in the development of techniques for analysis. One of the critical issues surrounding neuroimaging analyses has been how to establish a valid assessment of statistical significance. Although details in the approach can vary, the general process involves taking the substantial amount of data collected and reducing it to meaningful patterns of functional brain activation. To discuss the typical procedures for accomplishing this task, this article focuses on the analysis of functional magnetic resonance imaging (fMRI) data; however, many of the concerns and techniques are applicable to other brain activation methods involving time series data. This article reviews the basic issues surrounding data reduction, preprocessing, individual analyses, group inference, threshold setting, and alternative analysis techniques.

fMRI Analyses as Massive Data Reduction

Like many neuroimaging techniques, fMRI involves collecting a massive amount of data. Data are in the form of snapshots of the brain in action taken over several time points (temporal frames). Each snapshot of the brain is made up of thousands of voxels or cubes of brain area; that is, each image of the brain contains a scanner intensity value for each voxel at the time the image was acquired. Taken together, each voxel can be characterized by a time course of values, with one value for each temporal frame. The goal of the analysis is to reduce this massive amount of data into meaningful information about brain function. For example, a whole-brain image taken at a resolution of 4 mm × 4 mm × 4 mm (30 slices, 24 cm field of view, 64 × 64 acquisition matrix) yields approximately 120 000 voxels. In a single 1 h scan session, ten functional runs of 3.6 min each, with a repetition time (TR) of 1000 ms, yield 2160 values for each voxel. These 2160 values at each of the 120 000 voxels must be organized according to (1) what was happening cognitively during particular periods of time (e.g., what task was the participant doing at any given time) and (2) where in the brain the activity was fluctuating during those different cognitive activities. This article presents the typical procedures involved in going from large volumes of data to meaningful statistical conclusions and the issues that arise in their application.

Preprocessing

During the acquisition of a typical fMRI scan, several technical details must be reconciled before the data can be analyzed for meaningful patterns. Although the particular order of these steps may vary according to the preferences of particular researchers, the purpose and processes remain similar. First, when a given volume of the brain is acquired in a single TR, that is, one complete scan through the whole brain, the individual slices differ in the time at which they were acquired. For example, if 20 slices are acquired sequentially from the top of the brain to the bottom of the brain at a TR of 1.5 s, the first slice and the last slice are acquired 1.425 s apart. Therefore, in order to better synchronize the brain activation changes that occur throughout the scan, the volumes are subjected to slice-timing correction. Second, during a scan session, participants are asked to remain still, but there will naturally be some small amount of head movement. To account for this movement, the volumes must be realigned to put all the acquired images into the same space. In addition to correcting for head motion, this step will provide data on how much movement occurred in each direction; such information can be used to assess effects due to motion. A similar realignment (also called coregistration) is performed to align anatomical images to the functional images for localization and display purposes. If group analyses are planned, it is further necessary to get all participants' brains into the same shape and alignment. This is generally accomplished through warping or normalization of each participant's brain images to a single standard or template brain. Neuroimaging data coming from the scanner are inherently noisy. One method for addressing this noise is to use spatial smoothing, which typically involves taking a moving average of voxel values to create larger voxels. The degree of smoothing depends on the size and type of filter applied. Smoothing is typically performed with a Gaussian-shaped smoothing kernel often specified by its full width at half maximum. This value is generally chosen to approximate the expected size of functional activation blobs in the final statistical parametric maps (SPMs). Although this procedure reduces the spatial resolution of the image, with the appropriate selection of a filter, it can substantially improve the sensitivity by

overcoming the considerable noise present in the data (i.e., increasing the signal-to-noise ratio). Smoothing helps whiten the noise (an important consideration both when employing Gaussian random field theory to correct for multiple comparisons and when subjecting the data to a general linear model, as discussed below). Finally, there are a number of ways that data can be filtered to remove systematic noise that is related to factors other than the cognitive tasks of interest. For example, low-frequency changes such as linear drift of the intensity values are customarily removed, either by applying a filter during preprocessing or as part of the multiple regression used during the analyses described in the next section.

Figure 1 shows the time course for a voxel in the parietal cortex in a single participant over the course of a single scan run. The values reflect the raw signal and after various stages of preprocessing including slice-time correction, motion correction/coregistration, normalization to percentage signal change (to eliminate differences in the raw signal intensity that occur across scans), and spatial smoothing.

Modeling Data for Individual Participant

In its simplest form, the question of interest when looking at an individual participant is whether the activation in each voxel is fluctuating in conjunction with the changes in the cognitive states that were engaged during the scan session. To model the data, each time point of the scan run can be 'labeled' according to the type of stimulus being presented and/or the type of mental manipulation in which the participant was supposed to be engaged. Figure 2 shows the scan scheme for an event-related design in which participants performed mental rotation over the course of five scan runs. In each run, participants were presented with four different trial types: no rotation, 60° rotation, 120° rotation, and mirror-image trials in random order, approximately every 6 s. (The mental rotation example used throughout this paper is for illustrative purposes only. The data are only partially represented.) To code these data for analyses, correct and incorrect trials were separated out. The different solid, colored lines in Figure 2 indicate the time at which there were correct instances of each of the different trial types throughout one run of the experiment; dashed lines show trials that were answered incorrectly. There are several methods for organizing and understanding the relationship between the time course of each voxel and that of the cognitive tasks; three of the common approaches are described here.

Multiple Regression

The most common method for modeling the data from a single participant is to conduct a multiple

Figure 1 A single voxel time course from the left superior parietal lobule of a single subject over the course of one run. Blue line is the raw signal off the scanner; red line has been slice-time corrected, purple line has been motion corrected (coregistered), green line has been normalized by the mean of the run, and orange line has been spatially smoothed with nearby voxels in the brain.

Figure 2 Scan scheme for a single 240 s run of an event-related mental rotation experiment. Peaks reflect the time point at which a given trial began, color coded to reflect the correct trials for no rotation (solid black), 60° rotation (cyan), 120° rotation (blue), and mirror-image trials (red), plus all incorrect trials (dashed black).

regression analysis at every voxel. The preprocessed voxel time course serves as the dependent measure, and a general linear model is built with regressors constructed to (1) control for extraneous variables of no interest (e.g., session-specific variations and linear drift) and (2) test the effects of interest. Each regressor is constructed according to the expected pattern of activation for the effect of interest. For example, Figure 3 shows the design matrix for a possible set of regressors in the mental rotation experiment in Figure 2. The first 48 regressors represent 12 different scan runs. The following six regressors represent the different possible trial types from the experimental conditions. This is equivalent to separating out each line in Figure 2 such that each regressor reflects the time points at which one trial type occurred during the scan runs.

In fMRI, the blood flow to a brain region is sluggish compared with the timing of the cognitive events and tends to show a smooth increase and decrease over time. As such, prior to modeling the voxel time course, regressors may be time shifted and smoothed to match the expected hemodynamic response function (HRF). For example, one might use a gamma function as the canonical HRF (Figure 4). This HRF convolution increases the likely similarity between the expected and observed time courses in voxels that are responding to particular cognitive events. These convolved regressors are then used to conduct the multiple regression on each individual voxel in the brain separately. The basic equation is as follows:

$$y(t) = \mathbf{BX} + \varepsilon_t \qquad [1]$$

where **B** represents the vector of to-be-solved regression weights (βs), one for each of the regressors, **X** represents the design matrix with the convolved regressors, and ε_t is the error.

The output of the multiple regression is a β at each voxel for each regressor. The magnitude of a given β

Figure 3 An image of the design matrix generated using AFNI from the example fMRI experiment in which there were five runs of data along with five regressors of interest. Each column is a graphical representation of a single predictor entered into the model. Each row corresponds to a time point from the beginning of run 1 through the end of run 5. White regressor time points correspond to a value of 0, black corresponds to 1, and grayscale colors are intermediate values. The first 20 regressors are used to account for trending components (0, first, second, and third order) from each of the five runs, separately. The final five regressors of interest correspond to correct responses to the four trial types (conditions) in the experiment plus one additional regressor to model all incorrect trials. Each regressor has been convolved with a hemodynamic response function beginning at each time point when a stimulus of that type occurred.

Figure 4 An example of a gamma function that might be used as the canonical hemodynamic response function to adjust regressors for the temporal lag of the brain's blood oxygen level-dependent response.

Figure 5 Examples of event-related time courses from the right superior parietal cortex in a single individual. In this case, the time course reflects as single voxel (30, −48, 51 in Montreal Neurological Institute (MNI) coordinates). Additional potential dependent variables are indicated with dashed lines.

reflects how well that regressor predicts the activation pattern in that voxel. The comparison of these β values for different conditions of interest can provide an index for increases and decreases in relative activation. For example, if a particular brain region is more involved in task A than in task B, then the β value for the task A regressor will be larger than the β value for the task B regressor. It is these relative relationships that provide the information needed to make statistical inferences about which brain regions are significantly active for one experimental condition versus another. As such, these β values (or various combinations of them) serve as the dependent variables for subsequent analyses. The statistical inferences will be based on placing thresholds on these β values or the differences among them. At this stage, one can create an SPM for the individual participant, showing the regions of the brain that meet a particular statistical threshold (see the section titled 'Thresholds and correction for multiple comparisons').

Event-Related Averaging and Deconvolution

When dealing with blocked designs in fMRI, multiple regression has remained a standard approach. However, concerns have been raised about whether the assumptions underlying the multiple regression approach – in particular, the need to specify the shape of the HRF – are more problematic when the design involves individual trials. Therefore, for analyzing event-related designs, other options are available that attempt to use the observed data to establish the hemodynamic response for each event type of interest directly from the data.

The first alternative, event-related averaging, involves segmenting the time course of each voxel for each event type by identifying a peri-event time window, defined by the time point of a given event, a specified number of preevent time points, and a specified number of postevent time points. For example, one might specify a peri-event window beginning 2 s before an event and including the 16 s including and following an event. This same 18 s window would be selected for each occurrence of a given event type throughout the scan session. For each of the frames in the 18 s window, there would be a mean value across all instances, resulting in an average 18 s time course for the event (Figure 5). The size of the window around the event must be carefully determined in order to correctly capture the event-related activation. In slow event-related designs, the window must be selected to avoid taking temporal frames that are associated with the trials before or after the trial of interest. In rapid event-related designs, the window must capture the trial, but one must also ensure that the history of each trial type is equivalent (i.e., that the trial types have been appropriately randomized or counterbalanced). The output for each individual is a set of average HRF time courses, one for each event type at each voxel. From these event-related averages, additional variables can be derived for each trial type: time for the HRF to peak, peak amplitude, area under the HRF curve, and so forth.

The second alternative, deconvolution, refers to taking the fMRI time course and breaking it into separable components. Rather than convolving the trial structure with a canonical HRF, a mutiple regression is constructed to determine the shape of the HRF for each trial type. Unlike simple event-related averaging, deconvolution uses modeling to provide an estimate

of the magnitude of the response at each time point following the onset of a stimulus (or condition). The output of the deconvolution operation is the time course based on these estimates for each event type. This time course can be passed back into the statistical model in order to further contrast conditions. Like event-related averaging, these estimated time courses can be used to calculate additional dependent measures for comparison.

Group Analyses

Regardless of the processing stream used to analyze individuals, the goal of a group analysis is to identify common sources across individuals in order to make inferences about how the brain functions in the relevant population. By combining data across individuals that have been warped to a common space, one can utilize many standard statistical tests to assess differences among conditions. In a simple blocked design, the individual participants' β weights for two conditions can be used to calculate a paired *t*-test at each voxel in the brain. By extension, one can calculate an analysis of variance at each voxel for more than two conditions or determine which voxels have significant correlations with independent behavioral measures. At each voxel, one can then determine whether the test is significant on the basis of the threshold one has set as a criterion (the chosen α level; see the section titled 'Thresholds and correction for multiple comparisons'). More recently, nonparametric analyses have become increasingly popular and can be used in a similar manner.

In the mental rotation example, the β values for no rotation, 60° rotations, and 120° rotations from each individual were subjected to an analysis of variance (ANOVA); the resulting group SPM is shown in Figure 6. Several areas showed significant activation at various thresholds, indicating that these regions have differential activation in the conditions of interest.

Thresholds and Correction for Multiple Comparisons

The goal of presenting the SPM from an individual or group analysis is to visualize how the brain is 'activated' for a particular comparison. The pretty pictures of colored blobs overlaid on top of anatomical brain images commonly seen in scientific journals these days are a result of statistical thresholding. In principle, this SPM tells the reader which locations in the brain enjoyed a statistically significant amount of signal modulation for the specific test or contrast between conditions. One critical issue in determining what one will or will not see in the SPM resulting from either an individual or group analysis is the selection of a statistical threshold.

Nominally, a statistic can be computed for any independent observation (say, a voxel β weight value) and an appropriate α level can be set. The α level is defined as the probability of finding a false positive (a type I error in statistical terms). When a single voxel is under consideration, the relevant threshold is the height or intensity threshold. Height thresholds are set based on the probability that a particular voxel will have a statistical value (e.g., the t- or z-value). For example, with an uncorrected α level of 0.001, any voxel that has a *t*-value with a probability of 0.001 or smaller will be shown in color in the resulting SPM. In the typical SPM, the particular color conveys information about the magnitude of the statistic or probability associated with that voxel. Returning to the example, Figure 6 shows activation for the rotation versus no rotation contrast at three different height thresholds.

Setting a height threshold for each voxel (an uncorrected α) can be misleading. It assumes that each voxel is an independent test; however, fMRI involves repeating the statistic test at thousands of different voxels in the brain. As such, the false positive rate is much higher because of this repetition. To address the inflated false positive rates, several methods for

Figure 6 Example of a single slice ($x = -73$) from a group statistical parametric map showing areas of greater activation for mental rotation compared with no rotation at three different height thresholds (*p* values).

correcting the threshold have been developed. Some of the commonly used methods are discussed here.

The most stringent method is a Bonferroni correction, as is typically used in other realms of psychology and neuroscience. This correction is based on dividing the intended family-wise error rate (P_{FWE}) among the number of tests conducted. For any family of n values, the probability that all n tests will be less than α is $(1-\alpha)^n$. Therefore, the $P_{FWE} = 1-(1-\alpha)^n$. With small values of α, one can assume that $P_{FWE} \leq n^*\alpha$. To achieve the intended P_{FWE}, one simply tests each voxel at $\alpha_n = P_{FWE}\ n^{-1}$. The problem with such a correction harkens back to the wealth of data in standard fMRI. That is, if one is performing t-tests on 66 000 voxels, the appropriate correction for a desired $\alpha = 0.05$ would require voxels to be significant at height thresholds of 7.6×10^{-7}! An alternative use of the Bonferroni correction takes into account the spatial correlation in the brain; the number of independent values is actually smaller than the number of voxels because of correlations among neighboring voxels (due to physiology, preprocessing, etc.). Therefore, the correction can be adjusted according to the number of independent values, reducing the n of interest and increasing the height threshold per n.

One major issue with using the adjusted Bonferroni correction is the proper identification of the number of independent values. An alternative is to use random field theory (RFT) to find an appropriate correction. Put in simplified form, RFT correction involves first establishing the number of resolution elements (resels; Huettel et al.) on the basis of the total number of voxels and the smoothing kernal used in preprocessing ($n_{resels} << n_{voxels}$). Based on these resel counts, it is possible to estimate how many blobs of activation would be expected at different thresholds. These estimates reflect the expected Euler characteristics of the image and can be used to determine corrected thresholds. For example, if a particular Z threshold has a Euler characteristic of 0.05, then any observed activations can be said to have a probability of 0.05 or less due to chance. Thus, the corrected α becomes 0.05. In practice, RFT correction also accounts for the size and shape of the activated blobs to adjust the probabilities. RFT assumes that the noise present in the data is white (relatively equal contributions at all relevant frequencies), thus making it critical to perform spatial smoothing during preprocessing.

Bonferroni and RFT both control for error by adjusting the likelihood of any particular activation being a false positive. An alternative is to control the expected proportion of false positives using the false discovery rate (FDR). The FDR is determined from the distribution of probability values in the data. The basic approach is one of conditional probabilities. At a given threshold, some number of voxels will emerge as significant (N_S). FDR techniques then estimate how many of these are expected to be false positives. Multiple methods have been proposed for controlling these values, but they share the same basic approach. In general, this method is adaptive for neuroimaging because it depends on the amount of signal present. As such, it can allow for weaker designs. However, there are a number of concerns that have been raised about its practical application.

An additional approach to constraining the number of tests conducted is to constrain the search volume of interest. The use of small volume correction involves reducing the total number of voxels of interest by focusing on one or more specific regions. Unlike region of interest (ROI) analyses (see the section titled 'ROI analyses'), this approach imposes the restriction on the SPM. This approach can be effective when there are specific hypotheses about where activation is expected. Correction is still accomplished using one of the above corrections (Bonferroni, RFT, or FDR), but the total number of voxels in the volume of interest is substantially reduced. Conclusions are restricted to only those areas interrogated in the reduced brain volume.

The preceding methods of correction focus primarily on ways of adjusting the height threshold. Thresholds can be corrected by considering how meaningful it is to see activation in a single voxel. Even small brain regions (e.g., amygdala) are made up of multiple voxels. As such, we are typically looking for contiguous activation of voxels. To address this issue, one can set a threshold for contiguity: an extent threshold. Extent thresholds are set on the basis of the probability of having significant voxels (at a given height threshold) in close spatial proximity. Different combinations of height and extent can be used to establish the same corrected value, allowing some flexibility as a function of the regions one is most interested in observing.

ROI Analyses

In most neuroimaging studies, the researcher has clear hypotheses about the brain regions likely to be involved. As such, one approach to analyzing the data is to examine the fluctuations in activation that are occurring within those prespecified regions. ROI analyses can be used in a number of ways. The different methods are based on the way the ROIs are determined, and these methods can result in approaches that either are purely descriptive or allow for additional inferences.

For descriptive purposes, ROIs can be used to enhance and/or clarify other analyses. If a t-test or

ANOVA shows a significant cluster of activation, one can extract the mean β value for that region in each of the tasks and plot the values. Similarly, a region that shows a significant correlation with behavioral measures in a group SPM could be used as an ROI to extract the β values for each participant. This extraction would allow a plot of the correlation to help illustrate where the significant value came from. This ROI approach uses the observed differences to define the ROIs and is inherently for illustrative purposes only. Because the ROIs are not independently defined, they cannot be used for additional inferential tests.

When an analysis involves more than two conditions, the appropriate test at each voxel may be an ANOVA. Such an analysis can only determine voxels (and clusters) in which the conditions show a difference. To understand those differences, one must further analyze the differences between pairs of conditions. Rather than doing additional whole-brain contrasts for each pair, one can use the significant clusters defined by the ANOVA as ROIs. Using coordinates defined by the group analysis, one can extract the relevant β weights for each participant and use those values for *post hoc* graphing and contrasts. This approach still uses the original data set to determine the ROIs, but it can allow additional inferences about differences among conditions. For example, Figure 7 shows the activation in the superior parietal ROI that was significant in the ANOVA in Figure 6. By extracting the β values and subjecting them to ANOVA, one could easily make and visualize subsequent pairwise comparisons. Similar approaches may also involve using one contrast to define ROIs for other contrasts of interest.

Finally, ROIs can be used in place of a group analysis. For this type of analysis, ROIs must be determined independently of the data being analyzed. There are several ways that ROIs might be determined. First, one might use previous functional studies that have identified particular regions of activation that might be relevant. Provided these ROIs can be defined in the coordinates of the same standard space as the participants, then the data can be extracted for each individual in the defined region. For example, if previous studies have localized a subregion of the dorsolateral prefrontal cortex for object working memory, one could use the coordinates from those previous studies to define the ROI. For other regions, anatomical distinctions might be used to define ROIs in each person individually. For example, one might use known anatomical landmarks to identify the location and extent of each person's calcarine sulcus or hippocampus. Finally, one can also use localizer scans to define ROIs separately from the functional scans of interest. For example, if one is interested in attentional modulations in the visual cortex, one could first use flashing checkerboards to determine the retinotopy. In each of these cases, the ROIs are determined prior to analyses, and the main analyses are performed on the information extracted from the *a priori* ROIs.

In all the ROI analyses, the data of interest can take many forms. First, one can look at mean β weights for different conditions, as in Figure 7. This simple bar graph is appropriate for event-related designs and would be the primary outcome for any block design. Alternatively, for event-related designs, one could plot the group average of the event-related time courses for each condition in the ROI (Figure 8). From time courses, one could further evaluate different variables of interest, such as the time to peak, area under the curve, peak amplitude, or some combination of these measures; however, these measures should come from the individual event-related time courses rather than from the group (see Figure 4).

Figure 7 Mean b weight as a function of condition extracted from the right superior parietal cortex region of interest outlined in Figure 6. Error bars are SEM (std. error of mean).

Other Techniques

The preceding discussion is about general approaches to significance testing in fMRI. The majority of the topics apply to other types of time series data, particularly those with large data sets. However, there are numerous other techniques for making inferences about brain activation. Nonparametric tests have been suggested as a way of addressing concerns about the assumptions underlying the typical general linear model approaches. Techniques such as principal components analysis, independent components analysis, functional connectivity, and effective connectivity can be used in place of or in conjunction with the approach outlined above. These additional techniques attempt to provide information not

Figure 8 Group event-related average time courses taken from the peak voxel in the right superior parietal cortex region of interest outlined in Figure 6. Error bars are SEM (std. error of the mean).

readily available in a standard analysis. Other techniques will continue to emerge as the field evolves.

Introduction

The myriad neurological pathology that can affect the human brain during prenatal development and throughout life and the brain's limited self-repair capacity call for new therapeutic strategies. Our increasing knowledge about the fundamental biology and therapeutic potential of various stem cell types opened a new chapter in regenerative medicine. The initial work on rodent stem cells during the past two decades is now being successfully continued with stem cells of human origin and from different developmental stages. We have learned about key genes and cellular mechanisms that maintain the status of stem cells or lead to differentiated progeny. We have also learned about the multiple roles of stem cells during development, disease, and aging. It is now well established that stem cells are not only a valuable tool for cell replacement but also equipped with important additional properties that may be harnessed for cell protection, detoxification, and gene therapy ('chaperone effects').

Stem cell biology is being recognized as a continuum of development, and developmental processes are tightly regulated, both temporally and spatially. Better understanding of these developmental events is considered to be a key strategy for the successful use of stem cells (endogenous and grafted) for central nervous system (CNS) repair and functional recovery. For instance, the generation of functional neurons and glial cells during brain development requires a concerted coordination of cell proliferation, migration, cell type specification, and synaptic integration, all of which are also crucial for successful stem cell therapy.

Stem Cell Prototypes

Stem cells give rise to organs and maintain tissue integrity and homeostasis in the adult organism. There are different types of stem cells, including embryonic and somatic (fetal or adult derived), from which new cells can be derived. To fulfill the criteria of a stem cell, as opposed to a 'progenitor' cell, a single clonal cell must have the following functional properties: (1) it should be able to generate the cell types from the organ from which it was derived, and (2) it should be capable of 'self-renewal' (i.e., the ability to produce daughter cells with identical properties). The ability to populate a developing or injured region with appropriate cell types upon transplantation is another important stem cell feature that is well established with hematopoetic stem cells and awaits standardization in other organ systems, including the brain. In the following sections, we introduce two prototypical stem cells, embryonic stem cells (ESCs) and neural stem cells (NSCs), and discuss their potentials for neural repair.

Embryonic Stem Cells

ESCs have been derived from the inner cell mass of blastocysts of different species including human. They are pluripotent and able to yield mature cell types from all different germ layers. Work performed with mouse ESCs has provided proof of principle that pluripotent cell lines can be harnessed for developmental biological studies as well as for new therapeutics. Since significant species differences exist between mouse and human ESCs regarding signaling pathways and molecular regulation of pluripotency, it is pivotal to fully characterize and define the molecular mechanisms in human ESCs. Our understanding of human ESCs is increasing and knowledge is accumulating on improved cell culture conditions, long-term propagation, controlled differentiation, and transplantation into animal models of human disease.

The list of various cell types differentiated from human ESCs (e.g., neurons, cardiomyocytes, and hepatocytes) is continuously increasing. Pluripotent ESCs can be stepwise differentiated in the culture dish by recapitulating aspects of *in vivo* development and the use of relevant epigenetic factors. Importantly, the acquisition of a particular developmental stage of a cell is best characterized by considering morphological, immunophenotypic, and functional criteria. Unlimited access to specific functional human cells is expected to play an important role not only in therapeutic cell replacement but also for disease modeling and drug screening.

Neural Stem Cells

In contrast to pluripotent human ESCs, somatic stem cells are believed to be multipotent and thus capable of generating the major cell types limited to the tissue

of origin. Typically, the NSC is capable of producing neurons, astrocytes, and oligodendrocytes. Somatic/tissue-specific stem cells are the building blocks of organs during development and survive in specialized microenvironments ('stem cell niche') contributing to new cells throughout life. NSCs are multipotent (i.e., they have the ability to yield mature cells in all three fundamental neural lineages throughout the nervous system: neurons, astrocytes, and oligodendrocytes), have the ability to populate a developing region and/or repopulate an ablated or degenerated region of the CNS with appropriate cell types, and undergo self-renewal (i.e., the ability to produce daughter cells with identical properties). NSCs have been identified *in vitro*. No study has demonstrated the existence of multipotent NSCs *in vivo*. NSCs are highly abundant during embryogenesis, with a sharp decline soon after birth. In the adult nervous system, NSCs are confined to the subgranular zone (SGZ) in the dentate gyrus of the hippocampus and the subventricular zone (SVZ) lining the lateral ventricles. The newly born neurons in hippocampus have been suggested to improve memory and play a role in mood behavior such as stress and depression. Neuroblasts born in the SVZ migrate along the rostral migratory stream to the olfactory bulbs, where they differentiate into periglomerular and granule neurons. In brain regions such as amygdala, substantia nigra, and cortex, cells with stem cell characteristics *in vitro* have been isolated. Morphologically, NSCs share properties with both astrocytes and radial glia. The main characteristic is a long process that extends radially. Although no definitive marker has been suggested for NSCs, a substantial amount of work shows that they are positive for nestin, an intermediate filament protein, and glial fibrillary acidic protein, traditionally used to identify astrocytes.

NSCs or progenitor cells with a more restricted developmental potential can be generated from human ESCs or directly isolated from the developing CNS as well as from neurogenic regions of the adult brain. Historically, the first established NSC lines exploited knowledge accumulated on tumor viruses and immortalization. These cell lines have been invaluable in expanding our experience on basic stem cell biology and neural repair. Some of these multipotent cell lines, such as the C17.2 NSC line, are still widely used. However, NSCs that have not been genetically modified can also be propagated *in vitro* for extended periods of time using high concentrations of mitogenic factors such as basis fibroblast growth factor (bFGF) and epidermal growth factor (EGF). Neural stem/progenitor cells have been cultured as monolayers on coated substrates or as free-floating spherical aggregated, termed neurospheres.

Stem Cell Repertoire

Chaperone Effects

Initially, stem cells were exclusively considered as tools for cell replacement. However, there is much evidence now for robust additional biological properties (chaperone effects) of stem cells that may be exploited therapeutically. Chaperone effects of stem cells include the natural delivery of neurotrophic, cytoprotective, and anti-inflammatory molecules (e.g., glial cell line-derived neurotrophic factor, brain-derived neurotrophic factor (BDNF), and neurotrophin-3) in order to rescue dysfunctional cells. This concept of stem cell-based chaperone effects was first demonstrated in the brain of aged and Parkinsonian mice and later confirmed and extended to other organ systems and various diseases (e.g., bone marrow-derived mesenchymal stem cells (MSCs) or ESCs for cardiac disease, and umbilical cord cells in stroke).

Environmental Cues

Increasingly, the microenvironments within the CNS are providing insight into the molecular milieu regulating stem cell biology. A specialized microenvironment in the neurogenic regions is responsible for the continued self-renewal and differentiation of the stem cell pool. For example, these regions have a higher density of blood vessels releasing factors, such as vascular endothelial growth factor (VEGF) and BDNF, contributing to increased proliferation and neurogenesis. Different levels of growth factors can have fundamentally different effects on proliferation and differentiation. For example, low levels of insulin-like growth factor-1 (IGF-1) promote neurogenesis, whereas higher levels increase proliferation and oligodendrogenesis. Established protocols for the isolation of NSCs include the growth factors EGF and bFGF that sustain self-renewal of NSCs. Injection of these factors intracranially into mice has been shown to regulate both proliferation and differentiation *in vivo*. Neurotrophins such as BDNF in collaboration with retinoic acid and Wnt signaling regulate neurogenesis, and ciliary neurotrophic factor/leukemia inhibitory factor or bone morphogenic proteins induce gliogenesis. It is also know that the cellular milieu contributes to fate determination and cortical development, specifically through the effects of resident astrocytes in both the SVZ and the hippocampus. Physical exercise and enriched environment have been shown to promote neurogenesis in the SGZ. The effects from physical activity are partly mediated by IGF-1, VEGF, BDNF, and endogenous opioids. The characterization of the stem cell microenvironment will provide the molecular and cellular

scaffold on which stem cell therapy, both endogenous and exogenous, can be built.

Stem Cells as Vectors for Gene Therapy

Brain lesions can be focal and restricted to a certain brain region or widely distributed in the parenchyma. Ideally, both lesion types would be targeted with a specific and efficient delivery of therapeutic molecules and drugs. In fact, efficient delivery is still a major hurdle in gene therapy. The finding that endogenous and grafted NSCs display an extensive migratory potential and tropism toward brain lesions founded the idea that these cells may be used as therapeutic vectors. Proof-of-principle experiments in animal models of lysosomal storage diseases (for a widely distributed brain lesion) and brain tumors (for a focal lesion) have shown that genetically modified NSCs are powerful therapeutics to cross-correct hereditary enzymatic deficiencies or to dramatically reduce a tumor mass. Thus, NSCs hold great promise for both cell and gene therapy.

Stem Cell-Based CNS Repair

It is manifest that stem cells can be used to replace neuronal, astrocytic, and oligodendroglial cells lost due to various brain diseases. However, it is important to note that successful use of stem cell is probably dependent on many factors, including the nature and degree of injury, disease history and age of the patient, primarily affected cell types, the type of stem cell chosen for transplantation, and the site of grafting. Deeper insight into these parameters will be important to tailor patient-specific treatment paradigms in a clinical context.

Stem cells have been explored in a number of rodent and primate models of human neurological diseases. These studies showed successful survival, differentiation, and synaptic integration of grafted stem cells, which led to functional restoration and amelioration of symptoms. In the following sections, we discuss examples of stem cell-based CNS repair and the challenges that remain to be addressed prior to clinical application.

Parkinson's Disease

Parkinson's disease (PD) is characterized by a progressive deterioration and loss of nigrostriatal dopaminergic neurons in the substantia nigra. The consequence of this cell death in the ventral midbrain is a deficient dopamine neurotransmission in the target region, the striatum. Clinically, PD presents with symptoms such as tremor, rigidity, and bradykinesia. Patients transplanted with fetal mesencephalic grafts in the early 1990s have demonstrated that an ectopic transplantation of dopamine-producing cells into the striatum can restore motor function and ameliorate clinical symptoms. Because of the limited availability of fetal tissue, stem cells are expected to provide unlimited numbers of transplantable dopamine neurons.

Several studies using rodent and primate models of PD have demonstrated successful integration and functional improvement after grafting of dopaminergic neurons derived from both ESCs and NSCs. In primate models, monkey ESCs have been transplanted and animals evaluated for behavioral improvements. As with rodent models, functional improvements occur. Furthermore, these behavior assessments can be corroborated with functional neuroimaging (Figure 1).

Although considerable progress has been made in stem cell-based treatment of PD inanimals, many challenges remain before clinical translation. Human ESCs differentiate to dopaminergic neurons under various protocols, yet the creation of a purified and homogeneous population of dopaminergic neurons is challenging and needs improvement. Animal models for future investigation should increasingly include primates in order to refine the mechanics and logistics of transplantation. Patients in whom stem cell therapy will be the most effective with the least side effects should be defined. The effects of posttransplantation training and rehabilitation need to be better understood; it appears that these contribute to improved functional outcome in experimental animal models. The clinical experience with fetal grafts suggests that the patient's disease history is an important parameter and that cell therapy will not be the method of choice for every Parkinsonian patient; thus, patient selection will be pivotal for clinical improvements after graft placement. Finally, the adverse side effects such as dyskinesias observed in some patients after transplantation of fetal grafts need careful consideration, and the safety of human ESCs needs to be established prior to clinical transplantation.

Stroke

Arterial occlusion within the brain can lead to ischemia and infarction of brain parenchyma. The current treatment of stroke remains limited and is focused on neuroprotection to limit the expansion of the infarct and to possibly recover the cells within the ischemic penumbra. The use of recombinant tissue plasminogen activator in select clinical situations within a critical time window after the stroke event has led to improved clinical outcome. Unfortunately, the time constraints in which this treatment can be offered limit potential application to a very small group of stroke patients.

Hypoxic/ischemic injury can lead to substantial tissue loss and the formation of infarction cavities, which would be a major therapeutic obstacle for the survival

Figure 1 Function of embryonic stem (ES) cell-derived neurospheres in MPTP-treated monkeys. Behavioral scores (a) and PET study (b, c) of ES cell-transplanted ($n = 6$) and sham-operated animals ($n = 4$). (b) Mean K_i values from the entire putamen. (c) Increased ^{18}F-flourodopa uptake in the putamen of ES cell-transplanted animals. All values are mean ± SD.*$p < 0.05$. Reproduced from Takagi Y, Takahashi J, Saiki H, et al. (2005) Dopaminergic neurons generated from monkey embryonic stem cells function in a Parkinson primate model. *Journal of Clinical Investigation* 115: 102–109.

of newly seeded stem cells. Our group has demonstrated that extensively damaged brain areas can be repaired by the combined use of stem cells and polymer scaffolds that can be placed into the infarction cavity (Figure 2). It has been suggested that stem cells may be uniquely suited for stroke therapy given their inherent cytoprotective, anti-inflammatory, and restorative properties. Notably, early studies using other cellular therapies (e.g., human NT-2 teratocarcinoma line) demonstrated some functional improvement in stoke patients. However, the growth of stem cells is better controlled than any other immortalized cell line. Stem cell-derived and implanted neurons were shown to survive for more than 2 years in the human brain. Stem cell use in animal models of cerebral ischemia clearly demonstrates the ability of murine and human NSCs to engraft into the brain and survive, migrate, and differentiate leading to functional improvement. Other studies with murine NSCs have shown the potential of stem cell grafts to promote recovery in ischemic rats and recovery of sensorimotor deficits after transplantation into the striatum and cortex ipsilateral or contralateral to the stroke. In a clinical setting, cell transplants for stroke patients may be feasible even weeks after the ischemic event, allowing the patient to recover from the acute injury. Furthermore, several weeks may be needed to perform detailed neurophysiological and behavioral testing to allow selection of candidate patients. In accordance with a timetable that accounts for the most likely clinical scenario with patients, human somatic NSCs have led to functional recovery from stroke with improvement at both cortical and subcortical levels in various murine models of stroke. ESCs can be differentiated into NSCs following exposure to retinoic acid *in vitro* and have also demonstrated functional recovery in rodents.

Although regenerative cell therapy for stroke appears very promising, the use of stem cells is in its infancy. Clearly, the mechanisms that lead to beneficial effects after stem cell transplantation need to be better understood. For instance, it is important to determine whether the reported improvements are primarily the result of reconstitution of neural circuitry by cell replacement, the enhancement of intrinsic repair mechanisms (including the recruitment of endogenous stem cells), or both. Most likely, grafted and endogenous stem cells are effective through a multitude of mechanisms. It is possible that stem cells may be delivered to the injured brain not only by local intracerebral delivery but also by intravenous or intrathecal routes.

Spinal Cord Injury

Spinal cord injury (SCI) is a devastating ailment with little opportunity for treatment. The injury occurs from mechanical forces in the acute setting and is exacerbated by secondary inflammatory damage, both leading to neuronal death and demyelination. Accordingly, potential therapy would vary depending

Figure 2 Implantation of neural stem cell–pluripotent embryonic stem cell (NSC–PGA) complexes into a region of cavity formation following extensive hypoxic/ischemic (HI) brain injury and necrosis. (a) Brain of an untransplanted (non-Tx) mouse subjected to right HI injury with extensive infarction and cavitation of the ipsilateral right cortex, striatum, thalamus, and hippocampus (arrow). (b) Contrasting with a, the brain of a similarly injured mouse implanted with an NSC–PGA complex (PGA + NSCs), generated *in vitro* as described in a, into the infarction cavity 7 days after the induction of HI (arrow; $n = 60$). At maturity (age matched to the animal shown in a), the NSC–scaffold complex appears in this whole mount to have filled the cavity (arrow) and become incorporated into the infarcted cerebrum. (c, d) Higher magnification of representative coronal sections through that region, in which parenchyma appears to have filled in spaces between the dissolving black polymer fibers (arrow in c) and even to support neovascularization by host tissues, as seen in d. A blood vessel is indicated by the black arrows in d; the open arrow in d points to degrading black polymer fiber. Scale bar = 100 μm (c, d). Reproduced from Park KI, Teng YD, and Snyder EY (2002) The injured brain interacts reciprocally with neural stem cells supported by scaffolds to reconstitute lost tissue. *Nature Biotechnology* 20: 1111–1117.

on the time frame after injury, with minimizing inflammation the primary concern early after injury and regeneration the major goal when injury is in its chronic phase. The pathobiology of SCI is highly dependent on the time course in which the injured spinal cord is examined. This directs the transplantation of NSCs or their derivatives (e.g., oligodendrocytes for myelination) to carefully account for and maximize the timing of transplantation with consideration of cell survival of grafted cells. Studies have addressed some of these issues demonstrating the importance of both timing of transplantation and the role of growth factors in murine models of SCI treated with NSCs. Injured rats received NSC transplants at different time points that would correspond clinically with subacute and chronic SCI, respectively. The administration of growth factors, including EGF, bFGF, and platelet-derived growth factor, resulted in increased numbers of cells grafted into the injured spinal cord by either enhanced survival or increased proliferation. To determine if NSCs together with growth factors can lead to neurological improvement, animals were evaluated using three independent behavioral tasks, all of which showed significant improvements compared to control mice, with even some long-term improvements (Figure 3). Human CNS fetal-derived stem cells have been shown to survive, engraft, differentiate, and improve

Figure 3 Subacute transplantation of YFP–NPCs resulted in a significant locomotor recovery compared with injured rats in the control group. (a) BBB rating scale showed a significant improvement in the locomotor BBB score in transplanted rats 3 weeks after transplantation compared with plain injured and control groups ($n = 5$ for plain injured group and $n = 8$ for other groups). (b) Using grid-walk analysis, transplanted rats also showed fewer errors in hindlimb placements 5 and 6 weeks after transplantation compared with plain injured and control groups ($n = 5$ for plain injured group and $n = 8$ for other groups). (c) Representative footprints of normal, plain injured, control, and grafted rats ($n = 5$ for plain injured group and $n = 8$ for other groups) show improvement in interlimb coordination as well as angle of rotation in the transplanted group compared with the plain injured and control groups. (d, e) Footprint analysis revealed that transplantation with adult NPCs significantly improved interlimb coordination and reduced the hindlimb angle of rotation 5 and 6 weeks after transplantation. The data show the mean ± SEM. $^*p < 0.05$. Reproduced from Karimi-Abdolrezaee S, Eftekharpour E, Wang J, et al. (2006) Delayed transplantation of adult neural precursor cells promotes remyelination and functional neurological recovery after spinal cord injury. *Journal of Neuroscience* 26: 3377–3389.

locomotor skills after traumatic SCI in mice. Contusive SCI of the thoracic cord was treated with injection of human NSCs. Functional recovery was assessed and shown to be improved. Also, selective ablation of grafted cells with diphtheria toxin (murine cells are 100 000 times less sensitive to diphtheria toxin than human cells) was used for the targeted killing of human NSCs. This selective ablation led to reversal of symptomatic and behavioral improvement, providing further support that human NSCs can mediate functional recovery in murine SCI models. Despite demonstrating functional recovery in murine models of SCI with both murine and human NSCs, further investigation using primate models is critical prior to any human trials. Indeed, spinal cord anatomy is different in the rodent compared to primates and humans.

Neural regeneration is not without pitfalls; some studies have shown the creation of aberrant axonal

Figure 4 A subset of newborn layer V cortical neurons extends axons to the cervical spinal cord. (a) Both newborn and original layer V corticospinal motor neurons (CSMN) were retrogradely labeled by FG (blue). (b) Field expanded in (c)–(f) showing a BrdUrd^{+}/NeuN^{+}/FG^{+} triple-labeled adult-born neuron (arrow). (c–e) Individual images show that this BrdUrd^{+} nucleus (c, red) is located within this neuron, which is retrogradely labeled with FG from the cervical spinal cord (d, blue) and expresses NeuN (e, green). (f) Overlay showing BrdUrd^{+}/FG^{+}/NeuN^{+} neuron co-localization. (g) Higher magnification overlay of the same neuron from c–f. (h) A separate example of an adult-born neuron with a projection to the spinal cord. Laser-scanning confocal images were combined to produce three-dimensional reconstructions of newborn neurons. Viewing a BrdUrd^{+}/FG^{+} newborn neuron along its *x* (h′), *y* (h″), and *z* axes (h) unequivocally demonstrates the co-localization of BrdUrd and FG. (i) Quantification of BrdUrd^{+}/FG^{+} adult-born CSMN extending spinal projections from 12 to 56 weeks after induction of original CSMN apoptosis. Each point indicates the number of adult-born BrdUrd^{+}/FG^{+}neurons/mm^{3} in an individual animal; each bar indicates the mean Scale bar = 10 μm (b–e). Reproduced from Chen J, Magavi SS, Macklis JD, et al. (2004) Neurogenesis of corticospinal motor neurons extending spinal projection in adult mice. *Proceedings of the National Academy of Sciences of the United States of America* 46: 16357–16362.

sprouting which led to allodynia hypersensitivity. This may be related to excessive astroglial differentiation, highlighting the need for more controlled differentiation in order to both maximize functional recovery and minimize side effects. Along with increased understanding of cellular and molecular mechanisms, the timing and logistics of transplantation need to be improved, and noninvasive cellular imaging needs to be established.

Endogenous Stem Cell Recruitment for CNS Repair

The alternative or compliment to stem cell transplantation would be the manipulation of endogenous stem cells for therapeutic purposes. The advantages would include using the patient's own cells, not needing an invasive procedure, and obviating concern regarding the immunogenicity of transplanted cells. It appears that adult neurogenesis is restricted to the olfactory bulb and dentate gyrus of the hippocampus, but it is possible that some NSCs exist along the entire adult neuraxis.

Exploiting endogenous NSCs would require successful coordination of cell proliferation, differentiation, migration, and integration, and it does appear that some instructive signals remain in the adult CNS. However, most CNS regions are not permissive for neurogenesis under normal *in vivo* conditions, but some studies suggest that endogenous NSCs are primed to respond to environmental signals that exist primarily during pathological states. Accordingly, one approach to accentuate endogenous stem cell proliferation is the administration of growth factors. Intraventricular infusion of transforming growth factor-α into rodents with lesions of the substantia nigra dopaminergic neurons has led to functional improvements, putatively through recruitment of endogenous stem cells. Other likely bioactive molecules with potential to evoke a proliferative response in regions of the brain with multipotent cells are neurotrophins. Physiologically, neurotrophins are involved in cell cycle regulation, cell survival, and differentiation and are critical during normal development. Growth factor infusion can also promote proliferation of SVZ-derived progenitor cells, which gave rise to hippocampal CA1 pyramidal neurons in rodent stroke models, with

improvements in spatial orientation. Whether the neurogenic response creates neurons with long-term viability remains to be determined. Another candidate with efficacy in stroke models is erythropoietin, which has been shown to induce neurogenesis and functional improvement in rats. Furthermore, endogenous neural precursors can differentiate into new neurons that extend long-distance projections to the spinal cord in the adult rodent. Targeted apoptosis of corticospinal motor neurons was induced, and it was demonstrated that adult-born corticospinal motor neurons were generated extending from the motor cortex to the spinal cord (Figure 4).

Regarding neural repair, continued investigation into whether the diseased CNS can be treated with growth and differentiation factors to induce neural repair is required. As more is learned about the molecular signals and environmental cues, endogenous stem cells may prove to be a compliment or even replacement to transplantation of exogenous stem cells.

Other Stem Cells

The use of embryonic or somatic stem cells for brain repair is currently the focus of rigorous scientific investigation. Other stem cells have also been suggested as sources for cell therapy. For instance, some groups have found that mesenchymal stem cells (MSCs) can differentiate into astrocytes and neurons *in vitro* and *in vivo* and may have an advantage over ESCs or NSCs because they are a highly accessible source for the patient's own stem cells. However, there is controversy about the plasticity and developmental potential of MSCs. Some groups suggest that the findings with MSCs may be cell culture artifacts rather than true differentiation into unexpected cell types. Therefore, it is crucial to assay the differentiation of any stem cell into a particular cell type by combining morphological, immunophenotypic, and functional criteria. Currently, MSCs do not appear to be a realistic alternative to the use of ESCs or NSCs for neural repair.

Conclusion

Stem cell biology represents a strong foundation for neural repair. Experimental evidence suggests that this technology may be applicable to treat patients in the future. Since ESCs can be multiplied indefinitely and have the potential to give rise to a variety of functional human cells, it is conceivable that stem cells will play an important role in disease modeling and drug testing. Moreover, since stem cells mimic aspects of normal development, these cells may be used to study early steps of human development which would not be accessible for experimentation otherwise.

We have highlighted current problems in the rapidly progressing stem cell field, which involve safety issues, standardization of the protocols used, development of rigorous assays for characterization, and accumulation of experimental data in primate models of human disease. Realistic candidate diseases and patients who may benefit from stem cell therapy need to be defined before any clinical application. Since clinicians and stem cell biologists share a strong common interest to understand and treat human disease, stem cells have the true potential to transform modern medicine.

Stereoscopic Vision

A J Parker, University of Oxford, Oxford, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Taken literally, stereoscopic vision describes the ability of the visual brain to register a sense of three-dimensional shape and form from visual inputs. In current usage, stereoscopic vision often refers uniquely to the sense of depth derived from the two eyes. This usage excludes a number of things that might be considered stereoscopic vision, such as the sense of depth arising from the motion parallax generated when subjects translate themselves through the visual environment. This article is primarily concerned with binocular stereoscopic vision.

Current usage also means that the term 'stereoscopic vision' tends to include a number of issues relevant to binocular vision that are unrelated to the perception of three dimensions. One example is singleness of vision: namely, the generation of perception of a single object by the two eyes by means of their co-coordinated use. Double vision is easily experienced for an individual object by raising a finger before the two eyes while continuing to look at a distant object, such as a church tower. Unusual circumstances, often a head injury or other neurological condition affecting the coordination of the two eyes, are required for all visual objects to look double.

Binocular Viewing Can Provide a Sense of Depth

When humans view a solid, three-dimensional object, each eye receives a slightly different view (see Figure 1) of the object. For the solid sphere (t) in Figure 1, the left eye (m) sees rather more of the left-hand side of the sphere before the surface of the sphere is occluded by its rim. Conversely, the right eye (n) sees a little more of the right-hand side of the sphere. Ptolemy, Leonardo da Vinci, and many in between understood such matters clearly. However, the ability of binocular geometry to provide a sense of depth was fundamentally misunderstood until the striking demonstrations due to Charles Wheatstone (1802–75; see Figure 2).

Wheatstone arranged for each eye to be given a different view in the most direct way, by showing each eye a physically different picture to look at. When the pictures viewed by the left and right eyes approximate the views that the eyes would receive when viewing a real object in natural binocular viewing, the visual brain responds to those views as if a real object in depth were being displayed.

Wheatstone's discovery generated intense scientific debate throughout the rest of the nineteenth century. For example, the need for real, physical movements of the eyes to gain a sense of depth was hotly contested until the critical experiment of Dove, who demonstrated that a sense of stereoscopic depth is produced by even the briefest flashed exposure that leaves the eyes no time to move. Integration of binocular stereo depth with other sources of information about three dimensions was intensively researched; for example, Helmholtz appreciated that there are strong similarities between depth from binocular stereopsis and depth from motion parallax but, critically, that one of these depth cues can supply information that is absent from the other. The link between binocular stereopsis and binocular eye movements was investigated, including the important links with changes in the focusing power of the eyes' lenses, known as accommodation. All this work was reviewed by Helmholtz and his acolytes toward the end of the nineteenth century.

Wheatstone's discovery also generated huge popular interest. Coupled with the development of photography, the stereoscope became a source of home entertainment. Many Victorian parlors housed one, and large collections of stereo pictures were generated. It is alleged that the stereoscope was put aside only when its persistent use to view salacious images became so widely known that its presence in a living room became an immediate source of embarrassment. (The same images are often regarded nowadays as signifying the innocence of a bygone age, and stereoscopic photography now has its place among nostalgia technology.)

Such a combination of high scientific and popular interest could not fail to challenge egos, and the discovery of the stereoscope was disputed hotly. There is no doubt that David Brewster's version that used lenses for viewing was much more convenient for popular viewing and thus became the canonical form, but Brewster's claims to priority were always regarded as misplaced.

Geometry of Binocular Viewing

The viewing geometry that Wheatstone had identified was subject to intensive analysis during the nineteenth and early twentieth centuries. This work

Figure 1 Leonardo da Vinci (top left) understood that each eye obtains a slightly different view of the world. For objects close to the head, some features on the surface of a solid object are occluded from one eye's view but are visible to the other eye. The diagram at the top right is derived from Leonardo's own drawing, adapted by Wade NJ, Ono H, and Lillakas L (2001) Leonardo da Vinci's struggles with representations of reality. *Leonardo* 34: 3, with permission from MIT Press Journals. The lower panel shows a figure from Descartes's *De Homine*, in which the schematic of connecting the left and right eyes to a single binocular target in the central nervous system is proposed.

established the concept of 'binocular disparity' as the fundamental measurement employed by the visual system to gain a sense of binocular stereoscopic depth. Binocular disparity is the angular difference between two landmarks viewed binocularly (see Figure 3).

Corresponding Points

This phase of study also introduced the concept of 'corresponding visual points' between the left and right eyes. For example, points that are 3 mm horizontal to the left of the fovea in the left and right eyes are corresponding points, whereas points that are 3 mm to the left in one eye and 2.9 mm to the left in the other eye are noncorresponding. If both eyes are looking at a single object in the world, then corresponding points on the retina project out to a set of geometrically defined locations in three-dimensional space. For the case of a plane, defined by the line joining the two eyes and the binocular fixation point, the locations of corresponding points defined a circle, the 'Vieth-Muller circle,' passing through the binocular fixation point and the optical centers of the two eyes.

Much of this development was directed toward understanding the perception of three-dimensional space by human observers. Imagine a person is looking at an array of objects lying in different directions and at different distances with respect to the binocular fixation point. If the person closes first one eye and then the other, given that each eye is at a different position, do these objects appear to lie in the same direction? The geometry of the Vieth-Muller circle provides a simple hypothesis, which is that objects will appear to lie in the same visual direction when they lie on anatomically corresponding points. This hypothesis is close to correct, but there are distinct patterns of deviation from the Vieth-Muller circle, and formulations of other curves and surfaces have been developed to describe the locations of points that are in visual, as opposed to anatomical, correspondence.

The concept of corresponding points is also important in considering the binocular coordination of the movements of the eyes. If the eyes are fixating an object at a particular distance from the observer's head, then the eyes will need to rotate inward with respect to each other if the object is near the head. Inspection of a new object at a different viewing distance therefore requires an adjustment, inward or outward, of the binocular alignment, if the new object is to fall on the foveae of both eyes. The size and direction of the adjustment is given by the binocular disparity between the currently viewed object and the new one.

Absolute and Relative Disparity

One way of defining an origin for measurement of disparity is therefore to use the current binocular fixation point. Anatomically corresponding points have a disparity of zero, and noncorresponding points may have a positive or negative disparity, depending on whether they project to points farther than or nearer than the distance to the fixation point. Since this definition can be employed even when the fixation point is just notional (a location in space with no visible object, toward which the foveae project), it is useful to give this concept of disparity the label 'absolute disparity.'

This definition of disparity may be contrasted with the concept of 'relative disparity,' which is defined as the disparity between two visible features. Here these two features are separated by one visual angle as seen from the left eye and a different visual angle as seen from the right eye: relative disparity is therefore the difference in these two angles. Note that, as the eyes move, the visual angle between the two features is not altered by rotations of the eye. Thus the relative disparity between two visible features is independent

Figure 2 Charles Wheatstone and his mirror stereoscope. The drawing of the stereoscope shows drawings (E and E′) reflected by mirrors (A and A′) set at an angle so as to direct the reflected images toward a viewer. Wheatstone's observations with this device led him to conclude that binocular disparity was a sufficient stimulus by itself to give rise to a sensation of stereoscopic depth.

of the choice of binocular fixation point, which means that relative disparity is a useful description of the stimulus that is purely visual, not reliant on eye position.

In the psychological literature, the term 'disparity' is often taken to mean relative disparity, but in optometry, physiology, and ophthalmology, disparity is more likely to refer to absolute disparity.

First Steps to Neuronal Mechanisms

A major step forward in the understanding of binocular stereoscopic vision came in the 1960s. Two advances were especially significant. First, Bela Julesz, working at Bell Laboratories, invented the random dot stereogram (RDS; see Figure 4) and exploited this new paradigm to define and explore what he termed 'cyclopean vision.' Cyclopean refers to the mythical giant Cyclops, who had just one eye in the center of his forehead. Julesz's RDS consisted of fields of randomly bright and dark pixels, which were correlated between the left and right eyes' images. When placed in a stereoscope, a region of this figure was revealed as segregated from the background because it was at a different binocular depth (see Figure 4). Figures demonstrating stereoscopic segregation had been prepared before, but Julesz's development of a computer-based method was truly original and profoundly influential. Julesz argued that the perception of the revealed figure reflects central

Figure 3 Diagram showing the definition of absolute and relative disparity. (a) The eyes are looking at point O. The angles α and β between the line of fixation to O and the projection of point N are different as viewed with the left (L) and right (R) eyes. N projects to a point in the right eye that is farther from the fovea (F) than is the point from the fovea in the left eye. N therefore has a nonzero absolute disparity whereas O has a zero absolute disparity. (b) The eyes have shifted to a new fixation point. Now, both O and N have nonzero absolute disparities. However, the relationship between O and N has not changed: Angles α and β still describe the angular separation of O and N. In both (a) and (b), the relative disparity between N and O is given by the quantity (β−α).

Figure 4 A random dot stereogram (RDS). When the left and right eye's images are viewed in a stereoscope, a region of different depth in the center emerges. The principle was apparently first published by Cajal, who devised it as a means of secret writing. The upper panel shows a stereoscopic camera taking the image of written text on a plate B at a different distance from the camouflage background A. If either the left or right photographic plate is viewed alone, the message cannot be decoded. Presumably, the intent was to send each image via a different route. The lower panel shows a modern RDS of the type invented by Julesz. When the left and right eye's images are fused binocularly, a circle segregates in depth from the background square.

processing by the brain, separate from the influence of either eye alone. He conducted a series of studies that investigated the classical visual illusions presented in their novel cyclopean form.

The other advance was the first identification of single neurons that are sensitive to the disparity of visual stimuli. In the late 1950s, Hubel and Wiesel had discovered that some neurons in the visual cortex often respond selectively to the orientation of visual contours and are sensitive to stimuli over a limited region of visual space (the receptive field) in both the left and right eyes. These neurons showed 'binocular summation': the response to the simultaneous stimulation of left and right eyes was stronger than the response to either eye alone. Two research groups, Nikara, Bishop, and Pettigrew, working in Australia, and Barlow, Blakemore, and Pettigrew, in the United States, presented new findings that some number of these visual neurons are specifically most sensitive when the independent stimulation of the left and right eyes falls on noncorresponding, as opposed to corresponding, points. Such neurons therefore give their greatest response to a nonzero disparity, and as the disparity is adjusted away from this optimal value, the response of the neuron declines. A neuron that responds optimally to stimulation of noncorresponding points is sensitive to the absolute disparity of the stimulus. This work established that there were neurons sensitive to different values within range of nonzero disparities, implying a population of neurons that is capable of encoding a range of binocular depths with respect to the binocular fixation point (see Figure 5). Another consequence was to give an unambiguous physiological interpretation to the concept of binocular corresponding points developed in earlier work.

Computational Stereo

These two developments set the scene for most modern experimental studies of stereoscopic vision. Julesz also identified a different conceptual aim; he sought to specify an automatic, computational method for processing a stereoscopic pair of images to extract the binocular depth. Marr developed an exceptionally broad view of the computational problem of early visual processing, which took in image processing, visual geometry, retinal and cortical physiology, artificial intelligence, and much more. Nonetheless, it

Figure 5 A range of neurons in cat visual cortex that have their greatest response at different binocular depths. The numbered dots represent visual stimuli. The dottled lines show the lines of right to the cat's fixation point. The Vieth–Muller circle is the circle passing through the fixation point and the optic centers of the cat's eyes. From Barlow HB, Blakemore C, and Pettigrew JD (1967) The neural mechanism of binocular depth discrimination. *Journal of Physiology* (*London*) 193(2): 327–342, with permission from Wiley-Blackwell Publishing Ltd.

is significant that Marr, working with T Poggio, took the problem of stereoscopic vision as a vehicle for carrying forward his more general program. A particularly exciting aim was that of mapping components of the computation onto the actions of individual nerve cells.

Development of Stereo Vision

An important element of Hubel and Wiesel's neurophysiological studies revealed how the visual system develops during early life. They argued that there is a period of high plasticity during early development. During this period, the neural apparatus must receive appropriate visual stimulation; otherwise the neurons fail to connect appropriately to one another. Much of the investigation of this so-called critical period was based on the study of binocularity in the visual cortex. Interventions such as depriving one eye of vision result in that eye's having a weaker, or even absent, influence on primary visual cortical (V1) neurons. The importance of concurrent input to both eyes was highlighted by the finding that alternating occlusion of each eye resulted in a visual cortex in which there were almost no binocular neurons but large numbers of neurons responsive exclusively to stimulation of either the left eye or the right eye. A similar pattern of cortical organization was found when a squint was induced by surgical intervention that resulted in the misalignment of the left and right eyes. Loss of binocularity is a central element of the human clinical syndrome of strabismus and associated amblyopia, in which the disruption of vision in childhood may lead in effect to blindness in one eye due to that eye's functional disconnection from the visual cortex. Hubel and Wiesel emphasized the importance of visual stimulation in selectively retaining cortical connections that had already been set up by genetic instruction, while others, notably Blakemore, highlighted the possibility that environmental influences could induce the formation of new connections.

Current Progress in Understanding Binocular Stereopsis

The Binocular Energy Model

At the physiological level, an important modern development was to understand the way in which the initial stages of disparity detection proceed. Ohzawa and Freeman, later joined by DeAngelis, found that many disparity-sensitive neurons in the V1 behave as if the initial stage of binocular combination is a simple addition of the excitation arising from each eye. The initial work on this problem used sinusoidal grating stimuli, in which the relative phases of the sinusoids in the left and right eye were adjusted parametrically to measure the binocular combination rule used by the neurons. A number of observations led them to propose that binocular disparity might be detected by means of either a mechanism that is specifically sensitive to interocular phase or (as originally implied) a mechanism that encodes a positional shift between the two eyes' receptive fields. Overall, their experimental findings pointed to a two-stage model of disparity detection. Disparity detection arises by thresholding and squaring the output of an initial detector and then combining

signals from multiple initial detectors, either phase- or position-sensitive; the combination of signals encompasses detectors with the same disparity sensitivity over a small range of locations in the visual field. This model was termed the 'energy model' since the operation of squaring that is embedded within it parallels the definition of – and method for calculating – the energy of an electrical signal. This model has been very successful in capturing a wide variety of findings about the functional properties of disparity-selective neurons in V1. Although a number of adjustments and elaborations to the model have been proposed, the substantial elements of the structure have remained.

Other Species

All these studies focused on the properties of neurons in the V1, which is the earliest stage at which disparity-sensitive neurons are found. During the 1970s and 1980s, the neural basis of stereopsis was extended considerably. First, other species were examined; for example, the owl's visual wulst also contains neurons selective for binocular disparity. Notwithstanding the fact that the anatomical projections from retina to brain are organized differently in owls and mammals, the forward-facing eyes of the owl are associated with the capacity to detect stereoscopic depth, and there are strong similarities in the neural apparatus involved in all species. Second, many different visual cortical areas were explored, mostly in the macaque monkey. The multiplicity of visual areas, initially identified by Zeki, proved to have a variety of specializations for processing different aspects of the visual image, such as color and motion. For stereoscopic vision, the work of G Poggio established unambiguously the presence of disparity selectivity in V1, V2, and V3, while the work of Hubel and Livingstone suggested that binocular neurons (by implication responsible for the perception of stereo depth) were especially concentrated in compartments of V1 and V2, identifiable on the basis of histological staining for the mitochondrial enzyme cytochrome oxidase; these were the regions between cytochrome oxidase blobs in V1 and the thick stripes in V2.

From Disparity Detection to Depth Perception

Although neurons both inside and outside the V1 were explored in detail, most experiments tended to carry over the paradigms established for V1 into other cortical areas. This ultimately proved to be a limitation. The reason was that disparity selectivity at the physiological level was dominated by the conceptual framework set up by the earliest investigations, which grounded their framework for understanding the concept of retinal correspondence described earlier. Work in human psychophysics, particularly due to Westheimer, pointed out that relative disparity was a much more relevant parameter for describing the outcome of perceptual experiments. This highlighted a gap in the conceptual framework for understanding binocular stereoscopic vision at the neuronal level. Neuronal studies were working with a framework linked to retinal correspondence and hence to absolute disparity (defined earlier), whereas perceptual studies pointed to relative disparity. A number of other perceptual properties of stereoscopic vision are at variance with the simple detection mechanisms implied by studies in V1, even those motivated by computational principles implemented in the energy model.

Cumming and Parker therefore initiated a program to compare the responses of single neurons at various levels in the visual system of nonhuman primates against the perceptual response to binocular stereo depth. The focus was to identify the extent to which neuronal responses in particular brain regions could explain the perceptual characteristics of binocular stereoscopic vision. This work demonstrated, for example, that neurons in V1 did not signal relative disparity whereas at least some neurons in cortical area V2 did indeed respond to relative disparity. Evidence from a number of laboratories has continued to develop the picture that stereoscopic depth processing is elaborated within the extrastriate visual areas beyond the early disparity-detection mechanisms in V1. This concept is also consistent with the conclusions from more recent developmental studies, in which visual processing has been disrupted experimentally or owing to human clinical conditions. These studies have indicated that some of the deficits in visual performance arise from disruptions of neuronal processing in extrastriate visual areas, which bring additional losses in performance over and above those attributable to the effects observed in V1.

Cortical area V5/MT, mostly studied in relation to the processing of visual motion, has proved to have an important role in binocular stereoscopic vision. In particular, DeAngelis, working initially in Newsome's laboratory, has revealed a number of neuronal signals identifiable in V5/MT that are specific to the performance of certain stereo tasks. These signals are separate from signals that are generated simply by the presence of certain binocular disparities within the stimulus. Thus, V5/MT carries not just simple sensory signals but also task-related signals for certain perceptual judgments of stereo depth. V5/MT lies in the dorsal stream of extrastriate visual pathways. Meanwhile, in the ventral stream, Janssen, working in Orban's group, has shown that brain area Tes, in the inferotemporal cortex,

carries signals about the three-dimensional shape of surfaces, specified by binocular disparity.

Current thinking suggests a broad division of functional involvement of dorsal and ventral extrastriate areas in different aspects of binocular stereoscopic vision. The ventral stream appears to be mainly concerned with exploiting stereoscopic depth for shape perception. The dorsal stream carries signals for controlling binocular eye movements, for orienting the observer in the visual environment, and for segregating different depth planes so that visuomotor tracking behavior can be sustained. The dorsal stream appears to make use of a simple correlation-based stereo algorithm, broadly similar to the energy model in V1, while the ventral stream may use a more sophisticated stereo algorithm that sustains detailed point-to-point matching of binocular features between the eyes.

Stimulant and Wake-Promoting Substances

C Ballas and D F Dinges, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

Modafinil

Modafinil is a nonamphetamine, wakefulness-promoting drug that has Food and Drug Administration (FDA) approval for the treatment of excessive sleepiness in the following disorders: narcolepsy, residual sleepiness in continuous positive airway pressure-treated obstructive sleep apnea, and shift work sleep disorder. Modafinil has been extensively studied for its effects in these disorders, as well as in sleep-deprived healthy adults. In the latter studies, modafinil was found to reduce physiological sleepiness and improve a wide range of cognitive deficits from sleep deprivation that varied from 36 to 88 h awake. Compared to placebo, modafinil reduced sleep-deprivation deficits on the following cognitive and behavioral tasks: reaction times, vigilant attention, alertness, short-term memory, mathematical calculation speed, logical reasoning, and simulated performance.

Modafinil is designated a controlled substance, Schedule IV, which means it is considered to have less potential for abuse than amphetamines and other schedule I–III stimulants. Although not FDA-approved for attention deficit hyperactivity disorder (ADHD), two clinical trials showed that modafinil resulted in significant improvement in ADHD symptoms, especially attention and concentration outcomes. However, it was associated with Stevens–Johnson syndrome in one child, and approval was rejected pending further investigation.

Modafinil Metabolism and Elimination

Modafinil is the metabolite of adrafinil, lacking adrafinil's terminal amide hydroxyl group. Modafinil exists in racemic form; the I-R-modafinil enantiomer is called armodafinil, and has separate FDA approval. The R enantiomer has a 10- to 14-h half-life, compared to 3 or 4 h for the S enantiomer. Modafinil has a protein binding of 60% and volume of distribution (V_d) of 0.8 l kg^{-1}. The half-life is approximately 12 h. Modafinil is converted primarily to the inactive modafinil acid and modafinil sulfone via CYP3A4/5. The *d*-form is cleared three times faster than the l-form.

Modafinil Pharmacology

The precise mechanism of action of modafinil is not well understood. It has weak affinity for the dopamine transporter and almost negligible affinity for the norepinephrine transporter. However, in the absence of functional dopamine transporters (e.g., DAT knockout mice), modafinil fails to exert any wakefulness-promoting actions. Medications that inhibit dopaminergic activity, including D1 and D2 blockers and tyrosine hydroxylase inhibitors, fail to inhibit modafinil.

Modafinil inhibits striatal and globus pallidus GABA activity. At doses equivalent to 50 times normal therapeutic doses, it can also enhance glutamate in the striatum. The medial preoptic area and posterior hypothalamus are primarily controlled by tonic GABA inhibition, and consequently it may be that modafinil's effect on glutamate could be blocked with $GABA_A$ antagonists. Modafinil was found at high doses to increase serotonin in the medial preoptic area and posterior hypothalamus, and it was found at lower doses in the cortex and amygdale. Dorsal raphe nuclei receive projections from orexin–hypocretin neurons in the lateral hypothalamus, and they show increases in serotonin with modafinil administration. At therapeutic doses modafinil has no direct effect on serotonin, but it has been found to synergistically augment serotonin increases to fluoxetine and imipramine. Modafinil appears to have minimal effects on the endocrine system, and it has not been associated with significant changes in circadian and sleep modulated hormones such as melatonin, growth hormone, and cortisol.

Loss of orexin–hypocretin cells is associated with narcolepsy, and orexin knockout animals exhibit narcoleptic phenotypes. Because of modafinil's demonstrated efficacy for treating excessive sleepiness in narcolepsy, it was thought that modafinil might exert its effect on orexin–hypocretin cells, which are located only in the lateral hypothalamus but have projections to a wide variety of brain areas. Modafinil was found to increase c-fos immunoreactivity in both orexin–hypocretin neurons and tuberomammilary neurons while having minimal effect in the suprachiasmatic nucleus and anterior hypothalamus. However, modafinil still retains its activity on wakefulness even in orexin–hypocretin receptor knockout animals. In fact, some researchers have found that modafinil has stronger wakefulness-promoting activity in such knockout animals. However, its putative effects via orexin–hypocretin neurons, which are also important in feeding behaviors, have not been associated with effects on food intake. Modafinil appears to also inhibit neurons in the ventrolateral preoptic (VLPO) area, which is the putative sleep switch. This enhances histaminergic activity (i.e., decreases VLPO

inhibition of histaminergic activity), which further promotes wakefulness.

Modafinil Adverse Reactions and Safety

Modafinil is generally well tolerated, with the most common reported side effects including headache and insomnia. In phase III trials, three patients with left ventricular hypertrophy and mitral valve prolapse experienced transient ischemic changes on electrocardiogram. As noted previously, one child in a controlled trial had a rash suggestive of Stevens–Johnson syndrome. Modafinil is otherwise relatively safe in overdose, and even chronic usage of high doses has not been found to be associated with significant adverse effects, even after abrupt discontinuation.

Amphetamines

The US Drug Enforcement Agency has listed amphetamines as Schedule II drugs under the Controlled Substances Act because of their high potential for abuse. They are approved by the FDA for the treatment of narcolepsy and ADHD, and several double-blind, placebo-controlled trials in adults and children have found efficacy for this purpose.

Amphetamines have been studied and used for conditions not formally approved by the FDA. These include cognitive dysfunctions associated with brain injury and stroke, and fatigue associated with multiple sclerosis and HIV. Amphetamines have also been studied as augmentation agents in the treatment of depression; however, their efficacy appears to be only moderate, and their effects are concentrated in the expected areas of fatigue and apathy.

Studies on healthy adults have found that amphetamines can improve performance on a variety of tests during sleep deprivation, including visual and auditory reaction times and short-term memory. Subjects in almost all trials have reported subjective feelings of improvements in attention, memory, concentration, and fatigue – even when these were not found on objective outcomes.

Amphetamines have long been known to improve wakefulness and decrease sleep. Whether taken 15 h before sleep or immediately before sleep, they decrease sleep duration. These effects may last into the second night, with further (although lesser) decreases in sleep duration. Amphetamines also affect sleep architecture by decreasing the duration of all sleep stages, and they increase the percentage of light stage 1 sleep. These effects may last into the second night after amphetamine dosing.

Amphetamine Structure–Activity Relationships

In general, amphetamines and their derivatives have three parts that influence their activity: the phenyl, isopropyl, and amine groups. Addition of a CH3 group to the amine carbon creates amphetamines and other chemicals with stimulant properties (e.g., bupropion, ephedrine, cathinone, and fenfluramine). Addition of methoxy groups to the phenyl groups creates hallucinogens (e.g., mescaline and 3,4-methylenedioxy-*N*-methylamphetamine (MDMA)). For example, 'Ecstasy' (MDMA) is built on a methamphetamine backbone with an aromatic substituted dimethoxy ring. The absence of the methyl group on terminal amine (i.e., 3,4-methylenedioxy-*N*-amphetamine (MDA), 'Love') further increases the hallucinogenic potency and duration. Collectively, these stimulant/hallucinogen hybrids are referred to as entactogens. Key differences in the activity of amphetamine versus methamphetamine are described later.

The most important structural alterations to the clinically relevant amphetamines consist of the creation of a secondary substituted amine and changes in stereospecificity. The addition of a methyl group to the amine creates levo (L-amphetamine) or dextro (D-amphetamine), which are considerably more potent than amphetamine. However, the L- and D-forms differ in their relative merits and strengths. The dextro form is twice as potent as the levo form in keeping one awake, but both have equivalent effects on rapid eye movement sleep and cataplexy. They do not differ in MAO-A or -B activity, or with regard to norepinephrine efflux. However, the dextro form is markedly more potent in dopamine efflux and reuptake. Importantly, rat experiments have shown that the levo form is considerably less potent (four times less potent) than the dextro form in reinforcement paradigms.

Amphetamine Metabolism and Elimination

Lipid solubility is high for amphetamines and more so for methamphetamine. This allows for rapid absorption and peak levels within 2 h. Its V_d is $5\,l\,kg^{-1}$, with an elimination half-life that varies greatly but is on the order of 20 h. The dextro form is more rapidly eliminated than the levo form. In general, the amount of unchanged amphetamine excreted in urine differs with the pH of the urine. Acidification of urine can double the unchanged fraction to approximately 60%. What is not excreted unchanged is metabolized to phenylacetone, which is then oxidized to benzoic acid and excreted as hippuric acid.

Amphetamine Pharmacology

Amphetamines exert two main effects on the dopaminergic system. Vesicles located inside the presynaptic

terminal contain dopamine. They release dopamine into the presynaptic terminal, which is then shuttled out into the synaptic cleft via dopamine transporter (DAT) molecules located on the surface of the presynaptic terminal. Simultaneously, the DAT transports an amount of dopamine back into the terminal. Thus, the transporter serves to release dopamine from the presynaptic terminal into the cleft and/or reuptake dopamine from the cleft into the presynaptic terminal. It is bidirectional, and its kinetics are dependent to a large degree on concentration gradients.

Amphetamine exerts actions in both places. It causes release of dopamine from the vesicles as well as blocking reuptake of dopamine at the DAT. Importantly, amphetamine promotes the outward release of dopamine through the transporter as well. Thus, amphetamine acts on both sides of the bidirectional DAT. Interestingly, amphetamine must first become a substrate of the DAT and be taken into the terminal in order for it to then act to promote efflux. It is this necessary property that has led some to examine the role of blocking the DAT in order to prevent neurotoxins (e.g., MPTP, a model for Parkinson's disease) from entering the terminal and subsequently destroying it.

Additional feedback control of dopamine regulation is provided by norepinephrine. Blockade of the norepinephrine transporter (NET) leads to increased dopamine release and increased amphetamine-related behaviors. Some confusion arises because of the often misleading names of the transporters. The NET and DAT are 70% homologous, and they are both sodium/chloride-dependent transporters. The norepinephrine transporter actually transports norepinephrine and dopamine in the prefrontal cortex, in contrast to the nucleus accumbens, in which the NET has little effect on dopamine. Consequently, NET inhibitors would have a major impact on dopamine levels in the prefrontal cortex but no effect in the nucleus accumbens. This partly explains why amphetamine, a potent NET inhibitor in the prefrontal cortex, raises dopamine there more than methamphetamine, which has minimal effects on the NET. In the nucleus accumbens, both amphetamine and methamphetamine raise dopamine levels equivalently because they are both acting solely through the strength of the DAT.

This same effect is responsible for the often confusing observation that atomoxetine, a 'selective' NET inhibitor, raises dopamine levels as much as clinically equivalent doses of amphetamine in the prefrontal cortex, but it has no effect on dopamine in the nucleus accumbens. From this, it can be seen how atomoxetine may improve cognition (through dopamine and/or norepinephrine in the prefrontal cortex) without causing reinforcement or addiction (the absence of dopamine effects in the nucleus accumbens).

Dopamine efflux is apparently mediated through a change in transporter confirmation. Amphetamine binding to the DAT allows for sodium influx, which in turn causes a calcium influx. This calcium then mediates protein kinase activation that results in the phosphorylation of the N-terminus of the DAT. This appears to relate only to dopamine efflux because deletion of N-terminal amino acids affects dopamine efflux but has no effect on reuptake.

Protein kinase C (PKC) is integral for mediating dopamine efflux and amphetamine's effects; blockade of PKC decreases or abolishes the locomotor activation of amphetamines, and PKC activators cause effects that are similar to those of amphetamine with a similar release of dopamine. PKC activity requires intracellular calcium, further identifying the specific isoform (classical over nonclassical isoforms) of PKC relevant to amphetamine activity.

Behavioral sensitization to the effects of amphetamines is known. However, even before behavioral sensitization, repeated exposure to amphetamine leads to a sensitization of the release of dopamine in the ventral tegmental area and striatal regions of the brain. Investigations have elucidated how dopamine efflux sensitization through the NET is calcium and calcium/calmodulin dependent. Amphetamines increase intracellular calcium through N- and L-type calcium channels. Calcium/calmodulin protein kinase II is activated, which promotes dopamine efflux. Inhibitors of calcium calmodulin protein kinase II block this efflux. This is in contrast to ordinary dopamine efflux after acute doses of amphetamines, which are neither calcium related nor affected by such inhibitors. Additionally, vesicular release of dopamine is not related to calcium or calcium/calmodulin.

Amphetamine Adverse Reactions and Safety

As noted previously, the high abuse potential and risk of dependence and side effects have resulted in the FDA listing amphetamines as Schedule II drugs. Their positive effects on alertness and cognitive functions must be carefully weighed against their unwanted effects on subjective state, disruptions of sleep physiology, cardiovascular and metabolic dysregulation, and abuse liability.

Caffeine

Caffeine is the most commonly used stimulant in the world. Coffee, its primary delivery vehicle, is the second largest commodity traded, after oil. Curiously, despite its popularity, important misconceptions about caffeine persist. The caffeine content in artificial beverages

such as soda is generally well controlled, ranging from 80 mg in an 8 oz. energy drink to 38 and 45 mg in two popular colas. The caffeine for these beverages is largely derived from the decaffeination of coffee. The caffeine content in coffee varies for numerous reasons. Each (fresh) coffee bean contains different amounts of caffeine. For example, Arabica – the 'higher quality' bean used in fine coffees and espresso – has half the caffeine of Robusta, the bean used in canned supermarket coffees. Simply roasting the coffee bean (to form dark roast or light roast) can decrease the caffeine content as the volatile caffeine is burned away. However, water is also lost in this process. Thus, by bean weight, dark roast contains more caffeine, but by bean volume (i.e., by measurement with tablespoons) a cup of dark roast will contain less caffeine than light roast. Amounts can vary significantly; light roast Colombia Supremo has a caffeine content of 1.3%, whereas dark roast Sumatras and mocha javas contain 0.02%. Similarly, a typical 1 oz. espresso drink will contain half the caffeine of a regular coffee due to the roasting, as well as the limited amount of water used in the preparation.

Espresso is not a type of bean; it is a fine grind of conceivably any coffee, although typically Arabica. Hot water is forced through the bean at high pressures (130 psi) to extract the oils in the coffee, including the caffeine. Because the 'espresso bean' is generally of the dark roast and Arabica variety, it will contain less caffeine than coffee. However, the primary determinant is the amount of water used and the length of time the water comes in contact with the grounds.

Finally, the caffeine content varies based on the subtleties of preparation. The same coffee from a coffee shop can have significant variability of caffeine content from day to day; differences in the amount of water or coffee used by each preparer can have a great impact. Additionally, home-brewed coffees are generally prepared using more water and consumed in greater volumes.

Caffeine has been shown to improve wakefulness and cognitive performance across a variety of measures (e.g., reaction time, attention, and memory), especially in sleep-deprived subjects. Such effects are found at a variety of caffeine doses. However, doses higher than 200 mg are generally superior to lower doses in improving performance on tasks and sustaining the improvement for longer time periods. Additionally, the longer the duration of sleep deprivation, the greater the caffeine dose necessary to reverse the effects.

Experiments in mice have established caffeine's reinforcing effects, and among prospective trials in healthy adults, a preference was demonstrated for caffeine over decaffeinated controls. Preference appears to be limited to dietary doses, such that increasingly higher doses lead to decreased preference, and avoidance occurs for doses higher than 400 mg. Caffeine reinforcement is also mood and context dependent, with those who prefer the effects of caffeine more likely to choose it. Similarly, negative mood states such as anxiety decrease caffeine preference. It is known that withdrawal effects such as headache or drowsiness reliably predict subsequent caffeine preference. Interestingly, a level of physical dependence (without withdrawal) predicts preference and enjoyment of caffeine, but in the absence of physical dependence this choice is significantly lessened.

There is evidence that caffeine may be protective against Parkinson's disease. It has been observed that caffeine consumption was inversely correlated to Parkinson's disease risk. Using various models of induced Parkinson's disease in mice (e.g., 6-OHDA and MPTP), caffeine was shown to have a protective effect on dopamine levels. This appears to be via its inhibition on A2a adenosine receptors. Decreases in dopamine result in increased glutaminergic activity, which causes destruction of dopaminergic neurons in the substantia nigra. Not inconsequentially, caffeine exerts positive pharmacokinetic effects on Parkinson's disease medications, shortening the time to maximal plasma concentration and the effects of levodopa. The effects of caffeine with levodopa appear to be additive or even synergistic.

An important source of confounding information about caffeine is the tendency to extrapolate acute dosing studies to the effects of chronic use and vice versa. For example, acute administration of 500 mg of caffeine lowers the seizure threshold and is a common maneuver prior to electroconvulsive therapy. However, chronic use (14 days) of caffeine in fact reduces the severity of seizures. Adenosine has anticonvulsant properties, perhaps via inhibition of glutamate or aspartate, and thus it is reasonable to expect that caffeine may alter seizure susceptibility via blockade of adenosine receptors.

Caffeine provides benefits in physical exertion on both performance and endurance. It has even been found that in dietary doses caffeine can reduce by almost half the subjective rating of pain induced by 30 min of exertion. Although its effects on performance are not profound, in competition sports these may be very significant, which may explain why caffeine was once banned by the International Anti-Doping Agency but subsequently taken off the list due to its widespread use. Importantly, the effects of caffeine on performance and endurance are not apparently related to glycogen use or muscle lactate

(i.e., anaerobic metabolism). Whether these gains are the direct result of increased sympathetic activity or through some other mechanism is not clear.

Caffeine Metabolism and Elimination

The solubility of caffeine varies substantially with temperature and is approximately 2.2 mg ml^{-1} (66 mg oz^{-1}.) at 25 °C and 180 mg ml^{-1} at 80 °C. Up to 90% of caffeine is hepatically metabolized, mostly to paraxanthine (80%) and theobromine (10%) and trivial theophylline (5%). Paraxanthine is generally further metabolized to inactive compounds before excretion. Importantly, this metabolism is species dependent and has some bearing on the interpretation of pharmacologic data. Rats metabolize less (30–40% excreted unchanged) and have markedly shorter half-lives (1 h for rat, and 3–5 h for human). Paraxanthine has similar effects as caffeine in terms of both its stimulant and its immune system effects. Theophylline is similarly active, but theobromine appears to be considerably less active.

Caffeine Pharmacology

Caffeine's clinical effect on alertness is mediated by nonselective antagonism of adenosine receptors (A1 more so than A2), which are widely distributed throughout the brain. Selectivity for the A2 receptor can be obtained by altering one methyl group with a larger alkyl group. Additionally, the potency can be increased by changing all of the methyls to larger groups.

Although generally not obtained in dietary doses, caffeine has a potent antagonistic effect on phosphodiesterase, which has the result of increasing cAMP and activating protein kinase A. This in turn blocks proinflammatory processes, such as lipopolysaccharide-induced production of tumor necrosis factor-α and interleukin (IL)-12, and promotes anti-inflammatory cytokines including IL-10 and mononuclear cells.

Caffeine's effects through adenosine antagonism are more predictable. Adenosine is released in response to tissue injury and induces collagen production and fibrosis in affected tissue (e.g., liver). Although caffeine is known to inhibit A1 adenosine receptors, data indicate that this may have little relationship to its wakefulness-promoting activity. Pure A1 antagonists will decrease sleep in mice, but A1 knockout mice do not respond to A1 antagonists. Although it may therefore seem logical to conclude that A1 is necessary for sleep, A1 knockout mice do not sleep any longer or shorter than wild-type mice; it is only their sensitivity to A1 antagonists that is different.

Caffeine promoted wakefulness in wild-type mice, but in contrast to the expectation, it also promoted wakefulness in A1 knockouts. It had no effect, however, on A2a knockouts. Taken together, these findings suggest that A1 and A2 receptors work in tandem to regulate wakefulness and sleep, and that a degree of compensation exists, especially for A1 by A2a. Additionally, it suggests that caffeine's wakefulness effects are not related to its majority effect on A1 but, rather, its 'minor' pharmacologic effect – which becomes the main clinical effect – on A2a receptors. This is further supported by location-specific effects of caffeine's stimulant properties in striatal neurons, in which A2a receptors are abundant.

Caffeine Adverse Reactions and Safety

The safety of caffeine as a food and beverage additive has been evaluated, with the conclusion that caffeine added to beverages at a level of 0.02% or less does not present a health risk. Caffeine has been shown to produce a transient increase in blood pressure, but a number of studies have failed to link caffeine with cardiovascular disease. Caffeine may be associated with a small increase in spontaneous abortion in the first trimester of pregnancy, and caffeine can significantly increase 24 h urine output. Because caffeine is not a prescription medication, standard dosing and side effect information is not available. The information in the *Physicians Desk Reference for Nonprescription Drugs and Dietary Supplements* for the product Nō-Dōz, which contains 200 mg of caffeine, indicates that the product may cause "nervousness, irritability, sleeplessness and, occasionally, rapid heart beat." Few research studies report carefully controlled side effect data from matched caffeine and placebo groups. Some investigators estimate that as many as 10% of adults develop the syndrome of caffeinism, which is defined as the daily consumption of large amounts of caffeine (usually in excess of 500 mg day^{-1}). Symptoms of caffeinism or caffeine intoxication include restlessness, nervousness, excitement, insomnia, flushed face, diuresis, gastrointestinal disturbance, muscle twitching, rambling speech, tachycardia, and agitation. The lethal acute adult dose of caffeine is approximately 5–10 g (approximately 75 cups of coffee).

Stomatogastric Ganglion Models

A I Selverston and M I Rabinovich, University of California at San Diego, La Jolla, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The stomatogastric system of crustaceans is one of a large number of invertebrate central pattern-generating circuits that have been investigated during the past 40 years. It can be considered a 'model' system with which to understand the mechanism underlying rhythmic behaviors in higher animals. The heart of the system is the 30-celled stomatogastric ganglion (STG) containing two central pattern generators (CPGs): the pyloric, which controls the pyloric region of the stomach, and the gastric, which innervates three ossicles (teeth) within the stomach. The pyloric CPG operates at a frequency of approximately 2 Hz and is composed of 13 motor neurons and one interneuron. The slower gastric CPG has an *in vitro* frequency of approximately 0.1 Hz. It is composed of 10 motor neurons and one interneuron. The synaptic connections between all of these neurons have been fully described, so the two CPGs are the most well-known neural circuits available in terms of cell-to-cell interactions. With so much information known about this system, one might assume that it is easy to understand exactly how it works. In fact, due to the complexity of the nonlinear interactions, it is not. Modeling may be the only way to understand the two networks and predict how they will respond to various inputs and perturbations in a way that allows them to retain the correct motor functions. The following are the principal modeling advantages of the preparation:

- The motor output patterns can be correlated with muscle contractions, thus directly linking the neuronal activity with behavior.
- 'Fictive' spatiotemporal patterns consisting of bursts of action potentials can be recorded from the motor nerves for many hours *in vitro* when the two 'higher' commissural ganglia are left attached.
- Neurons are large, easily identifiable, and display subthreshold excitatory and inhibitory potentials – important for identifying the integrative properties of the neurons.
- Up to eight neurons can be recorded simultaneously with intracellular electrodes.
- Command input from higher centers, sensory feedback, and neuromodulatory substances can all modify bursting and pattern formation, in some cases rather severely.

Detailed biophysical information for some of the identified stomatogastric neurons has been measured and the relative strengths and time courses of many of the chemical synapses are also known. Assembling all of this reductionistic data into a coherent system has proven challenging. In principle, one would like to explain the following features of this (or any) CPG:

1. What is the origin of the rhythmogenesis?
2. How are the patterns of bursts established?
3. Are rhythmogenic and pattern formation mechanisms separate?
4. How can the competing interests of robustness and flexibility be reconciled?
5. How is the system turned on and off?
6. How is the frequency established?
7. What is the mechanism for retaining optimal phase relationships at different frequencies?

Although researchers have attempted to answer these questions by trying to explain the experimental data verbally, such attempts are limited and cannot provide a quantitative description of the many phenomena observed. For example, a verbal model cannot predict what will occur when a selective perturbation to the system is imposed. Models that use the available experimental data to simulate the pyloric or gastric CPGs attempt to mimic the production of normal spatiotemporal patterns as well as have predictive value. Models of small CPGs can help to formulate the basic principles underlying central motor generators in general. For example, are there certain universal phenomena that can be found in all rhythmic CPGs? If there are general principles, it is probable that they will be found at the molecular level, whereas CPG networks in different species will have mostly idiosyncratic synaptic arrangements between neurons – that is, neural CPG circuit topology may vary for different operational requirements in different species. The stomatogastric CPGs, particularly the pyloric circuit, have been used to attempt to answer many questions about neural circuits. Both individual STG neurons and pairs of neurons and small networks have been modeled. In addition, the STG has been most widely used for computer/electronic neuron interfacing with biological neurons in so-called hybrid circuits.

Overview of the Stomatogastric System

To study the infrastructure underlying rhythmic behaviors, only invertebrate preparations are experimentally tractable at all levels of analysis. The

Figure 1 The crustacean stomatogastric system innervates the stomach shown here in side view. The nerves can be seen coursing along the surface of the stomach wall. The stomatogastric ganglion (STG) sits at the top of the stomach. CG, commissural ganglion; DVN, dorsal ventricular nerve; ION, inferior esophageal nerve; IVN, inferior esophageal nerve; LVN, lateral ventricular nerve; SGN, stomatogastric nerve; SON, superior esophageal nerve; v-LVN, ventral part of lateral ventricular nerve. Motor nerves: ALN, anterior lateral nerve to gm1; AMN, anterior median nerve to c7; DGN, dorsal gastric nerve to gm4; LGN, lateral gastric nerve to gm6b; LPGN, lateral posterior gastric nerve to gm3a; LPN, lateral pyloric nerve to p2a; MGN, median gastric nerve to gm9; MVN, median ventricular nerve to cv2 and vcd; PDN, pyloric dilator nerve to cpv2b; PYN, pyloric nerve to muscles p2b, p8–9, p10, p7, and p13.

stomatogastric circuits have thus been studied from the level of the molecular structure of ion channels to the modulation of gastric teeth behavior by neuromodulators. As mentioned previously, there are two rhythms, the gastric and the pyloric. The gastric rhythm is for 'chewing' food that has been swallowed and stored in the cardiac sac portion of the stomach (Figure 1). As with our own masticatory behavior, gastric mill (GM) behavior is episodic and highly flexible, depending on the consistency of the food present. The pyloric rhythm controls a pumping/filtering apparatus at the caudal end of the stomach, and although it's speed can be adjusted, it appears to work almost continuously. The neurons that comprise both CPGs, like many invertebrate CPGs, are few in number and the patterns are robust (Figure 2). The microcircuits formed by these neurons have been known for more than 30 years and are shown in Figure 3. The neurons in both CPGs have two functions. Their biophysical properties and synaptic interactions cooperate to generate multiphase rhythms within the ganglion (i.e., they function like premotor interneurons in vertebrates). All but two of them are also motor neurons that send bursts of impulses to the muscles. The two neurotransmitters in the ganglion – glutamate and acetylcholine – make mostly inhibitory connections onto other neurons within the ganglion but make excitatory neuromuscular synapses peripherally. In addition, like synapses in the retina, synapses in the STG release transmitter as a graded function of the membrane voltage in the presynaptic terminals and not just as pulsatile events following spike invasion of the terminal.

STG Output Patterns

When the STG and its associated nerves are removed from the wall of the stomach and the two commissural and the single esophageal ganglia are left connected, both the pyloric and gastric rhythms will burst for many hours (Figure 2). The patterns of spiking activity in the motor nerves correspond closely with the natural behaviors of the stomach. The pyloric dilator (PD) neuron burst is followed sequentially by lateral pyloric (LP) and pyloric (PY) bursts. This three-phase sequence acts on pyloric muscles to first dilate the pyloric region since pairs of pyloric muscles pull in opposite directions (Figure 1). This is followed by a rostral-to-caudal wave of muscle contractions with the whole system acting like a pump. The bursts in the GM units also correspond to the movements of the three teeth of the GM which have been studied extensively by video endoscopy. The lateral gastric (LG) and median gastric (MG) traces, whose burst

Figure 2 Simultaneous intracellular recordings from individual neurons of the pyloric and gastric CPGs. The spikes on the top of each burst form the patterns of activity seen in each motor nerve. The location of each neuron in the two circuits is shown in Figure 3. AB, anterior burster; AM, anterior median; DG, dorsal gastric; GM, gastric mill; IC, inferior cardiac; Int 1, interneuron 1; LG, lateral gastric; LP, lateral pyloric; LPG, lateral posterior gastric; MG, median gastric; PD, pyloric dilator; PY, pyloric; VD, ventricular dilator.

onsets are shifted slightly, close the two lateral teeth while strong lateral posterior gastric (LPG) bursts that occur in antiphase open the lateral teeth. The dorsal gastric (DG) and anterior median (AM) reset the medial tooth and help with contractions of the cardiac sac while the GMs act out of phase with DG to provide the power stroke movements of the medial tooth. Heinzel described a small variation of this behavior which occurs spontaneously. Instead of the lateral teeth coming together first and the medial tooth grinding over them, in some instances he observed all three teeth coming together at the same time – a behavior he referred to as 'squeeze.'

The CPGs and Some Associated Circuitry

The pyloric and GM neural circuits are shown in Figure 3. The pyloric circuit is composed of two PD cells, eight PY cells, and one each of the ventricular dilator (VD), LP, inferior cardiac (IC), and anterior burster (AB) cells. In a combined preparation with the two commissural ganglia and the single esophageal ganglion intact, all of the neurons in the pyloric network burst intrinsically. However, because they require neuromodulatory inputs from the commissurals, they are referred to as 'conditional bursters.' Without this modulatory input, the intrinsic conductances underlying bursting are not sufficiently activated and the cells are either silent or fire tonically but not in bursts. The AB neuron has the fastest rhythm, thus acting as a pacemaker for the other pyloric cells. By deleting neurons from the circuit sequentially, it has been shown how the synaptic connectivity and the intrinsic burstiness combine to produce a robust three-phase burst pattern. The ionic mechanism for bursting is basically a decrease in the potassium leak current that depolarizes the neuron until a voltage-gated calcium and sodium current is activated. This increases the rate of the depolarization and activates fast spiking and plateau currents. Inactivation of the sodium and calcium currents combined with calcium-activated potassium current brings the cell back to its resting potential. Other currents, particularly I_A and I_H, play an important role in burst timing and are considered later. It is important to note here that the rhythmicity is due to the intrinsic properties of the neurons. The network properties form the pattern by the appropriate use of inhibitory synapses and also may contribute to the rhythmicity.

The inhibitory synapses in the GM CPG play the determinant role in pattern formation and a major contributory role in rhythmogenesis. When neurons are isolated pharmacologically, only the DG and AM neurons appear to have intrinsic pacemaker properties. The key LG and DG neurons evoke two types of inhibitory postsynaptic potentials (IPSPs) in follower neurons. The fast type rises rapidly (100–300 ms), is mediated by an increased chloride and potassium conductance, and resembles the glutaminergic IPSP described for the pyloric CPG. The second, slow type of IPSPs has a long rise time (1 or 2 s) and is mediated by an increased conductance to potassium. The fast inhibition occurs alone at connections from DG and LG to power stroke motor neurons (MG and GM). Slow inhibition occurs in parallel with fast inhibition (producing dual-component responses) at LG to LPG and interneuron 1.

Although the two CPGs control separate oscillatory rhythms, there are many direct synaptic and electrotonic connections between neurons in each circuit. In addition, several neurons that are located in the commissural ganglia receive inhibitory synaptic inputs from the neurons in each CPG and therefore send pyloric and gastric timed inputs to neurons in both CPGs in a kind of closed feedback loop. This is most apparent on intracellular recordings from the DG and AM neurons which show bursts of excitatory postsynaptic potentials (EPSP) that originate from P cells that are modulated by the AB neuron. Since the pyloric and gastric CPGs operate at different

Figure 3 Pyloric and gastric mill neural circuits, including descending neurons from the commissural ganglia and sensory neurons on the stomach wall. Triangles represent chemical excitatory synapses, black dots represent chemical inhibitory synapses, and resistors are gap junctions. Neurons at the top of the figure (above the dashed line) are various excitatory neurons, the P cells and E cells, the IVN fibers from the brain, and various sensory receptor cells. Pyloric CPG: AB, anterior burster; IC, inferior cardiac; LP, lateral pyloric; PD, pyloric dilator; PY, pyloric; VD, ventricular dilator. Gastric CPG: AM, anterior median; DG, dorsal gastric; GM, gastric mill; Int 1, interneuron 1; LG, lateral gastric; LPG, lateral posterior gastric; MG, median gastric.

frequencies, the possible functions of these connections as well as the general computational problem of coupling oscillators running at different frequencies pose interesting questions.

Ion Channels in STG Neurons

As already mentioned, several voltage-gated conductances are responsible for the intrinsic burst-generating mechanisms found in STG neurons. Other channels are important in controlling various aspects of the neural patterns produced by the STG. The somata of STG neurons contain only outward current channels and are therefore inexcitable. Interestingly, when isolated neuronal somata are placed in culture, after a few days inward current-carrying channels are expressed and neurons begin to burst.

Two other currents which play an important role in determining the characteristics of the pattern are I_H and I_A. I_H is activated by hyperpolarization of the membrane and plays a role in determining the extent of postinhibitory rebound following inhibition. I_A is a transient depolarization activated K current that delays the onset of bursting. Voltage

clamp studies on individual pyloric neurons have shown that the distribution of I_A channels differs between cells. It is largest in PD and PY cells, smaller in AB, LP, and IC cells, and not detectable in the VD cell. When I_A currents are blocked with 4-AP, the cycle period is decreased by approximately 20%, there is a general enhancement of activity in all of the cells, and there is a change in the phasing of follower cells with respect to the PD/AB pacemaker group.

Neuromodulation

The gastric and pyloric CPGs are subject to the influence of neuromodulatory substances released into the ganglion nonspecifically or as a result of being transported by the blood. More than 20 neuromodulatory substances (mostly small peptides and amines) have been identified by immunohistochemistry in neurons that project to the STG. How these substances are used in the life of the animal is known only in a few cases (e.g., cholecystokinin). However, when they are applied to the ganglion in physiological dosages, they have profound effects on the motor patterns that last for many hours. The mechanism of action has been shown to be a result of G-protein activation of second-messenger cascades and an increased concentration of different kinases leading to the phosphorylation of specific channels in specific neurons. Because this changes the biophysical properties of the neurons and their synapses, there is a functional rewiring of the circuit. The consistent effects of particular neuromodulators depend on the fact that the biophysical properties and the types and densities of channels in the neurons comprising the STG circuitry are consistent from animal to animal.

Models of Observed Phenomena

Models of Single STG Neurons

If one considers the complexity of even a single neuron – its various ionic fluxes, intracellular mechanisms, responses to synaptic inputs, etc. – it is reasonable to assume that a single isolated cell is a high-dimensional system with some noise (i.e., requiring many equations to describe all of its functional variables). A nonlinear dynamical analysis using a global false nearest neighbor paradigm, however, showed that the synaptically isolated but still stationary bursting LP neuron has an attractor that demonstrates relatively low dimensional dynamics – on the order of 4 or 5 (Figure 4). In addition, the spikes in the bursts of this cell develop chaotic behavior toward the end of the bursts that could be shown by phase portraits or Lypunov exponent measurements. Not all neurons in the gastric or pyloric system were examined, but it is likely that other neurons have chaotic properties as well.

Figure 4 (Top) Chaotic membrane potential time series of a synaptically isolated LP neuron from the pyloric CPG. (Bottom) State space attractor reconstructed from the voltage measurements of the LP neuron shown in the top panel using delayed coordinates $[x(t), y(t), z(t)] = [V(t), V(t-T), V(t-2T)]$. This attractor is characterized by two positive Lyapunov exponents.

Many models of single neurons have been made, both simplified and conductance based. These have had varying degrees of success. It is important to emphasize that a simple reproduction of the stationary burst pattern is only the first step in creating a satisfactory model. Any model, to be adequate, has to be able to describe the transient dynamics as well. An isolated LP neuron model can be successfully made with a Hindmarsh–Rose (H–R) single compartment model consisting of only three equations. This model can show chaotic as well as regular behavior simply by adjusting the parameters. Adding a fourth polynomial equation to the original H–R formulation shown here produces chaotic behavior over a much more realistic regime range. The original equations shown here describe membrane voltage (x) and a fast (y) and a slow (z) current:

$$\frac{dx(t)}{dt} = ay(t) + bx^2(t) - cx^3(t) - dz(t) + I$$

$$\frac{dy(t)}{dt} = e - fx^2(t) - y(t) - gw(t)$$

$$\frac{dz(t)}{dt} = \mu(-z(t) + s(x(t) + h))$$

A much slower current (w) is given by

$$\frac{dw(t)}{dt} = v(-kw(t) + r(y(t) + l))$$

The slow current could represent any slow process, such as an inositol triphosphate-controlled movement

of internal calcium in and out of the endoplasmic reticulum calcium stores. It is the slower kinetics of this process, combined with the faster inward and outward membrane currents, that generates the appropriate chaotic behavior (Figure 5).

The AB neuron has also been numerically simulated using a Hodgkin–Huxley-type model that was able to produce various kinds of rhythmic behaviors in response to neuromodulators or channel blocking neurotoxins that were similar to the responses observed experimentally. By constructing two-dimensional maps of the parameter space, the changes in firing patterns of the models could be determined. Using a bifurcation analysis, regions in which the model's behavior transitioned from tonic firing to bursting could be shown. The model also mimicked the results of blocking I_A with 4-AP over a range of I_A reductions. Overexpression of I_H in PD neurons has also been modeled. The increase in this current causes a dramatic change in PD activity by depolarizing the minimum membrane potential, thereby reducing the amplitude of the oscillation. This leads to decreased time to the first spike in the burst, an increase in the duty cycle, and an increase in the number of spikes per burst.

Manipulation of both I_A and I_H using molecular biological techniques indicates that there is an activity-independent regulation of these channel proteins. An increase in either protein alone has little effect on cell firing properties in PD, LP, VD, and IC neurons. Two hypotheses might explain this remarkable observation. There might be a mislocalization of, for example, the protein Shal (for I_A) to the soma and initial neurites so as to be remote from the integrating region of the neuropile. Alternatively, the increase in I_A could be balanced by a homeostatic increase in I_H. A multicompartment model with the I_A current located in the soma and primary neurites produced simulations that were much greater than those observed experimentally with Shal-injected neurons. However, a model in which the ratios of I_A and I_H were kept constant showed complete compensation, suggesting that an activity-independent homeostatic mechanism maintained constant spiking–bursting neural activity after increasing the amount of I_A in the neuron.

The basis of most H–H-type models for identified invertebrate neurons is that the maximum conductances for each channel type remain constant. However, clearly there is channel protein turnover during the life of a neuron, so mechanisms must exist to keep the expression of each channel protein constant or, as has been suggested, at least keep the activity level of the neuron constant. Here, the idea is that protein

Figure 5 A conductance-based model of the LP neuron. Nine separate conductances were tuned to produce the output shown for different levels of applied DC current. (a) Responses in biological neuron to applied DC currents (b) are model responses to the same current levels. Red boxes show portions of the curve that are magnified in time.

expression is influenced by the electrical activity of the cell. There is experimental evidence from mammalian neurons that this is the case and evidence from STG work that there is also an activity-independent modification of channels that results from injection of specific channel mRNA into the neuron. Activity-dependent conductances in STG neurons have been modeled using internal calcium sensors as measures of cell activity and then up to three different equations have been used to transform the calcium concentration to changes in the maximum conductance values for the neuron. These models suggest that the maximal conductance values are not fixed parameters but, rather, dynamic and able to produce different cell behaviors by constantly adjusting the ratios of different ionic conductances. However, there is little evidence linking internal calcium concentration to changes in gene expression in STG neurons.

The idea, based on modeling, that there is a range of different conductance value ratios that can lead to the same activity profile has been extended to include very large numbers of combinations in a so-called database approach. Usually, conductance-based models use some form of tuning algorithm to obtain parameter values that produce the correct voltage responses to specific regimes. This can be a long and laborious process if the model is to be structurally stable under a variety of perturbations. There are two ways to avoid this problem. One is to determine the exact parameter values from stationary experimental data. However, this is usually not possible for various technical reasons associated with the complex morphology of neurons and the inability to voltage clamp at the precise location of voltage-sensitive currents. An alternative method, using modeling techniques, is to build a large database of many possible combinations (arbitrarily limited) of biophysical parameters and select those combinations which produce voltage patterns that match a template representing a time series of the biological voltage outputs for the cell. This suggests that neurons (and synapses) can have many different combinations of values for their conductances, some with as large as a 30-fold difference. The biological evidence to support this idea is weak, however, and there are many reasons why identified neurons could not have such a large degree of variability between animals, the most relevant of which would be that there is always a consistent response in particular identified neurons to a single neuromodulator or to a specific channel blocker.

The effect of the neuromodulator dopamine (DA) on PY and LP activity has been modeled in conjunction with experimental work showing that DA reduces the I_A current significantly. By reducing this current in PY neurons, a phenomenon known as postinhibitory rebound is altered in a way that causes a phase advance. The mechanism appears to be due to a reduction of the slowly inactivating component of the I_A current shifting the voltage activation curve in the depolarizing direction. A similar model of the LP neuron confirmed experimental data that indicated DA caused a reduction in both I_A and I_H and a significant delay in first spike latency.

Models of Synapses

Models of synapses in the STG have taken into account not only strength but also time course and nonlinear temporal changes. Models of chemical synapses have to automatically adjust the amplitude of the EPSP or IPSP to the voltage difference between the actual potential and the reversal potential. More developed models have incorporated nonlinear synaptic properties such as short-term facilitation and depression and long-term potentiation and long-term depression. Since there are also many electrical synapses, equations describing the bidirectional and unidirectional (or rectifying) flow of current have been constructed. Equations for chemical synapses typically take the following form:

$$I_{\text{syn}} = gS(V - V_{\text{rev}})$$

$$\tau \frac{\mathrm{d}S}{\mathrm{d}t} = R - S$$

$$\tau \frac{\mathrm{d}R}{\mathrm{d}t} = \Theta(V - V_{\text{th}}) - R$$

where the threshold potential for transmitter release is V_{th}, τ is the synaptic timescale, R and S are the presynaptic and bound transmitter, and Θ is the Heaviside step function.

These models have been used to examine the dynamics of mixed chemical and electrical synapses or the role of synapses in the functioning of the STG networks. For example, an important property of a motor network is the ability to keep optimal phase relationships over a variable frequency range. Depressing synapses may be able to achieve this function by changing synaptic strength as their frequency speeds up or slows down.

Neurons coupled with gap junctions have shown some surprising results. Two PD neurons, normally coupled very strongly, fire together in a bursting–spiking pattern (Figure 6(a)). Modeling two electrically coupled neurons shows that neurons with chaotic bursting activity can be synchronized and regularized by the electrical connection. Furthermore, in the model, changing the strength of the coupling can produce different regimes of in-phase and out-of-phase bursting. This modeling result was confirmed experimentally by using an artificial electrical synapse

Figure 6 Artificial electrical coupling between two living chaotic PD cells of the stomatogastric ganglion of crustacean can demonstrate both synchronous and asynchronous regimes of activity. In this case, the artificial electrical synapse was built on top of the existing natural coupling between the two PD cells. The figure shows different synchronization levels (a–d) as a function of the artificial coupling g_a and a DC current injected I in one of the cells. (a) With their natural coupling $g_a = 0$, the two cells are synchronized and display irregular spiking–bursting activity. (b) With an artificial electrical coupling that changes the sign of the current $g_a = -200$ nS, and thus compensates the natural coupling, the two neurons behave independently. (c) Increasing the negative conductance leads to a regularized antiphase spiking activity (by mimicking mutual inhibitory synapses). (d) With no artificial coupling but adding a DC current, the two neurons are synchronized displaying tonic spiking activity.

between two PD cells. It is possible to study transitions between synchrony and asynchrony between the two neurons simply by changing the current flow between the cells (Figure 6).

Models of Pyloric Spatiotemporal Patterns

The two patterns shown in Figure 2 are the three-phase pyloric with a frequency of approximately 2 Hz and the five-phase gastric with a frequency of approximately 0.1 Hz. These spatiotemporal patterns are the result of the synaptic interactions and the biophysical properties of each neuron. The synaptic interactions can be seen in the simplified circuit diagrams shown in Figure 3. Because of the very large number of interactions, it is not possible to determine the mechanisms responsible for the performance of these CPGs by a simple inspection of the circuit. It is also not possible to predict the effects of perturbations even if the precise nature of the perturbation is known. Ideally, we want to be able to explain how the basic features of the pattern are produced (i.e., the genesis of the bursts and their phase relationships). In addition, we want to know how such parameters as burst length, frequency, and duty cycle are produced and maintained. Also, perhaps most difficult, we want to know how the combined cellular and synaptic properties remain robust while at the same time flexible enough to respond to sensory input and perturbations.

Most computer models of STG networks have thus far been limited to simplified subsets of neurons. For example, pairs or triplets of STG neurons coupled with inhibitory chemical synapses or pairs of neurons coupled with electrical synapses with the same topology as is found in the biological circuit can produce the three-phase pyloric pattern. For example, the pyloric network can be reduced to three oscillatory neurons representing the PD/AB group, the single LP neuron, and the eight PY neurons connected with inhibitory synapses.

Modeling Robustness and Adaptability

The CPG concept was built around the idea that behaviorally relevant spatiotemporal cyclic patterns are generated by groups of nerve cells without the need for rhythmic inputs from higher centers or sensory feedback from the structures that are moving. If activated, isolated invertebrate preparations can generate such rhythms for many hours and, as a result, have been extremely important in attempting to understand how the simultaneous cooperative interactions between many cellular and synaptic parameters can produce robust and stable spatiotemporal patterns whose mathematical image is a limit cycle.

Generally, neural oscillations can arise either through interactions among neurons (network-based mechanism) or through interactions among currents in individual neurons (pacemaker mechanism). The stomatogastric CPGs appear to use elements of both mechanisms. In the pyloric CPG, all of the neurons have intrinsic bursting activity but the fastest burster, the AB, acts as the pacemaker for the entire CPG circuit. The intrinsic currents are not constitutively active but require activation by neuromodulators; thus, they are called conditional bursters. In the gastric CPG, only one or two neurons have intrinsic bursting capability and the synaptic connections act to determine the pattern by exciting or inhibiting other neurons at the appropriate time. Networks with bursting neurons are extremely robust and have generally been thought to be present in systems in which the rhythmic activity is active more or less continuously. In the second case, the synaptic interactions between mostly nonbursty neurons generate the rhythmic activity, and many

schemes for the topology necessary to do this have been proposed. Usually, reciprocal inhibition serves as the basis for generating bursts in neurons that control antagonistic muscles, and there are many examples of cells in pattern-generating microcircuits connected this way. Network-based circuits are usually found for behaviors which are intermittent in nature and which require a greater degree of flexibility than those based on pacemaker cells. An example of a three-neuron CPG phase portrait is shown in Figure 7. The effect of a hyperpolarizing current in PD leads to changes in the pattern, as reflected by the phase portrait in Figures 7(b) and 7(c), but the fundamental activity of the network continues.

Despite the fact that the stomatogastric CPGs are the most thoroughly investigated neural networks, data on many important control parameters are lacking. This information is necessary to build a complete model, one that is able to predict the observable phenomena discussed previously. However, based on some important general ideas from nonlinear dynamics, it is possible to build a sufficiently realistic STG model capable of expressing dynamical principles, even without a detailed knowledge of all the morphological and neurophysiological details of the specific neurons and synapses. The success of such models is determined by the universality of the underlying dynamical principles: robustness, reproducibility, flexibility, and adaptivity. Based on these principles, CPGs have to be strongly dissipative (i.e., to return to the normal mode of activity quickly after a perturbation (robustness and reproducibility)) and to be structurally stable (i.e., to be able to keep the general form of the behavior even if the parameters of the network are changed slightly). At the same time, a CPG has to be sensitive (i.e., able to change the mode of activity) as a result of command inputs from above and/or sensory feedback. Mathematically, the robustness of a rhythmic CPG means that in the state space of the CPG there exists a limit cycle with a large basin of attraction. Structural stability means that the system is located far enough away from the bifurcation boundaries in the control parameter space that it will not be degraded by spontaneous variations in its parameters.

Figure 7 (a) Phase portrait of typical CPG output. The data were recorded in the pyloric CPG of the lobster stomatogastric ganglion. Each axis represents the firing rate of one of three pyloric neurons: LP, VD, and PD. The orbit of the oscillating pyloric system is shown in blue and the average orbit is shown in red. (b) The same as in a, but with a hyperpolarizing DC current injected into the PD. (c) The difference between the averaged orbits. (d) Time series of the membrane potentials of the three neurons.

Figure 8 Minimal model of the pyloric CPG illustrates winnerless competition and the continuous sequencing of the bursts produced by the three-cell pyloric network. (a) Schematic diagram of the three-neuron network used for rate modeling. Black dots represent chemical inhibitory synapses with strengths given in nanoseconds. (b) Phase portrait of the model: the limit cycle corresponding to the rhythmic activity. (c) Robustness in the presence of noise: noise introduced into the model shows no effect on the order of activation for each type of neuron.

The dissipativity of the stomatogastric CPGs is guaranteed by the high percentage of inhibitory synaptic connections. Structural stability and sensitivity are maintained by the organization of the neural network. How nature solves the fundamental contradiction between robustness and sensitivity is a very difficult question. Nonlinear dynamics suggests this may be done by the coexistence of many attractors (multistability), which is good for sensitivity but bad for robustness: under the action of noise, the system will randomly move along the basins to different attractors. This means that each attractor has to be global, or at least have a big basin. In theory, however, it is possible to make a system with a single global heteroclinic attractor in such a way that if the informational input is changed, the topology of the attractor will be altered (i.e., new heteroclinic stable orbits will be formed depending on which neurons are affected by the inputs). The result is that new spatiotemporal patterns will be generated by the CPG for different signals (sensory, command, or neuromodulatory) that are external to the ganglion. A winnerless competition network is able to model these phenomena (Figure 8).

Summary

The stomatogastric nervous system and the two CPGs it contains have been modeled from the cellular to the network level. The primary goal has been to unify the enormous amount of reductionistic data that have been obtained for this preparation and use them to simulate the behavior of the preparation. In fact, it is not possible to handle such a large amount of data without some kind of modeling. It was originally hoped that by taking a modeling approach, some general principles of small network operation would be found that might extend to other small networks or possibility to complex microcircuit modules in the brain. To some extent, this has been achieved with phenomena first described in invertebrate preparations now used commonly to describe mechanisms in the nervous systems of higher animals. This is especially true for cellular mechanisms. Models for describing the operation of systems of neurons, however, are more likely to be idiosyncratic, and individualized models for these systems will probably be as close to an explanatory principle of CPG behavior as is possible to achieve. More general properties of CPGs, such as robustness and flexibility, appear to be more independent of specific topologies and may benefit from a dynamic analysis such as has been discussed here. Many of the questions posed at the beginning of this article have been answered for the STG. There are still many left unanswered, however, and these will be the direction of future experimental and modeling work on this amazing preparation.

Strategic Control of Memory

Introduction

Cognitive control mechanisms permit memory to be accessed strategically and so aid in bringing knowledge to mind that is relevant to current decisions and actions. A fundamental component of the strategic control of memory is the resolution of interference from competing, irrelevant representations. This article considers how the ventrolateral prefrontal cortex (VLPFC) regulates mnemonic competition in multiple memory systems. We initially discuss how damage to lateral prefrontal cortex impacts mnemonic function and then consider recent neuroimaging and focal lesion findings that highlight the distinct roles that subregions of the VLPFC play in the control of memory.

Lateral Prefrontal Cortex

The lateral prefrontal cortex (PFC) consists of ventral, dorsal, and frontopolar subregions. In this article, we primarily focus on the function of VLPFC. In the human (Figure 1(a)), VLPFC corresponds to the inferior frontal gyrus, which includes (moving caudally to rostrally) the inferior frontal pars opercularis (Brodmann area (BA) 44), inferior frontal pars triangularis (BA 45), and inferior frontal pars orbitalis (an area that Petrides and Pandya term area 47/12, which corresponds to the lateral portion of BA 47). Whereas Petrides and Pandya refer to area 47/12 and BA 45 collectively as the mid-VLPFC, distinguishing these regions from the caudally situated BA 44, in this article we functionally distinguish area 47/12 from BA 45. Thus, we use anterior VLPFC to refer to the inferior frontal pars orbitalis (area 47/12), mid-VLPFC to refer to the pars triangularis (BA 45), and posterior VLPFC to refer to the pars opercularis (BA 44). We note that the caudal portion of area 47/12 actually lies ventral (rather than rostral) to BA 45 (Figure 1(a)). The inferior frontal sulcus in humans (and the principal sulcus in monkeys) marks the approximate boundary between the VLPFC and the dorsolateral PFC (DLPFC). In terms of anatomical connectivity, the VLPFC is strongly connected with cortical areas in the lateral temporal lobe and medial temporal lobe (MTL), including (but not limited to) the inferotemporal cortex, superior temporal cortex, and, more medially, perirhinal and parahippocampal cortices.

Mnemonic Deficits Following Lateral Prefrontal Damage

Neuropsychological studies in humans and lesion studies in animals indicate that insult to the lateral PFC can produce memory impairments that are qualitatively distinct from those observed following MTL damage. Whereas MTL damage results in an amnesic condition that reflects the inability to encode and retrieve new declarative memories – long-term memories for events (episodic memory) and facts (semantic memory) – lateral PFC damage impairs the strategic regulation of multiple forms of memory, including declarative memory and working memory. Significantly, impairments in episodic memory, semantic memory, and working memory following lateral PFC damage are often most apparent when performance requires the resolution of interference, which led Moscovitch, Shimamura, and others to propose that lateral PFC subserves cognitive control mechanisms that regulate how we work with or dynamically filter memory.

Episodic Memory Deficits

Patients with lateral PFC damage show modest impairments in their ability to encode and retrieve episodic memories, with these deficits being particularly apparent when memory for target information is required in the face of distraction. Here we illustrate these deficits by highlighting a number of well-documented paradigms in which PFC patients are impaired.

First, PFC patients show disproportionate deficits on tests of free recall compared to item recognition. Theorists have argued that the unconstrained nature of free recall increases the likelihood of mnemonic competition or interference. Second, even within recognition tests, PFC patients show impairments when distracter items at test (foils) are similar to items from the study list. In other words, PFC patients suffer interference from items that are similar to those they studied, as evidenced by false claims of having studied these items. Third, in tests of source memory, in which memories for individual items must be attributed to a particular learning context – a discrimination that presents high interference because irrelevant contexts are often highly salient – PFC patients exhibit disproportionate deficits relative to tests of item recognition. Fourth, the use of AB–AC learning paradigms reveals that learning an AC association is disproportionately impaired in PFC patients (i.e., patients show a heightened sensitivity to proactive interference). In such paradigms, the patient's

Figure 1 Anatomical divisions of the ventrolateral prefrontal cortex (VLPFC) in the human: (a) representation of the cytoarchitectonic subdivisions of the lateral prefrontal cortex (PFC); (b) coronal slices through the PFC depicting the anatomical boundaries that define the mid-VLPFC and anterior VLPFC. The subregions of the VLPFC include the pars orbitalis, pars triangularis, and pars opercularis, corresponding to the anterior VLPFC (area 47/12), mid-VLPFC (area 45), and posterior VLPFC (area 44), respectively. (Note that we use the term mid-VLPFC to refer to area 45 only, adopting anterior VLPFC to refer to area 47/12.) As shown in (b), both the anterior and mid-VLPFC lie ventral to the inferior frontal sulcus (1). In caudal slices, the mid-VLPFC is bounded ventrally by the insular sulcus (2), and in rostral slices it is bounded by the horizontal ramus of the lateral fissure (3). The anterior VLPFC is bounded ventrally and medially by the orbital gyrus (4). (a) Adapted from Petrides M and Pandya DN (2002) Comparative cytoarchitectonic analysis of the human and the macaque ventrolateral prefrontal cortex and corticocortical connection patterns in the monkey. *European Journal of Neuoscience* 16: 291–310. (b) From Badre D and Wagner AD (2007) Left ventrolateral prefrontal cortex and the cognitive control of memory. *Neuropsychologia* 45(13): 2883–2901.

memory for AC pairs is largely compromised by increased intrusions of the earlier learned AB associations. Moreover, even when sequentially studying two unrelated lists of items (i.e., the lists do not share common associates), PFC patients show disproportionate list 1 interference when trying to learn list 2. Finally, when PFC patients are provided with a subset of items from a previously studied list as retrieval cues (i.e., part-list cueing), the high salience of the provided items results in increased impairment in the patients' ability to recall the remaining (unpresented) items from the list. Collectively, these and other observations indicate that the ability to resolve interference in episodic memory is compromised following lateral PFC damage.

Semantic Memory Deficits

Just as PFC patients show impairments in unconstrained episodic memory tests, they also show deficits in unconstrained tests of semantic retrieval. For example, patients show reduced total output on verbal fluency tasks, which involve freely generating as many unique exemplars as possible in response to a semantic or orthographic cue. This impairment is thought to partially reflect patients' heightened sensitivity to output interference stemming from the initially retrieved exemplars. Significantly, this interference-dependent deficit during semantic or lexical retrieval stands in contrast to the typically unimpaired ability of PFC patients to recognize semantic structure or evaluate semantic relationships. Beyond verbal fluency tasks, patients with damage to the left lateral PFC fail to show normal semantic priming when the meaning of a semantic cue (the prime) is a context-dependent homograph, compared to words with less ambiguous meanings. This impairment may be due to PFC patients failing to retrieve the appropriate stimulus meaning when the prime is ambiguous, thereby preventing priming from occurring. Both these deficits are consistent with the perspective that the lateral PFC is recruited during controlled semantic retrieval, as well as when interference between competing semantic or lexical representations must be resolved.

Working Memory Deficits

In tests of working memory, PFC patients are often unimpaired, as measured by simple tests of verbal span. However, in tests in which maintenance is complicated by interference from irrelevant information, lateral PFC damage tends to result in impairment. For example, in delayed recognition tests, PFC patients are particularly sensitive to the presence of distracters during the delay. When compared to patients with damage to the MTL, PFC patients show impairments at all delay intervals as long as

distracters are present, whereas patients with MTL damage show impairments principally at long delays. A similar observation comes from studies of PFC-lesioned monkeys. Whereas it was initially believed that PFC-lesioned monkeys were unable to remember the location of a food item that was hidden for only a short delay, it was later shown that this apparent memory deficit could be eliminated if the delay period was held in total darkness. In other words, the monkey's memory deficit was a function of the interfering effects of visual input during the delay period. Strikingly, not only do PFC patients show impaired working memory performance due to distracters, but PFC patients also show exaggerated electrophysiological responses in cortical areas that process the modality of the distracting information, suggesting that when distraction is present, the PFC is responsible for gating activity in regions that would otherwise process the distracting information. Further evidence that lateral PFC damage results in an inability to filter or gate irrelevant distracting information comes from studies of negative priming. In such studies, healthy controls typically showed increased reaction times when processing a stimulus that was previously a distracter (i.e., these previous distracters showed negative priming). By contrast, frontal patients showed the reverse effect – facilitated processing of stimuli that previously served as distracters – which suggests that the patients had difficulty preventing the processing of the distracters.

Functional Specificity within Lateral Prefrontal Cortex

Although data from frontal patients provide compelling evidence that one contribution of the lateral PFC to the strategic control of memory is to regulate interference, the lack of anatomical specificity that typically accompanies naturally occurring PFC lesions in humans often precludes the determination of the specific functional contributions of particular PFC subregions. In an attempt to specify the mechanistic contributions of the subregions of the VLPFC to the control of memory, we consider in the next section evidence from functional neuroimaging studies and from recent reports of patients with lesions focused on subregions of VLPFC. As we discuss, extant data implicate the mid-VLPFC as a key component of the neural circuitry that resolves mnemonic interference, be it within working memory, semantic memory, or episodic memory.

Memory and the VLPFC

Focal lesion studies with monkeys have shown that damage to the inferior convexity (the monkey homolog of the human inferior frontal gyrus), but not to the DLPFC, causes perseverative tendencies in contexts in which the prior response learning must be reversed. Similar perseverative errors are a classic hallmark of human frontal lobe damage, as is often revealed through errors on the Wisconsin Card Sorting Task, when subjects must override a previously established, but now irrelevant, response set. As already noted, the strategic control of working memory, semantic memory, and episodic memory often requires conceptually similar mechanisms that permit the overriding of interference from irrelevant representations. Functional neuroimaging data in humans, complemented by focal lesion evidence, now indicate that the left mid-VLPFC regulates mnemonic interference by enabling the selection of relevant representations in the face of mnemonic conflict, whereas the left anterior VLPFC controls access to, and guides the retrieval of, long-term semantic knowledge. Response override or inhibition, by contrast, appears to differentially depend on regions in the human right VLPFC.

Left Mid-VLPFC and Interference in Working Memory

Extensive evidence for the role of the left mid-VLPFC (BA 45) in resolving mnemonic interference comes from a variant of the Sternberg working memory paradigm (Figure 2(a)). In this task, participants encode a target set of stimuli (e.g., four letters), which they then attempt to maintain in working memory across a brief delay. Following the delay, a probe (e.g., a letter) is presented and participants make a yes/no decision as to whether the probe is in the currently maintained memory set. Critically, some negative probes (i.e., probes to which the subject should respond no) come from the immediately preceding memory set (negative recent probes), whereas other negative probes have not appeared in either the present or the preceding memory sets (negative nonrecent probes) (Figure 2(a)). Given this structure, negative recent probes are associated with interference because subjects must attribute the familiarity of the probe to its having been in the preceding memory set to correctly reject the probe as not being a member of the current memory set. Thus, comparisons of negative recent to negative nonrecent trials provide leverage on the neural mechanisms that are engaged in the face of this mnemonic interference.

Jonides and colleagues were the first to demonstrate that functional activation in the left mid-VLPFC is greater during negative recent relative to negative nonrecent trials, a pattern that has been replicated and extended by others (Figure 2(b)). Subsequent data indicated that (1) the response in the left mid-VLPFC during negative recent trials is

Figure 2 Interference resolution in the Sternberg working memory task: (a) a representative version of the task; (b) representative fMRI data. As shown in (a), during the task subjects maintain a set of four letters in working memory until a probe letter appears, at which point subjects indicate whether the probe is a member of the currently maintained set (positive probe) or is not a member of the current set (negative probe). Interference occurs when a probe is not a member of the current set, but is a member of the immediately preceding set (negative recent probe), relative to situations in which the probe is a member neither of the current set nor of the immediately preceding set (negative nonrecent probe). In (b), the fMRI data reveal greater activation during negative recent vs. negative nonrecent trials in the left mid-VLPFC (circled), reflecting that the presence of interference in working memory is accompanied by greater recruitment of the left mid-VLPFC. fMRI, functional magnetic resonance imaging; L, left; VLPFC, ventrolateral prefrontal cortex. restricted to the probe period of the trial, which is consistent with the fact that interference is a function of the probe's familiarity, and (2) when directly interrogating the DLPFC, a similar difference between negative recent and nonrecent trials is not typically observed, suggesting a specific role of the left mid-VLPFC in resolving interference in this task. Moreover, in a compelling study motivated by the aforementioned neuroimaging data, Thompson-Schill and colleagues showed that PFC patients with damage that spared the left VLPFC demonstrated interference effects that were comparable in magnitude to those in healthy controls, whereas one patient, R.C., with a focal lesion that damaged almost the entire extent of the left BA 45, exhibited an exacerbated interference effect despite relatively normal working memory performance when interference was minimal. Complementing these data, Postle and colleagues observed that when repetitive transcranial magnetic stimulation (TMS) – which transiently disrupts cortical function – was applied to the left VLPFC during the probe period in healthy humans there was a similar increase in susceptibility to interference to that seen in patient R.C. By contrast, TMS disruption of the primary motor, primary somatosensory, or supplemental motor area did not affect the ability to resolve interference in this task. Collectively, these data demonstrate that the left mid-VLPFC makes necessary contributions to resolving interference from currently irrelevant information in working memory. A leading hypothesis is that this region enables the selection of relevant active information over irrelevant active representations.

Left VLPFC and Declarative Memory Retrieval

Complementing the working memory literature implicating the left mid-VLPFC in resolving interference from recently activated but now irrelevant mnemonic representations are patient and imaging data that suggest that the left mid-VLPFC also supports selection during retrieval from declarative memory (i.e., semantic and episodic memory). For example, as already discussed, demands on interference resolution during semantic retrieval may be greater when available retrieval cues are unconstrained, and it is under these conditions that left PFC patients show impairments in generating semantic knowledge.

Such impairments may reflect an inability to select relevant representations from among competing alternatives.

Functional neuroimaging and focal lesion data converge on the left mid-VLPFC as being central for mediating the selection of relevant semantic representations. For example, in an influential functional magnetic resonance imaging (fMRI) study, Thompson-Schill and colleagues compared semantic processing under conditions that varied the demands placed on selection. Across several tasks, low-selection conditions were constructed such that they involved retrieving dominant, or prepotent, semantic information, whereas high-selection conditions involved retrieving nondominant semantic information from among competing representations. Significantly, the imaging data revealed that the left VLPFC (BAs 44 and 45) was consistently more active during the high-selection (vs. low-selection) conditions, demonstrating that this is a replicable characteristic of left mid-and/or posterior VLPFC function. Subsequent neuropsychological work by Thompson-Schill and colleagues revealed that it is the proportion of damage to this left VLPFC region, but not the gross lesion size, that strongly predicts the magnitude of behavioral impairment on high-selection semantic retrieval tasks.

Related data have increased the precision of our understanding of left mid-VLPFC function and its relation to the functions of the surrounding anterior and posterior VLPFC subregions. In particular, Badre and colleagues demonstrated that selection demands during semantic processing tasks are specifically associated with the same left mid-VLPFC subregion (BA 45; pars triangularis) that resolves interference in working memory tasks (**Figure 3(a)**). Moreover, these researchers observed a functional dissociation within the left VLPFC, indicating that the left mid-VLPFC supports selection from among active representations, whereas the more rostrally and ventrally situated left anterior VLPFC subregion (area 47/12; pars orbitalis) controls the retrieval of semantic representations stored in the lateral temporal cortical areas. This functional distinction between the left mid-VLPFC and anterior VLPFC appears replicable and generalizeable; Gold and colleagues reported a similar functional pattern using a lexical decision task – namely that the left anterior VLPFC was associated with controlled semantic retrieval and the left mid-VLPFC was associated with resolving interference from irrelevant active representations.

Evidence for functional segregation within the left VLPFC has also come from studies comparing semantic versus phonological control. For example, neuroimaging studies of phonological rehearsal and phonological analysis of stimuli have implicated the left posterior VLPFC (BA 44; pars opercularis), suggesting that this VLPFC subregion is critical for representing and maintaining phonological codes. On the other hand, neuroimaging studies of semantic retrieval and analysis of stimuli have implicated the left anterior VLPFC. Significantly, these dissociations between the left anterior and posterior VLPFC have been observed in studies that directly contrasted tasks that differentially depend on semantic and phonological control. Moreover, Devlin and colleagues have shown that TMS to the left anterior VLPFC differentially disrupts concurrent semantic processing, whereas TMS to the left posterior VLPFC differentially disrupts concurrent phonological processing, demonstrating that these subregions are necessary for distinct forms of control.

Functional distinctions between the left VLPFC subregions are also apparent during tasks that probe episodic memory. For example, Dobbins and colleagues observed that the left mid-VLPFC is associated with selecting between episodic details in the course of making a source judgment (**Figure 3(b)**), whereas the left anterior VLPFC is associated with semantically elaborating on the cues used to probe episodic memory. Further, during episodic encoding, Dolan, Fletcher, and colleagues demonstrated that left mid-VLPFC activity increases when prior learning interferes with to-be-encoded information (i.e., when the resolution of proactive interference is required). Collectively, these data suggest that the left mid-VLPFC contributes to the resolution of interference during all forms of declarative memory, whereas the left anterior VLPFC controls the retrieval of semantic knowledge that is not retrieved in an automatic (bottom-up) manner. Moreover, when considered along with the evidence that the left mid-VLPFC resolves interference within working memory, extant data favor the hypothesis that the left mid-VLPFC serves a domain-general role of resolving mnemonic interference.

Right VLPFC and the Control of Memory

We have thus far focused on how the left VLPFC contributes to interference resolution and other forms of cognitive control; however, it should be emphasized that the right VLPFC is sometimes coactive with the left VLPFC during tasks that require overcoming mnemonic conflict. Nevertheless, although the right VLPFC may support control functions that are conceptually analogous to those supported by the left VLPFC, it appears that (in the human) the right VLPFC at least partially differs from the left VLPFC in the domain of knowledge on which is operates. For example, Aron and colleagues, among others,

Figure 3 PFC contributions to the control of declarative memory: (a) a behavioral selection measure derived from performance during various semantic retrieval tasks; (b) the left mid-VLPFC during episodic retrieval; (c) the left anterior and right posterior VLPFC during episodic retrieval. In (a), the selection measure was exclusively associated with the magnitude of activation in the left mid-VLPFC (left). For example, this selection measure was tightly correlated with the magnitude of interference-related activation in the left mid-VLPFC during semantic retrieval (right). As shown in (b), during episodic retrieval, the left mid-VLPFC was differentially engaged when source details (conceptual or perceptual) were selectively retrieved, compared to simple item recognition. As shown in (c), during episodic retrieval, the left anterior VLPFC (1) was selectively engaged during recollection of conceptual source details, functionally coupling with the middle temporal cortex (2). By contrast, the right posterior VLPFC (3) was engaged during perceptual recollection and during recognition of familiar vs. novel objects, functionally coupling with the inferior temporal cortex (4). L, left; PFC, prefrontal cortex; VLPFC, ventrolateral prefrontal cortex. (a) Adapted from Badre D and Wagner AD (2005) Frontal lobe mechanisms that resolve proactive interference. *Cerebral Cortex* 15: 2003–2012. (b, c) Adapted from Dobbins IG and Wagner AD (2005) Domain-general and domain-sensitive prefrontal mechanisms for recollecting events and detecting novelty. *Cerebral Cortex* 15: 1768–1778.

reported that functional activation in the posterior aspect of the right VLPFC is consistently implicated in situations in which prepotent motor responses must be inhibited or when well-learned stimulus–response contingencies must be reconfigured. Moreover, these researchers demonstrated that when the right VLPFC is damaged, subjects display increased susceptibility to interference at the response level, highlighting the necessary contribution of this VLPFC subregion to response inhibition.

By contrast, other data indicate that the right VLPFC may contribute to the orienting of visual attention toward task-relevant object representations (and away from distracters). Significantly, with respect to the control of memory, this latter role of the right VLPFC in orienting to visuo-object representations has been observed in a number of mnemonic contexts, including discriminating novel from encountered visual objects, encoding faces and complex visual scenes into episodic memory, recollecting object–object associations, and recollecting perceptual details about previously encountered objects (Figure 3(c)). Thus, the extent to which the right VLPFC (as opposed to the left VLPFC) is engaged at least partially depends on the modality of the mnemonic representations attended, with the right VLPFC preferentially engaged during visuospatial processing and the left VLPFC engaged during phonological and semantic processing (Figure 3(c)). Significantly, although the right VLPFC has been implicated in visuo-object attention and in resolving competition at the response level, functional understanding of the subregions within the right VLPFC is not as well advanced as that of the homologous structures in the left VLPFC.

Concluding Comments

Interference resolution is a fundamental aspect of efficient mnemonic processing and may represent a principal way in which cognitive control interacts with memory. This interaction is critically enabled by control mechanisms that depend on the lateral PFC for their operation. This article focuses on the delineation of the mechanisms supported by the VLPFC, but it should be noted that the VLPFC must dynamically interact with the posterior neocortical association areas and with the MTL to implement the control of memory. Further, although VLPFC functions are clearly important for the resolution of mnemonic interference, the VLPFC also interacts with the DLPFC and frontopolar cortical areas that subserve other forms of cognitive control. Next we briefly illustrate each of these points.

To regulate memory-relevant processes, PFC control mechanisms must interact with systems that support or store long-term mnemonic representations. One line of evidence for such frontal-posterior interactions comes in the form of coactivations within functional neuroimaging studies. For example, fMRI studies of episodic remembering indicate that the left anterior VLPFC coactivates with the left middle temporal cortical areas that represent conceptual knowledge during controlled attempts to recollect such details about the past (Figure 3(c)). Analogously, the right VLPFC coactives with bilateral occipito-temporal areas that represent visuo-object form during attempts to recollect such details (Figure 3(c)). Moreover, as previously alluded to, lesions to the lateral PFC result in the failure to regulate processing in such posterior neocortical areas, demonstrating that the lateral PFC is necessary for gating the processing of distracting or interfering stimuli. Collectively, these data illustrate the top-down role of PFC control mechanisms in regulating perception, memory, and action.

With respect to cross-regional interactions within the PFC, it is important to emphasize that other structures in the DLPFC and frontopolar cortex are also often engaged in situations in which control must be implemented to accomplish a mnemonic goal. For example, DLPFC activation is frequently observed during complex working memory tasks, during attempts to remember past events, and during many tasks that require response selection or the resolution of response conflict. Although the specific nature of interactions between the DLPFC and VLPFC have yet to be well characterized, it is hypothesized that the DLPFC may operate at a higher stage in the processing hierarchy relative to the VLPFC, serving to perform operations on the products of VLPFC processing.

Thus, it is clear that the strategic control of memory is multifaceted. Future research promises to further illuminate how cognitive control emerges through lateral PFC function, allowing us to strategically wrest control of our memories, bringing them in line with current goals.

Stress and Cognition

Introduction

Prior to becoming part of our day-to-day conversations, the term 'stress' was used by engineers to explain forces that can put strain on a structure. For example, one could place strain on a piece of metal in such a way that it would break like glass when it reached its stress level. In 1936, Hans Selye borrowed the term of stress from the field of engineering and talked about stress as being a nonspecific phenomenon representing the intersection of symptoms produced by a wide variety of noxious agents. For many years, Selye tested various conditions (e.g., fasting, extreme cold, operative injuries, and drug administration) that would produce morphological changes in the body that were representative of a stress response, such as enlargement of the adrenal gland, atrophy of the thymus, and gastric ulceration. Selye's view of the concept of stress was that the determinants of the stress response are nonspecific, that is, many unspecific conditions can put strain on the organism and lead to disease, the same way that many unspecific conditions can put strain on a piece of metal and break it like glass.

Not all researchers agreed with Selye's model, particularly with the notion that the determinants of the stress response are nonspecific. The reason for this was simple. While Selye spent his entire career working on physical stressors (e.g., heat, cold, and pain), we all know that some of the worst stressors we encounter in life are psychological in nature, and are induced by our interpretation of events. For this reason, a psychologist named John Mason spent many years evaluating stress hormone levels in humans subjected to various conditions that he thought would be stressful, in order to describe the psychological characteristics that would make any condition stressful, to anyone exposed to it.

By summarizing the results of studies measuring the circulating levels of these hormones before and after individuals were exposed to various jobs or situations that were deemed to be stressful (e.g., air-traffic controllers or parachute jumping), Mason was able to describe three main psychological determinants that would induce a stress response in any individual exposed to them. Using this methodology, he showed that in order for a situation to induce a stress response from the body, it has to be interpreted as being novel, and/or unpredictable, and/or the individual must have the feeling that he/she does not have control over the situation. Although this work led to a general debate between Selye and Mason, further studies confirmed that the determinants of the stress response are highly specific, and therefore, potentially predictable and measurable. More recently, a meta-analysis of the determinants of psychological stress in human added the component of social evaluative threat as a fourth characteristic of a situation that is a potent inducer of a physiological stress response in humans.

The Relativity of Stress

From this short historical background, we can now define stress as being a threat, real or implied, to homeostasis. In this sense, stress can be absolute (a real threat induced by an earthquake in a town, leading to a significant stress response in every person facing this threat), or it can be relative (an implied threat induced by the interpretation of a situation as being novel, and/or unpredictable and/or uncontrollable – for example, a public speaking task).

Absolute stressors serve adaptive purposes and are those events or situations that will necessarily lead to a stress response in the majority (if not the totality) of individuals when they are first confronted with it. Being in or witnessing an accident, confronting a dangerous animal, and being submitted to extreme cold or heat are all examples of absolute stressors. These extreme and particular situations constitute absolute stressors in that, due to their aversive nature, a stress response has to be elicited for one's survival and/or well-being. In our western societies, absolute stressors are rare, but are nonetheless those that elicit the greatest physiological response and most vivid memories. Conversely, relative stressors are those events or situations that will elicit a stress response only in a certain proportion of individuals. Moreover, this response may be mild or large. For example, having to unexpectedly deliver a speech may be very stressful for a given individual, and not at all for another. Consequently, large inter-individual variations in the stress response to psychological challenges have been frequently reported.

The stressor is the event itself, such as the earthquake in the case of the absolute stress, or the public speech in the case of the relative stress. The stress response is the body's reaction to the event, and it is this body's response to stress that is the foundation for the studies that determine the impact of stress on cognitive function. The reason for this is that the

stress hormones that are secreted in response to an absolute or relative stress, and particularly the glucocorticoids, are steroids that can easily cross the blood–brain barrier and access the brain, where they can influence learning and memory by binding to glucocorticoid receptors (GRs) localized in various brain regions known to be involved in learning and memory.

Stress Hormones

When a situation is interpreted as being stressful, it triggers the activation of the hypothalamic–pituitary–adrenal (HPA) axis whereby neurons in the hypothalamus, a brain structure often termed the 'master gland,' releases a hormone called corticotropin-releasing factor (CRF). The release of CRF triggers the subsequent secretion and release of another hormone called adrenocorticotropin (ACTH) from the pituitary gland, also located in the brain. When ACTH is secreted by the pituitary gland, it travels in the blood and reaches the adrenal glands, which are located above the kidneys, and triggers secretion of the so-called stress hormones. There are two main stress hormones, the glucocorticoids (called corticosterone in animals, and cortisol in humans) and the catecholamines (epinephrine and norepinephrine). The acute secretion of glucocorticoids and catecholamines in response to a stressor constitutes the primary mediators in the chain of hormonal events triggered in response to stress. When these two hormones are secreted in response to stress, they act on the body to give rise to the fight-or-flight response whereby one would, for instance, experience an increase in heart rate and blood pressure.

Glucocorticoids have a variety of different effects in target systems throughout the organism, which can be summarized as aiming to increase the availability of energy substrates in different parts of the body, and allow for optimal adaptation to changing demands of the environment. While the activation of the HPA axis can be regarded as a basic adaptive mechanism in response to change, prolonged activation of this system presents a health risk to the organism. The highly catabolic glucocorticoids antagonize insulin and increase blood pressure, thus increasing the risk for developing diabetes, hypertension, and arterial disease. Also, growth and tissue repair are impaired. Furthermore, activation of the HPA axis suppresses immune functions, which in a chronic state can be considered harmful for the organism, since it is associated with increased risk of infection.

Given their liposoluble characteristics, the glucocorticoids can easily cross the blood–brain barrier and access the brain where they bind to receptors. Three of the most important brain areas containing GRs are the hippocampus, amygdala, and frontal lobes, which are brain structures known to be involved in learning and memory. Although epinephrine does not readily access the brain due to absence of lipophilic properties, it can still act on the brain through its action on the sensory vagus outside of the blood–brain barrier, with information transmitted into the brain via the nucleus of the solitary tract. The most important brain area containing adrenergic receptors is the amygdala, which has been shown to play an important role in fear processing and memory for emotionally relevant information.

Important Characteristics of Glucocorticoids

Under basal conditions, glucocorticoid secretion exhibits a 24-h circadian profile in which glucocorticoid concentrations present a morning maximum in humans (the circadian peak), and slowly declining levels in the late afternoon, evening, and nocturnal period (the circadian trough), and an abrupt elevation after the first few hours of sleep. Circulating glucocorticoids bind with high affinity to two receptor subtypes, the mineralocorticoid receptor (MR or type I) and GR or type II.

Although both receptor types have been implicated in mediating glucocorticoid feedback effects, there are two major differences between MR and GR receptors. First, MRs bind glucocorticoids with an affinity that is about 6–10 times higher than that of GRs. This differential affinity results in a striking difference in occupation of the two receptor types under different conditions and time of day. Thus, during the circadian trough (the p.m. phase in humans and the a.m. phase in rats), the endogenous hormone occupies more than 90% of MRs, but only 10% of GRs. However, during stress and/or the circadian peak of glucocorticoid secretion (the a.m. phase in humans and the p.m. phase in rats), MRs are saturated, and there is occupation of approximately 67–74% of GRs.

The second major difference between these two receptor types is related to their distribution in the brain. The MR is exclusively present in the limbic system, with a preferential distribution in the hippocampus, parahippocampal gyrus, entorhinal, and insular cortices. On the contrary, the GR is present in both subcortical (paraventricular nucleus and other hypothalamic nuclei, the hippocampus, and parahippocampal gyrus) and cortical structures, with a preferential distribution in the prefrontal cortex. As we will see in the following sections, the impact of glucocorticoids on cognitive function can be best understood in terms of the differential effects of MR and GR activation.

Positive Effects of the Stress Response on Cognition

Because of their actions on brain structures known to be involved in fear detection and memory for emotionally relevant information, the stress hormones enhance the formation of the so-called 'flashbulb memories' of events related with strong emotions that are usually associated with an absolute stress. This process involves the amygdala, and the pathway for encoding these memories involves the interaction between neurotransmitters in the amygdala and in related brain areas such as the hippocampus, along with circulating levels of catecholamines and glucocorticoids. The importance of the stress hormones on memory for emotionally relevant information has been recently confirmed by studies in which blockade of either glucocorticoid or norepinephrine activity impaired the recall of emotionally relevant information. Consequently, secretion of these primary stress mediators is necessary for the adequate encoding of emotionally relevant information during an absolute stress. This enhancement of memory for stimuli inducing stressful and/or emotional responses may be essential for species' survival.

At the same time as the brain encodes information and controls the behavioral responses to stress, it is also changed structurally and chemically by those experiences. Although for a long time it was thought that the brain of adult mammals does not generate new nerve cells, more recent evidence showed that neurons are born in the adult mammalian brain. Interestingly, in the adult brain, the generation of new neurons (called neurogenesis) occurs in two regions. The first region is the subventricular zone in the wall of the lateral ventricle, where new interneurons are generated for the olfactory bulb, and the second region is the subgranular zone of the dentate gyrus of the hippocampus, which gives rise to the granule cells. Recent evidence show that adult neurogenesis in the dentate gyrus of the hippocampus is a feature of all mammalian species, occurring in rats, mice, tree shrews, marmosets, macaques, and humans. Although the functional significance of hippocampal neurogenesis has been questioned in the past, a study reported that neurogenesis in the adult is involved in the formation of trace memories, suggesting that the new neurons actually contribute to the function of the adult brain.

Comparative studies of different species show that hippocampal volume is increased in mammalian and avian species that depend critically on spatial memory for survival. Examples of such critical memory skills involve home-range navigation, migration, brood parasitism, and memory-based cache recovery in birds that hide food. This association between performance of spatial tasks and hippocampal size can be explained in terms of the impact of environmental demands (stress) on hippocampal volume, rather than the converse. For example, it has been reported that the hippocampus of titmice and chickadees increases in volume in association with the experience of storing and recovering food cache. This result shows that in animals, there can be an experience-dependent hippocampal growth that occurs at a relatively late stage in development. Similar results of experience-based changes in hippocampal volumes have been reported in humans. Maguire and collaborators tested the hypothesis that the ability of taxi cab drivers to navigate to a specific destination correlates with hippocampal volume. They showed that compared to age-matched controls, the taxi drivers had larger posterior hippocampi. Although these results surely do not confirm that the experience of driving a taxi in the complex streets of London has a significant effect on hippocampal volumes, they nonetheless raise the intriguing possibility of hippocampal plasticity in response to environmental demands.

Negative Effects of the Stress Response on Cognition

While short-term responses of the brain to novel and potentially threatening situations may be adaptive and result in new learning and acquired behavioral strategies for coping, as may be the case for absolute stress, repeated stress can cause both cognitive impairments and structural changes in the hippocampus. These processes may be occurring somewhat independently of each other and contribute in various degrees to different pathophysiological situations involving traumatic stress, depression, or aging.

The cognitive effects of long-term elevations of glucocorticoids in human populations have been studied in disorders affecting glucocorticoid levels and using exogenous administration of the synthetic compound to healthy subjects. Mental disturbances mimicking mild dementia (such as decrements in simple and complex attentional tasks, verbal and visual memory, encoding, storage and retrieval) have been described in depressed patients with hypercortisolism, and in steroid psychosis following glucocorticoid treatment. Similar cognitive deficits are also reported in patients suffering from Cushing's disease, a medical condition in which endogenous levels of glucocorticoids are chronically elevated. During human aging, a significant proportion of elderly individuals present an endogenous increase of glucocorticoid levels, and this increase has been related to impaired memory performance.

Chronic exposure to stress has also been shown to be associated with structural changes of the hippocampus. For example, treatment of adult rats with corticosterone decreases the proliferation of granule cell precursors, while removal of adrenal steroids stimulates the generation of new granule neurons. Given the suppressive actions of glucocorticoids on hippocampal neurogenesis, stressful experiences have been suggested to inhibit cell proliferation in adulthood, a hypothesis that has been demonstrated. Long-term stressful experience decreases the number of adult-generated neurons in the dentate gyrus in various species, including the rat, tree shrew, and marmoset. In a similar vein, repeated stress also produces prolonged suppression of cell proliferation in the dentate gyrus of the adult tree shrew. Stress-induced decreases in dentate gyrus cell proliferation could also contribute, in line with atrophy of the pyramidal cells of the hippocampus, to changes in hippocampal volumes observed after chronic exposure to stress.

Smaller hippocampal volumes associated with chronic elevations of glucocorticoids have also been reported in humans. Over the past two decades, many studies revealed the presence of smaller hippocampal volumes in various psychiatric disorders such as depression, posttraumatic stress disorder, and schizophrenia, all of which involve glucocorticoid level dysregulations. Hippocampal atrophy associated with chronic exposure to high levels of glucocorticoids is also reported in Cushing's patients and in elderly individuals. A recent study of Cushing's patients revealed that surgical treatment of hypercortisolism in these patients leads to a reversal of the glucocorticoid-induced hippocampal atrophy reported to occur in this population, with an average volume increase of 3.2%, and variations up to 10% in some patients. This is a significant finding since it implies the possibility of functional reorganization of the hippocampus, once the chronic stress has been taken away. Reversibility and/or preventability of such atrophy are major topics for future research, as is the implication of such treatment for cognitive function.

Positive Effects Meeting Negative Effects: The Inverted-U Shape Function

There is a great paradox in the field of stress research that relates to the fact that stress hormones are sometimes associated with positive effects and sometimes associated with negative effects on cognition. This apparent discrepancy in the data can be explained by the fact that in both animals and humans, many studies reveal the presence of an inverted-U shape function between circulating stress hormone levels and memory performance, so that up to an optimal level, glucocorticoids can enhance cognitive performance, while above this optimal level, glucocorticoids impair cognitive performance. A model has been developed and suggests the presence of an inverted-U shape function between circulating levels of glucocorticoids and cognitive performance (**Figure 1**). More importantly, this model is based on the two types of GRs found in the brain.

Remember that given their differential affinity for glucocorticoids, the MRs will always be almost saturated (100% activated) before the GRs can start to be activated. During periods of stress or high levels of glucocorticoids (the a.m. phase in humans), both MRs and GRs will thus be saturated. Many studies performed in rodents have reported that the ratio of MR/GR occupation is a major determinant of the direction of glucocorticoid-induced cognitive changes. For example, long-term potentiation (LTP), a proposed neurobiological substrate of memory formation, has been shown to be optimal when glucocorticoid levels are mildly elevated, that is, when the ratio of MR/GR occupation is high. In contrast, significant decreases in LTP are observed after adrenalectomy, when MR occupancy is very low, or after exogenous administration of synthetic glucocorticoids, which activate GRs and deplete cortisol, again resulting in low occupancy of MRs.

Some authors have reinterpreted the well-known inverted-U shape function between circulating levels of glucocorticoids and cognitive performance, in line with the MR/GR ratio hypothesis. In this view, cognitive function can be enhanced when most of the MRs and only part of the GRs are activated (top of the inverted-U shape function; increased MR/GR ratio). However, when circulating levels of glucocorticoids are significantly decreased or increased (extremes of the inverted-U shape function; low MR/GR ratio), cognitive impairments will result. The authors suggested that the negative view of glucocorticoid actions on human cognitive function could be partly explained by limitations in previous human experimental designs, which did not allow differential manipulation of MR and GR levels. In order to do this, such studies should measure cognitive function when glucocorticoid occupancy is decreased (rather than increased), thus allowing functional measures of MR/GR occupancy on learning and memory.

Recent studies have tested this hypothesis and confirmed it. A first study measured whether memory performance in young, normal adults can be modulated by a hormone removal–replacement protocol in which one pharmacologically manipulates circulating levels of cortisol and measures subsequent memory performance. In this protocol, the authors used a

Figure 1 Schematic representation of the stress response and its impact on cognition. First, perception of an absolute or relative stressor triggers the secretion of corticotropin-releasing factor (CRF) by the hypothalamus, which then acts on the pituitary gland to induce secretion of adrenocorticotropin (ACTH). ACTH travels in the bloodstream and reaches the adrenal gland located on top of the kidneys and induces secretion of glucocorticoids. Because of their liposoluble properties, glucocorticoids easily cross the blood–brain barrier where they act on the hypothalamus and pituitary gland to shut down further secretion of CRF and ACTH, and they also access various brain regions where two types of glucocorticoid receptors (GRs) are located. The mineralocorticoid receptor (MR) has an affinity that is 6 to 10 times higher than that of the GR. Consequently, it has been proposed that the inverted-U shape function that relates circulating levels of glucocorticoids and memory performance is best explained by the differential activation of MR and GR receptors at different circulating levels of glucocorticoids. Low circulating levels of glucocorticoids mostly activate MRs and this is thought to be associated with the positive (left side of the inverted-U shape function) effects of glucocorticoids. In contrast, high circulating levels of glucocorticoids saturate MR and activate and/or saturate GRs (depending on the magnitude of the glucocorticoid increase) and this activation of MR and GR is thought to be associated with the impairing (right side of the inverted-U shape function) effects of glucocorticoids on cognition.

within-subject double-blind experimental protocol in which they first induced a chemical lowering of glucocorticoid levels by administration of metyrapone, a potent inhibitor of glucocorticoid synthesis, and then restored baseline circulating glucocorticoid levels with subsequent infusion of hydrocortisone. Memory performance of participants under each of these conditions was compared to that measured on a placebo day. The results showed that the metyrapone treatment significantly impaired memory, while hydrocortisone replacement restored performance at placebo level.

In a second study, the authors took advantage of the circadian variation in circulating levels of glucocorticoids and tested the impact of a bolus injection of 35 mg of hydrocortisone on memory performance in the afternoon. The idea behind this experiment was to test the impact of hydrocortisone in the late afternoon, at a time of very low cortisol concentrations, that is, at a time of low MR/GR ratio. It was postulated that if the ratio of MR/GR activation is involved in glucocorticoid-induced memory changes, administration of hydrocortisone in the late afternoon should increase the MR/GR ratio, and lead to increased memory performance when compared to placebo. The results confirmed the hypothesis, as it was shown that administration of hydrocortisone in the afternoon led to significantly faster detection times on the memory test when compared to administration of placebo.

In a third study, authors took advantage of the circadian variation in circulating levels of glucocorticoids and tested memory performance after exposure to a psychological stressor in participants who were stressed in the a.m. or p.m. phase. Here, the authors added a new variable in the protocol, and tested the potential differential impact of MR and GR activation on recall of neutral versus emotional information.

Young, normal adults were submitted to a psychological stress task before viewing a story composed of emotionally negative and neutral segments, and memory performance was assessed by a 1-week postlearning delayed recall. Results show that stress-induced increases in salivary glucocorticoid levels impaired delayed recall of emotionally arousing material in the a.m. group, but not in the p.m. group. There was no effect of stress on memory for neutral material. Altogether, these findings suggest that stressing participants in the a.m. phase, at a time of high circulating levels of corticosteroids, can overstimulate MR and GR receptors in the brain, impairing declarative memory for emotionally arousing material unrelated to the stressor. These findings suggest that the experimental context, that is, time of day at which the experiment occurs, the nature of the to-be-remembered material (remembering the stressful event itself or material unrelated to the stressor), and the valence of the to-be-remembered material (emotionally arousing vs. neutral), modulates the effects of stress on human memory.

Conclusion

After two centuries of research on the effects of glucocorticoids on human cognitive function, we have come to view the actions of this steroid as being modulatory rather than direct. History has taught us two important things. First, these steroids could access the brain and lead to changes in cognitive function. Second, glucocorticoids' action on cognitive process can be positive, and that the positive or negative effects of glucocorticoids depend on the balance of the two GR types known to exist today.

The story was supposed to become simpler as new discoveries were being made about the actions of glucocorticoids on the animal and human brains. Yet, it became more complex, dynamic, and difficult to grasp. Indeed, we now suspect that important variables related to the testing environment itself can have an important impact on the stress response and, consequently, can predict its impact on cognitive performance. Here, time of day, the valence, and the nature of the information to be learned were summarized as examples of the types of variables that have to be controlled when assessing the effects of glucocorticoids on cognition in humans, since these factors have been shown to impact on either the stress response itself and/or its effect on cognitive performance in humans populations. However, as complex as the story will get, it tells us that the glucocorticoid hormone is a very important player in the interface between the brain and the environment. This renders the study of its action more exciting than ever.

Stress and Neural Involvement in Metabolism

Stress

Stress was defined by Day in 2005 as "the multisystem response of the body to challenges that overwhelm or threaten to overwhelm the selective homeostatic mechanisms of the organism." This definition incorporates both Cannon's notion of homeostasis, an active defense of important body system variables, and Selye's original notion of stress, the body's nonspecific response to challenge. With such challenges there are immediate behavioral, autonomic, and neuroendocrine responses that appear to be have been designed to deal with the stressor, as effectively as possible. These occur through ensuring adequate muscular perfusion and tone, as well as energy supplies, particularly glucose and free fatty acids (FFAs), to support behavioral responses, whether escape, aggression, thermoregulation, or food intake. The multisystem response outputs are represented by the autonomic nervous system, including the adrenal medulla, which secretes catecholamines, and the adrenal cortex, which secretes glucocorticoids (GCs).

Thresholds

Day's definition of stress requires that the eliciting challenge must be of sufficiently high intensity so that discrete system-specific mechanisms are predicted to be, or are, inadequate to maintain homeostasis. Thresholds for responses of the stress systems are usually well beyond those that provoke specific responses, underlining this definition of stress. For example, with experience, a psychological threat that is introduced under conditions that allow behavioral escape does not cause a stress response, whereas the same stimulus administered under conditions that prevent escape does provoke elevated GCs. Similarly, experimentally induced decreases in blood volume, blood oxygen content, or blood glucose produce highly specific responses in the cardiovascular, respiratory, and glucose-regulating systems at initial steps, whereas at values beyond the threshold the same stimuli produce dose-related increases in catecholaminergic and glucocorticoid responses (Figure 1).The threshold for increasing autonomic outflow, however, is frequently different from that for glucocorticoid secretion. It is the brain stress response network, driven by corticotropin-releasing factor (CRF), that coordinates these multisystem responses to high intensity or persistent stressors.

CRF Stress Network

Clusters of cells that can express CRF are present in brain. Under conditions of stress and elevated GCs, CRF is induced in these neurons and at other sites in adults. Moreover, in adults that were stressed as neonates, these CRF cell groups appear to be permanently induced. In addition, CRF receptors (CRFRs) are found throughout the brain and play a key role in the multisystem responses to stress. The cluster of cells in the central nuclei of the amygdala (CeA) seems to be critical in the coordination of responses that alter activity of CRF-expressing cells in the bed nuclei of the stria terminalis as well as in the autonomic- and neuroendocrine-directed axons of cells in the hypothalamic paraventricular nuclei (PVN). Output from the CeA impinges directly on autonomic outflow from the lateral hypothalamus (LH), and indirectly on the hypothalamic PVN. Brain pretreatment with CRFR-1 antagonists diminishes or blocks many behavioral, autonomic, and neuroendocrine responses to stimuli that normally induce stress.

A single, punctate stimulus sufficient to engage the central stress network seems to have few long-term effects on the brain or metabolism. By contrast, very high-intensity single stimuli, or repeated or prolonged stimuli that sustain activity in the central stress network, may have considerable effects because of the persistent elevation in GCs and activity of CRF neurons that, in turn, interact with all monoaminergic cell groups to alter secretion of the monoamines throughout the brain, thus both sustaining and amplifying the initial effects of adequate stimuli.

In the following sections, we first discuss the metabolic consequences of increased activity in the central stress circuit – with respect to actions of GCs and the autonomic nervous system, including adrenal medullary secretion – on energy balance. Then we discuss some of the consequences of the autonomic and GC responses on the brain. Finally, we discuss the utility of these responses, both in the light of their evolutionary value and in the context of current, developed Western societies.

Stress Responses and Metabolism

The initial autonomic and endocrine responses to adequate stressors serve to maintain concentrations of critical fuels in the circulation for sustained use by the brain, heart, and exercising skeletal muscle.

Figure 1 There are thresholds at which multisystem responses of the stress network occur (ACTH, adrenocorticotropic hormone). Below threshold, specific systems are capable of maintaining homeostasis. When stress responses occur, they are proportional to the magnitude of the insult.

Energy is stored in the body as glycogen, lipid, and protein, all of which are mobilized through actions of the autonomic nervous system and GCs in response to increased activity of the central stress response network. Thus, in the periphery, the multisystem stress responses are highly catabolic, resulting in loss of energy stores and body weight. Responses to sympathetic neural and adrenal medullary activation are rapid, and within minutes cells release preformed energy that is stored as glycogen and lipid. By contrast, most peripheral actions of the GCs are slower, increasing the rate of supply of glucose and FFAs into the vascular system by increasing the synthesis and activities of critical cellular enzymes.

Stress and Autonomic Outflow Pathways

Much of our knowledge of central autonomic pattern generators has come from the use of viral transneuronal tracer studies, in which the target innervated organ is injected with pseudorabies virus (PRV), and retrograde transport of the virus is determined over time. Using this technique, and others, a relatively small number of cell groups are seen to be directly involved in autonomic outflow from the hypothalamus to the innervated tissue. Because the live virus can replicate in cell bodies and then infect the axons afferent to the cell body, with the appropriate controls, synaptic chains of neurons can be distinguished over time after injection of virus into a specific organ. Virus is identified in the first-stage efferent sympathetic and parasympathetic cell groups in the spinal cord and medulla, as are neuronal retrograde tracers that cannot go beyond a single cell. Adrenergic neurons in C1 in the ventrolateral medulla, the medullary raphe nuclei, and adjacent medulla; the A5 group of noradrenergic neurons in the ventrolateral pons; and cells in the paraventricular nucleus and adjacent LH are filled with virus with increasing time after injections into a variety of organs; these structures are all part of the autonomic output limb of the central stress network. Although there are only a few cell groups that generally serve to supply autonomic outflow, both sympathetic outflow and parasympathetic outflow are highly selective, so that control can be manipulated organ by organ. In the PVN, for instance, there is a rough topographic relationship between the laterality of the virus-infected neurons and the body organ injected.

Stress and Secretion of GCs

The multisystem response to adequate stimuli, whether physical or psychological, involves activation of the hypothalamic–pituitary–adrenal (HPA) axis and, consequently, stimulation of the synthesis and release of GCs from the adrenal cortex. This response acts to prevent or reduce deleterious changes in essential homeostatic systems. Although metabolic changes are the focus here, it should be recognized that GCs also have major effects on the immune, cardiovascular, gastrointestinal, and skeletal systems as well. In the hypothalamus, major cell groups are heavily involved with integration inputs from stimuli and outputs through

the behavioral, autonomic, and neuroendocrine motor systems. These heavily interconnected cell groups have been designated the hypothalamic visceromotor pattern generators (HVPGs) by Thompson and Swanson. The dorsomedial hypothalamic (DMH) nuclei appear to be the dominant cell group of this network. Blockade of activity in the DMH eliminates or greatly reduces both HPA and autonomic responses to many stimuli.

The motor neurohormones involved in the HPA axis are CRF and arginine vasopressin (AVP). CRF is synthesized by neurons in the parvocellular region of the paraventricular nucleus. When activated, these neurons, which project into the median eminence, secrete CRF and this diffuses into the hypophyseal portal system to promote the release of adrenocorticotropic hormone (ACTH) from the corticotropes of the anterior pituitary. AVP is also expressed in the CRF-containing cells in the PVN and synergizes with the stimulatory actions of CRF at the level of the corticotrope. Secreted ACTH then acts at the adrenal gland to stimulate the rate of processing of cholesterol to pregnenolone, the rate-limiting step of GC synthesis, and this results in elevated circulating levels of cortisol (humans) or corticosterone (rodents).

GC Feedback

Activity of the HPA axis is tightly regulated through complex negative feedback and positive, feed-forward loops that restore circulating GC concentrations to those appropriate to the ongoing physiology of the organism. Negative feedback shows three temporally discrete domains: fast, early delayed, and late delayed feedback. Fast feedback occurs within the first few minutes of the stress response and appears to be nongenomic in nature, possibly involving the endocannabinoids. Early delayed feedback appears after 30 min and is usually maximal after 2 h postexposure, though the effect can persist for up to 24 h. This type of feedback critically requires *de novo* generation of second messengers to inhibit the release of CRF/AVP and ACTH. Thus, the duration of ACTH secreted in response to a punctate stimulus is limited by the GC negative feedback system. Late, delayed feedback is found when supraphysiological levels of GCs have persisted for days or even weeks, as in treatment with exogenous steroids or with Cushing's disease. This time domain is characterized by inhibition of CRF, AVP, and ACTH synthesis and release, and adrenal atrophy; recovery from chronic elevations in exogenously administered GC is very slow. But, with chronic stress, elevations in GC positively regulate recruited CRF neurons in the amygdala to stimulate further activity in the HPA axis. Thus, there are major distinctions between the chronic effects of GC that depend on whether the central stress network is engaged.

Stress and Maintenance of Blood Glucose

Stress has important effects on carbohydrate metabolism, affecting the synthesis, storage, and release of glucose, as well as the release and action of key regulators, notably insulin (Figure 2). Critical to this is the GC-induced development of insulin resistance, which is a consequence of the reduced action of insulin in target tissues (such as liver, adipose tissue, and muscle). The acute consequence of insulin resistance is much slower glucose removal from blood into insulin-sensitive tissues, and thus higher circulating glucose concentrations.

Liver

The liver is key to establishing blood glucose concentrations by maintaining a balance between the uptake and storage of glucose as glycogen (glycogenesis) and the synthesis and release of glucose (gluconeogenesis and glycogenolysis); the former is opposed by the process of glycolysis. There are several key regulatory enzymes involved in these processes and these form substrate cycles, in which cycling between the substrates and products of the enzymes occur. These cycles form a system in which the rate and direction of flux can be finely regulated.The enzymes specific for gluconeogenesis – phosphoenolpyruvate carboxykinase (PEPCK), fructose 1, 6-bisphosphatase, and glucose-6-phosphatase (G-6-Pase) – and for glycolysis – pyruvate kinase, 6-phosphofructo-1-kinase, and glucokinase – make sensitive control possible. Glucose homeostasis is usually controlled by insulin and the insulin-like growth factors. Increased activity of the brain CRF stress network stimulates sympathetic and HPA activity. GCs oppose the actions of insulin and promote gluconeogenesis. The net outcome of GC action on the liver is an increase in hepatic glucose output. Consequently, greater amounts of insulin are required to reduce glucose release from the liver. Treatment with exogenous GCs increases plasma insulin concentrations in relation to the dose of steroid given, and insulin secretion may increase markedly. The catecholamines (epinephrine and norepinephrine) rapidly stimulate glycogenolysis and the release of glucose into the circulation.

Prevailing Glucose Levels Are Also Influenced by Adipose Tissue

Glucose enters the adipocyte via glucose transporters, GLUT1 and GLUT4, in adipose tissue. Most of the

Figure 2 Multisystem stress response on metabolism mediated by the sympathetic nervous system (SNS) and HPA axis. PEPCK, phosphoenolpyruvate carboxykinase; G-6-Pase, glucose-6-phosphatase; HSL, hormone-sensitive lipase; LPL, lipoprotein lipase; GCs, glucocorticoids; GLUT, glucose transporter; FFA, free fatty acid.

glucose is metabolized to lactate or used as glycerol for subsequent conversion to triglycerides. Insulin promotes translocation of GLUT4 to the plasma membrane, thus facilitating glucose uptake. This action is antagonized by GCs. Similar GC-induced dysregulation of GLUT4 translocation also occurs in muscle. As in liver, catecholamines stimulate glycogenolysis in muscle; the glucose-6-phosphate generated is used by muscle for energy. Importantly, however, the amount of lactate released by muscle increases with increasing exercise. This lactate can be used by brain for energy in addition to the energy supplied by glucose.

GCs and catecholamines (acting via α-adrenergic receptors) also reduce insulin secretion from pancreatic beta cells in experimental animals and reduce the frequency of insulin release in fasted humans. However, this action is always modified by the circulating glucose concentrations, which must be controlled by insulin. Thus, at any given steady-state concentration of GC, the higher the GC concentration, the higher the insulin concentration will be, despite the fact that persistent stress reduces overall insulin concentrations. As with the HPA axis, long-term treatment with exogenous GCs inhibits sympathetic nervous system (SNS) outflow; however, when chronically elevated GCs are accompanied by a chronic stressor, SNS outflow is increased. Thus, the response to GCs in both systems depends entirely on whether an adequate stressor has recruited the central stress network and CRF.

Stress and Lipid Metabolism

White Adipose Tissue

White adipose tissue (WAT) cells are composed primarily of stored lipid; about 90% of the cell volume consists of a lipid droplet. Lipids are removed from the circulation through the action of lipoprotein lipase (LPL), which releases triacyl fatty acids from their complexes with phosphoprotein moieties of lipoproteins that allow them to circulate in watery solution (Figure 2). LPL is found in high density on capillary endothelia and its concentration and activity are increased by GCs and insulin, and its activity is (probably indirectly) inhibited through the actions of catecholamines on cytokines produced in WAT. Thus, when GC and insulin are elevated but sympathetic neural outflow is low, as in conditions of exogenous GC treatment, fatty acids from gut- and liver-generated lipoproteins can be readily stored in WAT. In adipocytes, the activity of the major fatty acid-mobilizing

enzyme, hormone-sensitive lipase (HSL), is also regulated by insulin, GCs, and the catecholamines. However, the degree of regulation is highly depot dependent, and intraabdominal fat stores that provide FFAs and glycerol via the portal vein directly to the liver appear to be the stores that are most sensitive to regulation by the central CRF stress network.

Brown Adipose Tissue

Specialized fat depots having cells with large numbers of mitochondria containing uncoupling protein-1 (UCP-1) is called brown adipose tissue (BAT); UCP-1 mediates an outward proton leak, resulting in nonshivering thermogenesis. BAT is present in small mammals and human newborns, but not adult humans, and is heavily innervated by sympathetic neural outflow. BAT has been studied in rodents as a model for the hypothalamic regulation of thermogenesis. Because much less is known about the central nervous system (CNS) regulation of the sympathetic outflow to WAT, and because many of the hypothalamic neurons that regulate BAT activity probably also regulate WAT activity, the neural regulation of BAT is addressed here.

Central Stress Network and BAT Function

CRF administered into the brain increases SNS outflow and affects blood pressure, heart rate, gastric acid secretion, and intestinal motility, in addition to causing alterations in lipid metabolism. Chronic intracerebroventricular (icv) infusions of CRF increase blood glucose, sympathetic neural outflow to interscapular BAT (iBAT), UCP-1 in iBAT, iBAT nonshivering thermogenesis, and catecholamine and FFA release from adipose tissue depots. Increased sympathetic neural outflow is directly responsible for the increase in thermogenesis that develops after icv injections of CRF; when neural drive to BAT persists, negative energy balance and weight loss result.

Central Hypothalamic Outputs to BAT

Viral transneuronal tract tracing confirms that neurons in the hypothalamic dorsomedial nucleus (DMN), PVN, and medial preoptic area (MPOA) contain multisynaptic connections to both WAT and BAT. The role of CRF on SNS drive is supported by several lines of evidence that focus on the hypothalamus as a major site for coordinating thermoregulation through its actions on downstream sympathetic premotor ganglion neurons (SPGNs) (Figure 3). CRF-synthesizing neurons, probably in the PVN, bed nucleus of the stria terminalis (BNST), and amygdala, seem to be responsible for stress-induced alterations in SNS outflow to iBAT. Recent studies show that direct injection of CRF into the DMH or the MPOA results in increased SNS outflow to iBAT. Inhibition of DMH activity blocks iBAT activation after injections of CRF into the MPOA, and inhibition of activity in neurons of the pontine anterior nucleus raphe pallidus blocks the stimulatory effects of CRF injected into the DMH. Therefore, in the sympathetic regulation of iBAT thermogenesis, CRF inputs into the hypothalamic MPOA and into the DMH stimulate output from raphe pallidus to the SPGNs in the spinal cord and thus regulate the activity of iBAT. It is likely that similar autonomic output pathways exist for the control of lipolysis in WAT.

Stress and Protein Metabolism

Because stress couples increased autonomic neural and HPA outflows, a typical result of chronic stress is loss of muscle protein mass. Although the amount of initial fat mass determines the amount of protein lost with stress, there is always some protein loss. Protein is degraded to amino acids, which enter the circulation and are taken up and used by liver for gluconeogenesis (Figure 2).

GC treatment of experimental animals causes loss of muscle protein associated with a reduction in the protein synthesis rate. In addition, increased protein breakdown rates have also been reported. Key to the nature of the loss of protein with GC treatment appears to be age, with a shift from GC-induced muscle protein breakdown to GC-induced reduction in muscle protein synthesis with advancing age. This has also been observed both in patients with Cushing's syndrome, who exhibit marked muscle wasting that results in profound weakness, and after intensive cortisol administration for a number of clinical conditions.

Stress and Body Weight

In male rodents, which grow throughout young adulthood, the administration of chronic or repeated stressors characteristically results in decreased chow intake and increased metabolic rate (both probably mediated by the central CRF stress response network); both responses combine to yield decreased rates of ponderal growth. Stressors result in loss of peripheral fat and protein and, with high levels of SNS outflow and GCs (and relatively high insulin levels), reallocation of energy storage into central fat depots. In part, this also occurs because the stress response inhibits the normal ongoing anabolic activity provided by both the growth hormone and gonadal axes – again, probably through central actions of CRF.

Figure 3 Corticotropin-releasing factor (CRF), via intracerebroventricular (icv) administration or into the medial preoptic area (MPOA – hypothalamic visceromotor pattern generator, HVPG) or dorsomedial nuclei (DMN), but not paraventricular nuclei (PVN), stimulates central SNS outflow to brown adipose tissue (BAT) and thermogenesis. This set of outputs mediating heat generation may be common for the central stress network that results in increased BAT activity seen after exposure to many stressors. CeA, central nuclei of the amygdala; BNST, bed nucleus of the stria terminalis; EEA, excitatory amino acid; ACTH, adrenocorticotropic hormone; SPGN, sympathetic premotor ganglion neuron.

Consequences of Stress-Induced Elevations of GCs and Catecholamines on the Brain

In addition to the actions of GCs and catecholamines on peripheral tissue targets, the brain is also a target for both of these stress response hormones. And both have actions in the processes of learning and memory: GCs markedly facilitate both search and aggressive behaviors as well as the preferential intake of calories from highly palatable sweet or fat foods. The latter effects appear to be mediated by association of GCs with relatively low-affinity glucocorticoid receptors, thus requiring high circulating concentrations of the steroid.

Learning and Memory

Catecholamines and GCs secreted during stress act through cells in the basolateral amygdala (BLA) to consolidate memories of events that are accompanied by emotional arousal. Although elevated circulating catecholamine concentrations do not enter the brain, they probably act through vagal afferent nerves to stimulate catecholamine secretion from the A2 cell group in the nucleus of the tractus solitarius, and/or from the A6 cell group in the locus coeruleus. Axons from both cell groups impinge on neurons in the BLA and, through β-adrenoceptors, activate cyclic adenosine monophosphate (cAMP)/protein kinase in these neurons. GCs interact with norepinephrine at the postsynaptic level in cells of the BLA, to increase the efficacy of the downstream cascade, and also facilitate noradrenergic brain stem cell groups that project to the BLA in consolidation of the memory of arousing stimuli.

However, high circulating concentrations of GCs also inhibit the retrieval of memories and working memory, which also depend on the integrity of the BLA and the secretion of norepinephrine into the BLA. GCs acting in the amygdala facilitate the rate of extinction of fear-induced startle. However, GCs appear to act throughout brain to modify memory consolidation and retrieval, whereas, in the tested paradigms that rely on emotional arousal, the BLA appears to be the critical site of action of the catecholamines. Thus, learning during stress is more efficient in part because of stress hormone secretion, but memory recall is damped with persistently elevated GCs, perhaps allowing more flexible choices to occur.

Running and Search Behaviors

In adrenalectomized rats, both running and search behaviors depend on GCs. In the absence of GCs, adrenalectomized animals run very little and exhibit no search behavior under conditions appropriate to increased searching; running and search behaviors are

restored to normal at low normal concentrations of GCs. In a study on search behavior, food was restricted so that the adrenalectomized rats were maintained at ~90% of their normal body weight in order to motivate them to both drink sucrose and search for it. In the absence of GCs, when sucrose in the solution was greatly reduced, search behavior was not increased, despite the increased need for calories, although in the presence of GCs, search behavior doubled. Extrapolating, it appears that GCs secreted in response to stress enable appropriate search behaviors that could reduce or eliminate the stressor.

Aggressive Behavior

As with learning and memory, GCs have bimodal effects on aggression; moreover, aggression stimulates GC secretion in vertebrate species. The rapid effects of GCs stimulate, or potentiate, aggressive behavior, but the chronic actions appear to reduce aggression, and these effects are primarily observed in social subordinates that have persistently elevated GC concentrations. It appears that, like the action of GCs on inhibition of the HPA axis, there are distinct temporal domains for the effects of GCs on aggression. The rapid effect of GCs is to increase aggressiveness, resulting in directed attacks, primarily to the more protected parts of the attacked animal, so that little permanent damage is done, and few attacks at the vulnerable sites (head, neck, and underbelly), which can result in severe, life-threatening damage. Interestingly, in the absence of high, stress-engendered GC concentrations, attacks focus to a greater extent on sites that can cause great damage to the recipient.

Chronic and persistent elevations in GCs are associated with depression-like and subordinate behaviors and serve to reduce overall activity and aggressive behavior, through mechanisms that are not well understood. The effects of GCs on aggression serve to provide more efficient competition, promoting the survival of the individual and transmittal of its genes under conditions of limited resources.

Calorie Ingestion

Stressors reduce calorie intake in vertebrates, probably through the increase in hypothalamic CRF secretion, which is anorexogenic. However, GCs modulate the choice and amount of substances ingested. In adrenalectomized rats without concomitant stress, GC replacement is dose related to ingestion of sweet (sucrose, saccharin) and fat (lard) substances, but without effect on ingestion of normal (relatively unpalatable) chow. These findings support those that show increased intake of palatable foods, generally dense in sugar and fat, in people who have undergone acute stress. Stressed rats with daily elevations in GCs, given their choice of chow, sucrose, and lard to ingest, may increase the proportion of the latter in their total intake. However, this is not always the case, and whether intake of lard and sugar is increased with stressors may represent the outcome of conflicting hedonic and memorial effects of the active central stress network and GCs. Nonetheless, persistent ingestion of calories from sucrose or lard does reduce acute HPA response to stressors and appears to reduce activity in the central stress response network. When GCs and insulin are elevated together as a result of increased lard and sugar intake, and then the abdominal fat depots preferentially store excess calories. Both hormones act to increase LPL (Figure 2), particularly in abdominal fat depots, and elevated insulin levels also counteract the lipid- and glycogen-mobilizing effects of the catecholamines.

However, because GCs affect learning and memory as well as calorie ingestion, the prior association between stress-induced ingestion of palatable foods may become habitual after the end of the stressor. Thus, the threshold for indulging in palatable foods with minor stress may decrease. Although this association does not appear to have much downside from an evolutionary standpoint, it has a distinct potential downside in current Western cultures.

Stress and Neural Involvement in Metabolism – Upside and Downside

The Upside

The central CRF-induced stress response network is designed to increase fitness of the animal to cope with adversity, as are the GC and catecholaminergic hormones. The actions of the central network and secreted hormones effect behaviors and metabolic changes that promote survival of the individual. These systems can be seen overall as a concerted effort to maintain calorie stores while serving calorie needs. It is highly likely throughout evolutionary time that the hunt for and utilization of calories have been a paramount necessity, and it is unlikely that overindulgence in calories occurred over the long run. The actions of the CRF network and its autonomic and endocrine outputs are clearly not detrimental in any major fashion. Longevity in rodents and subhuman primates is considerably extended by restricted feeding and limiting calories to 40–60% of normal *ad libitum* amounts. Under these conditions, GCs and some autonomic outflows are elevated during the entire extended life span of the rodent. Thus, *per se*, tonic activation of parts of the stress response system is not inimical to the duration of life, nor does it

promote the increased obesity, cardiovascular disease, metabolic syndrome, and type 2 diabetes that are seen with increasing frequency throughout our Western-style civilizations.

The Downside

The Western lifestyle includes the availability of plentiful, inexpensive foods – particularly those rich in sugar and fat. Also, there is far less physical activity demanded of those living the Western lifestyle. Thus, given the known central and peripheral actions of the catecholamines and GCs, and their interactions with high intake levels of sugary and fatty foods, it seems clear that this modern lifestyle can lead to the previously cited ills of our civilization. Current socioeconomic stressors are pervasive and not readily relievable, and pleasurable calories are easily available for consumption and have the effect of reducing the negative effects on mood (on activity in the stress response network). A sequence of chronic stressors, with elevated GCs, together with increased consumption of sugar and fat, will selectively increase abdominal adipose stores, because of the molding effects of elevated stress hormones on the deposition of excess calories. Large abdominal fat stores are strongly associated with cardiovascular disease, stroke, type 2 diabetes, and the metabolic syndrome. Stress reduction by means other than eating would seem to be an answer to the problem until evolutionary changes catch up with society and the mechanisms involved in calorie acquisition, stores, and mobilization become less important to the human organism.

Stress and Neuronal Plasticity

B S McEwen, The Rockefeller University, New York, NY, USA

Introduction

The brain is the key organ of the stress response insofar as it processes information and determines whether an event or situation is threatening. Moreover, the outputs of the brain include regulation of autonomic, neuroendocrine and immune function, and behavioral responses that can be health promoting or health damaging. The brain is an adaptable organ, and both acute and chronic stress produce structural as well as neurochemical alterations that are, for the most part, reversible. Yet, severe insults such as seizures, strokes, and head trauma cause permanent damage, and there is also reason to believe that severe and prolonged stress, as well as disorders such as major depression, may also lead to permanent neural damage if they go on for a very long time.

Animal models have provided clues as to how the brain adapts to acute and repeated stress, and the hippocampus is the best-studied brain region. The hippocampus, which is an important brain structure for spatial, contextual, and declarative memory contains receptors for adrenal steroids, which regulate excitability and the morphological changes together with glutamate as well as other neurotransmitters and a host of endogenous neurochemicals.

This article first discusses the hippocampus and then turns to two other stress-sensitive brain structures, namely, the amygdala and prefrontal cortex. It then considers the behavioral consequences of remodeling of neural connections by stress and whether the remodeling increases or decreases the vulnerability of the brain to permanent damage. Finally, the relevance of the structural changes to the mood and anxiety disorders is discussed.

Adaptive Structural Plasticity

One of the ways that stress hormones modulate function within the brain is by changing the structure of neurons. Within the hippocampus, the input from the entorhinal cortex to the dentate gyrus is ramified by the connections between the dentate gyrus and the CA3 pyramidal neurons. One granule neuron innervates, on average, 12 CA3 neurons, and each CA3 neuron innervates, on average, 50 other CA3 neurons via axon collaterals, as well as 25 inhibitory cells via other axon collaterals. The net result is a 600-fold amplification of excitation, as well as a 300-fold amplification of inhibition, that provides some degree of control of the system.

As to why this type of circuitry exists, the dentate gyrus-CA3 system is believed to play a role in the memory of sequences of events, although long-term storage of memory occurs in other brain regions. But, because the DG-CA3 system is so delicately balanced in its function and vulnerability to damage, there is also adaptive structural plasticity, in that new neurons continue to be produced in the dentate gyrus throughout adult life, and CA3 pyramidal cells undergo a reversible remodeling of their dendrites in conditions such as hibernation and chronic stress. The role of this plasticity may be to protect against permanent damage.

Neurogenesis in the Dentate Gyrus

The subgranular layer of the dentate gyrus contains cells that have some properties of astrocytes (e.g., expression of glial fibrillary acidic protein) and which give rise to granule neurons. After bromodeoxyuridine (BrdU) administration to label DNA of dividing cells, these newly born cells appear as clusters in the inner part of the granule cell layer, where a substantial number of them will go on to differentiate into granule neurons within as little as 7 days. In the adult rat, 9000 new neurons are born per day and survive with a half-life of 28 days.

There are many hormonal, neurochemical, and behavioral modulators of neurogenesis and cell survival in the dentate gyrus including estradiol, insulin-like growth factor-1 (IGF-1), antidepressants, voluntary exercise, and hippocampal-dependent learning. With respect to stress, certain types of acute stress and many chronic stressors suppress neurogenesis or cell survival in the dentate gyrus, and the mediators of these inhibitory effects include excitatory amino acids acting via *N*-methyl-D-aspartate (NMDA) receptors and endogenous opioids.

Remodeling of Dendrites

Another form of structural plasticity is the remodeling of dendrites in the hippocampus. Chronic restraint stress causes retraction and simplification of dendrites in the CA3 region of the hippocampus. Such dendritic reorganization is found in both dominant and subordinate rats undergoing adaptation of psychosocial stress in the visible burrow system and it is independent of adrenal size.

What this result emphasizes is that it is not adrenal size or presumed amount of physiological stress *per se* that determines dendritic remodeling but a complex set of other factors that modulate neuronal structure. Indeed, in species of mammals that hibernate, dendritic remodeling is a reversible process and occurs within hours of the onset of hibernation in European hamsters and ground squirrels, and it is also reversible within hours of wakening of the animals from torpor. This implies that reorganization of the cytoskeleton is taking place rapidly and reversibly and that changes in dendrite length and branching are not 'damage' but a form of structural plasticity.

Mechanisms of Structural Remodeling

Adrenal steroids are important mediators of remodeling of hippocampal neurons during repeated stress, and exogenous adrenal steroids can also cause remodeling in the absence of an external stressor. The role of adrenal steroids may involve interactions with neurochemical systems in the hippocampus, including serotonin, γ-aminobutyric acid (GABA), and excitatory amino acids. Probably the most important interactions are those with excitatory amino acids such as glutamate. Excitatory amino acids released by the mossy fiber pathway play a key role in the remodeling of the CA3 region of the hippocampus, and regulation of glutamate release by adrenal steroids may play an important role.

Among the consequences of restraint stress is the elevation of extracellular glutamate levels, leading to induction of glial glutamate transporters as well as increased activation of the nuclear transcription factor, phosphoCREB. Moreover, 21d chronic restraint stress (21d CRS) leads to depletion of clear vesicles from mossy fiber terminals and increased expression of presynaptic proteins involved in vesicle release. Taken together with the fact that vesicles that remain in the mossy fiber terminal are near active synaptic zones, this implies that CRS increases the release of glutamate.

Extracellular molecules play a role in remodeling. Neural cell adhesion molecule (NCAM) and its polysialated-NCAM (PSA-NCAM) as well as L1 are expressed in the dentate gyrus and CA3 region and the expression of both NCAM, L1, and PSA-NCAM are regulated by 21d CRS. Tissue plasminogen activator (tPA) is an extracellular protease and signaling molecule that is released with neural activity and is required for chronic stress-induced loss of spines and NMDA receptor subunits on CA1 neurons.

Within the neuronal cytoskeleton, the remodeling of hippocampal neurons by chronic stress and hibernation alters the acetylation of microtubule subunits that is consistent with a more stable cytoskeleton and alters microtubule associated proteins, including the phosphorylation of a soluble form of tau, which is increased in hiberation and reversed when hibernation is terminated.

Neurotrophic factors also play a role in dendritic branching and length in that brain-derived neurotrophic factor (BDNF)+/− mice show a less branched dendritic tree and do not show a further reduction of CA3 dendrite length with chronic stress, whereas wild-type mice show reduced dendritic branching. However, there is contradictory information thus far concerning whether CRS reduces BDNF mRNA levels, some reporting a decrease and other studies reporting no change. This may reflect the balance of two opposing forces, namely, that stress triggers increased BDNF synthesis to replace depletion of BDNF caused by stress. BDNF and corticosteroids appear to oppose each other – with BDNF reversing reduced excitability in hippocampal neurons induced by stress levels of corticosterone.

Corticotrophin releasing factor (CRF) is a key mediator of many aspects related to stress. CRF in the paraventricular nucleus regulates adrenocorticotropin (ACTH) release from the anterior pituitary gland, whereas CRF in the central amygdala is involved in control of behavioral and autonomic responses to stress including the release of tPA that is an essential part of stress-induced anxiety and structural plasticity in the medial amygdala. CRF in the hippocampus is expressed in a subset of GABA neurons (Cajal-Retzius cells) in the developing hippocampus, and early life stress produces a delayed effect that reduces cognitive function and the number of CA3 neurons, as well as decreased branching of hippocampal pyramidal neurons. Indeed, CRH inhibits dendritic branching in hippocampal cultures *in vitro*.

What about Permanent Damage as a Result of Stress?

There is always concern that severe and prolonged stress may damage the brain. In the case of depressive illness, there is a high degree of life-time recurrence of major depression, which suggests that an underlying pathophysiological process is involved. What is being learned from animal models of stress and trauma effects in the hippocampus is that the remodeling of the hippocampus in response to stress is largely reversible if chronic stress is terminated at the end of 3 weeks. Yet, it is well established that glucocorticoids exacerbate damage to the hippocampus caused by ischemia and seizures. Nevertheless, the brain protects itself, as for example, in the phenomenon of

ischemia preconditioning: that is, prior stimulation of the hippocampus by a small ischemic event can induce a protective mechanism that may reduce the damage produced by a full-scale ischemic event. It is not clear if the same mechanisms might be operative when stress is applied, although there is evidence that 21d CRS increases the vulnerability to excitotoxic damage by ibotenic acid applied directly into the hippocampus. The unanswered question is whether the damage would have been worse if the dendritic retraction that occurs after 21d CRS had not occurred.

We do know that in the hippocampus there is a delicate balance between the generation of damage and destruction and the mechanisms that lead to dendrite retraction during more gradual repetitive stimulation, which may be a protective response that reduces the excitatory input without totally disconnecting the circuit functionally.

Stress-Induced Changes in the Prefrontal Cortex and Amygdala

Repeated stress also causes changes in other brain regions such as the prefrontal cortex and amygdala. Repeated stress causes dendritic shortening in medial prefrontal cortex but produces dendritic growth in neurons in amygdala, as well as in orbitofrontal cortex. Along with many other brain regions, the amygdala and prefrontal cortex also contain adrenal steroid receptors; however, the role of adrenal steroids, excitatory amino acids, and other mediators has not yet been studied in these brain regions. Nevertheless, in the amygdala, there is some evidence regarding mechanism, in that tPA is required for acute stress not only to activate indices of structural plasticity but also to enhance anxiety. These effects occur in the medial and central amygdala and not in basolateral amygdala, and the release of CRH acting via CRH1 receptors appears to be responsible.

Behavioral Effects of Acute and Chronic Stress

Acute stress induces spine synapses in CA1 region of hippocampus and chronic stress also increases spine synapse formation in amygdala but decreases it in hippocampus. Moreover, chronic stress for 21 days or longer impairs hippocampal-dependent cognitive function and enhances amygdala-dependent unlearned fear and fear conditioning, which are consistent with the opposite effects of stress on hippocampal and amygdala structure. Chronic stress also increases aggression between animals living in the same cage, and this is likely to reflect another aspect of hyperactivity of the amygdala. Behavioral correlates of remodeling in the prefrontal cortex include impairment in attention set shifting, possibly reflecting structural remodeling in the medial prefrontal cortex.

Relationship to Anxiety and Mood Disorders

Life events are known to precipitate depressive illness in individuals with certain genetic predispositions. Moreover, brain regions such as the hippocampus, amygdala, and prefrontal cortex show altered patterns of activity in positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) and also demonstrate changes in volume of these structures with recurrent depression: decreased volume of hippocampus and prefrontal cortex and amygdala. Interestingly, amygdala volume has been reported to increase in the first episode of depression, whereas hippocampal volume is not decreased. It has been known for some time that stress hormones such as cortisol are involved in psychopathology, reflecting emotional arousal and psychic disorganization rather than the specific disorder *per se*. We now know that adrenocortical hormones enter the brain and produce a wide range of effects upon it.

In Cushing's disease, there are depressive symptoms that can be relieved by surgical correction of the hypercortisolemia. Both major depression and Cushing's disease are associated with chronic elevation of cortisol that results in gradual loss of minerals from bone and abdominal obesity. In major depressive illness, as well as in Cushing's disease, the duration of the illness and not the age of the subjects predicts a progressive reduction in volume of the hippocampus, determined by structural magnetic resonance imaging. Moreover, there are a variety of other anxiety-related disorders, such as posttraumatic stress disorder (PTSD) and borderline personality disorder, in which atrophy of the hippocampus has been reported, suggesting that this is a common process reflecting chronic imbalance in the activity of adaptive systems, such as the hypothalamic–pitutary–adrenal (HPA) axis, but also including endogenous neurotransmitters, such as glutamate.

Conclusion

Animal stress models not only suggest how the human brain may change under repeated stress, but they also provide mechanistic clues about stress-induced anxiety and behavioral depression, which are relevant to human mood and anxiety disorders. For example, psychosocial stress in an animal model of depressive illness, resident-intruder stress in the tree shrew, suppresses neurogenesis and causes dendritic shrinkage in hippocampus.

Translational studies of brain changes in major mood and anxiety disorders (such as unipolar and bipolar depression and PTSD) show that changes in volume of structures (such as hippocampus, prefrontal cortex, and amygdala) must be considered as part of the neurobiological consequences of these illnesses. Structural remodeling in these brain regions is important for human psychiatric disorders because the altered circuitry is likely to contribute to impaired cognitive function and affect regulation. Moreover, stress is widely acknowledged as a predisposing and precipitating factor in psychiatric illness. Thus, animal models are relevant to human psychiatric disorders by showing the delicate balance between protection and damage and by providing mechanisms that raise the hopeful possibility that brain changes, in at least some major psychiatric disorders, may be treatable if we can find the right agents or therapies and intervene in time.

Stress and Parasympathetic Control

S W Porges, University of Illinois at Chicago, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Traditionally, the autonomic nervous system is conceptualized as the paired antagonism between the sympathetic and the parasympathetic nervous system. These components of the autonomic nervous system, based on the region of the brain and spinal cord in which the autonomic nerves (i.e., preganglionic fibers) have their origin, compete functionally by either increasing or decreasing activity of specific target organs. The sympathetic system is defined by the autonomic fibers that exit thoracic and lumbar segments of the spinal cord. The parasympathetic system is defined by the autonomic fibers that exit either the brain stem via the cranial nerves (primarily via the vagus) or the sacral segments of the spinal cord. Since most organs in the viscera receive both sympathetic and vagal input, the regulation of the autonomic nervous system has been modeled as a balance system.

Central nervous system regulation of visceral organs is the focus of several historic publications. For example, in *The Expression of Emotions in Man and Animals*, Darwin described the dynamic neural relationship between the heart and the brain. He stated that

> when the heart is affected it reacts on the brain; and the state of the brain again reacts through the pneumogastric [vagus] nerve on the heart; so that under any excitement there will be much mutual action and reaction between these, the two most important organs of the body.

From Darwin's perspective, the vagus as a cranial nerve was a direct portal to and from the brain. Although Darwin acknowledged the bidirectional communication between the viscera and the brain, the subsequent formal description of the autonomic nervous system minimized the importance of central regulatory structures and afferents. A focus on the peripheral motor nerves with an emphasis on the paired antagonism between sympathetic and parasympathetic efferent pathways on the target visceral organs resulted in a lack of interest in afferent influences to the brain stem areas regulating specific efferent pathways. This early conceptualization of the vagus focused on an undifferentiated efferent pathway that was assumed to modulate 'tone' concurrently to several target organs. Thus, neural circuits regulating the supradiaphragmatic (e.g., myelinated vagal pathways originating in the nucleus ambiguus and terminating primarily above the diaphragm) were not functionally distinguished from the subdiaphragmatic (e.g., unmyelinated vagal pathways originating in the dorsal motor nucleus of the vagus and terminating primarily below the diaphragm). Without this distinction, research and theory focused on the paired antagonism between the parasympathetic and sympathetic innervation to target organs. The consequence of an emphasis on paired antagonism in physiology was an acceptance and use of global constructs focusing on peripheral physiology such as autonomic balance, sympathetic tone, and vagal tone. Ironically, the origin of modern research on stress physiology is often linked to the classical conditioning of autonomic activity, which, as Pavlov demonstrated, requires the involvement of higher brain structures in the modulation of visceral responses.

In the mid-1950s, W Hess proposed that the 'autonomic' nervous system was not solely 'vegetative' and automatic but, rather, was an integrated system with both peripheral and central neurons. In 1949, Hess was awarded the Nobel Prize in Physiology or Medicine. His Nobel lecture was titled 'The central control of activity of internal organs.' In the lecture, Hess acknowledged the importance of the prevailing model of the autonomic nervous system, which emphasized the paired antagonistic innervations of the internal organs and the definition of sympathetic and parasympathetic functions. However, he went well beyond this conceptualization to emphasize the importance of central structures in the regulation of visceral state by describing his studies that demonstrated the influence of the hypothalamus on the autonomic nervous system. By emphasizing the central mechanisms that mediate the dynamic regulation of peripheral organs, Hess anticipated the need for methodologies and technologies to continuously monitor the neural circuits involving both defined brain structures and peripheral nerves in the regulation of visceral function and state and to move from the prevailing conceptualization of autonomic nervous system as a peripheral system. The lecture provides a succinct statement: (1) to emphasize the importance of feedback circuits linking peripheral organs to brain structures and the bidirectionality of these feedback circuits and (2) to acknowledge that, although much can be learned about neural structures and functions via traditional experimental paradigms (e.g., neural blockade, surgery, and electrical stimulation), the dynamic feedback circuits cannot be adequately studied through these paradigms.

Arousal Theory and Stress Responses

For more than a century, researchers have measured autonomic variables (e.g., heart rate and palmar sweat gland activity) as indicators of emotional state related to perceived stress (e.g., fear, mental effort, workload, and anxiety). Historically, arousal theories provided scientists who studied brain–behavior relations with a model that assumed that activation of peripheral physiological measures regulated by the sympathetic branch of the autonomic nervous system provided 'sensitive' indicators of brain 'arousal' or 'activation.' This view was based on a rudimentary understanding of the autonomic nervous system in which changes in easily measured peripheral organs (e.g., sweat glands and heart) were assumed to be accurate indicators of how the brain was processing emotional stimuli. Usually, the emotional states were associated with fight-or-flight behaviors and the sympathetic–adrenal system (e.g., increases in heart rate, sweat gland activity, and circulating catecholamines) initially described by Cannon as well as the increased activity of the hypothalamic–pituitary–adrenal (HPA) axis with an emphasis on cortisol as a dependent variable in stress research as initially described by Selye.

Measures due, in part, to their availability and their neuroanatomical association with the target organs of the sympathetic nervous system (i.e., sweat and heart rate) and with secretions from the adrenal medulla (i.e., epinephrine and norepinephrine) and the adrenal cortex (i.e., cortisol) have become the primary physiological variables used to assess stress. An acceptance of a unitary arousal system created a research environment that neglected several important factors, including an understanding of the brain structures that regulate autonomic function; how these structures evolved from the most primitive vertebrates to mammals; how the autonomic nervous system interacts with the immune system, the HPA axis, and the neuropeptides, oxytocin, and vasopressin; and the co-evolution of stress and coping strategies with the increasing complexity of the autonomic nervous system. Missing from the dialog on stress is the role of the parasympathetic nervous system and especially the vagus with its bidirectional portal between the brain and specific visceral organs.

The Mammalian Nervous System Is a Product of Evolution

Embedded in the mammalian nervous system are neuroanatomical structures related to the expression and experience of stress. Via evolutionary processes, the mammalian nervous system has emerged with specific features that react to the challenge to maintain visceral homeostasis. Stress, simply defined, is the product of demands on the nervous system that result in a deviation from homeostasis. In general, the domains of homeostasis, which have been monitored, have focused on the visceral systems involved in cardiovascular, digestive, reproductive, and immune functions. Adaptive and successful coping to stress results in minimizing the magnitude and duration of this deviation. To survive, mammals must determine friend from foe, when an environment is safe, and communicate with their social unit. These survival-related behaviors limit the extent to which a mammal can be physically approached, whether vocalizations will be understood, and whether coalitions can be established. Moreover, these behavioral strategies, which are used to navigate through the 'stress of life,' form the bedrock on which social behaviors and higher cognitive processes can be developed and expressed. Thus, learning and other expansive mental processes must be structured, manipulated, and studied within the context of how the environment fosters or ameliorates stress-related physiological states.

Table 1 illustrates the phylogenetic differences in the structures that regulate the heart in vertebrates. The heart is selected because the regulation of the heart determines the availability of the metabolic resources required for mobilization as well as for growth and restoration. For example, cardiac output must be regulated to remain calm in safe environments, to mobilize for fight-or-flight behaviors, or to immobilize for death feigning or avoidance behaviors. To regulate cardiac output, several efferent structures have evolved. These structures represent two global and often opposing systems: (1) a sympathetic–catecholamine system including catecholamine-secreting chromaffin tissue and spinal sympathetic nerves and (2) a vagal system (a component of the parasympathetic nervous system)

Table 1 Phylogenetic shifts in vertebrate cardiac control

Group	*CHM*	*DVC*	*SNS*	*AD/m*	*VVC*
Jawless fish	X^+	(X^+)			
Cartilaginous fish	X^+	X^-			
Bony fish	X^+	X^-	X^+		
Amphibians	X^+	X^-	X^+		
Reptiles	X^+	X^-	X^+	X^+	
Mammals	X^+	X^-	X^+	X^+	X^-

CHM, chromaffin tissue; DVC, dorsal vagal complex with vagal efferent pathways originating in the dorsal motor nucleus of the vagus and vagal afferents terminating in the nucleus tractus solitarius; SNS, spinal sympathetic nervous system; AD/m, adrenal medulla; VVC, ventral vagal complex with efferent pathways originating in the nucleus ambiguus that regulate visceral structures (heart, bronchi, and thymus) and striated muscles via special visceral efferents and afferents via the tractus solitarius, trigeminal, and facial nerve.

with branches originating in the medullary source nuclei (i.e., dorsal motor nucleus of the vagus and nucleus ambiguus).

Unlike other vertebrates with a cardioinhibitory vagus, the mammalian vagus contains two branches. One branch originates in the dorsal motor nucleus of the vagus and provides the primary neural regulation of subdiaphragmatic organs such as the digestive tract. However, at the level of the heart and unlike more primitive vertebrates, the efferent vagal pathways that originate in the dorsal motor nucleus of the vagus do not play a major role in the normal dynamic regulation of cardiac output. Rather, during embryological development in mammals, cells from the dorsal motor nucleus of the vagus migrate ventrally and laterally to the nucleus ambiguus. There, they form the cell bodies for the visceromotor myelinated axons that provide potent inhibition of the sinoatrial node, the pacemaker for the heart.

Three principles can be extracted by investigating the phylogeny of the regulation of the vertebrate heart. First, there is a phylogenetic shift in the regulation of the heart from endocrine communication to unmyelinated nerves and, finally, myelinated nerves. Second, there is a development of opposing neural mechanisms of excitation and inhibition to provide rapid regulation of graded metabolic output. Third, with increased cortical development, the cortex exhibits greater control over the brain stem via direct (e.g., corticobulbar) and indirect (e.g., corticoreticular) neural pathways originating in motor cortex and terminating in the source nuclei of the myelinated motor nerves emerging from the brain stem (e.g., specific neural pathways embedded within cranial nerves V, VII, IX, X, and XI), controlling visceromotor structures (i.e., heart, bronchi, and thymus) and somatomotor structures (muscles of the face and head) that results in a neural circuit that functions to facilitate social behavior and to maintain calm behavioral states.

These phylogenetic principles provide a basis for investigating the parasympathetic contribution to stress reactions and recovery. In general, phylogenetic development results in increased neural control of the heart via the myelinated mammalian vagal system, which can promote transitory mobilization and the expression of sympathetic tone without requiring sympathetic or adrenal activation. With this new vagal system, transitory incursions into the environment or withdrawals from a potential predator can be initiated without the severe biological cost of the metabolic excitation associated with sympathetic–adrenal activation. Paralleling this change in neural control of the heart is an enhanced neural control of the face, larynx, and pharynx that enables complex facial gestures and vocalizations associated with social communication. This phylogenetic course results in greater central nervous system regulation of behavior, especially that needed to engage and disengage with environmental challenges.

Polyvagal Theory: Three Phylogenetic Systems Related to Stress Reactivity

The polyvagal theory emphasizes the phylogenetic origins of brain structures that regulate social and defensive behaviors. The polyvagal theory proposes that the evolution of the mammalian autonomic nervous system provides the neurophysiological substrates for emotional experiences, affective processes, and stress responses. The theory proposes that physiological state limits the range of adaptive behaviors and psychological experiences. In this context, the evolution of the nervous system determines the range of emotional expression, the quality of communication, and the ability to regulate bodily and behavioral state including the expression and recovery of stress-related responses. Relevant to adaptive stress responses, the theory makes the following assumptions:

1. Evolution has modified the structures of the autonomic nervous system.
2. The mammalian autonomic nervous system retains vestiges of phylogenetically older autonomic nervous systems.
3. Emotional regulation and social behavior are functional derivatives of structural changes in the autonomic nervous system due to evolutionary processes.
4. In mammals, the autonomic nervous system response strategy to challenge follows a phylogenetic hierarchy, starting with the newest structures and, when all else fails, reverting to the most primitive structural system.
5. The phylogenentic stage of the autonomic nervous system determines the behavioral, physiological, and affective features of stress reactivity.

The polyvagal theory emphasizes and documents the neurophysiological and neuroanatomical distinction between the two branches of the vagus (i.e., the tenth cranial nerve) and proposes that each vagal branch is associated with a different adaptive behavioral and physiological response strategy to stressful events. The theory describes three phylogenetic stages of the development of the mammalian autonomic nervous system (Table 2). These stages reflect the emergence of three distinct subsystems, which are phylogenetically ordered and behaviorally linked to communication (e.g., facial expression, vocalization, and listening), mobilization

Table 2 Phylogenetic stages of the neural control of the heart proposed by the polyvagal theory

Stage	*Autonomic nervous system component*	*Behavioral function*	*Lower motor neurons*
III	Myelinated vagus (ventral vagal complex)	Social communication, self-soothing and calming, inhibit 'arousal'	Nucleus ambiguus
II	Sympathetic–adrenal system	Mobilization (active avoidance)	Spinal cord
I	Unmyelinated vagus (dorsal vagal complex)	Immobilization (death feigning, passive avoidance)	Dorsal motor nucleus of the vagus

(e.g., fight-or-flight behaviors), and immobilization (e.g., death feigning, behavioral 'shutdown,' and syncope). The mobilization system is dependent on the functioning of the sympathetic nervous system. The most phylogenetically primitive component, the immobilization system, is dependent on the unmyelinated or 'vegetative' vagus, which is shared with most vertebrates. With increased neural complexity due to phylogenetic development, the organism's behavioral and affective repertoire is enriched. These subsystems provide a framework to study the vagal contribution to the regulation of stress responses.

The mammalian vagus functions as an active vagal brake in which rapid inhibition and disinhibition of vagal tone to the heart can support behavioral mobilization or self-sooth and calm an individual. When the vagal tone to the pacemaker is high, the vagus acts as a restraint or brake limiting heart rate. When vagal tone to the pacemaker is low, there is little or no inhibition of the pacemaker. Due to vagal influences to the sinoatrial node (i.e., the heart's pacemaker), resting heart rate is substantially lower than the intrinsic rate of the pacemaker. In mammals, the primary vagal inhibitory pathways occur through the myelinated vagus originating in the nucleus ambiguus. Consistent with assumptions of the polyvagal theory, the vagal brake contributes to the modulation of cardiac output by decreasing or increasing the inhibitory vagal control of the heart to influence rate and thereby adjust metabolic resources to support either mobilization or social engagement behaviors.

By transitory downregulation of the cardioinhibitory vagal tone to the heart (i.e., removing the vagal brake), the mammal is capable of rapid increases in cardiac output without activating the sympathetic–adrenal system. By engaging this system, rather than the sympathetic–adrenal system, mammals have an opportunity to rapidly increase metabolic output for immediate mobilization. Under prolonged challenge, the sympathetic system may also be activated. By rapidly re-engaging the vagal system, the sympathetic input to the heart is inhibited, resulting in a decrease in metabolic output and a calm behavioral state.

The Vagal Brake: Parasympathetic Regulation of the 'Stress' Response

Due to the tonic vagal influences to the sinoatrial node, resting heart rate is substantially lower than the intrinsic rate of the pacemaker. When the vagal tone to the pacemaker is high, the vagus acts as a brake on the rate at which the heart is beating. When vagal tone to the pacemaker is low, there is little or no inhibition of the pacemaker. Thus, the vagal brake may be used as a construct to describe the functional modulation of heart rate by the myelinated vagal efferent pathways. Neurophysiologically, the vagal brake provides a mechanism to support the metabolic requirements for mobilization and communication behaviors. Functionally, the vagal brake, by modulating visceral state, enables the individual to rapidly engage and disengage with objects and other individuals and to promote self-soothing behaviors and calm behavioral states. Thus, withdrawal of the vagal brake is associated with an adaptive stress response and a reinstatement of the vagal brake with recovery.

Withdrawal of the vagal brake will facilitate the recruitment of other neural mechanisms (e.g., excitation of sympathetic or the unmyelinated vagal pathways) and neural chemical mechanisms (e.g., stimulation of the HPA axis) to regulate physiological state. Thus, consistent with the polyvagal theory, if the vagal brake is not functioning or will not serve the survival needs of the organism, then the phylogenetically 'older' systems (e.g., the sympathetic–adrenal system or unmyelinated vagus originating in the dorsal motor nucleus of the vagus) will be recruited to regulate metabolic output to deal with environmental challenges. For example, if the vagal brake is not functioning, there is the potential for greater dependence on the sympathetic excitation of the cardiovascular system.

The Social Engagement System

Mammals have evolved to have a well-defined neurally mediated social engagement system. Embryologically, components of several cranial nerves develop

together (i.e., myelinated vagal pathways from the nucleus ambiguus and special visceral efferent pathways from cranial nerves V, VII, IX, X, and XI) to form the neural substrate of a social engagement system. This system provides the neural gatekeepers for social–emotional interactions. The social engagement system has a control component in the cortex (i.e., upper motor neurons) that regulates brain stem nuclei (i.e., lower motor neurons) to control eyelid opening (e.g., looking), facial muscles (e.g., emotional expression), middle ear muscles (e.g., extracting human voice from background noise), muscles of mastication (e.g., ingestion), laryngeal and pharyngeal muscles (e.g., vocalization and language), and head-turning muscles (e.g., social gesture and orientation). Collectively, these muscles function as filters and control social engagement with the environment. The neural control of these muscles determines social experiences. In addition, the source nuclei (i.e., lower motor neurons) of these nerves, which are located in the brain stem, communicate directly with an inhibitory neural circuit that slows heart rate, lowers blood pressure, and actively reduces arousal to promote calm states consistent with the metabolic demands of growth and restoration of neurophysiological systems. Direct corticobulbar pathways reflect the influence of frontal areas of the cortex (i.e., upper motor neurons) on the regulation of this system. Thus, the social nervous system is intimately related to stress reactivity. In addition, the anatomical structures involved in the social engagement system have neurophysiological interactions with the HPA axis, the neuropeptides of oxytocin and vasopressin, and the immune system. Thus, the social engagement system, as illustrated in Figure 1, provides a theoretical model to explain the interactive and stress-related functions of several physiological systems that have central regulatory components but are expressed in the periphery.

Figure 1 The social engagement system. Social communication is determined by the cortical regulation of medullary nuclei via corticobulbar pathways. The social engagement system consists of a somatomotor component (i.e., special visceral efferent pathways that regulate the striated muscles of the face and head) and a visceromotor component (i.e., the myelinated vagus that regulates the heart and bronchi). Solid rectangles indicate the somatomotor component, and dashed rectangles indicate the visceromotor component.

Vagal Regulation of the HPA Axis

The vagus is involved in the regulation of the HPA axis. Vagal afferents exhibit an inhibitory influence on the HPA axis and reduce cortisol secretion. Studies have demonstrated a covariation between increases in cortisol and decreases in cardiac vagal tone (i.e., measured by the amplitude of respiratory sinus arrhythmia). Thus, there appears to be a coordinated response that functions to promote metabolic activity and mobilization behaviors by withdrawal of vagal tone through the myelinated vagus and increasing both sympathetic activity and activation of the HPA axis. In general, the functioning of the adrenal cortex and the secretion of cortisol appear to be integrated into the mobilization function of the autonomic nervous system by increasing sympathetic activation and circulating catecholamines. These effects suggest that, consistent with the phylogenetic approach described in the polyvagal theory, cortisol secretion may be related to maintenance of mobilization (i.e., the conversion of norepinephrine into epinephrine) for fight-or-flight behaviors and in the recovery from the lactate buildup that may contribute to a functional oxygen debt (i.e., gluconeogenesis).

In addition, reports of dysregulation of the HPA axis, low cortisol, or low cortisol reactivity in disorders such as schizophrenia and posttraumatic stress disorder and also the consequences of neglect and abuse in children may be explained within the context of a phylogenetically ordered response strategy (i.e., polyvagal theory). For example, if mobilization strategies (i.e., fight-or-flight behaviors) are ineffective in removing the individual from the stressor and in modulating the effect of the stress, then the nervous system may degrade to a phylogenetically earlier level of organization. Thus, low cortisol or a hyporesponsive HPA axis may reflect a neural strategy associated with immobilization (i.e., passive avoidance) that would require a reduction in energy resources.

Immune Function

The vagus has been implicated in the immune system. Studies have demonstrated the important role of subdiaphragmatic vagal afferents in conveying information regarding visceral state to the brain.

The studies conceptualize the afferent vagus as providing a signal alerting the central structures regulating immune function. A few studies have described motor pathways via the vagus to the thymus. The link between the vagal function and the immune system is not clear. However, it might be plausible to speculate that the neural mediation of the myelinated vagus, via direct influence on thymus and direct inhibition of the sympathetic nervous system, may trigger a physiological state that would promote immune function. Likewise, withdrawal of vagal tone to the heart, increased sympathetic tone, and the release of cortisol have been associated with suppressed immune function.

Oxytocin/Vasopressin

Because the peripheral influences of oxytocin and vasopressin function through feedback, primarily via afferent vagal pathways, the peripheral effects of these peptides are less clear and may be level dependent or differ as a function of acute versus chronic exposure. For example, it is possible that peripheral vasopressin, by stimulating vagal afferents, may trigger massive vagal responses via the dorsal motor nucleus of the vagus. In support of this speculation, it is known that in humans, peripheral vasopressin, and not oxytocin, is related to the nausea experienced during motion sickness. In addition, systemic vasopressin may induce a baroreceptor-mediated bradycardia and a decrease in plasma concentration of norepinephrine.

Based on the polyvagal theory, the mammalian vagus, with myelinated motor fibers originating in the nucleus ambiguus, provides a system for voluntary engagement with the environment, with special features associated with the prosocial behaviors of communication. Paralleling this evolutionary shift in the vagus is a mammalian modification of the hypothalamic regulation of the dorsal vagal complex (i.e., source nucleus of the afferent and efferent pathways of the unmyelinated vagus originating in the dorsal motor nucleus of the vagus and the nucleus of the solitary tract) via both oxytocin and vasopressin. The advent of specific receptors for oxytocin and vasopressin has increased the range of adaptive functions involving the unmyelinated vagus. In mammals, the dorsal motor nucleus of the vagus, the motor component of the dorsal vagal complex, is sensitive to oxytocin and insensitive to vasopressin. In contrast, the sensory components of the vagus, the nucleus of the solitary tract and area postrema, are most sensitive to vasopressin. Although the nucleus of the solitary tract has receptors for oxytocin, area postrema may not be directly influenced by oxytocin. The differential sensitivity of specific components of the dorsal vagal complex to these two neuropeptides (the differential effects of central and systemic release on visceral function and a potential level dependency) results in a wider range of response options, including maximizing mobilization behaviors and the co-opting of the primitive vagal system associated with immobilization to support 'antistress' functions such as social engagement and growth and restoration.

Phylogenetic Approach to the Study of Stress

The phylogenetic orientation focuses our interest on the parasympathetic neural structures and neurobehavioral systems that we share with or have adapted from our phylogenetic ancestry. First, the three response systems proposed in the polyvagal theory (i.e., cranial nerves to regulate the face, sympathetic–adrenal system to increase metabolic output, and an inhibitory vagal system to decrease metabolic output and promote freezing and defecation) are the products of distinct neurophysiological systems. Second, these distinct neurophysiological systems represent a phylogenetically dependent hierarchy, with the use of cranial nerves to regulate facial expression emerging in mammals (well developed in primates); the sympathetic–adrenal system shared with other vertebrates including reptiles; and the inhibitory vagal system shared with more primitive vertebrates, including amphibians, bony fish, and cartilaginous fish. The three systems represent different phylogenetic stages of neural development. This phylogenetic development starts with a primitive behavioral inhibition system, progresses to a fight-or-flight system, and, in humans (and other primates), culminates in a complex facial gesture and vocalization system. Thus, from a phylogenetic perspective, the nervous system of vertebrates evolved to support a greater range of behaviors and physiological states, including states that are often associated with stress.

The physiological responses associated with stress in mammals do not concisely fit into a single neurophysiological system. Although cortisol has often been labeled as the stress hormone, other systems clearly respond to stress. Moreover, there are situations of severe stress in which cortisol is neither responsive nor at a high level. By expanding the phylogenetic model proposed in the polyvagal theory to emphasize the interactions between parasympathetic mechanisms and the HPA axis, the hyporesponsive HPA can be interpreted as reflecting a primitive passive avoidance system. Thus, several systems with target organs at the periphery contribute to the organism's adaptation to challenge and stress. These neurobiological systems are not solely stress systems. Rather, they are intimately

involved in the dynamic regulation of homeostasis, growth and restoration, metabolism, and mobilization. These systems form a complex set of mutually interacting neurophysiological pathways that communicate via nerves and neurally active chemicals (e.g., neurotransmitters, neuropeptides, and hormones) to cope with survival challenges.

Stress and Suicide

M Boldrini and V Arango, Columbia University College of Physicians and Surgeons, and New York State Psychiatric Institute, New York, NY, USA

Introduction

Suicide is a worldwide public health problem accounting for nearly half of all violent deaths and resulting in 1 million fatalities each year. In 2001, the annual global toll from suicide exceeded the number of deaths by homicide (500 000) and war (230 000) (www.who.int; **Figure 1**). European nations have the highest suicide rates in the world, whereas Central and South American nations have the lowest, although this may be due to the notorious under-reporting that occurs in some countries.

Suicidal behavior is complex and multifaceted, involving genetics and psychosocial and biological factors. The presence of a psychiatric diagnosis, a family history of suicide, childhood abuse, and alcohol and drug abuse all play a central role in suicide. Physical illness and disabling pain can also increase suicide risk. Among psychosocial factors, poverty, unemployment, and social isolation can contribute to hopelessness, as can factors such as the loss of loved ones, breakdown in relationships, and legal or work-related problems.

Psychosocial–Environmental Stress Factors Contributing to Suicidal Behavior

When a change in suicide rates occurs within a short time, it is improbable that it is related to genetic factors, and it raises the possibility that stress is a major contributor to suicide risk. For example, Lithuania, a country with the highest suicide rate in the world (88.2 per 100 000), experienced a sharp decline in suicide rates in the 1980s, as did other Eastern European countries, as the result of the processes of democratization and an effective antialcohol campaign. The collapse of the Soviet Union and the independence of Lithuania and other Baltic states in the early 1990s resulted in a socially unstable situation and a dramatic increase in suicide rates.

Suicide rates increase in situations of extreme stress. During the Holocaust, annual suicide rates in concentration camps were approximately 25 000 per 100 000 and people were at greater risk for suicidal ideation. The high rate of suicide attempts among elderly patients who lived through the Holocaust and now reside in Israel highlights the need for intervention among those who experience traumatic events early in their lives.

Suicide rates are higher in rural than in urban areas in Lithuania, China, and the United States. Suicide predictors in rural China include lack of social support, stressful life events, lower education, poverty, and family disputes. Other predictors are depression, previous suicide attempt, high chronic stress, acute stress, low quality of life, severe interpersonal conflict, a family history of suicidal behavior, and a friend or associate with suicidal behavior. Social isolation, poverty, and unemployment have also been implicated in suicide in rural areas and can occur in the presence or absence of psychopathology.

More than 90% of people who commit suicide or suicide attempters have a diagnosable psychiatric illness. Approximately 60% of all suicides are related to mood disorders, and the rest are related to schizophrenia, alcoholism, substance abuse, and personality disorders. Most psychiatric patients do not commit suicide, so a psychiatric disorder alone is certainly a risk factor but not a sufficient condition to precipitate suicide.

Protective psychosocial factors against suicidal behavior include religious affiliation, parenthood, being married, having reasons for living, fear of social disapproval, moral objections to suicide, and greater coping skills. Psychopathological traits can account for different suicide rates: lower aggression/impulsivity has been identified as a factor for the lower suicide rate in Spain compared to New York.

Antistress factors: Resilience

In studying suicide, one must consider the variables related to resilience in the face of stress or a psychiatric disorder. Children raised in stressful settings who exhibit successful adaptation have good intellectual functioning, effective self-regulation of emotions, positive self-concept, optimism, altruism, the ability to convert traumatic helplessness into learned helpfulness, and an active coping style in the face of stressors. Data on adult resilience come from studies of men in combat and show the importance of bonding with a group sharing a mission and having the capacity to tolerate high levels of fear and still perform effectively. Glucocorticoids and dehydroepiandrosterone (DHEA) are secreted in response to stress. Cortisol has regulatory effects on the hippocampus, amygdala, and prefrontal cortex and facilitates the encoding of emotion-related

Figure 1 Map of suicide rates per 100 000 as of 2002, the most recent year available.

memory. DHEA promotes psychological resilience and there is a negative correlation between DHEA and the severity of posttraumatic stress disorder (PTSD). Also, several studies have found a negative correlation between plasma DHEA levels and depressive symptoms.

Animal Models

The first nonhuman primate study of early adversity used animals raised in social impoverishment with same-aged peers rather than with their mothers (Table 1). Peer-reared monkeys have lower serotonergic activity than maternally raised monkeys, with the defect persisting into adulthood and being associated with greater aggression and impulsivity. Appropriate parental input is critically important for normative development of the hypothalamic–pituitary–adrenal (HPA) axis and neurotransmitter system function. Primates removed from their mothers and deprived of early participation in complex social groups later exhibit aberrations in neurochemical function, neuroendocrine stress axis activity, and many aspects of social behavior. However, individual variation in susceptibility to environmental manipulation remains. A gene–environment interaction has been demonstrated in the rhesus macaque between a serotonin transporter gene promoter polymorphism and early rearing experience. Male monkeys raised without their mothers showed a monoamine oxidase A (MAOA) genotype–environment interaction effect on competitive behavior, with neither MAOA gene promoter polymorphism nor early rearing experience alone being sufficient to influence behavior, confirming that genetic susceptibility or vulnerability is critically dependent on environmental modulation.

Early Life Stressful Experiences

A history of child abuse is associated with a greater risk for depression and suicidal behavior in adult life independent of impulsivity, aggression, and borderline personality disorder. Risk for suicidal behavior in families of probands with mood disorders appears related to childhood abuse in probands, together with early onset of mood disorders and aggressive/impulsive traits. Individuals with a greater genetic risk for mood disorders and suicide are more likely to respond to stress by developing a depressive episode or exhibiting suicidal behavior.

There is a significant interaction between childhood maltreatment and low MAOA activity-associated alleles in modulating the risk for antisocial behavior, aggression, and violence. Low MAOA activity was a

Table 1 Early life environmental adversity and gene–environment interaction: effects on behavior

Study[a]	*Species*	*Test*	*Stress situation*	*Consequent alteration*
1	Monkeys	Early adversity	Social impoverishment, peer-reared	Lower serotonergic activity
2	Monkeys	Early adversity	Social impoverishment, peer-reared	Neurochemical function, neuroendocrine stress axis activity, social behavior
3	Monkeys	Early adversity	Peer-reared	Lower serotonergic activity, greater aggression and impulsivity
4	Human	Early adversity	History of child abuse	Risk for depression and suicidal behavior in adult
5, 6	Human	Early adversity	Child abuse	Suicidal behavior in adult
7	Human	Early adversity	Sexual abuse	Suicidal behavior in adult
8–10	Monkeys	Early adversity + genotype	Rearing adverse experience	Behavioral changes in serotonin transporter gene promoter polymorphism carriers
11, 12	Human	Early adversity + genotype	Childhood maltreatment	Antisocial behavior, aggressiveness, and violence in low-activity MAOA alleles carriers
13	Male human	Early adversity + genotype	History of abuse before 15 years	Higher impulsivity in low-activity MAOA alleles carriers
14	Male monkeys	Environmental modulation + genotype	Rearing adverse experience	Impaired social competition in low-activity MAOA gene promoter polymorphism carriers

risk factor only when combined with an adverse childhood environment, a finding replicated in a community-based sample. We reported that the lower expression allele of MAOA gene was associated with a history of early abuse (before 15 years of age) and with higher impulsivity in males, suggesting that the genetic variation may spare females of the effects of early abuse experiences on impulsive traits in adulthood.

Maltreatment, as defined by maternal rejection, loss of a primary caregiver, harsh discipline, physical or sexual abuse, interparental violence, parental neglect, or inconsistent discipline, is a risk factor for conduct disorder. Adverse parenting can involve neglect, but physical or sexual abuse has been more commonly studied for its impact on suicidal behavior. Severity of childhood sexual, but not physical, abuse predicted adult suicidal behavior independent of other known risk factors. The odds of a patient who was sexually abused as a child attempting suicide in adulthood are more than 10 times those of a patient who was never sexually abused.

Hypothalamic–Pituitary–Adrenal Axis

A great deal of work on depression and suicide has focused on the stress network, the HPA axis. In fact, hypercortisolism is a well-documented abnormality in mood disorders. People who commit suicide were found to have heavier adrenal glands than those who do not commit suicide, higher levels of corticotropin-releasing hormone (CRH) in the cerebrospinal fluid

Table 2 Cortisol and the hypothalamic–pituitary–adrenal (HPA) axis in stress responses and major depression

(CSF), and fewer CRH receptors in the cortex. Patients with major depression also show adrenal gland hypertrophy by computerized tomography and more CRH-synthesizing neurons and mRNA in the paraventricular hypothalamic nucleus. The overactivity of the HPA axis and alterations in neuropeptide systems have also been reported in abused populations, as also demonstrated in animal studies of maternal separation. Early life stress-induced changes of neuropeptide Y and CRH in adult rat brain can be modified by lithium treatment (Table 2).

Extrahypothalamic CRH System

CRH neurons are localized in central nervous system (CNS) areas other than the hypothalamus in several species, including nonhuman primates and humans. We were the first to describe a group of CRH immunoreactive neurons in the pedunculopontine tegmental nucleus and laterodorsal complex in the brain stem of humans that also expressed CRH mRNA. These neurons are located close to the locus coeruleus (LC), the dorsal raphe nucleus (DRN) and median raphe nucleus, and the substantia nigra – all monoaminergic nuclei that are differentially innervated by CRH axons. The noradrenergic LC receives the strongest CRH innervation, followed by the serotonergic DRN, with the dopaminergic substantia nigra having a very light innervation. The specificity of this anatomical localization may dictate the differential influence that CRH may exert on a specific neurotransmitter system.

Noradrenergic System

People who commit suicide have less norepinephrine (NE) in the brain stem but more α_2-adrenergic receptors, perhaps secondary to lower NE. In depressed suicides fewer LC neurons were found compared to controls (Table 3). There are conflicting results regarding tyrosine hydroxylase (TH; the rate-limiting enzyme in the biosynthesis of NE), which has been reported to be higher by some and lower by others. TH increases were reported when increased NE release led to transmitter depletion. Therefore, TH immunoreactivity could be state dependent, which would explain the conflicting results in the literature. In the prefrontal cortex, suicides have higher β-adrenergic binding, higher levels of NE, and higher α_1-adrenergic binding in specific cortical layers.

Table 3 Stress and suicide-related brain changes

Study[a]	*Species*	*Condition*	*Changes*
1	Rat	Chronic restraint stress	Apical dendrites of CA3 pyramidal neurons atrophy
2	Rat	Exposure to excess glucocorticoids	Decreased dendritic length and number of apical dendritic branch points
3	Human	Suicide	Serotonin transporter and 5-HT_{1A} binding changes localized to the ventral prefrontal cortex
4	Human	Suicide	Fewer locus coeruleus neurons
5–12	Human	Depression and anxiety	Fewer neurons and/or glia, lower size and/or cell density and dendritic length in prefrontal cortex and/or hippocampus
13	Human	Impulsive/violent subjects	Lower frontal and midbrain serotonin transporter binding
14	Rodents	Chronic stress	Reduced 5-HT_{1A} receptor protein and mRNA in hippocampus
15	Rat	Behavioral stress-induced depression	Cell death and dendritic shrinkage in the hippocampus
16	Human	Suicide	Fewer SERT mRNA expressing neurons in dorsal raphe
17	Human	Depression	Lower orbital frontal cortex serotonin 5-HT_{1A} receptor binding in higher lifetime aggression subjects
18	Human	Psychological trauma	Vulnerability to develop psychopathology in subjects with smaller hippocampus
19	Rat	Immobilization stress	Increased tryptophan hydroxylase
20	Human	Suicide	Increased tryptophan hydroxylase in dorsal raphe
21	Human	Suicide	Higher mRNA levels of tryptophan hydroxylase
22	Human	Suicide	More (and denser) serotonergic neurons in dorsal raphe

These noradrenergic changes in suicide may be stress related. In fact, increased noradrenergic and cortisol-dependent stress responses are reported in depression. Moreover, exposure to adverse childhood experiences can result in exaggerated sympathetic responses to stress in adulthood and such an effect would further deplete NE. Therefore, TH upregulation in the LC of suicide victims could potentially be a temporary response of the noradrenergic system to excessive NE release associated with the stress of the suicidal ideation. Animal studies show that both prolonged and brief maternal separation that occurs early produces persistent changes in tissue levels of brain monoamines and their metabolites in middle-aged female rats.

There is no correlation between CSF levels of NE, epinephrine, or their metabolites and suicidal behavior. Severe anxiety or agitation is associated with NE overactivity and also higher suicide risk and overactivity of the HPA axis. Urinary levels of 3-methoxy-4-hydroxyphenylglycol are higher in inpatients 24 h after a suicide attempt, indicating increased NE turnover following an attempt.

Children with PTSD have more suicidal ideation and attempts, excrete more NE and dopamine, and have more urinary free cortisol than overanxious children and healthy controls. Levels are correlated with duration and severity of illness.

In summary, studies on people who commit suicide and on patients with PTSD indicate that these stressed patients have higher NE activity, a finding not present in unstressed patients or animals. Increased noradrenergic activity together with fewer LC noradrenergic neurons and tone lead to NE depletion, increasing hopelessness. Thus, NE hyperactivity is state/stress related and probably has a precipitating role in suicidal behavior.

Serotonergic System

The HPA axis has a bidirectional relationship with the serotonergic system. There is a dose-dependent increase in tryptophan hydroxylase (TPH) protein and mRNA in rats subjected to immobilization stress. Higher TPH immunoreactivity and higher mRNA levels of the brain-expressed TPH gene, TPH2, were found in the DRN of depressed suicides compared to controls. In the prefrontal cortex of suicides, TPH immunoreactivity was also higher, as were TPH2 mRNA levels (Table 3). This may be a stress effect because dexamethasone and stress raise TPH immunoreactivity in the raphe nuclei.

Genetic studies on the TPH2 gene report an association with suicide but not with schizophrenia or schizophrenic subjects who died by suicide. Other investigators have searched for associations between variants of the TPH2 gene and psychiatric disorders and suicide. However, only one functional ARG441HIS missense variant was identified in the coding region of the TPH2 gene and found to be present in approximately 10% of a population of elder major depressives, and it was not detected in a cohort affected with bipolar disorder. When expressed in PC12 cells, this genetic variant was found to decrease serotonin levels by 80% compared to wild type, demonstrating that this single nucleotide polymorphism (SNP) is a loss-of-function mutation. This SNP appears to represent a rare functional polymorphism since it has not been found in several other populations studied.

The TPH1 gene is not expressed in the brain as abundantly as in the periphery, and a polymorphism (A779C) has been associated with suicide-related behavior. This association was found in a meta-analysis that also suggested that this specific allele has a dose-dependent effect on the risk of suicidal behavior, at least in Caucasians. Courtet suggested that TPH may be a quantitative risk factor because a greater effect of the gene leads to more pronounced serotonergic dysfunction with higher levels of anger and more severe suicidal acts. TPH1 alleles were associated with a blunted prolactin response to fenfluramine and with low CSF levels of 5-hydroxyindolacetic acid in healthy volunteers, reflecting possible serotonergic alterations outside the nervous system. Therefore, in stress situations TPH expression might be increased, but in psychiatric populations there might be a genetic impairment of the gene in the brain, which may lead to altered serotonergic responses in the CNS that may facilitate suicidal acts. Outside the CNS, TPH1 alterations may impair autonomic responses to fear and stress, resulting in a failure to cope with these situations and consequent proportional anger and more severe suicidal acts.

Chronic stress reduces 5-HT_{1A} receptor protein and mRNA in the hippocampus of rodents, an effect prevented by adrenalectomy (Table 3). 5-HT_{1A} receptor knockout mice are anxious, but when the receptor is rescued during the perinatal period, rather than during early adulthood, the mice do not exhibit anxious behavior. This reversal may be related to some structural changes in the brain that can impair resilience to stress. Serotonin and the 5-HT_{1A} receptor have an important role in development, including neural growth, cellular homeostasis, and antiapoptosis. Gene polymorphisms of the human 5-HT_{1A} receptor have been studied in psychiatric populations. The 5-HT_{1A} receptor promoter region C(-1019)G polymorphism was found to have a significant association with schizophrenia and substance use disorder but not with major depression, bipolar disorder, alcoholism, panic disorder, or suicide attempt. Therefore, it seems that the mechanism potentially responsible for 5-HT_{1A} receptor changes in suicide is not a genetic alteration but, rather, an expression alteration perhaps related to plasticity responses to stress.

Serotonin and Cell Proliferation and Survival

Stimulation of 5-HT_{1A} receptor is necessary for the proliferative response of cells treated with 5-HT. 5-HT_{1A} receptor knockout mice do not show increased neurogenesis and behavioral changes after

treatment with antidepressant drugs. In addition, behavioral stress-induced depression in animals is associated with cell death and dendritic shrinkage that can be reversed in the hippocampus by treatment with antidepressants and neurotrophins. It has been proposed that cell survival can be mediated by the 5-HT_{1A} receptor via inhibition of caspase-3 and other proapoptotic proteins. Remarkably, one study suggests that the expression of Akt1, Bcl-2, and other antiapoptotic proteins is decreased in the cortex of schizophrenics, and that the antimania drug Li^+ increases the number of Bcl-2 immunoreactive cells in several layers of the frontal cortex, dentate gyrus, and striatum of rats.

Dopaminergic System

Significant strides have been made in understanding how the brain regulates reward and motivation (hedonia), response to fear (effective behaviors despite fear), and social behaviors (altruism, and bonding and teamwork). The neural mechanisms that mediate these functions are relevant to how an individual responds to extreme stress and may account for the resilience to suicidal thoughts. The mesolimbic dopamine pathways, originating in the ventral tegmental area (VTA), are involved in reward and hedonic tone. Other regions involved in dopamine signaling are the dorsal and ventral striatum (i.e., nucleus accumbens) and the amygdala. Functional interactions between dopamine, glutamate, *N*-methyl-D-aspartate (NMDA), and dopamine receptors are critical to the proper functioning of reward circuits. Neurons of the orbital frontal cortex, a target of the VTA, have the ability to discriminate among rewards based on their motivational value.

The dopaminergic system appears abnormal in depression, and it may be associated with suicidal behavior. A low level of homovanillic acid in CSF is found in depressed suicide attempters, and this abnormality is specifically associated with the attempter status. Preclinical studies indicate that there may be a genetically determined mesocortical and mesoaccumbens dopamine response to stress that relates to learned helplessness. The severity of depression was shown to correlate with the rewarding effects of amphetamine, via a mechanism possibly related to synaptic dopamine depletion with upregulation of dopamine receptors.

No alteration of mRNA for dopamine D1 and D2 receptors was found in the caudate nucleus of suicide victims, nor dopamine D4 receptor binding. Our studies have found no differences in D1, D2, or dopamine transporter in suicides compared to controls. The role of dopamine in suicide is not compelling, and low dopaminergic tone seems to be associated with depression.

Sex Hormones

Another mechanism of defective versus resilient response to stress might be related to sex hormones. Aggression is the aspect of human behavior most often linked to testosterone concentrations, and suicide is more frequent in men. Psychological stress is associated with decreases in testosterone levels, and soldiers participating in physically and psychologically stressful training exercises show a lowering of testosterone levels. Also, lower plasma testosterone is associated with depression in men. On the other hand, estrogen (as well as progesterone) produces a relative resistance to glucocorticoid feedback. These data suggest that physiological doses of estradiol are inhibitory to stress responsiveness. These hormonal differences might play a role in the different rates of suicide in men and women.

Neuroanatomical Studies

Brain imaging and postmortem studies in depressed and anxious individuals have demonstrated atrophy of the prefrontal cortex and hippocampus, as indicated by fewer neurons and glia, lower size and/or cell density, and reduced dendritic length. A study of monozygotic twins discordant for trauma exposure found evidence that smaller hippocampal volume may constitute a risk factor for the development of stress-related psychopathology (Table 3).

The cognitive framework for decision making is relevant to suicidal behavior and volitional acts. Both implicate the ventromedial prefrontal cortex, as well as the amygdala and somatosensory and insular cortex, and the underlying white matter. There are reports of changes in amygdala volume in depression. The amygdala also modulates conditioned responses to rewarding stimuli, being part of a circuit involving subiculum, bed nucleus of the stria terminalis, nucleus accumbens, and medial prefrontal cortex. The cyclic adenosine monophosphate (cAMP) pathway and cAMP response element binding protein in the amygdala promote both aversive and rewarding associations. These neural networks establish the emotional value of a reward memory, as well as its strength and persistence. The molecular basis for such plasticity is just beginning to be understood.

During the expression of fear-related behaviors, the lateral amygdala engages the central nucleus, which projects to areas of the hypothalamus and brain

stem that mediate the autonomic, endocrine, and behavioral responses associated with fear. Failure to achieve an adequate level of activation of the medial prefrontal cortex after memory extinction might lead to persistent fear responses. Individuals with the capacity to function well after experiencing states of high fear may have potent medial prefrontal cortex inhibition of amygdala responsiveness.

The ventral prefrontal cortex is believed to play a role in behavioral inhibition and in the expression of emotions. Damage to the ventromedial prefrontal cortex results in defects of social behavior, including a failure to observe social conventions and a tendency to make poor decisions. The orbitofrontal cortex has been implicated in the neurobiology of suicide. This region is activated during response inhibition and decision making. Therefore, the prefrontal cortex provides insight into consequences of future actions, and its dysfunction might contribute to a reduced judgment of the consequence of a final act, facilitating the possibility of acting on suicidal thoughts in these patients. Impaired decision making and impulsive behavior are associated with suicidality. The orbital prefrontal and anterior cingulate cortices are also part of an anatomical circuitry of emotion and aggression. The activation of these regions is part of an effort to suppress emotions and enrolls an inhibitory projection to the amygdala. Imaging studies using positron emission tomography (PET) also indicate an inverse relationship between the activity of the prefrontal cortex and that of the amygdala.

A single photon emission computed tomography study of borderline or antisocial personality disorder patients found lower regional cerebral blood flow in brain areas associated with self-harm or harm to others. These regions included the right lateral temporal cortex (BA21), the right frontopolar cortex (BA10), and the right ventrolateral prefrontal cortex (BA47). Females with impulsive borderline personality disorder who attempted suicide showed PET hypometabolism in the medial orbital frontal cortex bilaterally, including BA9–BA11, compared to healthy controls. Lower frontal and midbrain serotonin transporter binding was observed in impulsive/violent subjects compared to controls, and an inverse correlation was found between 5-HT_{1A} binding and 5-HT_{2A} binding in the orbitofrontal cortex and lifetime aggression. Inferior frontal white matter microstructural defects, as shown by lower fractional anisotropy, have been found in association with aggressive impulsivity in males with schizophrenia. In suicide victims, the changes in serotonin transport protein (SERT) and 5-HT_{1A} binding are localized to the ventral prefrontal cortex, whereas SERT changes in depression are widespread (Table 3). Therefore, the implication of ventral prefrontal cortex in suicide appears to be related to behavioral control and not to depression.

Conclusions

Only a small fraction of patients with suicidal thoughts attempt suicide, few attempts prove to be fatal, and risk factors for suicide attempts (e.g., younger and female) and completions (e.g., older and male) differ markedly. The assessment of suicide risk should include the evaluation of the socio/environmental status and whether protective/precipitating factors exist, including characteristics of resilience.

Genes and environment interact in stress responses leading to phenotype expression (suicidal behavior). The interaction between genes and environment has long been acknowledged to account for significant individual variation in susceptibility or resilience to risk factors. This interaction seems to change the function of the neurotransmitters systems. One of the environmental factors thought to play a critical role in leading to the risk for complex behavioral disorders is early experience, particularly during infancy and early childhood. Stress seems to have an important role in the expression of psychobiological factors that contribute to suicide. Suicide may be the result of not only gene–gene interactions but also gene–environmental interactions, but little attention has been paid to this possible interplay.

Psychosocial factors are often associated with and not independent from psychiatric illness. Psychiatric disorders can provoke job or relationship failure or prevent the beginning of stable employment or stable relationships. Moreover, psychiatric illness and psychosocial adversity can combine to increase a person's hopelessness and thereby potentially increase the risk for suicidal behavior. It is difficult to separate the impact of psychosocial adversity from that of psychiatric illness.

The concept of allostatic load as a cumulative measure of physiological dysregulation over multiple systems has proven to be useful as a predictor of functional decline in elderly men and women. This concept could be used in the study of suicide in order to identify cumulative neurobiological/stress-related abnormalities that may be prognostic of poor outcome.

Stress and Vulnerability to Brain Damage

C D Conrad, R L Wright, and K J McLaughlin, Arizona State University, Tempe, AZ, USA

Introduction

The stress response is critical for the success of an individual and helps one adapt to changes in the environment. The hippocampus, a brain region involved with learning and memory, is particularly sensitive to stress hormones and responds to them through changes in structure, neurochemistry, and excitability. In isolation, acute stress does not impact overall hippocampal health, but acute stress does exacerbate hippocampal damage when combined with a metabolic challenge. On the other hand, chronic stress is directly responsible for hippocampal dendritic retraction, which can compromise hippocampal function, such as spatial memory. When chronic stress ends, hippocampal dendritic retraction can reverse to its prestress condition, which also restores hippocampal function. However, hippocampal volume reductions or neuronal dendritic retraction may increase the risk for hippocampal cell death from other insults or conditions. Understanding these risks and taking steps to avoid or attenuate the impact of stress can help mitigate the potential negative effects of stress on the body and brain.

The Stress Response

The resources of the body are partitioned among many competing needs for an organism's long-term survival; these include digestion, reproduction, and growth. A stress response allows energy to be commandeered for immediate use because an organism will not survive unless energy is redirected to serve these urgent needs, such as escape or defense against real or perceived danger. The immediate response to a stressor, an event that triggers a stress response, requires energy sources to be diverted away from digestion, reproduction, and growth and to be redirected toward the heart, skeletal muscles, and brain. All of these changes enhance an individual's immediate needs for surviving a threat.

The hormonal changes in response to a stressor involve two main components: the sympathetic nervous system (SNS) and the hypothalamic–pituitary–adrenal (HPA) axis. The SNS is activated relatively quickly in response to a stressor because neural activation triggers the adrenal medulla to release epinephrine within seconds after stressor onset. Epinephrine increases heart rate, dilates the pupils, and enhances blood flow to the muscles, while decreasing blood flow to the digestive and reproductive tracts. In contrast to the fast-acting SNS, the HPA axis eventually triggers the adrenal cortex to release glucocorticoids, which are stress steroids that include cortisol in humans and corticosterone in rats and mice. Since HPA axis activation is hormonally mediated, glucocorticoid release takes much longer than epinephrine release, with peak glucocorticoid levels in the bloodstream occurring 15–30 min after stressor onset. Glucocorticoids make energy available, mainly through gluconeogenesis, which is the breakdown of protein into glucose, and inhibit the storage of sugar by blocking insulin actions. The HPA axis complements the SNS by providing energy resources after the initial reserves are depleted.

Hippocampal Vulnerability to Damage Following Acute Stress

While acute stress is essential for individuals to respond to their environment, acute stress can have negative ramifications on the brain under certain circumstances. One brain region that is particularly vulnerable to stress is the hippocampus, which is thought to be susceptible to stress for at least two reasons. First, the hippocampus contains a high number of receptors for glucocorticoids, which may make the hippocampus sensitive to changes in glucocorticoid levels. Indeed, many of the changes found in the hippocampus following acute stress can be produced by exogenous glucocorticoids and prevented by drugs that interfere with glucocorticoid release and/or actions. Second, the role of the hippocampus in learning and memory necessitates that the hippocampus remain labile and this plasticity may make it vulnerable to the influence of acute stress.

Acute stress or glucocorticoid elevations can influence the hippocampus in different ways, which may include neurogenesis inhibition, neurochemistry alterations, neuron excitability changes, and even neuron death. The hippocampus is one of the few brain regions whereby neurogenesis continues beyond development into adulthood. However, proliferating cells in the hippocampus are markedly reduced following a single exposure to a stressful experience or glucocorticoids. Several neurotransmitter systems and neurotrophic factors are altered by acute stress and glucocorticoids. Acute stress and glucocorticoids facilitate the release or responsiveness of serotonin (5-HT), glutamate, norepinephrine (noradrenaline), and nerve growth factors (NGFs), alters the inhibitory tone of the γ-aminobutyric acid (GABA) system, and

decreases brain-derived nerve growth factor (BDNF). The changes in each of these systems can have profound effects on the hippocampus. For example, enhanced 5-HT tends to negatively modulate hippocampal functioning and reduced BDNF can hinder structural plasticity within the hippocampus. Acute stress and glucocorticoids can also influence electrophysiological properties such as calcium conductance, a process that influences neurotransmitter release and cell communication. All of these processes are highly regulated under a tightly coordinated system so that alterations following acute stress are quickly returned to the prestress condition.

The mechanisms underlying acute stress effects on hippocampal neurogenesis, neurochemistry, and neuron excitability differ from those underlying hippocampal cell death. First, changes in hippocampal neurogenesis, neurochemistry, and neuron excitability are reversible, whereas hippocampal cell loss is permanent. Second, glucocorticoid elevations directly mediate the actions of acute stress on hippocampal neurogenesis, neurochemistry, and electrophysiology, but glucocorticoids alone fail to kill hippocampal neurons. Instead, acute stress compromises hippocampal neurons by reducing their ability to withstand a concurrent metabolic challenge. A metabolic challenge refers to abnormal metabolic events such as ischemia (localized blood flow obstruction), stroke (generalized blood flow obstruction), hypoxia (lack of oxygen), hypoglycemia/hyperglycemia (abnormal sugar levels), and malnutrition (insufficient nutrition, minerals, and vitamins). When severe, any of these metabolic events by themselves can be damaging to the hippocampus and other brain regions. Although, when one of these events occurs in a small brief episode, individuals may recover without noticeable brain damage. Moreover, the individuals may not even recognize that they experienced a metabolic event. However, when the small, typically uneventful metabolic event coincides with acute stress and elevated glucocorticoids, the hippocampus can become sufficiently compromised, such that brain damage occurs. Individuals experiencing stroke or ischemic challenges showed more neuron loss within the hippocampus following acute stress or elevated glucocorticoids than when ischemia occurred alone. Studies with animals have shown that neurotoxins applied to the hippocampus at subthreshold levels of neurotoxicity caused severe hippocampal neuronal death when the subthreshold level of neurotoxin coincided with acute stress or glucocorticoid elevations. Thus, changes in hippocampal neurogenesis, neurochemistry, and electrophysiology can be altered by acute stress alone, whereas hippocampal cell death requires acute stress to coincide with a metabolic challenge.

As people age, the probability of experiencing a metabolic challenge increases, and the likelihood that acute stress exacerbates damage to the hippocampus is enhanced. Moreover, the hippocampus participates in the regulation of the HPA axis and damage to the hippocampus disrupts HPA axis activity, producing a cascading cycle that leads to more damage. For example, hippocampal damage elevates basal levels of glucocorticoids and delays glucocorticoid recovery to baseline following a stressor. Consequently, a metabolic challenge that produces a small degree of hippocampal damage will increase the probability of further damage because this individual will have elevated glucocorticoids that can exacerbate hippocampal damage following a recurrent metabolic challenge. The relevance of small, subthreshold metabolic challenges is hypothesized to influence other neurological conditions. For example, small inconspicuous strokes or cerebrovascular accidents, which are referred to as silent cerebral infarctions (SCIs), are hypothesized to underlie late-onset depression. The risk factors for SCI are cigarette smoking and hypertension. These findings can be extrapolated to indicate that cigarette smoking and hypertension can further increase one's vulnerability to metabolic challenges and the likelihood of experiencing hippocampal damage exacerbated by stress. Thus, acute stress is important and essential for proper functioning and survival of an individual, but can have negative ramifications including irreversible brain damage under some circumstances.

Hippocampal Vulnerability to Damage Following Chronic Stress

Early, ground-breaking studies in the 1970s and 1980s by Aus Der Mühlen, Landfield, Sapolsky, and McEwen first revealed that the brain is negatively impacted by chronic stress, which is defined as the persistence of acute stress or repeated exposure to separate episodes of acute stress. These seminal studies demonstrated that chronic stress can potentially damage the brain in guinea pigs and rodents. Subsequent studies showed that prolonged and elevated glucocorticoids mediated the neuronal loss within the hippocampus caused by chronic stress in laboratory animals. However, recent work in the 1990s and early 2000s indicated that chronic stress or glucocorticoids, alone, were insufficient to produce hippocampal damage in nonhuman primates and humans. Consequently, chronic stress and glucocorticoids were hypothesized to contribute to eventual hippocampal cell death, but they were not the sole determinant for killing hippocampal neurons.

A less extreme change in the hippocampus following chronic stress, but far more reliable than cell

death, is dendritic retraction. Chronic stress consistently causes hippocampal dendritic retraction, which is characterized by decreased dendritic branch points and total dendritic length. Dendritic arbors are specialized regions of the neuron that receive information from neuronal afferents and alterations in dendritic trees can influence neuronal communication. The primary regions of the hippocampus are the cornu ammon regions (CA1, CA2, CA3, CA4) and the dentate gyrus, with the CA3 region being the most vulnerable because it expresses dendritic retraction first in response to chronic stress. In addition to the hippocampus, chronic stress produces dendritic retraction in neurons of the prefrontal cortex and increases dendritic complexity in neurons of the amygdala. Thus, chronic stress influences neuronal architecture in several brain regions.

Many of the neurotransmitters that are altered by acute stress are involved in producing hippocampal dendritic retraction following chronic stress (Figure 1). Chronic stress causes hippocampal CA3 dendritic retraction through glucocorticoids that most likely act on glucocorticoid receptors (GR or type II). Chronic stress reduces dendritic arborization through mechanisms that include enhancing 5-HT and glutamate transmission, and altering GABA and neurotrophic expression. Any one or a combination of changes in hippocampal neurochemistry following chronic stress may contribute to hippocampal dendritic retraction.

Figure 1 Repeated glucocorticoid (GC) elevations from chronic stress directly influence CA3 hippocampal neurons and their afferents (dentate gyrus granule cells, associational/commissural fibers (A/C), entorhinal cortex (EC)), because all of these cells express glucocorticoid receptors (GR). Excess glutamate (Glu via *N*-methyl-D-aspartate receptor (NMDA)) and serotonin (5-HT) as well as altered inhibitory tone from interneurons and gamma-aminobutyric acid (GABA) modulate CA3 dendritic retraction. Reduced levels of brain-derived neurotropic factor (BDNF), which is retrogradely transported to CA3 neurons may permit CA3 dendritic retraction. Solid arrows: enhanced tone permits CA3 dendritic retraction; open arrows: reduced tone permits CA3 dendritic retraction. Reproduced from Conrad CD (2006) What is the functional significance of chronic stress-induced CA3 dendritic retraction within the hippocampus? *Behavioral and Cognitive Neuroscience Reviews* 5: 41–60, with permission from Sage Press.

Hippocampal dendritic retraction following chronic stress may be a compensatory response to protect against extended excitatory amino acid stimulation, which can kill neurons. Consequently, dendritic restructuring may be a mechanism that allows the hippocampus to maintain stability through change (termed homeostasis, and recently termed allostasis). The price of maintaining homeostasis/allostasis under adverse conditions is termed, allostatic load. The consequence of this dendritic restructuring and allostatic load can be detrimental. For example, the presence of hippocampal dendritic retraction has typically corresponded to impaired hippocampal function, such as impaired spatial memory. Interventions that block hippocampal dendritic retraction also prevent spatial memory deficits. Moreover, CA3 hippocampal neurons expressing dendritic retraction following chronic stress are more likely to be killed following a neurotoxin challenge compared to neurons that fail to express dendritic retraction. Another hypothesis is that neurons expressing dendritic retraction are progressing toward neuronal death; however, chronic stress does not always lead to brain damage. Moreover, other brain regions, such as the amygdala, show enhanced dendritic arborization. So, it seems unlikely that both decreases and increases in dendritic complexity will progress to cell death. Thus, hippocampal neurons expressing dendritic retraction may express this type of plasticity as a compensatory response to continual stress and glucocorticoids, but at the risk of compromising efficient function and even the survival of neurons within the hippocampus following a metabolic challenge.

Factors That Influence Hippocampal Vulnerability to Chronic Stress

When an individual is under chronic stress and expresses hippocampal dendritic retraction or volume reductions, then this individual may be at an increased risk for irreversible brain damage. Although not every individual exposed to chronic stress shows debilitating symptoms, as some individuals fully recover following a bout of chronic stress, others exhibit long-term symptoms. Thus, a group of individuals can show a wide range of responses to chronic stress

conditions that appear similar. What produces these individual differences, and why do some individuals recover while others do not? Several factors can influence an individual's vulnerability to chronic stress; these include genetics, early life exposure to adversity, gender, and coping strategies.

Influence of Genetics on the Hippocampus Vulnerability to Chronic Stress

Factors that can facilitate or mitigate the expression of dendritic retraction following chronic stress will influence the hippocampus' vulnerability to cognitive dysfunction and susceptibility to damage. Neurochemical alterations can have a profound influence on hippocampal sensitivity to brain damage. As examples, individuals expressing few receptors for neurotropic factors or those with a high sensitivity to glutamate, which can lower the threshold for seizures, may be more inclined to experience structural changes to the hippocampus that will increase the risk for hippocampal damage than individuals with a high sensitivity for neurotropins and low sensitivity to glutamate. Anxiety predisposition can also guide one's susceptibility for increased risk of hippocampal damage. Rats that are prescreened for anxiety profile and then subjected to chronic stress show a very interesting pattern. Those rats characterized as high anxiety experience poor hippocampal cognitive function and altered hippocampal neurochemical profiles following chronic stress, whereas rats characterized as low anxiety performed well on hippocampal-dependent tasks and had nearly stable hippocampal neurochemical profiles. Particular strains of mice that are more fearful than normal and have elevated HPA axis activity show an increased risk of hippocampus to damage. Even maternal care can significantly influence the function of the HPA axis of the developing pups and this may be a mechanism by which genetics can influence maternal behavior (e.g., amount of maternal licking and grooming in rats), which can lead to dramatic differences in the pup's stress reactivity.

Influence of Early Life Events on Hippocampal Vulnerability to Chronic Stress

Early life experiences can influence the development of the HPA axis and subsequent HPA axis function later in life that includes alterations in the hippocampus. Removing rat pups from the mother (dam) for various periods early in life is a well-established model of early life variations in parental attention. When rat pups are briefly removed from the dam (3–15 min), the dam spends more time licking and grooming the pups when they are returned. Increased licking and grooming induced by brief maternal separation can alter the reactivity of the HPA axis. These pups exposed to brief separation show in adulthood increased GR in the hippocampus, decreased corticotrophin-releasing factor (CRF) synthesis and reduced secretion of adrenocorticotrophin hormone (ACTH), and glucocorticoids in response to stress. Consequently, the hippocampus has an enhanced capacity to detect glucocorticoids and can efficiently contribute to HPA axis negative feedback. In contrast, when the dam–pup separation is extended (3–6 h), the pups show an increased hormonal response to stressors later in life characterized by increased CRF mRNA and decreased glucocorticoid negative feedback on the HPA axis following a stressor. This reduced capacity to detect glucocorticoids contributes to inefficient negative feedback on the HPA axis, which can further contribute to increased CRF, ACTH, and glucocorticoid release from the hypothalamus, pituitary, and adrenal, respectively. A critical difference between the brief dam–pup separation (3–15 min) and the extended dam–pup separation (3–6 h) is the increased attention of the dams toward their pups. Dams that have been separated from their pups for extended durations are unable to provide sufficient attention to overcome the negative impact of the separation on the pups. Humans show similar patterns as observed with rodents in that individuals whose parents emotionally neglected them, or experienced harsh and inconsistent parenting when they were children, show a greater risk for depression, alcoholism, and anxiety disorders. Therefore, it appears that early life experiences can alter the function of the adult brain across animals and humans, with the hippocampus being particularly susceptible to the influence of early life exposure to stress hormones.

Maternal separation for extended periods also alters the serotonergic system. In monkeys and rats, extended maternal separation increases serotonin levels in adulthood. Since serotonin contributes to hippocampal dendritic retraction, enhanced serotonin levels following this developmental manipulation may contribute to hippocampal susceptibility to damage following insults in adulthood. Changes in the serotonin system early in life may work together with increased activity of the HPA axis to make the adult more susceptible to dendritic retraction as well as more permanent brain damage from other insults.

The prenatal period is another developmental stage that is susceptible to the effects of stress and glucocorticoids on the HPA axis and the hippocampus. Generally, the placenta protects the fetus from stress and high levels of glucocorticoids that the mother may experience. The placenta inactivates glucocorticoids to prevent the majority of circulating glucocorticoids from reaching the fetus. However, the fetus

can exhibit long-lasting effects following exposure to high levels of glucocorticoids through the administration of synthetic glucocorticoids, drugs with some glucocorticoid activity, or from extremely high levels of maternal glucocorticoids. In nonhuman primates, exposure to synthetic glucocorticoids, such as dexamethasone, during gestation produces hippocampal volume reductions that last into adulthood. In rats, prenatal exposure to glucocorticoids reduces the number of hippocampal receptors for glucocorticoids (GR and mineralocorticoid (MR)), and elevates the basal secretion of glucocorticoids even in adulthood. These findings show that exposure of the developing fetus to elevated glucocorticoids can permanently alter the HPA axis. These HPA axis changes can increase the exposure of the hippocampus to glucocorticoids, which may further compromise the hippocampus (Figure 2).

Influence of Gender on Hippocampal Vulnerability to Chronic Stress

The hippocampus is sexually dimorphic in both its anatomy and neurochemistry and these dimorphisms contribute to sex differences in stress sensitivity. In general, females have a larger hippocampus than males, while males have a more complex CA1 dendritic tree than females until late in life. The receptors that detect glucocorticoids (GR and MR) are abundant in the hippocampus of both sexes. Yet, females appear to have a greater overall binding capacity for glucocorticoids and show nearly 20% higher basal and stress levels of glucocorticoids than males. In contrast, the male hippocampus has a high affinity for glucocorticoids and hippocampal GR downregulates following adrenalectomy. Moreover, androgen administration downregulates GR without altering MR. Yet, MR may contribute to sex differences in response to glucocorticoids because ovarian hormones exert their actions primarily on the MR. All of these variables contribute to sexual dimorphisms within the hippocampus following chronic stress.

Chronic stress produces clear sex differences in the expression of GR, which may contribute to sex distinctions in hippocampal CA3 dendritic retraction. In males, chronic stress downregulates hippocampal GR and MR mRNA, while in females, chronic stress fails to alter hippocampal GR mRNA and even upregulates MR mRNA. These changes in receptor expression for males and females may influence the sensitivity of the hippocampus to chronic stress. Indeed, male rats express robust CA3 hippocampal dendritic retraction, while female rats show mild CA3 dendritic retraction. Males are thought to show a higher degree of hippocampal dendritic retraction than females because the dendritic tree affected by chronic stress in males is the apical region, which is three times larger than the basal region that is influenced by chronic stress in females. Moreover, two measures are typically used to detect changes in dendritic arbors (dendritic length and branch points)

Figure 2 Diagram of the effects of early life experiences on the development of the HPA axis and the possible outcomes for hippocampal brain damage. The black boxes outlined in solid lines with white lettering indicate events that occur in early life. The shaded boxes outlined in dashed lines indicate outcomes that persist into adulthood. GR, glucocorticoid receptors.

and chronic stress alters both measures in males, while only reducing dendritic branch points in females. In another example, when the hippocampus of chronically stressed rats is challenged with a neurotoxin, the male hippocampus is more susceptible to cell death than the female hippocampus. These findings are taken to suggest that chronic stress makes the hippocampus of males more vulnerable to brain damage than the hippocampus of females.

Sex differences in chronic stress-induced changes in neurotransmitter systems can also contribute to sexual dimorphisms in hippocampal vulnerability to chronic stress. Males display decreased levels of dopamine in both the medial prefrontal cortex and the amygdala and show increased levels of GABA in the CA3 region of the hippocampus in response to chronic stress. In contrast, chronic stress increases norepinephrine and serotonin levels in female CA3 neurons, and no significant changes are evident in the prefrontal cortex (including any changes in GABA). Therefore, chronic stress exerts sex-specific alterations on several neurotransmitter systems, and these changes may contribute to the differences seen in CA3 dendritic retraction.

Gonadal hormones are an important component underlying CA3 dendritic retraction following chronic stress. In gonadally intact, female rats, chronic stress produces mild CA3 dendritic retraction, which is exacerbated following ovariectomy, the removal of endogenous ovarian hormones (Figure 3). These findings suggest that estrogen may protect against CA3 dendritic retraction following chronic stress and corroborates findings showing that estrogen attenuates brain damage following ischemia, oxidative stress, and neurological disorders, including Alzheimer's and Parkinson's disease. While ovariectomy nearly eliminates estrogen and progesterone, changes in cholinergic and dopaminergic systems are also observed. Estrogen replacement reverses these alterations and may protect the brain through the activation of these neurotransmitter systems. Moreover, in males, testosterone can attenuate hippocampal damage caused by severe stress. Thus, gonadal hormones may dampen the potentially negative effects of chronic stress on the hippocampus.

Coping and Behaviors that Mitigate Hippocampal Vulnerability to Chronic Stress

The negative effects of stress on the brain, endocrine system, and behavior can be mitigated by a healthy lifestyle and positive social interactions. A high-fat diet increases glucocorticoid levels, reduces the ability of rats to habituate to stressors, and makes rats more susceptible to dendritic retraction. So, a low-fat diet may help to shield one from the adverse consequences of stress. Getting enough sleep also helps to maintain a healthy stress response, as people who sleep less than 4 h a night for several consecutive nights have high glucocorticoid levels in the evening when these glucocorticoid levels should be at their lowest. After a full night's sleep, glucocorticoid levels return to normal. Social support is another powerful regulator of the HPA axis in social animals including humans. In humans, social support consists of positive interactions with other individuals. Close relationships such as with a spouse or close friend seem be more valuable than the support of acquaintances. In animals exposed to a laboratory stressor, social support reduces the glucocorticoid response with important gender differences. Males are more likely to be stressed by social crowding, whereas females are stressed by social isolation. Thus, females may benefit more from group interactions during a stressful period than males. Moreover, stable social hierarchies and being in close proximity to others of the social group lead to low stress hormone levels compared to situations of social unrest or separation. Positive interactions, as perceived by the individual, can help mediate the stress response by allowing emotions associated with that stressor to be expressed. Thus, lifestyle can influence the HPA axis, which leads to a healthy stress response and reduced susceptibility to the adverse effects of stress.

An important consideration of these findings is that the type of activity that one is engaged in at the time of glucocorticoid elevations is more important in determining brain susceptibility to damage than whether glucocorticoids are solely elevated. For instance, exercise protects the body and brain against the ravages of stress by (1) increasing dendritic complexity and regional brain volume, (2) stimulating neurogenesis within the hippocampus, and (3) alleviating symptoms of depressed patients. However, exercise elevates stress hormones and the glucocorticoid response. Thus, exercise produces advantageous effects on hippocampal health while elevating glucocorticoids. In another example, exposure of a rat to a predator, a highly stressful experience, impairs subsequent memory ability on a task that requires hippocampal function. The predator exposure elevates glucocorticoids levels and attenuating glucocorticoid elevations can prevent the memory deficits. While glucocorticoid elevations appear to mediate the memory impairment, elevating glucocorticoids using a different activity, such as allowing access to sexually receptive females, fails to alter cognitive performance. These studies indicate that the susceptibility of the brain to damage following glucocorticoid elevations is highly intricate and most likely involves a complex interplay between glucocorticoid

Figure 3 Camera lucida tracings of CA3 hippocampal neurons. The top two neurons show that chronic stress (6 h restraint/day for 21 days) produces CA3 dendritic retraction in the apical (top) region of males. The middle two neurons show that a similar chronic stress manipulation produces CA3 dendritic retraction in the basal (bottom) region in gonadally intact females. However, CA3 dendritic retraction is mild because chronic stress reduced dendritic branch points without affecting dendritic length. The bottom two neurons show that chronic stress causes robust dendritic retraction in chronically stressed females following ovariectomy. Dendritic retraction is considered robust because both apical and basal dendritic trees are altered and dendritic retraction is reduced as determined by both measures of dendritic branch points and length. Note that the bottom two neurons represent the long-shafted type of neuron, which is more likely to express dendritic retraction following chronic stress than the short-shafted neuron type, which is represented in the top and middle panels. Top two neurons are reproduced from McEwen BS, Conrad CD, Kuroda Y, Frankfurt M, Maqarinos AM, and McKittrick C (1997) Prevention of stress-induced morphological and cognitive consequences. *European Neuropsychopharmacology* 7: S323–S328, with permission from Elsevier. Middle two neurons are reproduced from Galea LAM, McEwen BS, Tanapat P, Deak T, Spencer RL, and Dhabar FS (1997) Sex differences in dendritic atrophy of CA3 pyramidal neurons in response to chronic restraint stress. *Neuroscience* 81: 689–697, with permission from Elsevier. Bottom two neurons are reproduced from McLaughlin K, Baran SE, Wright RL, and Conrad CD (2005) Chronic stress enhances spatial memory in ovariectomized female rats despite CA3 dendritic retraction: Possible involvement of CA1 neurons. *Neuroscience* 135: 1045–1054, with permission from Elsevier.

levels and the brain regions activated at the time of glucocorticoid elevations, as opposed to being solely dependent upon glucocorticoid increases.

Conclusion and Parallels between the Animal and Human Literature

Hippocampal dendritic retraction in animal studies has important parallels with the literature on humans. Ten days following the termination of chronic stress in rodents, CA3 dendritic retraction reverses to the prestress condition and is essentially indistinguishable from nonstressed controls. Individuals diagnosed with Cushing's disease, characterized by the hypersecretion of glucocorticoids, show reduced hippocampal volumes based upon functional magnetic resonance imaging (fMRI) techniques. After treatment, the hippocampal volumes of Cushing's

patients show significant increases. A common characteristic of individuals with major depression is glucocorticoid hypersecretion and hippocampal volume reduction, which is corrected with antidepressant treatment. The restoration or partial reversal of hippocampal volume shrinkage following treatment suggests that irreversible cell death is an unlikely mechanism and instead, reversible processes such as dendritic retraction may be involved. Another parallel between the animal and human literature is that chronic stress exacerbates hippocampal damage in vulnerable conditions. In rodents, hippocampal damage by neurotoxin challenge is worsened following chronic stress when hippocampal dendritic retraction is present. Humans show similar vulnerabilities in that the hippocampus is susceptible to damage when chronic stress precedes or coincides with conditions such as AIDS, obesity, depression, and Alzheimer's disease. Thus, chronic stress can increase the risk for hippocampal vulnerability to permanent damage.

Stress Response and Self-Esteem

The Situational Characteristics of a Stressful Situation

One of the most influential articles on the characteristics of stress in the field of psychoneuroendocrinology was contributed in 1968 by John Mason, who had reviewed and summarized the available stress literature at the time. He concluded that novelty, unpredictability, high ego involvement, anticipation of negative consequences, and uncontrollability are the five main factors that contribute to the perception of a situation as stressful. Although not all of these factors are solely situational characteristics, Mason's hallmark article was often referred to as defining the aspects of the situation that contribute to the experience of stress. In the late 1980s and early 1990s, the psychoneuroendocrine and stress research field received an increase in attention by the advent of noninvasive and inexpensive hormonal measurement techniques that made the inclusion of hormonal measures feasible for a wide range of researchers and studies. Thus, at the end of the last millennium, Bondi and Picardi reviewed over 100 research articles investigating psychological aspects of stress and concluded that the uncontrollability of the situation significantly contributes to the experience of stress, and that a stressful situation can contribute to perceptions causing irritability and tension. Finally, an influential and important review was contributed by Dickerson and Kemeny in 2004, who again reviewed the available stress literature at the time and, through the means of conducting a meta-analysis, concluded that it is the situational aspect of 'social evaluative threat' that determines the stressfulness of a situation.

The best known psychosocial stressor, the public speaking task, is likely to contain all the elements that these three reviews have identified, but it is the social evaluative threat that seems to be at the heart of the stress experience. The authors of these reviews formulated a conceptual framework within which the social evaluative threat had a special connotation: they argued that throughout evolution, a social self-preservation system was important for the survival of the individual as well as the species. It can be further argued that the hormonal stress system might be the physiological correlate of the self-preservation system, to provide increased metabolic resources in times of social threat and thus increased demand. Independent of the validation of this model, however, it is likely that a situation that contains a social evaluative threat component will also have elements of uncontrollability, unpredictability, and high ego involvement, together with the other factors that were identified early on, and as such the recent refinements to the elements defining a stressful situation integrate well with the earlier findings made in that regard.

Personality Characteristics That Contribute to the Perception of Stress

One of the most influential figures in stress research, Lazarus, noted early on that stressful conditions per se fail to produce reliable effects on task performance. Keeping all situational variables constant, the same stressor can have minimal effect, lead to performance improvement, or result in significant performance impairment across different subjects. This led Lazarus and others to suggest that individual differences in psychological variables are likely to interact with situational components, and what is considered threatening for some, and thus stressful and performance impairing, might be perceived as stimulating by others, and thus produce beneficial effects.

Subsequent research by Lazarus and others identified the process of evaluation as crucial in explaining the impact of psychological variables on the stress response. Any internal or external stimulus is perceived as stressful only if it is evaluated as harmful, or threatening. This evaluation process is simplistically explained by a comparison of the demands of the situation with the available resources within the individual. If the resources exceed the demands, the situation is judged positively (challenging, stimulating), but if the demands exceed the resources, the situation is likely to be considered negatively (threatening, dangerous). Personality characteristics, especially self-esteem and locus of control, are likely to influence the perception of one's own resources as well as the perception of the demands.

Self-esteem is defined as the value we place on ourselves. Epidemiological studies have shown that low self-esteem is associated with negative life outcomes, including substance abuse, delinquency, unhappiness, depression, and worsened recovery after illnesses. On the other hand, high self-esteem has been linked to increased health and longevity. In studies of aging, a positive self-concept has been identified to play a key role in successful aging, predicting independence, cognitive stability, and general health in old age.

Internal locus of control can be defined as the perception that one's outcomes are determined by one's actions. Not surprisingly, internal locus of control and self-esteem are usually highly correlated. The key link of these variables to the experience of stress lies in their impact on the evaluation of any given situation. We postulate that in the evaluation of whether a given situation is perceived as threatening or challenging, self-esteem and internal locus of control systematically interact with situational factors. If a person attributes little importance to him/herself, and thinks he/she has little impact on the outcome of his or her own actions, this person will find more situations uncontrollable and unpredictable, and consequently will evaluate more situations as threatening and harmful.

Psychoneuroendocrinological Studies Showing the Role of Self-Esteem and Locus of Control in the Perception of Stress

We have been able to find support for this model in several psychoneuroendocrinological studies, using different laboratory stressors. In a computerized mental arithmetic task, we manipulated the performance (thus inducing failure) to invoke stress. In the setup used in this task, 52 students performed the task on computer terminals in front of them. Half of the students were exposed to a difficult version leading to low performance, compared to an easy version of the task with high performance for the other half. The students played the task in three 3-min segments, and had to announce their performance score after each segment to the investigator, who wrote the scores down on a board for everybody to see. Saliva sampling before, throughout, and after the task allowed us to assess the cortisol dynamics in relation to this paradigm. Interestingly, this task only triggered a significant cortisol release in the subjects who were in the low-performance group, and had low self-esteem and low internal locus of control. Neither low performance alone, nor low self-esteem and internal locus of control alone, were significant predictors of cortisol release, supporting the notion that these personality variables produce effects only in interaction with a potentially stressful situation. We suggest that the evaluation of the situation is at the core of this interaction.

In a second study, we used the 'public speaking' paradigm, where subjects have to give a speech and perform serial subtraction tasks in front of an audience, usually for a total of about 10 min. The audience consists of two to three persons who maintain a neutral facial expression throughout the subject's presentation. During the speech, the audience interacts with the subject only to indicate the amount of time that is left to talk, or to ask specific questions. During the serial subtraction task, the subject is interrupted only when making a mistake. The subject is then corrected and instructed to start the task over. The task has been shown to be a powerful stressor, stimulating the hypothalamic–pituitary–adrenal (HPA) axis and leading to significant free cortisol increases within 15–30 min following the onset of the task. In this study, we aimed to validate the hypothesis that in humans, repeated exposure to the same stressor will lead to quick habituation of the stress response. In order to test the habituation of the stress response, a total of 20 young healthy male college students were exposed to the public speaking stressor on five subsequent days. For this purpose, the public speaking was modified using different speech topics and serial subtraction tasks on each day. Interestingly, we found that only 13 of the 20 students showed the typical habituation pattern, with a normal stress response on day 1 being significantly reduced on day 2, and no longer present on the subsequent days. In the seven remaining students, however, the cortisol stress response continued to be present on all days. When analyzing the available psychological variables, it became apparent that low internal locus of control and low self-esteem were the best predictors of a lack of habituation of the cortisol stress response to repeated stress exposure. This can be interpreted as a sign that these personality variables systematically interact with the evaluation of a situation during repeated exposure.

The Hippocampus as a Possible Mediator of the Relationship between Self-Esteem, Locus of Control, and Stress

Although only very few studies on brain correlates of personality variables and endocrine function in humans are available, a picture emerges that puts the spotlight on the hippocampus as a likely mediator between the reported personality variations and stress responses. On the one hand, the hippocampus is one of the major limbic system structures involved in the regulation of the stress response. Psychological stress involves ambivalent signals that require considerable evaluation before a stress response is initiated. The limbic system and the hippocampus are implicated in assessing the salience of stimuli. Within the HPA system, one relevant limbic connection involves the hippocampus to the hypothalamus via the bed-nucleus of the stria terminalis, and the paraventricular nucleus. Interestingly, these connections are mostly inhibitory, and numerous studies show the role of the

hippocampus in inhibiting the HPA. This observation led researchers to suggest that a smaller hippocampus might be linked to higher HPA axis activity, since the hippocampus serves to inhibit HPA axis activity. Indeed, numerous studies over the past two decades have contributed evidence to show how excessive HPA axis activity is linked to smaller hippocampal volumes. Early models postulated that associations between hippocampal volumes and HPA axis activity might represent the consequence of excessive exposure of the hippocampus to glucocorticoids, due to their powerful neurotoxic properties.

More recently however, evidence has surfaced that allows for a link between naturally occurring variations in hippocampal volumes and HPA function. Functionally, the hippocampus is the primary structure for memory contextualization, and it is here that a link to self-esteem and locus of control could occur. When faced with a potentially threatening and harmful situation, memories of past events are employed to contribute to the evaluation of the current event. However, if specific situational and environmental characteristics associated with negative past events cannot be recalled, this lack of awareness of situational circumstance can lead to an overgeneralization of negative past events, and thus an increased likelihood to consider the current situations as stressful as well. Thus, poor contextualization mediated by the hippocampus could be linked to higher stress responses on the one hand, and lower self-esteem on the other. A hippocampus smaller in size might be at higher risk for poor memory contextualization and thus overgeneralization of negative events. We recently tested this hypothesis of a link between hippocampal volumes, personality variables, and stress responses in 20 healthy young male college students. All students underwent extensive psychological assessment for personality variables, including self-esteem and locus of control. In addition, they underwent magnetic resonance imaging employing a structural T1-weighted acquisition protocol, which produces high-resolution images of the cerebrum. A recently developed manual segmentation protocol was then applied to all images; this included non-uniformity correction, signal-intensity normalization, and Tailarach-like transformation for standardization of brain size. This protocol then allows for manual assessment of hippocampal volumes. Finally, all students were exposed to a computerized stress task, similar to the previously described mental arithmetic task. Saliva samples before, during, and after the task accompanied the testing to capture the cortisol stress response. Results first replicated earlier findings of mental arithmetic stress: only the students with low self-esteem and low internal locus of control showed a significant release of cortisol. Extending earlier findings, however, a correlation emerged between the cortisol stress response and self-esteem ($r = -0.45$, $p < 0.05$). Furthermore, a significant correlation emerged between the cortisol stress response and the total hippocampal volume ($r = -0.53$, $p = 0.03$), suggesting that the size of the hippocampus is related to the regulation of the HPA. Finally, supporting our initial hypothesis, we also observed a link between internal locus of control and hippocampal volume ($r = 0.66$, $p = 0.006$), and self-esteem and hippocampal volume ($r = 0.58$, $p = 0.02$). Using a recently developed voxel-based regression analysis, we were able to show subregions of the hippocampus specifically correlated with the interindividual variations in self-esteem and locus of control (**Figure 1**). These analyses can be interpreted as study participants scoring higher in self-esteem, and locus of control having higher signal intensities in the hippocampal regions that are significant in the analysis, showing which areas of the hippocampus are likely larger in the presence of high self-esteem and locus of control.

There is also some evidence that these effects are specific for the hippocampus. When employing total brain gray matter as control structure in correlations with both personality variables and cortisol response, none of the tested correlations was significant, suggesting that the observed relationships were indeed specific to this medial temporal lobe area that contains the hippocampus.

Conclusion: Personality Variables, Brain Structures, and Stress Responses

It will be a challenging task for future studies to ascertain the origin of the relationship observed here between personality variables, hippocampal volume, and stress response. There are a number of possibilities how these associations could develop. One such model puts naturally occurring variations in hippocampal volume at the origin of these functional relationships. It can be speculated that hippocampal volume is a consequence of multiple interacting factors during critical developmental stages, leading to the variation in hippocampal volumes that follows a normal distribution pattern. If, however, the size of this structure determines memory contextualization capabilities, this variation would then have personality and stress-related consequences. The impaired source monitoring would lead to an overgeneralization of the experience of failure and rejection, and consequently to a self-perception of being a failure or being socially rejected in general, which might produce low self-esteem and low locus of control during childhood and adolescence. The observed

Figure 1 Voxel-based regressional analysis between scores of self-esteem and locus of control and signal intensity in the hippocampus in a population of 20 healthy young men. Areas exceeding a threshold of $3 < t < -3$ are significant and suggest that high self-esteem and high internal locus of control are associated with larger areas of hippocampal gray matter, especially in the regions next to the quadrigeminal cistern, and the inferior horn of the lateral ventricle.

higher cortisol responses would then not be a direct consequence of small hippocampal volumes, but of the increased stress perception due to consistent unfavorable evaluations of ambiguous situations. Of course, the question arises why overgeneralization should then not also be an issue for positive life events – in other words, a general lack of source monitoring for both positive and negative life events, with no consequences on self-perception. One possible explanation here could be seen in the stress-specific function of the hippocampus within the limbic system. There is evidence that it is specifically the hippocampus (together with the anterior cingulate) that is involved in the stress response. It is also known that the anterior cingulate is particularly involved in error monitoring, which means its involvement is restricted to situations where a mismatch between expectations and reality occurs. These circumstances would make a specific role of the hippocampus in reaction to negative life events more probable.

Based on our findings to date, we suggest that reduced hippocampal volumes might play a role in the development of low self-esteem. This may in turn produce a higher susceptibility to perceive ambiguous situations as threatening, and thus stressful. The idea that hippocampal volume variation might be the cause for, rather than a consequence of, adverse functional and behavioral consequences has recently been proposed in conjunction with risk factors for psychopathology. Studies are emerging showing that smaller hippocampal volumes might be present prior to the onset of an illness. In our own studies, consistent differences in hippocampal volumes were present even among relatively young adults. This supports a model in which variations in brain morphology could become a pathway to certain personality

characteristics and behavioral phenotypes early in life, but longitudinal studies will be needed to examine these changes over time, and provide validation for the assumed associations.

Stress Response: Genetic Consequences

E Edwards, National Institute of Neurological Disorders and Stroke, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

The development of depression is a multifactorial process involving interactions of environmental and genetic factors. It imposes an enormous burden of illness on the medical system, as it affects about 15% of the population during the life span. The prominent clinical features of depression range from significant decrease of pleasure, interest, and cognitive abilities, to psychomotor dysfunction, to suicidal ideation, feeling of guilt, and psychosis. In addition, a host of vegetative symptoms, including anxiety, sleep disturbances, loss of appetite, weight loss, cardiovascular abnormalities, and gastrointestinal disturbances, have been demonstrated in depressed individuals.

Understanding the molecular and genetic bases of such a complex human condition has been hindered by the intricacy and inaccessibility of the human central nervous system. However, since the 1950s, the serendipitous discovery of agents to treat depression has inspired many hypotheses of the pathogenesis of depression. Most antidepressant drugs exert their therapeutic effects by modulating the presynaptic uptake transporters and degrading enzymes of serotonin and norepinephrine pathways. Consequently, investigators have focused research concerning the causality and treatment of depression on the metabolism of functional biogenic amines and the capacity of their respective receptors to alter intracellular signaling pathways and ultimately induce changes in gene activity.

Stress hormones have also been strongly linked to the pathogenesis of affective disorders, and exposure to a variety of stressors early in development modifies the regulation of hypothalamic and extrahypothalamic neurons, resulting in exaggerated and harmful endocrine-based physiological stress response later in life. Consequently, several research groups have formulated a hypothesis relating a dysfunction in stress hormone regulation to the causality of depression. Symptoms that are characteristics of depression include changes in functioning of the hypothalamic–pituitary–adrenocortical (HPA) system, resulting, in most depressed patients, in altered regulation of adrenocorticotropic hormone (ACTH) and cortisol secretory activity, impairment in corticosteroid receptor signaling, and increased secretion of corticotropin-releasing hormone.

Traditionally, researchers have encountered difficulties in developing and validating animal models of psychopathology because of the difficulties in providing direct evidence that the brain changes demonstrated in these models are identical to those in the human brain. Nevertheless, a variety of models of depression have been developed and they have advanced the study of the mechanisms of specific behaviors and their psychopathophysiology and have served as important screens for pharmacologic agents to treat depression. A wide range of animal models have been developed to date. They include models in which 'depressive behavior' is the result of pharmacologic treatment, the result of exposure to environmental stressors in development and in adulthood, and, more recently, the result of genetic selection or genetic manipulation. As discussed earlier, depression is heterogeneous in nature and there is great variability in the clinical responses to current antidepressants. A promising approach has been to identify key symptoms that can be studied in animals rather than trying to approximate the full spectrum of the clinical diagnosis of depression. A genetic model of affective disorder would allow the genetic analysis of polygenic traits that seem to underlie depression.

Key Considerations in Developing Models of Depression

Without a doubt, the basic goal for developing preclinical models is the overall relevance of the model to the human condition. Therefore the applicability of such models resides in their reflection of some intrinsic feature(s) of the human disorder, including heritability (see Tables 1 and 2). Reliability and validity are two key considerations to be considered when evaluating the possible effectiveness of an animal model. While the reliability of an animal model refers to the stability and reproducibility of the model, validity is established when criteria for at least one of several modes – namely face, construct, predictive, and etiological characteristic(s) – can be demonstrated. To meet the criteria for face validity the animal model should adhere to behaviors that are similar to those established as symptoms of the disorder. This particular validity marker as a sole mode of demonstration of a face validity animal model is sometimes difficult, relying on anthropomorphism; however, in other instances similarities can be rather meaningful. Another validity criterion is construct validity, which focuses on the relatedness of underlying mechanisms to the pathology and symptomatology of the human condition or disorder. On the other hand, predictive validity describes

Table 1 Behavioral features of some current models of depression[a]

SERT	↓	↓	↓	−	↑	?

[a]While the proposed strength of an animal model is often directly related to the number of deficits observed, each model has inherent advantages and disadvantages based on various validity measures of interest. In assessing the strength of any animal model, researchers need to address the dimensions of predictive, face, and construct validities. Face validity refers to phenomenological similarity between behaviors exhibited in the animal model and behaviors that are established as symptoms of the disorder being modeled. Predictive validity is considered by many researchers as particularly salient when determining the effectiveness of a model, since it is determined largely by response of a model to antidepressant drugs. Construct validity for an animal model relates to similarity in neurobiological mechanisms, etiology, or psychological mechanisms. As is the case in humans, behavioral characteristics associated with depressive disorders encompass a range of cognitive deficits and emotional behaviors. The behavioral features listed in this table are among the most important measures used in monitoring treatment effectiveness. A model with several behavioral deficits akin to those seen in human depression would be preferable for global assessment of drug efficacy. On the other hand, models with a single behavioral deficit may be more reliable for assessment of neurochemical mechanisms.

the extent to which an animal model will facilitate predictions in terms of responses to pharmacological agents used as treatment options. Etiological validity focuses on the underlying mechanisms that are responsible for the biological cause (including hereditability) or development of the behavior in the animal model and human.

Since it is established that genetic and environmental factors are known contributors to depressive disorders, the phenomenon in question in aspiring to the produce the most reliable preclinical model is the weight attributed to each factor, and how these factors act and interact remains to be clarified. Genetic studies with first-degree biological relatives of individuals with major depression demonstrate an enhanced likelihood (1.5–3 times) of suffering from this disorder as compared to the general population, while estimates of the heritability of unipolar depression range from 40% to 70%, which strongly underscores a genetic component. Although other studies demonstrate possible transmission of parental depression, such analysis maybe confounded by environmental contributions, since vulnerable genotypes may facilitate susceptibility to aversive life events and mediate individual differences in depression and its severity.

Given the weight of genotype in this disorder, one of the stronger and more relevant considerations in establishing a preclinical model of depression is heritability. As such, the various genetic animal models of depression have individually augmented our understanding of the neurobiological basis of the disorder and, in some cases, putative treatment paradigms.

Genetics Models of Depression: What Have We Learned So Far?

Animal models of depression have held the promise of providing a dynamic and integrated system that can be manipulated in order to increase our understanding of human mood disorders, test hypotheses about the etiology of these disorders, and potentially develop more effective therapies. However, appropriate models of human depression should fulfill as closely as possible the criteria described in the preceding section: strong phenomenology and similar path physiology (face validity), and comparable etiology (construct validity) and common treatment (predictive validity).

Note that the + or – symbol is not indicative of increase or decrease in the parameter featured. cLH, congenital learned helpless; FSL, Flinders Sensitive Line; WKY, Wistar Kyoto; $FBGR_{KO}$, forebrain, glucocorticoid receptor, knockout; HPA mutants, hypothalamic–pituitary–adrenal system mutation model; SERT, serotonin transporter knockout.

Twin, adoption, and family studies have suggested that genetic factors are important in the etiology of mood disorders. Hence, one approach to developing genetic models of depression has been to exploit long-term manipulations that simulate predisposition to depression, rather than a depressive response to a precipitating event. Other approaches have been designed by introduction and/or disruption of genes that are involved in the main molecular and biochemical mechanisms associated with depression: the monoamine system, the HPA system and the neurotrophin system.

Genetic Models of Depression

Congenital Learned Helpless Model

Exposure to uncontrollable stress in animals has been linked to significant changes in endocrine activity and central nervous system neurochemistry, increased autonomic system activation, immunosuppression, and a host of behavioral outcomes, including a deficit in learning to escape the uncontrollable stressor. This 'learned helplessness' (LH) phenomenon has been used as a model of depression and has shown good predictive validity for the treatment of human depression, as it is reversed by the administration of electroconvulsive therapy (ECT) as well as by monoamine oxidase (MAO) inhibitors, tricyclic antidepressants, and serotonin reuptake blockers. In many laboratories, learned helplessness is induced by exposure to an inescapable or uncontrollable electric footshock, and when naive Sprague-Dawley rats are subjected to this paradigm, approximately 20% will fail to exhibit escape avoidance behavior. Interestingly, the development of LH behavior is determined by a strong genetic component, as the vulnerability to LH is markedly increased by selective breeding. Indeed, after several generations of selective breeding, a strain of rats, termed congenital learned helpless (cLH), emerged; cLH rats exhibit an increased vulnerability to helplessness even in the absence of prior exposure to uncontrollable stress. In addition to the cLH strain, a control strain of rats was concurrently bred to exhibit a relative resistance to helpless behavior (cNLH). cLH and cNLH rats present a similar behavioral phenotype until challenged

by inescapable shock, and this model simulates an increased risk for precipitation of depression. The congenital learned helpless rat has been validated as a good animal model of depression and has provided a unique model system to identify specific biological markers of clinical psychopathology and to gain further understanding of the etiology of affective disorders.

Systematic investigations of the biochemical, neurochemical, behavioral, and genetic features of congenital learned helplessness over the past 15 years have resulted in the identification of a number of significant differences between the cLH and cNLH strains. For example, the upregulation of hippocampal β-adrenergic receptors and a corresponding downregulation in hypothalamic β-adrenergic receptors, both of which return to normal after antidepressant treatment, have been demonstrated. An imbalance in the serotonin system and a differential regulation of serotonin (5-hydroxytryptamine; 5-HT) receptors are also hallmarks of the cLH strain: increase in 5-HT_{1B} and $5HT_2$ receptors and changes in serotonin uptake and serotonin release are noted. Disturbances in serotonergic mechanisms have been demonstrated in depressed patients. Although it remains unclear by which mechanism serotonin reuptake inhibitors (SSRIs) exert their antidepressant action, there is a clear relationship between chronic SSRI and increased 5-HT levels in the frontal cortex. There is growing evidence to support a key role of the serotonin type 1A (5-HT_{1A}) receptor as a regulator of treatment response. Ressler and Nemeroff proposed that monoaminergic alterations, whether serotonergic or adrenergic, maybe more relevant when these changes are confined to specific brain regions subserving selective symptomatology. For example, these investigators contended that cortical disruption may mediate cognitive deficits, that thalamic sites may account for deficits in arousal status, and that hypothalamic abnormalities are associated with alterations in appetite and libido, and that the cortical–hippocampal–amygdala circuitry accounts for the stress and fear responses. Since the monoaminergic neurotransmitter systems are part of this entire neural circuitry, such a thesis is not unreasonable.

Abnormalities in the regulation of the HPA axis and endogenous glucocorticoid (GC) receptor-mediated responses in the brain have been demonstrated in the cLH strain rats: cLH rats have a selective desensitization of GC-mediated gene expression in the limbic system; in addition, cLH rats exhibit significantly lower endogenous plasma corticosterone levels as compared to cNLH rats and also display a diminished stress response to a variety of stressors. Also, cLH rats undergo a differential response in the development of the HPA axis and the phenotypic/genetic profiles of this rat strain influence the long-term response to challenge after early exposure to stress. Using quantitative cytochrome oxidase histochemistry, we have reported that cortical metabolism in cLH rats does closely resemble that of depressed humans. In the cLH rats, metabolism was found to be decreased in dorsal frontal, medial orbital, and anterior cingulate cortex, but increased in the subgenual region of the cingulate cortex and the same changes have been reported in depressed patients, as determined by positron emission tomography and magnetic resonance imaging techniques. A recent comparison of the levels of gene expression in different signaling molecules and various brain regions of the cLH and cNLH strains has identified interesting changes in the intracellular signaling that may confer vulnerability to mood disorders: reduced cAMP-dependent protein kinase A (PKACα) mRNA expression in hippocampus, prefrontal cortex and striatum; reduced levels of cAMP response element-binding (CREB) protein in the hippocampus; and reduced expression of glycogen synthase-3β (GSK-3β) mRNA. These findings agree well with most previous human and animal studies.

Flinder Sensitive Line Rat Model

Although the Flinders Sensitive Line (FSL) rat developed in 1993 by Overstreet and colleagues emerged as an eminent selectively bred animal model of depression, the researchers were initially in pursuit of another goal. Indeed the FSL project was initiated to develop an animal resistant to the pesticide diisopropylfluorophosphate (DFP), a long-acting cholinesterase inhibitor. However, the cholinergic–adrenergic theory of depression and mania, which proposed that cholinergic abnormalities such as supersensitivity to anticholinesterase agents were one of the underlying causes of depression, led to the assessment of the FSL model for the reaction of FSL rats to antidepressant drugs.

Over time, the FSL strain has exhibited many relevant features of depression, including psychomotor retardation, reduced appetite and weight repression, elevated rapid eye movement (REM) sleep, and reduced REM sleep latency. A key feature of this model is its excellent predictive validity. The FSL animal is less mobile on the forced swim test (FST), in which increased immobility is associated with 'depressive-like' behavior. More importantly this strain shows decrements in immobility following chronic, but not acute, treatment with desipramine and sertraline, compared to controls. This pharmacological response has been shown to be selective to antidepressants, since psychomotor stimulants such as amphetamines are

ineffective. Furthermore, rolipram and a melatonin agonist were shown to have antiimmobility effects in the FSL rats and later to have antidepressant effects in humans. Thus, the FSL rat model of depression exhibits some behavioral, neurochemical, and pharmacological features that have been reported in depressed individuals, and has been very effective in detecting antidepressants.

Finally, neurochemical and/or pharmacological evidence suggests that the FSL rat exhibits changes consistent with the cholinergic, serotonergic, dopaminergic, neuropeptide Y (NPY), and circadian rhythm models, but not with the noradrenergic, HPA axis, or γ-aminobutyric acid (GABA)ergic models of depression. Since many of these abnormalities have been demonstrated in humans, and the Flinders rats respond well to many classes of antidepressant drugs, the FSL rat model has been put forth as a particularly effective predictive model, and as such may be used for detecting novel antidepressants.

Wistar Kyoto Model

The Wistar Kyoto (WKY) rats were originally bred as normotensive controls for the spontaneous hypertensive line (SHR) rats. These rats have been used extensively in physiological studies relating to hypertension, but were also shown to exhibit a battery of distinct behavioral features. These behavioral alterations appeared concordant with accepted face validity markers of depression. For example, the WKY rat exhibits increased immobility duration in the forced swim test (a test used as a marker for 'behavioral despair'). More importantly, the increased immobility duration in the swim test was prevented by chronic (but not acute) antidepressant treatment. WKY rats also exhibit decreased activity in the open-field test (a test for novelty exploration and anxiety) and enhanced 'anhedonia' (as measured by decreased consumption of a sugar-based solution) in response to chronic mild stress and acute stress.

In addition to behavioral measures, the WKY strain also demonstrates endogenous central neurotransmitter alterations, including monoaminergic abnormalities, with dopaminergic and noradrenergic neurotransmitter systems and thyroid-stimulating hormone systems, compared with control animals. However, a critical feature of this animal model is HPA dysregulation, manifested as alterations in basal plasma levels of ACTH and corticosterone (CORT), as well as enhanced responses to stressors as measured by exaggerated ACTH and CORT levels postexposure to both acute and chronic stress. Such a composite of neuroendocrine and behavioral hyperresponsiveness to stress , along with the co-occurrence of anxiety features in this model, facilitates the uniqueness of the WKY rat as both a genetic and stress-induced animal model of depression.

Genomic Models of Depression

Corticosteroid Receptor Transgenic and Knockout Mice

A dysfunctional HPA axis is a common feature of patients with major depression, and this HPA dysfunction has been associated with a reduction in glucocorticoid receptor (GR) number and function. Clinical studies that support this hypothesis include reports of a reduction in GRs in the peripheral tissues of depressed patients and the successful treatment of psychotic depression with the glucocorticoid receptor antagonist, mifepristone.

Some recent preclinical studies hypothesize that a primary defect in forebrain GRs will alter both behavioral and physiological responses to stress. Consequently, investigators have used the homologous recombination approach to generate mice that are heterozygous for GR deletion. These mice display a marked reduction in the expression of GRs but also exhibit a behavioral phenotype that is sensitive to stress and parallels depression. Recent studies have also described the production of knockout mice with conditional disruption of forebrain (FB) GRs (thus named $FBGR_{KO}$ mice) that show increased depression-related behavior and impairments in negative feedback regulation of the HPA axis. In these mice, GRs are disrupted in the hippocampus and cortex but not in the central nucleus of the amygdala, paraventricular nucleus (PVN), or pituitary. $FBGR_{KO}$ mice exhibit increased locomotor activity, increased impulsivity when exposed to stress, and increased despair-related behavior in the tail suspension and forced swim test.

Transgenic mice expressing GR antisense mainly in neuronal tissue have also been tested as potential animal models of depression. These mice exhibit significant impairment in GR function in the brain. Moreover, several behavioral and neuroendocrine symptoms common to human depression have been exhibited in these mice, including reduced negative feedback sensitivity to dexamethasone and enhanced stress response to pharmacological and emotional stimuli.

HPA-System Mutation Models

HPA dysregulation is a central recurring theme in most genetically engineered models currently utilized to study depression. Given the prominence of HPA dysregulation in depression and the absence of a specific gene target linked to depression, this approach

has been valuable, yet challenging. Several mutants with distinct alterations in the corticotropin-releasing hormone (CRH) neuronal system have been generated and tested in the past decade, and the feasibility of generating a homozygous CRH knockout mouse was demonstrated as early as 1995 by Muglia and colleagues. Characterization of this model has demonstrated no gross behavioral deficits or viability issues. As expected, these animals exhibited a compromised but functional HPA axis, with compensatory mechanisms facilitating vasopressin release in response to decreases in ACTH. Similarly, in models with CRH overexpression, there are no correlates of specific depressive-like behaviors, but links to anxiety- and fear-related behaviors have emerged. These findings have lead researchers to develop and test the impact of a CRH antagonist on depression. Outside of CRH, there are other neuropeptides in the CRH family, namely the urocortins, that researchers propose may be orchestrating some of these responses. Given that urocortin 1 has a high affinity for both CRH receptors CRHR1 and CRHR2, its action is similar to that of CRH. Mutations in urocortin 1, however, did not alter the HPA axis, and its impact on anxiety remains debatable. Due to the complexity of depressive disorders, the use of mice models with a single gene variant is proving challenging as a viable construct to explore depression. Newer strategies for conditional inactivation or overexpression of factors involved in the HPA axis are emerging to facilitate better understanding of the molecular targets involved. The identification and characterization of mice deficient for abcb1-type (multidrug resistance gene1-type) P glycoprotein – which controls access of endogenous glucocorticoids into the central nervous system, thereby regulating all components of the HPA axis – may prove useful in the exploration of genetics, HPA regulation, and depression.

Serotonin Transporter Knockout

Among the three monoamines implicated in depression, serotonin (5-HT) has been the most extensively studied. Hence, alterations of the molecular mechanisms that modulate the levels of 5-HT at the synaptic cleft have provided a new avenue to create different mouse lines with potential as models of depression. One such line, the serotonin transporter (SERT) knockout, is based on disruption of the serotonin reuptake transporter (5-HTT) gene, leading to critical changes in the inactivation and control of serotonergic neurotransmission. Mice lacking the SERT gene exhibit excess 5-HT during embryonic development but display a marked reduction in 5-HT in adulthood. The SERT knockout mice also show marked reduction from wild-type mice in 5-HT_{1A} receptor protein and mRNA expression in the dorsal raphe, hypothalamus, amygdala, and septum, but marked increase in the hippocampus. Similarly, 5-HT_{2A} receptor density is also reduced in 5-HTT knockout mice.

Clinical and epidemiology studies have supported the involvement of serotonin neurotransmission in the etiology of depression. Hence, in certain clinical populations, a 44-base-pair sequence in the serotonin transporter promoter (SERT-linked promoter; SERTLPR) has been associated with increased vulnerability to affective disorder. Individuals with one or two copies of the short allele of the SERT promoter polymorphism show more depressive symptoms. Moreover, SERT is downregulated in the brains of depressed patients. These studies have prompted the systematic assessment of the behavioral phenotype of the SERT knockout as a potential model of human depression and anxiety. The SERT knockout mouse display a pattern of hypolocomotion, increased anxiety-like behaviors, reduced aggression, and reduced social interaction. Interestingly, the SERT mouse showed an increased propensity to learned helpless behavior. However, there were no differences between SERT knockout and wild-type mice in an anhedonia-based paradigm, the sucrose preference test.

In summary, while each animal model discussed herein has some behavioral features that parallel human depression, the obvious limitation of mutant models is that they have a single, possibly region-specific, mutation, whereas human depression has a multifactorial and multigenetic pathology. An additional caveat is the lack of a comprehensive assessment of the impact of genetic predisposition, early life stress, and acute or chronic stress exposure in these models. So far, none of the mouse mutants could be viewed as animal models of depression that fulfill all three criteria that reproduce aspects of human pathology: face validity (phenomenological and pathophysiological similarity), construct validity (comparable etiology), and predictive validity response to common treatment. However, each of the three mutant lines discussed herein offer opportunities to study selected symptoms such as anxiety, stress response, and a number of complex behaviors associated with HPA disturbances.

Future Directions

Translational Research Approaches: Optimal Utilization of Genetic Models of Depression

While we have made significant strides in understanding the molecular, cellular, and genetic bases of mood disorders, including depression and manic depression mechanisms, the development of new drugs that would provide effective therapies for a heterogeneous

population of depressed subjects is still lagging. Large subsets of depressed patients do not respond to any of the currently available therapies, and the root of failure in new drug development has been attributed to a mismatch of appropriate drug and patient, inappropriate dose and dosing schedule, undetectable effects, and species differences. Translational research in the genomic era seeks to minimize the risk associated with failure in drug development and to ensure that development and registration of new compounds are allocated optimally.

It will be difficult to fully realize the benefits of the genomic era, without the establishment of strong partnerships between the academic communities and preclinical and clinical researchers from industry, all having the common goal to identify the relevant endophenotypes of chronic depression and to develop appropriate test models for this condition. It is also necessary that clinical trial designs go beyond the standard measurement scales (e.g., Hamilton Rating Scale of Depression; HAM-D) and include endpoints more relevant to the behavioral and physiological measures done in animal models, so that better estimates of causality can be tested.

The current emphasis on translational research promises to be an important development in achieving preclinical and clinical congruence of results. We currently have evidence that some procedures used in animal research can be used in humans. For example, the use of progressive ratios for monetary reward in depressed patients can be related to the use of this schedule of reinforcement for more basic rewards in animals. Similarly, anhedonia is considered as a candidate behavioral endophenotype of depression, and rodent models of learned helplessness and chronic mild stress (CMS) are characterized by specific behavioral abnormalities such as anhedonia, reduced activity, and passivity.

Three basic technologies are currently being used in translational research programs focused on therapy development: gene-based target discovery, combinatorial chemistry, and high-throughput screening. In translational research for neuropsychiatric disorders, a major goal of gene-based target selection has been to break out of the box of monoamine-based therapies. The bioinformatics screening of the human genome provides a rich alternative source of potential targets and validation strategies. For drug discovery efforts for depression, the use of species such as the flatworm (*Caenorhabditis elegans*) has led to the identification of new genes that can suppress behaviors such as egg-laying and nose contraction that are not affected in serotonin-defective mutants. In addition, the use of combinatorial chemistry allows the systematic generation of multiple variants of small organic molecules that can be assayed for interaction against a chosen drug target. High-throughput screening also allows the screening of several hundred thousand small molecules in a short time and provides a useful start for analysis of structure–function relationships that will guide the optimization of lead compounds.

The use of these technologies needs to be coupled with testing of new targets in disease models in rodents, including those of directed mutants. Promising directions include collaborative efforts between industry, academia, and funding agencies, to provide a systematic phenotypic evaluation of large numbers of novel mutant mouse strain; increasing use of genetic models to identify genes associated with variable responses to drugs; combination of forward and reverse genetics and pharmacology to identify and validate drug targets, as well as to discover and develop new drugs; and strategies that identify individuals vulnerable to specific phenotypes and relate these to animal models and then exploit this vulnerability as a factor to discover candidate genes.

Gene Expression Profiling

A promising approach in increasing our understanding of the pathophysiology of depression is the generation of gene expression profiles in cellular and animal models as well as in clinical samples. Before the development of microarray technology, investigators examined the mRNA or protein levels of only a few genes at a time. Typically, these genes were selected on the basis of a hypothesis or a prediction regarding a possible mechanism and potential therapeutic strategies. With current advances in mRNA profiling, such as DNA microarray, it is possible to perform genome-wide gene expression analysis in a hypothesis-free manner. One caveat of such studies in complex human disorders, such mood disorders, will be the large number of genes that would have to be validated for their potential as causative factors or as novel drug targets. The use of gene expression profiling has already allowed us to identify unknown molecular cascades involved in mental disorders. For example, Aston and others have reported that oligodendrocyte-related genes are downregulated in major depression. Choudary and others have hypothesized that astroglial dysfunction plays a role in major depression, based on their findings of downregulation of glial high-affinity glutamate transporters SLC1A2 and SLC1A3, as well as glutamate ammonia ligase, which are predominantly in astroglia. By contrast, no changes in gene expression have been identified in the prefrontal cortex of any patient with major depression who committed suicide.

While the analysis of expression profiling holds the promise of generating comprehensive and comparable data sets in complex disorders, microarray studies of the brain are quite challenging. There are still significant limitations in detection sensitivity and dilution of signal differences due to cellular heterogeneity masking disease effects. With new technology such as laser-capture microdissection, and signal amplification protocols that require small amounts of starting materials, the technique should overcome the limitations of postmortem brain samples. One area that needs special attention is the utilization of gene profiling data to reveal drug treatment effect on gene expression. A number of key components, such as selection of animals, choice of drug, dosage, method of administration, duration of treatment, and environment, will have to be fully investigated for their potential effect on gene expression profiles.

Despite all of the shortcomings of the currently available gene profiling studies, this field holds great promise for the treatment of depression by facilitating genetic prediction to response and identification of drug targets. Moreover, the technology of expression profiling at the protein level is rapidly developing and we should soon be able to superimpose gene expression profiling on data sets obtained from proteomics, epigenetic, and polymorphism data sets.

Imaging Approaches

There are many different imaging approaches being utilized to study depression in humans, including magnetic resonance imaging (MRI), functional MRI (fMRI), and positron emission tomography (PET). Imaging approaches are particularly useful for exploring the circuitry, chemistry, and neuroanatomy underlying this complex disorder. Current MRI studies have led to a debate about the role of hippocampal volume in depression from lack of association to a reduction in volume. Several PET studies show an association between enhanced severity of depressive symptoms with decreased metabolism of the anterior cingulate cortex and dysfunction in the monoaminergic systems. However, many of the functional imaging studies in depression assess emotional responses. Such studies suggest greater activation of the left amygdala by fearful faces in acutely depressed patients while others demonstrate greater bilateral amygdala activation with aversive visual stimuli in patients with depression. In general, fMRI studies have proposed that experimental or pathological changes in mood state are associated with reciprocal changes in activity of limbic–subcortical and frontoparietal systems. Researchers hypothesize that the limbic–subcortical regions are more activated, and frontoparietal circuits are less activated, by sadness, and that effective antidepressant agents correct this abnormal responsivity in patients with depression.

A few imaging studies have provided additional support for the validity of some animal models of depression. For example, the congenital learned helpless rat shows activation patterns in frontal and cingulated regions of the brain that are comparable to those seen in humans. PET studies in the cynomolgus monkey model of depression demonstrate a correlation between behavioral depression and change in serotonin receptor binding potentials. Imaging studies offer the ability to use noninvasive methods in genetically vulnerable individuals and animal models to explore further the underlying biological mechanisms and neurocircuitry subserving complex disorders. It is, however, important to be aware of the importance of selecting the appropriate genetic background for the development of these animal models, due to the potential variability of morphometric and metabolic endophenotypes.

Stress Response: Neural and Feedback Regulation of the HPA Axis

J P Herman, University of Cincinnati, Cincinnati, OH, USA

© 2009 Elsevier Ltd. All rights reserved.

The Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal (HPA) axis is essential for adaptation to physical or psychological stress. Glucocorticoid hormones, which are the ultimate product of HPA axis activation, act on multiple bodily systems to maintain homeostasis. Many of the effects of glucocorticoids are beneficial for short-term survival but can be counterproductive or even deleterious if prolonged. Therefore, the activation and inhibition of glucocorticoid is a temporally regulated process involving rapid neuronal activation and efficient feedback inhibition.

Stimulation of the HPA axis occurs in reaction to or in anticipation of physiologic challenge. Reactive or 'reflexive' release of glucocorticoids occurs in response to physiological challenges (e.g., blood loss, hemorrhage). This type of response is initiated by stimuli that signal a direct threat to homeostasis or survival and can be triggered without conscious perception. However, it is important to note that organisms also generate 'anticipatory' HPA axis responses to environmental cues associated with threats to survival or homeostasis. Thus, stimuli that predict adversity can generate a glucocorticoid response in the absence of an existing physiologic insult. These responses are generated by comparison of environmental stimuli with either innate programs (e.g., instinctual fear of predators) or memories (e.g., prior experience with a painful or fearful stimulus). The relevance of the anticipatory response hinges on the predicted need for an adaptive hormonal response, with the glucocorticoid secretory process begun in preparation of a survival challenge (prolonged flight, fight, and injury).

Glucocorticoid release is commonly associated with an inferred state of 'stress.' From the perspective of this article, 'stress' can be defined as 'a real or perceived threat to homeostasis or well-being.' There are four somewhat distinct 'stress' responses: behavioral change, activation of the sympathoadrenomedullary system, activation of the HPA axis, and activation of the immune system, roughly in order of threshold and timing. The glucocorticoid stress response addressed in this article is but one component of an integrated set of responses to stress.

The hypothalamic paraventricular nucleus (PVN) is responsible for regulation of HPA axis stress responses (Figure 1). Activation of the HPA axis is mediated by neurosecretory neurons localized in the medial parvocellular zone of this nucleus. These neurons project to blood vessels in the external lamina of the median eminence, where they release numerous adrenocorticotropin (ACTH) 'secretagogues,' the most important of which are corticotropin-releasing hormone (CRH) and arginine vasopressin.

The medial parvocellular PVN is in receipt of synaptic innervation from a relatively circumscribed set of central nervous system structures, summarized in Figure 2. In general, PVN projection neurons are localized in regions known to receive first- or second-order inputs from somatic nociceptors, visceral afferents, or humoral sensory pathways. Thus, the majority of PVN-projecting neurons are positioned to evoke rapid, reflexive activation of the HPA axis. These PVN projection neurons can in turn be influenced by inputs from cortical and limbic structures, which are likely to transduce anticipatory activation.

Glucocorticoids released following stress exert classical negative feedback effects on the HPA axis. Feedback effects of glucocorticoids occur in distinct time domains. Fast feedback occurs within minutes and is nongenomic in nature. Fast feedback is sensitive to the rate of change in circulating glucocorticoid levels and is essential for rapid termination of PVN activation and ACTH release normally seen during an acute stress response. The nongenomic mechanism involves membrane glucocorticoid receptors. Delayed feedback occurs over hours to days and involves genomic mechanisms. Delayed feedback is sensitive to the levels of circulating glucocorticoids rather than the rate of rise.

Glucocorticoid negative feedback may be mediated at multiple levels. The nuclear glucocorticoid receptor is though to regulate genomic negative feedback, perhaps in conjunction with permissive actions of the mineralocorticoid receptor, which binds glucocorticoids with high affinity and is extensively bound even under unstressed conditions. The glucocorticoid receptor is abundantly expressed in the pituitary, PVN, and numerous brain regions implicated in HPA axis regulation, all of which may contribute to negative feedback.

It is important that regulation of the HPA axis can be mediated by peripheral feedback factors other than glucocorticoids. For example, ingestion of a caloric load (e.g., sucrose consumption) can inhibit activation of the HPA axis independent of glucocorticoid secretion. The neural mechanism subserving this alternative feedback pathway remains to be determined.

Figure 1 Schematic of the hypothalamic–pituitary–adrenal (HPA) axis. Stress triggers activation of paraventricular hypothalamic nucleus (PVN) neurons, causing release of corticotropin releasing hormone (CRH), and co-secretagogues (such as arginine vasopressin (AVP) in the portal vessels of the median eminence. Secretagogues travel via the portal blood to the anterior pituitary, where they elicit secretion of adrenocorticotrophic hormone (ACTH). ACTH travels via the systemic circulation to the adrenal cortex, causing synthesis and secretion of glucocorticoids.

Direct Pathways Controlling HPA Axis Activation

Brain Stem

The PVN receives a large input from noradrenergic and adrenergic neurons of the nucleus tractus solitarius (NTS). Lesions of these neurons or their terminals attenuate HPA axis stress responses to reflexive stressors, whereas direct adrenergic receptor stimulation activates CRH and ACTH secretion, confirming that norepinephrine (and perhaps epinephrine) neurons are necessary and sufficient for stress activation of the HPA axis. However, the influence of NTS norepinephrine–epinephrine on anticipatory stress responses is not observed consistently, suggesting that anticipatory excitation occurs by other mechanisms.

The NTS also contains a noncatecholaminergic PVN-projecting cell population. Many of these cells contain important peptidergic neuromodulators (e.g., glucagon-like peptide-1, neuropeptide Y) that are HPA axis excitatory, and there is evidence that these peptides may participate in generation of both reflexive and anticipatory stress responses.

Serotonergic systems also participate in HPA axis activation by way of projections from the midbrain and pontine raphe nuclei. Serotonergic innervation of the PVN is more circumscribed than that of the NTS, and modulation of extra-PVN serotonin can also have potent actions on HPA axis activity. The relative strengths of direct versus indirect serotonin serotonergic modulation of the stress response remain to be resolved.

Lamina Terminalis System

The PVN is in direct receipt of information on fluid and electrolyte status by way of the subfornical organ–lamina terminalis system. Signals are relayed through direct projections of the subfornical organ, median preoptic nucleus, and organum vasculosum of the lamina terminalis to medial parvocellular PVN neurons. These regions are critically involved in control of osmoregulation and drinking behavior, and this pathway may be critical for initiation of HPA responses to thirst or dehydration.

Hypothalamus

The PVN receives massive input from numerous regions of the hypothalamus, a large component of which is γ-aminobutyricacidergic (GABAergic; inhibitory). GABA inputs to the PVN originate in numerous hypothalamic nuclei concerned with homeostatic regulation, including the dorsomedial hypothalamus (autonomic function), preoptic area (thermoregulation), arcuate nucleus (energy balance), and lateral hypothalamus (ingestive behavior).

The PVN also receives input from hypothalamic neuropeptidergic (e.g., corticotrophin releasing factor, melanocortin) and glutamatergic neurons. These inputs are presumably excitatory and may serve to activate the HPA axis in response to homeostatic imbalance. Thus, hypothalamic inputs are sufficient to both excite and inhibit the PVN, consistent with a role in maintenance of homeostasis.

Bed Nucleus of the Stria Terminalis

Direct nonhypothalamic forebrain inputs to the parvocellular PVN are largely confined to discrete subnuclei of the bed nucleus of the stria terminalis (BST). The influence of the BST on HPA function is complex. Posterior regions of the BST inhibit HPA axis responses to stress, whereas ventrolateral PVN projecting neurons provide excitatory input. This complexity may be related to differential limbic inputs to these regions, as noted below.

Figure 2 Direct projections to the paraventricular hypothalamic nucleus (PVN). Excitatory inputs are in green, inhibitory in pink. The PVN receives predominantly excitatory inputs from brain stem noradrenergic (NE), neuropeptidergic (NP), and serotonergic (5-hydroxytryptamine; 5-HT) cell groups, as well as from circumventircular structures (such as the subfornical organ). Inputs from the hypothalamus and bed nucleus of the stria terminalis can be excitatory (glutamate (Glu) or NPs) or inhibitory (γ-aminobutyric acid; GABA), depending on location. Neurons in the immediate vicinity of the PVN may serve as local inhibitors of HPA axis activation. NTS, nucleus tractus solitarius.

Thalamus

Neurons in auditory-responsive posterior thalamic nuclei, including the subparafascicular and posterior intralaminar regions, send direct projections to the medial parvocellular PVN and are likely involved in pathways mediating activation of the HPA axis by auditory stimuli.

Local PVN Information Processing

The PVN is well positioned to receive direct input from blood- and CSF-borne factors. The PVN has a dense nonfenestrated capillary plexus that can allow ready access to blood–brain barrier permeable factors, including glucocorticoids. Thus, the PVN is one site of potential glucocorticoid negative feedback regulation of the HPA axis. Brain microvessels may also play a major role in communicating immune (cytokine) signals to the CNS, through activation of prostaglandin biosynthesis. Notably, the medial parvocellular PVN richly expresses prostaglandin receptors, suggesting a capacity for local integration of immune signals within the PVN proper.

Neurons of the PVN have limited dendritic extensions that largely remain within the nucleus proper. This morphological arrangement supports intranuclear communication among different PVN subdivisions (e.g., magnocellular divisions projecting to the neurohypophysis), which may subserve intrinsic modulation of excitability. The restricted dendritic branching scheme also prevents parvocellular PVN neurons from sampling the peri-PVN region, which is richly invested with terminals and axons from limbic structures such as the hippocampus, prefrontal cortex, and lateral septum. This arrangement likely prevents direct modulation of HPA axis function by descending limbic structures.

The peri-PVN region contains large numbers of GABAergic neurons, some of which project into the PVN proper. The peri-PVN region receives rich input

from limbic structures, hypothalamic cell groups, and serotonin neurons, suggesting that it may play a role in 'gating' of information coming into the PVN.

Indirect Paths to the PVN

Limbic brain structures modulate anticipatory HPA responses to stress. These structures, including regions such as the hippocampus, prefrontal cortex, amygdala, septum, and midline thalamus, are critical for emotional responses and memory and are logical candidates for modulating pituitary–adrenal secretions with respect to prior experience. These regions have no substantial direct interactions with medial parvocellular PVN neurons, requiring intermediary neurons to relay their influence on ACTH secretagogue release (see **Figure 3**).

Hippocampus

The hippocampus is involved in terminating HPA axis responses to stress. Accumulating evidence indicates that the hippocampus is involved in inhibiting anticipatory but not reflexive stress responses, perhaps consistent with its role in memory and information processing. The observation that hippocampal damage can delay termination of corticosterone release is consistent with a role in glucocorticoid negative feedback inhibition of the HPA axis. This hypothesis is supported by rich localization of glucocorticoid receptors in the hippocampus and by functional studies demonstrating diminished feedback efficacy following hippocampal lesions, local glucocorticoid receptor inactivation, or hippocampal–cortical glucocorticoid receptor gene deletion.

Anatomical tracing studies reveal that the hippocampus can communicate with the PVN by way of relay neurons in the hypothalamus and BST. Given that the output of the hippocampus is largely excitatory, it is likely that inhibition is mediated by activation of inhibitory, PVN-projecting GABAergic neurons in these regions.

Medial Prefrontal Cortex

The medial prefrontal cortex also modulates HPA axis activation, albeit in a more complex fashion. Numerous studies indicate that dorsal components of the medial prefrontal cortex inhibit anticipatory but not reflexive HPA axis responses and may be another site for glucocorticoid negative feedback signaling. Conversely, the more ventral components of

Figure 3 Simplified schematic of possible bisynaptic limbic connections with the paraventricular hypothalamic nucleus (PVN). Regions such as the hippocampus and medial prefrontal cortex inhibit the HPA axis by supplying excitatory glutamatergic innervation of PVN-projecting GABAergic neurons in the bed nucleus of the stria terminalis, hypothalamus, and peri-PVN region (see **Figure 2**). In contrast, amygdalar activation of the HPA axis is likely to occur by disinhibition, involving GABAergic inhibition of GABA projecting PVN neurons. Glu, glutamate.

the medial prefrontal cortex (e.g., infralimbic cortex) heavily innervate subcortical autonomic sites and may be involved in stress excitation. There is also some evidence that ventral medial prefrontal cortex excitation of the stress response is lateralized in the rat (driven by the right hemisphere).

Anatomical studies indicate that the prefrontal cortex does not innervate the PVN to any substantial degree. Dorsal regions of the medial prefrontal cortex project to regions such as the BST as well as a number of non-PVN projecting regulatory regions, whereas ventral regions (encompassing the infralimbic cortex) innervate autonomic regions such as the ventral BST, central amygdala, and NTS. Thus, like the hippocampus, HPA regulation by the medial prefrontal cortex is indirect.

Amygdala

In contrast with the hippocampus and medial prefrontal cortex, amygdaloid nuclei appear to stimulate the HPA axis. However, there is considerable functional differentiation among individual amygdalar regions. The central amygdaloid nucleus is involved in activation of the HPA axis to reflexive but not anticipatory stressors, whereas the medial amygdala appears to selectively involved in generation of anticipatory responses.

Projection neurons of the central and medial amygdala are primarily GABAergic and do not directly innervate the PVN. However, both regions project heavily to the BST and preoptic area, which contain populations of GABAergic PVN-projecting neurons. Therefore, excitatory effects on HPA axis stress responses are likely mediated by inhibition of GABA neurons in the hypothalamus or BST, effectively resulting in activation by disinhibition.

Lateral Septum

Lateral septal lesions are known to produce a constellation of behavioral and autonomic symptoms consistent with extreme anxiety ('septal rage'). Not surprisingly, this region inhibits HPA axis stress responses. Neurons in this area are activated by a variety of 'anticipatory' stressors but show little induction following activation of the 'reactive' stress pathway, suggesting selective involvement in the former process.

The anatomy of the septal region predicts prominent interactions with hypothalamic and midbrain PVN-projecting regions. As the majority of lateral septal neurons express GABA as their primary transmitter, it is likely that the HPA inhibitory effects of this region are mediated by inhibition of excitatory projections to the PVN.

Thalamus

Several recent reports implicate midline limbic thalamic nuclei in HPA axis regulation. Of the known stress-responsive thalamic nuclei, the paraventricular thalamus appears to play a major role in integrating HPA axis responses to repeated stressors, mediating both stress habituation and sensitization of responses to new stressors. The influence of the paraventicular thalamus is likely to be communicated by way of hypothalamic nuclei (e.g., dorsomedial nucleus).

Hypothalamus

There are several hypothalamic regions that appear able to interact with the PVN through intrahypothalamic relays. Prominent among these is the suprachiasmatic nucleus, which is the major integrator of circadian HPA rhythmicity, and the ventromedial nucleus, which is concerned with energy balance. Both regions interconnect with the PVN through intrahypothalamic relays, including the dorsomedial nucleus and lateral hypothalamus.

Brain Stem

Noradrenergic neurons of the locus coeruleus do not project directly to the medial parvocellular PVN. Nonetheless, lesions of this cell group reduce HPA axis stress responses, implying a transsynaptic excitatory action. This may also be the case for serotonin, as reduction of serotonergic neurotransmission in the amygdala reduces HPA axis responses to stress. In addition, the excitatory action of brain stem acetylcholine on CRH and ACTH release appears to be mediated by norepinephrine neurons of the NTS.

Principles Governing Neurocircuit Regulation of the HPA Axis

The organization of PVN inputs indicates that stress responses are dependent on the overall 'set' of central sensorial input, involving synthesis of homeostatic and cognitive information. Circuits that process reflexive responses have direct access to PVN neurons and tend to be excitatory in nature. These pathways are positioned to communicate sensory information regarding homeostatic imbalance, consistent with a mechanism for rapid adaptation to adversity. \In contrast, anticipatory responses appear to be activated by disinhibition, whereby amygdalar neurons 'turn off' GABAergic projections to the PVN. These GABAergic neurons are strategically positioned in hypothalamic nuclei regulating homeostatic function, providing a possible means for polysensorial cognitive inputs to override ongoing homeostatic regulatory information.

Stress-induced HPA axis activity is temporally limited by inhibitory inputs from the hypothalamus and forebrain. Hypothalamic inputs can directly relay inhibitory information from homeostatic effector pathways. In contrast, forebrain outflow from hippocampus and medial prefrontal cortex mediate inhibition by intermediary synapses, many of which involve hypothalamic homeostatic effector circuits. Thus, as was the case for the amygdala, the impact of hippocampal and cortical circuitry is positioned to act through modulating the ongoing activity of homeostatic pathways to the PVN.

Glucocorticoid negative feedback can be exerted at multiple levels of the neuraxis. Glucocorticoid receptors are present on PVN neurons, and these are involved in rapid as well as sustained feedback inhibition of the HPA axis. However, forebrain glucocorticoid receptors also play a role in inhibition of anticipatory HPA axis stress responses, mediated by effects of glucocorticoids on hippocampal and cortical output circuits.

Overall, regulation of the HPA axis appears to involve hierarchical processing of stressful information and glucocorticoid negative feedback. Reflexive responses represent a first line of defense and are directly wired to rapidly induce ACTH release. Anticipatory responses relay through nuclei that modulate reflexive HPA activation, providing a means by which psychological information can modulate or interact with homeostatic integration. Thus, the reflexive stress response is the default and is subject to modification by prior experience or innate programs. The hierarchical organization of brain stress integration is consistent with theories of brain evolution whereby increasingly complex functions are layered atop simpler reflex pathways.

Control of the HPA axis stress response is of substantial health significance. The impact of gross dysregulation of glucocorticoid secretion on metabolism and cardiovascular function is well known. In addition, more-subtle dysregulation of the HPA axis occurs in stress-related affective disease states, such as depression (hypersecretion) and posttraumatic stress disorder (hyposecretion). The HPA axis pathologies are intimately associated with altered activation or volume of the hippocampus, amygdala, and prefrontal cortices, suggesting that the disease process involves the anticipatory stress response. Thus, appropriate initiation and appropriate cessation of the HPA axis stress responses are a clear priority for both homeostatic balance and adaptation to adversity.

Introduction

The pioneering work of Hans Selye in the 1940s provided the first anatomical evidence suggesting a sex difference in the stress response by showing that the adrenal gland is larger in female animals than males. Subsequent studies show that the difference corresponds with a higher rate of basal- and stress-induced adrenal hormone secretion. Females exhibit a greater rise in adrenal glucocorticoid secretion in response to physical and psychologically stressful situations, as well as a larger diurnal fluctuation in plasma concentrations of glucocorticoids. In rodents, the magnitude of this sex difference is quite remarkable, with females often achieving peak levels of cortisol or corticosterone that are 1.5 to 2 times greater than that of males. In humans, gender-related stress responses are more complex and may depend upon the type of stressor. Current evidence suggests that women are more responsive to stressors that involve social interactions, whereas men are more responsive to those that involve achievement. Summaries of essential sex differences in the stress response of rodents and humans are provided in Tables 1 and 2.

The Hypothalamo-Pituitary-Adrenal Axis

In mammals, the secretion of glucocorticoid hormones from the adrenal cortex is controlled by the activity of the hypothalamo-pituitary-adrenal (HPA) axis. This neuroendocrine axis represents a cascade of neural and humoral signals driven by both the circadian pacemaker as well as the environment. Changing environmental conditions or perceived threats to homeostasis activate the HPA axis through neurons located in the paraventricular nucleus of the hypothalamus (PVN). These neurons integrate positive and negative inputs arising from other brain areas to coordinate the final response of the neuroendocrine brain. Central in this response are neurons located in the parvocellular part of the PVN that contain the neuropeptide, corticotropin-releasing hormone (CRH). The release of CRH to the hypophyseal portal system enhances synthesis and release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary. ACTH acts in turn on the adrenal cortex to cause a rise in plasma corticosteroids. Circulating corticosteroids subsequently act at the level of the pituitary, hypothalamus, and higher brain areas in a negative feedback loop to limit further hormone secretion.

Sex Differences in the Function of the HPA Axis

Although sex differences in the pituitary ACTH and adrenal corticosteroid responses to a stressor have been consistently reported in the literature, the mechanisms underlying these differences are largely unexplored. In general, the neuroendocrine response of females to stress is different from that of males. The female response is characterized by a greater and prolonged secretion of ACTH and adrenal corticosteroids suggesting enhanced stimulus salience as well as a reduced negative feedback. Gonadectomy of both males and females reduces the sex difference suggesting an essential role for circulating sex steroid hormones. Hormone replacement of gonadectomized animals can reinstate the sex difference. Estrogen enhances whereas testosterone treatment inhibits HPA reactivity. The mechanisms by which estrogen and testosterone act to influence HPA function are not completely resolved and will be addressed in some of the following sections of this article. Evidence for estrogen and testosterone acting at the adrenal gland, anterior pituitary, and hypothalamus has been reported.

Pituitary Hormone Secretion

The sex difference in adrenal function is in part, due to sex differences in the neuroendocrine axis that regulates adrenal hormone secretion. Similar to the sex differences in adrenal glucocorticoid release, sex differences exist in the release of ACTH, a hormone synthesized by the anterior pituitary gland that stimulates adrenal corticosteroid synthesis and secretion. Animal studies have demonstrated increases in ACTH following physical or psychological stressors and that this rise is greater and more prolonged in females compared to males. An enhanced ACTH response to CRH administration has been noted in female rats, suggesting that part of the sex difference in ACTH may arise as a result of differences in pituitary responsivity to CRH.

Hypothalamic Function

The secretion of ACTH from the anterior pituitary gland is in turn regulated by hormones which are synthesized by neurons in the paraventricular n. of

Table 1 Summary of selected sex differences in the rodent stress response

Parameter	*Females*	*Males*
ACTH secretion	+	
Corticosterone levels	+	
Response to CRH	+	
# of CRH neurons	+	
Amplitude of diurnal corticosterone rise	+	
Neural vasopressin levels		+
Corticosteroid binding globulin	+	
Vasopressin secretion	+

ACTH, adrenocorticotropic hormone; CRH, corticotrophin-releasing hormone; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; FST, forced swim test.

Table 2 Summary of selected sex differences in the human stress response

Parameter	*Females*	*Males*
Cardiovascular reactivity to emotional stress		+
ACTH response to exogenous CRH	+	
HPA reactivity to social stress	+	
HPA reactivity to performance stress		+
Clinical consequences related to stress		
Cardiovascular disease		+
Autoimmune disease	+	
Clinical depression	+	
Posttraumatic stress disorder	+	

the hypothalamus and released into the hypothalamo-hypophyseal portal vasculature. These hormones access the anterior pituitary gland to stimulate ACTH synthesis and secretion. The most important releasing factors for ACTH appear to be CRH and vasopressin. Both CRH and vasopressin are potent ACTH secretogogs and vasopressin potentiates the ACTH releasing activity of CRH several fold. Animal studies have shown that females have greater numbers of detectable CRH neurons within the paraventricular n. of the hypothalamus than males. Females also exhibit a more pronounced diurnal variation in hypothalamic CRH immunoreactivity than males. These data are consistent with the physiological data demonstrating a greater activation of the HPA axis in females.

In contrast, sex differences in vasopressin immunoreactivity have not been reported for the paraventricular n. of the hypothalamus; however, sex differences in vasopressin levels have been reported for other brain areas such as the bed nucleus of the stria terminalis. When sex differences in vasopressin are present, the amount of vasopressin is much greater in males than females. This perhaps indicates that sex differences in vasopressin are more relevant to behavior differences rather than hormone secretion. However, studies have demonstrated sex differences in the release of vasopressin to the circulation following a stressor. Whereas male rats do not release vasopressin following immobilization stress, females do. This sex difference in the functional response of vasopressin cells in the paraventricular n. of the hypothalamus to stressors, even in the absence of morphological gender differences in this nucleus may help explain sex differences in neuroendocrine responses.

Negative Feedback Regulation

The stimulatory limb of the HPA axis (CRH, vasopressin, and ACTH) is kept under continuous check by feedback inhibition. Thus, it is thought that one factor underlying sex differences in adrenal hormone secretion are gender differences in the intensity of feedback regulation. The negative feedback action of corticosteroids is mediated by two receptor types designated glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) that reside in neurons in the hypothalamus, hippocampus, and anterior pituitary gland, as well as other brain areas. Both receptors appear to be involved in differing aspects of feedback regulation.

Mineralocorticoid receptors, because of their high affinity for corticosteroids, are occupied during, and consequently regulate, basal hormone secretion. GRs, in contrast, exhibit a tenfold lower affinity for corticosteroids and are occupied following elevations in hormone. These receptors thereby function to return stress responsive elevations in corticosteroids back to baseline. Assuming that receptor number corresponds to the sensitivity of a tissue for hormone, a conclusion could be drawn that sex differences in the HPA axis may arise as a result of sex differences in the number of receptors in a given cell. More receptors would indicate greater negative feedback sensitivity and hence, lower basal- and stress-activated hormone secretion. Lower levels of receptor would indicate weaker negative feedback and thus, higher basal- and stress-responsive hormone secretion. Evidence for sex differences in the concentration of GR and MR and the function of GR and MR has been demonstrated with females tending to have lower levels of GR and MR in many brain regions including the hypothalamus and hippocampus. This pattern is consistent with that found in other tissues such as the thymus and liver. Given similar levels of hormone, GR- or MR-mediated functions (such as autoregulation

of the receptor) have been reported to be less sensitive to corticosteroid modulation in females compared to males.

Estrogen Modulation of HPA Axis Function

Previous studies have demonstrated that the estrogen status of females affect their endocrine response to stress. In rats, there is a relationship between the day of the estrous cycle and their plasma corticosteroid levels. Basal- and stress-responsive corticosteroid levels are higher on proestrus when estrogen levels are correspondingly high. Hormone replacement studies show that estrogen treatment of gonadectomized female and male rats enhances the basal- and stress-responsive secretion of ACTH and corticosteroids. These findings have been confirmed for humans in preclinical trials as well. Estrogen treatment of women and men enhances heart-rate and blood pressure increases as well as the ACTH and cortisol response to psychosocial or mental stressors.

The actual mechanism(s) by which estrogen alters stress-responsive ACTH and corticosterone (CORT) secretion is not known. At the hypothalamic level, increases in stress hormones could be a consequence of increased stimulation of PVN neurons, or reductions in inhibitory tone. Such possibilities are suggested by data showing increased expression of stress-inducible c-fos mRNA following E-treatment. The prolonged stress-responsive secretion of ACTH and corticosteroids, coupled with the elevated baseline secretion of ACTH and corticosteroids in female rats following estrogen treatment, also suggests the possibility of a disruption in HPA negative feedback mechanisms. Consistent with this, the suppression of CORT secretion by dexamethasone is impaired by E-treatment of male and female rats.

Progesterone Modulation of HPA Axis Function

Females have higher progesterone (P) levels than males and these levels increase following ovulation. P inhibits HPA function, perhaps to counteract the enhancing effects of estrogen at certain times of the female cycle. Progesterone prevents E-induced increases in CRH mRNA in the PVN of female monkeys. Progesterone also potentiates the inhibitory effects of CORT on ACTH release in ewes, and prevents the adrenalectomy (ADX)-induced upregulation of AVP mRNA in rats. Whether the actions of P are mediated by binding inhibitory neurotransmitter receptors, such as γ-aminobutyric acid (GABA), remains to be determined. However, since gonadectomy of male and female rats can reduce sex differences in HPA function, and P is higher in intact females and inhibits HPA function, this apparently rules out a role for P in establishing sex differences in HPA function.

Androgen Modulation of HPA Axis Function

Testosterone may contribute to the sex differences in HPA reactivity since testosterone has an action opposite that of estrogen in regulating the HPA axis. Gonadectomy of adult male rats increases CORT and ACTH responses to stress, and correspondingly, the expression of the immediate early gene, c-fos, in PVN neurons. Hormone replacement of gonadectomized male rats with testosterone or the non-aromatizable androgen, dihydrotestosterone, returns stress-responsive CORT and ACTH back to that of the intact male. Treatment of GDX's animals with dihydroxytryptamine (DHT) also inhibits the stress induction of c-fos mRNA in the PVN demonstrating that T's effects are not due to aromatization of testosterone to estrogen.

Although androgen can inhibit HPA axis function and reduce CRH immunoreactivity (ir) in the PVN, androgen receptors are not localized in CRH or AVP neurons within the PVN. Low levels of androgen receptors are found in the PVN, but these neurons are located in the parts of the PVN that project to spinal cord and brain stem autonomic nuclei. Consequently, it is assumed that androgen regulates PVN neuropeptide expression and secretion transsynaptically. Recent studies using stereotaxic surgery to locally apply DHT to the PVN of males demonstrate that DHT can affect PVN neurons, an effect that does not appear to be mediated by the androgen receptor, but rather through estrogen receptor-β. Local application of DHT to the PVN is as effective as peripherally administered DHT in inhibiting HPA function. Local application of 5α-androstane-3β, 17β-diol (3β-diol), a metabolite of DHT, was also as effective as DHT in inhibiting HPA function, as is local application of ERβ selective agonists. Counter-intuitively, the effects of DHT and 3β-diol can be blocked by simultaneous administration of an ER antagonist, but not an AR antagonist. Since 3β-diol can bind ERβ with moderate affinity, this seems to indicate that DHT is metabolized to ligands, such as 3β-diol, that preferentially bind ERβ, and that ERβ occupancy works to inhibit HPA function in the male.

Sex Differences in Behavioral Responses to Stress

Animal studies have provided much of what we know regarding sex differences in response to stress.

The acute response to stress is often studied in rats using paradigms, such as the elevated plus maze and the novel open-feild, that place them in a situation where their natural tendency to explore is opposed by their aversion to open, well-lighted spaces. In such circumstances, rats exhibit a series of well-described behaviors associated with the degree of fear or anxiety that is being experienced. Freezing, defecation, activity, and vocalization are a few good examples of these behaviors. Compared to males, females exhibit a smaller behavioral response to novel or aversive environments, showing less freezing and defecation, and more activity. Females are also more apt to return to explore a compartment in which they have been previously shocked.

Under some conditions, females show more adaptive responses to long-term stress exposure as well. Animal models of anxiety often utilize 'learned helplessness' paradigms to measure behavioral responses to acute and chronic stress. Such paradigms are useful to study the efficacy of antidepressant treatments in reversing the effects of stress. One of these paradigms is the Porsolt test, a widely employed forced-swim paradigm that has proved to be an effective assessment tool to measure the efficacy of antidepressant actions. The test involves placing an animal in a circular, inescapable chamber of warm water and measuring the latency to stop swimming, and length of time spent in floating immobility. Studies consistently show that females swim (struggle to escape) longer than males in this test. This difference occurs with acute stress exposure, as well as chronic exposure for several weeks.

Opposing effects have been reported when using 'learned helplessness' paradigms that employ repeated, intermittent, and/or inescapable shock. In such paradigms, the shock session is subsequently followed by a session in which animals are exposed to the same environment and given an opportunity to escape. When the paradigm involves exposing animals to one or two sessions of inescapable shock before allowing them access to escape, females have faster latencies to escape than males. However, when exposed to inescapable shock over many sessions before being allowed access to an escape chamber, some studies have found that males escape faster than females. It appears that this sex difference in adaptability may be dependent on levels of corticosterone, since reducing the poststress level of corticosterone in the female to the level attained in the male allows the adaptation to repeated restraint.

The role of the HPA axis in accounting for behavioral sex differences in response to stress is complex, and the use of animal models has yielded an incomplete picture to date. However, sex differences in stress-related behaviors in rodents may involve steroid regulation of serotonin. Serotonin synthesis and receptor expression are regulated by both glucocorticoids and gonadal steroids. Compared to males, females are reported to have higher levels of 5-HT in brain as well as increased rates of synthesis. These data are consistent with those showing a more rapid response in females to antidepressant actions in the Porsolt test.

Gender Differences in the Human Response to Stress

Like experimental animals, humans also exhibit sex differences in their stress response, including physiological, endocrine, and behavioral reactions. From a perspective of general health, the gender difference in cardiovascular reactivity is one of the most important. The resting heart rate in women is higher than in men, which is similar to male and female laboratory animals. However, in spite of their higher baseline, women exhibit less cardiovascular reactivity to stressful emotional situations than men, as reflected by smaller changes from baseline for both heart rate and blood pressure. The greater cardiovascular lability to emotional stressors in men is considered a major contributing factor to their increased risk of cardiovascular morbidity.

Gender differences in the cardiovascular response to physical stress are not as pronounced. Studies involving moderate exercise show that healthy young men and women exhibit no significant differences in exercise-induced increases in heart rate. However, increases in systolic blood pressure under these conditions are often reported to be greater in men than women.

Although the animal literature shows large and consistent sex differences in HPA activation, gender-related data in humans are much more equivocal. In response to physiological stress such as exercise, young men and women show no reliable differences in HPA activation. Other studies have reported an increased release of ACTH and prolonged cortisol response in women compared with men following CRH administration, which might be expected from the animal literature. However, this pattern may reflect the direct, physiological stimulation of pituitary corticotrophs, in contrast to an endogenous response following a psychological or physical stressor. As discussed below, gender differences in the endocrine stress response to psychological and physiological events are situational, and thus not likely to be a simple reflection of differences in CRH sensitivity at the level of the pituitary.

Early studies of the endocrine responses of men and women produced conflicting results, with some reporting endocrine patterns to stress that paralleled results in laboratory animals, and other reporting no gender differences. The work was complicated by the methodological problem of the need to use invasive procedures to obtain blood samples. In the past decade, stress reactivity studies of the HPA have been greatly improved by the advent of the salivary cortisol assay. This allows a stress-free, noninvasive method of collecting multiple cortisol samples from an individual over time in response to an experimental situation. Moreover, the assay measures the free cortisol, which is the biologically active fraction. This avoids the interpretive problems associated with measure total cortisol in plasma, of which approximately 90–95% is attached to cortisol binding globulin (CBG) and biologically unavailable.

The results from more recent studies indicate that gender differences in human HPA responsiveness to psychological stress depend upon the type of stress and the environmental circumstances in which it occurs. Studies of HPA activation during psychological stress that involves achievement situations show that ACTH and cortisol levels are higher in men than women, although women report greater subjective feelings of stress. This achievement-related pattern of increased HPA activation in men has been observed in a range of experimental and real life situations, including public speaking, mirror drawing, problem solving, and marital conflict. However, when the stressor involves social rejection, females have been found to exhibit higher cortisol levels than males. This is consistent with other studies showing that psychological factors associated with social stress, such as taking care of an elderly parent, have more impact on HPA reactivity in women than in men. Some investigators have suggested that gender differences in stress reactivity along social/achievement dimensions may reflect the evolutionary pressures of sex roles. Studies examining stress in the workplace tend to find few gender differences in HPA reactivity when the situation does not involve conflict with co-workers.

Compared to laboratory animals, much less is known about the influence of gonadal steroids on stress-related activation of the HPA in humans. A stimulatory role for estrogen on HPA activation is suggested by data from studies conducted during the menstrual cycle. During the follicular phase, when estrogen levels rise and peak at ovulation, stress-induced rises in cortisol are generally greater than those observed in the luteal phase. In the luteal phase, rising progesterone levels may counteract the influence of estrogen on HPA activation. Removal of the ovaries prior to menopause reduces the HPA sensitivity to CRH stimulation. However, estrogen's effect on HPA reactivity is not restricted to women, since normal men administered a short-term regimen of estrogen also exhibit increased HPA activity. One possible explanation for estrogen's effect on HPA reactivity comes from observations that estrogen therapy will increase circulating levels of CBG. Increases in CBG would result in a decrease in free, bioavailable cortisol, potentially reducing negative feedback regulation.

The modulatory role of gonadal hormones on human HPA reactivity has been examined in volunteers undergoing a reversible, chemical castration procedure. Men and women volunteers treated for 2 months with leuprolide, a synthetic analog of gonadotropin releasing hormone, which suppressed the secretion of gonadal steroids. This treatment permitted the examination of the HPA response to stress under conditions where estrogen and testosterone levels were low in both sexes. The results showed that men sex exhibited a significantly greater plasma ACTH response to CRH stimulation than women and a greater cortisol response to exercise. However, no gender differences were observed in HPA responsiveness using the ratio of ACTH to cortisol. With subsequent testosterone replacement in the men, CRH stimulation of ACTH was significantly increased but cortisol significantly decreased. These findings suggest that there may be an underlying organizational effect in brain as the source of gender differences in HPA reactivity.

Gender-Related Clinical Consequences of Stress

The mechanisms linking stress to disease states in humans are not well understood, but hormonal changes, induced by the stress response, are recognized as a major influence. Stress is not viewed as the cause of disease, but rather as a factor increasing an individual's susceptibility to it. Stress-induced elevations of plasma glucocorticoids have direct effects on behavior and physiology which can be modulated by gonadal steroids. It is the interaction between glucocorticoid and gonadal harmones on cellular responses that is believed to be the major factor in gender differences in stress-related disease. Receptors for glucocorticoids, androgens, and estrogens are widely distributed tissues that are stress-responsive, including brain, heart muscle, blood vessels, and immune tissues such as spleen, thymus, and bone marrow. In brain these receptors are located in regions that mediate emotional and autonomic responses to stress such as the hippocampus, hypothalamus, amygdala, and

prefontal cortex. It is the interaction between glucocorticoid and gonadal hormones on cellular responses that is believed to be the major factor in gender differences in stress-related disease.

Males have a significantly higher risk for having cardiovascular disease at an earlier age than women, and this risk is exacerbated by stress. Women are afforded a significant degree of protection through the actions of estrogen against arteriosclerosis. The gender difference subsides after menopause, with the result that risk of heart disease increases in older women.

In contrast, women are significantly more likely to suffer from autoimmune disorders such as lupus, rheumatoid arthritis, and irritable bowel syndrome. An interaction between estrogen and HPA activation has been proposed as a mediator of the sex-linked ratio of autoimmune disorders, which are approximately threefold more common in women. In contrast to the protective role estrogen plays in cardiovascular disease, estrogen may exacerbate immune responses through receptors present on thymocytes, macrophages, and endothelial cells, all of which also express GRs. The interaction between estrogen and glucocorticoids on immunomodulation appears to underlie the gender difference in autoimmune disease susceptibility.

Women are 2–3 times more likely to suffer from depression than men. The gender ratio is consistent across cultures in western society, indicating that biological factors, as opposed to local variations in psychosocial attitudes, are a primary contributor. Clinical studies consistently show that the HPA system is tonically hyperactive in endogenously depressed patients. However, no clear differences between men and women have emerged in HPA activity that might account for the gender difference in depression. The onset of clinical depression is well known to be exacerbated by life stress and data from several studies suggest that the gender bias in mood disorders involves an increased susceptibility in some women to the combined effects of stress and hormonal status. Thus, fluctuations in estrogen and progesterone across the menstrual cycle have been proposed to confer susceptibility to depression in women and this can be exacerbated by life stress. Finally, serotonin synthesis in brain is significantly greater in men than women, a factor that has been implicated in the increased risk for depression in women. This pattern of synthesis is opposite that reported in animals.

The odds ratio for women developing posttraumatic stress disorder (PTSD) is similar to depression. Following exposure to prolonged psychological trauma, women exhibit PTSD symptoms twice as frequently as men, even when the type of trauma is equivalent. Some studies have found that experiencing psychologically traumatizing events prior to puberty greatly increases the susceptibility to PTSD in adulthood in females compared to males. This suggests that organizational effects of hormones may play a significant role in the increased susceptibility of women. Hippocampal damage, which can be induced by chronically high levels of glucocorticoids, may play a role in PTSD based on studies showing a reduction in volume in PTSD patients. Consistent with this, the hippocampus has been shown to play a critical role in neural circuitry assessing threat. In animals, uncontrollable stress has been found to reduce spine density, a measure of synapse numbers, in the hippocampus of females, but increase it in males.

In summary, studies over the years have identified consistent sex differences in the hormonal and behavioral responses to stress in laboratory animals and humans. In general, the reactivity of the HPA axis to a stressor is greater in females, whereas behavioral stress responses are often more severe in males. Such data indicate that coping strategies are different between the sexes. Underlying these sex differences are both organizational and activational actions of gonadal steroid hormones on brain areas controlling neuroendocrine function and fear- or anxiety-related behaviors. While there is broad agreement between animal and human studies, human sex differences in stress reactivity are move dependent upon the type of stress and the response measured.

Stress, Cytokines and Depressive Illness

M K Cowles and A H Miller, Emory University School of Medicine, Atlanta, GA, USA

Introduction

Stress has long been accepted as a trigger for the onset of a number of diseases, including major depression. Nevertheless, the mechanisms by which stress translates into disease have yet to be fully elucidated. One possibility is the effect of stress on the immune system. Although much attention has been paid to the immunosuppressive effects of stress, recent data indicate that stress can activate certain aspects of immunity, specifically the innate inflammatory immune response. While inflammatory processes are well known to contribute to the development and progression of allergic disorders, autoimmune diseases, and infections, there has been increasing interest in the role of inflammatory responses in a number of other common medical conditions, including cardiovascular disease, diabetes, and cancer. New data suggest that inflammation may play a role in the pathophysiology of depression as well. Therefore, stress effects on the immune response, specifically the innate immune inflammatory response, may be an important and relevant pathway in the contribution of stress to disease, including psychiatric diseases such as depression.

Innate Immunity and the Inflammatory Response

The immune response can be divided into two broad categories – innate immunity (described later) and acquired immunity (comprising T and B lymphocytes that, respectively, mediate the cellular and humoral (antibody) responses to pathogen exposure). Both aspects of immunity are carried out by a series of cells and soluble factors, which work together to coordinate the response to foreign pathogens, neoplastically transformed cells, and cells and tissues that have been damaged or destroyed. All immune cells originate as hematopoietic stem cells that ultimately differentiate along either myeloid or lymphoid cell lines. Immune cell differentiation and function are guided by a number of factors, including cytokines. Cytokines are intercellular signaling molecules produced by a variety of cells, including activated neutrophils, monocytes/macrophages, lymphocytes, natural killer (NK) cells, glia (astrocytes and microglia), endothelial cells, fibroblasts, and adipocytes. Cytokine effects are both local and systemic, and for a particular cytokine there may be multiple cellular targets, resulting in a myriad of relevant effector functions. There are three general categories of cytokines: (1) mediators and regulators of innate immunity, (2) mediators and regulators of acquired immunity, and (3) stimulators of hematopoiesis. Table 1 summarizes the roles of these various cytokines.

Initial work with respect to the impact of stress and depression on immune function focused on inhibition of the acquired immune response. More recent evidence, however, supports the notion that stress and depression are also associated with activation of innate immune responses resulting in inflammation, which in turn, may contribute to the development of a number of medical disorders (see later) as well as alterations in behavior. The cellular components of the innate immune system include monocytes (which further differentiate into macrophages), neutrophils, and NK cells. Monocytes and neutrophils are derived from myeloid stem line whereas NK cells are derived from the lymphoid stem line. Monocytes, macrophages, and neutrophils are collectively referred to as phagocytes. Circulating mediators of innate immunity include complement, acute-phase proteins such as C-reactive protein (CRP), and cytokines including type I interferons (IFNs)-α and-β, tumor necrosis factor-α (TNF-α), IL-1, and IL-6. TNF-α, IL-1, and IL-6 are also referred to as proinflammatory cytokines.

Inflammation is characterized by a cellular response whereby the cytokines of the innate immune response promote the expression and release of chemokines and adhesion molecules in the local environment (Figure 1). Chemokines and adhesion molecules in turn support the collection of various innate immune cell subtypes at the site of pathogen invasion and/or tissue disruption/destruction; these subtypes include neutrophils and macrophages as well as elements of the acquired immune response such as activated T-helper and T-cytotoxic cells. In addition to the local response, cytokines can enter the peripheral circulation and stimulate the production of acute-phase proteins by the liver and interact with nervous system elements, leading to behavioral changes referred to as 'sickness behavior,' including depression, fatigue, and cognitive dysfunction (see later). The acute-phase response is geared to promote elimination of invading pathogens while at the same time inactivating potentially destructive enzymes (proteases) and the generation of oxygen radicals. Cytokine effects on the central nervous system may ultimately help to conserve energy in the service of

fever and other metabolic processes that support endogenous antibiosis and wound healing.

At the signal transduction level, activation of the transcription factor, nuclear factor-kappa B (NF-κB), plays a fundamental role in initiating the innate immune cascade, with the resultant production of multiple inflammatory mediators, including cytokines, chemokines, cellular adhesion molecules, acute-phase reactants, prostaglandins, nitric oxide, and the cyclooxygenase COX-2, as well as activating other stress responsive genes. NF-κB is activated by the interaction of pathogens with toll-like receptors on the surface of immune cells, notably macrophages. Toll-like receptors are pattern recognition molecules on innate immune cells that serve to recognize a few highly conserved structures present in many different microorganisms. Cytokine receptors (e.g., IL-1) containing the toll-like receptor binding domain also activate the NF-κB pathway. In addition to NF-κB, the mitogen-activated protein kinase (MAPK) cascade – including p38, extracellular signal-regulated kinase-1/2 (ERK-1/2), and c-Jun N-terminal kinase (JNK) – as well as the Janus kinase (JAK)-signal transducers and activators of transcription (STAT) signaling pathway also play an important role in initiating and maintaining the inflammatory response.

Although the inflammatory response is pivotal in providing a front-line defense against pathogen

Induction of cell death

Figure 1 Innate immunity: local and systemic responses to cytokine release secondary to tissue injury/infection. Locally, cytokines act on endothelial and tissue stromal cells. Tissue stromal cells produce chemotactic factors, recruiting other immune cells to the site of injury. The endothelial cells produce adhesion molecules, enhancing immune cell margination and diapedesis. In the brain, proinflammatory cytokines – including interleukins-1 and -6 (IL-1, IL-6) and tumor necrosis factor-α (TNF) – activate the hypothalamic–pituitary–adrenal (HPA) axis and induce behavioral changes that subserve the metabolic demands of fever and inflammation. The proinflammatory cytokines also induce the liver to produce acute-phase proteins. CAM, cellular adhesion molecule; IFN, interferon. invasion and tissue destruction, there is increasing appreciation that when the response is excessive or chronic, inflammation may have significant deleterious effects (Figure 2). Indeed, cardiovascular disease, including atherosclerotic heart disease and congestive heart failure, has been associated with elevated levels of CRP, TNF-α, IL-6, and IL-1β. These cytokines are believed to contribute to atherosclerotic plaque formation and cardiac irritability. Patients with diabetes have also been found to exhibit elevations of CRP, IL-6, and TNF-α, and inflammatory cytokines have been found to disrupt insulin receptor signaling and are associated with insulin resistance. Interestingly in this regard, genetically manipulated mice vulnerable to obesity and insulin resistance via overexpression of the gene for leptin exhibit normalization of glucose metabolic responses following disruption of inflammatory signaling pathways. Finally, inflammatory signaling pathways have been implicated in the neoplastic process, contributing to tumor cell growth and proliferation as well as to resistance to chemotherapeutic agents. Given the capacity of stress to activate inflammatory responses, there has been increasing interest as to whether stress-induced changes in the immune system may play a role in a number of diseases, including not only medical disorders (as noted previously) but also psychiatric illnesses such as depression (see later).

Stress and the Immune System

A wide variety of stressors have been shown to alter immune responses. In general, initial studies have indicated that exposure to acute and chronic stressors is associated with inhibition of acquired immune responses, especially the ability of T and B cells to proliferate *in vitro*. In the case of NK cells, chronic stress was shown to decrease NK cell numbers and activity, while acute stress was associated with increases in NK cell numbers. Although early studies on the effects of stress on immunity emphasized the immunosuppressive aspects of this relationship, more recently it has become apparent that acute and chronic stressors can also activate certain aspects of immunity, specifically the innate immune response. These findings have been apparent in both laboratory animals and humans and include the induction of proinflammatory cytokines, acute-phase reactants, chemokines, and adhesion molecules. In a recent study in humans, it was also shown that exposure to an acute psychosocial stressor (public speaking and mental arithmetic) can lead to the activation of

inflammatory signaling pathways. Indeed, within 10 min following stressor exposure, peripheral blood mononuclear cells from stressed individuals exhibited significantly increased NF-κB DNA binding as measured by electromobility shift assay. In attempts to reconcile the inhibitory effects of stress on acquired immune responses versus stress-induced activation of innate immune responses, the relationship between acquired and innate immune responses has been examined in rats immunized with keyhole limpet hemocyanin (KLH), which induces an antibody (B cell) response (acquired immunity). Interestingly, stress-induced decreases in antibody responses to KLH were reversed in animals pretreated with the IL-1 receptor antagonist. These findings suggest that activation of innate immune responses by stress may in turn contribute to stress-induced inhibition of acquired immune responses.

Regarding the mechanism of the effects of stress on the innate immune response, much attention has been paid to the sympathetic nervous system (**Figure 3**). Both alpha and beta adrenergic antagonists have been used to demonstrate that stress-induced catecholamines acting through alpha 1- and beta 2-adrenergic receptors are capable of inducing an inflammatory response, including the induction of proinflammatory cytokines in both the periphery and the brain. Of note, while alpha-adrenergic antagonists were effective in abrogating peripheral stress-induced proinflammatory cytokines, only beta-adrenergic receptor antagonists were effective in the brain.

Given the relative balance between sympathetic and parasympathetic nervous system responses at rest and during stress, it is interesting to note that activation of efferent parasympathetic nervous system pathways has been found to reduce inflammatory responses. This cholinergic anti-inflammatory pathway is mediated in the periphery by nicotinic acetylcholine receptors that contain the alpha 7 subunit and by muscarinic acetylcholine receptors in the brain. Indeed, both electrical stimulation of the vagus nerve (and thus parasympathetic outflow pathways) and peripheral administration of alpha 7 nicotinic acetylcholine receptor agonists have been shown to significantly reduce mortality and/or blood concentrations of TNF-α in rats exposed to high doses of endotoxin (which produces a massive inflammatory response). Similar effects have been found following central administration of muscarinic receptor agonists. Of note, vagal nerve stimulation, as currently employed to treat depression, stimulates afferent and not efferent parasympathetic pathways and therefore is not specifically designed to influence peripheral immune pathways. Finally, reduced heart rate variability, an indicator of relatively increased sympathetic versus parasympathetic tone, has been associated with evidence of an increased inflammatory response. Taken together, the data support the notion of a 'yin-yang' influence of autonomic nervous system pathways on the regulation of innate immune responses. The findings suggest that the effects of stress on immunity may in part be mediated by an impact on the balance of sympathetic and parasympathetic nervous system activity.

Depression and the Immune System

As with stress, initial work with respect to the immune system in depression revealed diminished functioning of the acquired immune response, primarily manifested by reduced T and B cell proliferative responses and reduced NK cell activity. More recent evidence, however, has supported the notion that in addition to alterations in acquired immune responses and NK cell activity, depression is associated with a hyperactivity of certain aspects of the innate immune response. Specifically, depressed patients have been found to exhibit increased proinflammatory cytokines in both peripheral blood and cerebrospinal fluid, increased acute-phase reactants, and increased expression of chemokines and adhesion molecules. Probably the most reproducible innate immune finding in patients with depression is increased levels of IL-6 and its downstream product from the liver, CRP. Not only have mean differences in inflammatory mediators been found in depressed patients versus control subjects, a number of studies have reported a dose-response relationship between severity of depression and commensurate increases in the concentrations of various inflammatory mediators. Interestingly, compared to other populations of depressed subjects, patients with treatment-resistant depression have been shown to be especially likely to exhibit elevations in inflammatory markers, including IL-6. In addition, IL-6 and TNF-α have been shown to be predictors of nonresponse to standard antidepressant medications. Finally, preliminary studies have indicated that polymorphisms in relevant cytokine genes may predict treatment response in populations of depressed patients.

In addition to evidence of increased inflammatory markers in depressed individuals, a large literature has demonstrated that cytokines of the innate immune response have the capacity to induce a depressive-like state. Indeed, peripherally or centrally administered cytokines induce a syndrome of 'sickness behavior,' which includes symptoms of anhedonia, anorexia, impaired sleep, fatigue, psychomotor slowing, and increased sensitivity to pain, all of which overlap with symptoms experienced by patients with major

Figure 3 Stress–immune interactions and depression. (a) Activation of nuclear factor-kappaB (NF-κB) through Toll-like receptors (TLR) during immune challenge leads to an inflammatory response (b), including the release of the proinflammatory cytokines tumor necrosis factor and interleukins (TNF-α, IL-1, and IL-6). (c) These cytokines, in turn, access the brain via leaky regions in the blood–brain barrier, active transport molecules, and afferent nerve fibers (e.g., sensory vagus), which relay information through the nucleus tractus solitarius (NTS). (d) Once in the brain, cytokine signals participate in pathways known to be involved in the development of depression, including altered metabolism of relevant neurotransmitters such as serotonin (5HT) and dopamine (DA), activation of corticotropin-releasing hormone (CRH) in the paraventricular nucleus (PVN) and the subsequent production and/or release of adrenocorticotropin (ACTH) and glucocorticoids (cortisol), and disruption of synaptic plasticity through alterations in relevant growth factors, such as brain-derived neurotropic factor (BDNF). (e) Exposure to environmental stressors promotes activation of inflammatory signaling (NF-κB) through increased outflow of proinflammatory sympathetic nervous system responses (release of norepinephrine (NE, orange), which binds to α and β adrenoceptors (αAR, βAR)). (f) Stressors also induce withdrawal of inhibitory motor vagal input responses (release of acetylcholine (ACh, blue), which binds to the α7 subunit of the nicotinic acetylcholine receptor (α7nAChR)). (g) Activation of the MAPK pathways, including p38 and Jun N-terminal kinase (JNK), inhibits the function of glucocorticoid receptors (GR), thereby releasing NF-κB from negative regulation by glucocorticoids (blue) released as a result of the HPA axis in response to stress; ERK, extracellular signal-regulated kinase. Reproduced from Raison CL, Capuron L, and Miller AH (2006) Cytokines sing the blues: Inflammation and the pathogenesis of depression. *Trends in Immunology* 227: 24–31, with permission from Elsevier.

depression. Although there are a vast number of studies in laboratory animals demonstrating that the administration of proinflammatory cytokines or their inducers (e.g., lipopolysaccharide) can reliably contribute to the development of sickness behavior, much of the literature in humans derives from patients being treated with the cytokine, IFN-α. IFN-α is an early innate cytokine released during viral infection and has both antiviral and antiproliferative properties. As such, IFN-α is used to treat viral infections and cancer. Despite being a useful therapeutic agent, IFN-α is notorious for causing

Table 2 Depression in the medically ill

Illness	*Prevalence of depression (%)*
Cardiovascular disease	16–27
Cancer	25–42
Diabetes mellitus	9–27
Cerebrovascular accident	20–27
Human immunodeficiency virus	6–12

significant depressive symptomatology in 30–50% of patients, depending on the dose. Furthermore, it has been shown that the depression that develops during IFN-α therapy is responsive to treatment with standard antidepressants, suggesting that this cytokine-induced depressive syndrome is analogous to depressive disorders found in medically healthy individuals.

Further supporting the relationship between cytokines and depression is the high rate of depressive disorders in patients with a wide range of medical disorders, the majority of which are associated with some element of tissue damage or destruction and resultant inflammation. As shown in Table 2, rates of depression in the medically ill are up to five times higher than that observed in the general population (5%). These rates vary depending on the type, severity, and number of comorbid medical illnesses. With regard to proinflammatory cytokines and depression in medically ill subjects, it is particularly interesting that recent placebo-controlled data demonstrated that administration of an antagonist to TNF-α was associated with a significant reduction in depressive symptoms in patients with psoriasis. Of note, the reduction of depressive symptoms in patients receiving the cytokine antagonist appeared to be independent of the effect of the antagonist on disease activity.

Regarding the mechanisms by which cytokines influence behavior, attention has been focused on how cytokine signals access the brain, what happens once they reach the brain, and what pathways they interact with to contribute to the development of depression. Because cytokines are too large to freely pass through the blood–brain barrier, investigators have examined how cytokine signals are communicated to the brain. Mechanisms include (1) passage through leaky regions in the blood–brain barrier, such as the circumventricular organs, (2) binding to cytokine-specific transport molecules expressed on brain endothelium, and (3) activation of vagal afferent fibers that transmit cytokine signals to specific brain nuclei, including the nucleus of the solitary tract and the paraventricular nucleus in the hypothalamus.

Once cytokine signals have reached the brain, there is a cytokine network within the brain characterized by protein and mRNA for cytokines and their receptors in multiple cell types. This network includes a rich expression in brain regions relevant to depression and cognition, including the limbic and reward (striatum) circuitry, hypothalamus, and prefrontal cortex. Most central nervous system cytokines emanate from microglia, astrocytes, and endothelial cells of the cerebrovasculature; however, cytokine and cytokine receptor expression in neurons has also been described. Microglia, astrocytes, and endothelial cells are also capable of producing inflammatory mediators, including chemokines, adhesion molecules, prostaglandins, nitric oxide, and COX-2.

Cytokines and the Pathophysiology of Depression

Activation of the cytokine network within the brain has been associated with effects on many of the pathways that have been shown to be relevant to the pathophysiology of depression, including neurotransmitter metabolism, neuroendocrine function, synaptic plasticity, and information processing (Figure 3).

Cytokine effects on neurotransmitter metabolism

Cytokine effects on neurotransmitter metabolism include alterations in the metabolism of dopamine, norepinephrine, and serotonin. The overlap between the effects of stress and the effects of cytokines on neurotransmitter metabolism are particularly intriguing and suggest that shared mechanisms may be involved.

The influence of inflammatory processes on serotonin metabolism is of particular note, especially given the relationship between inflammation and the activation of the metabolic enzyme, indolamine 2,3-dioxygenase(IDO), and the p38 MAPK cascade. IDO is responsible for breaking down tryptophan into kynurenine and quinolinic acid, thus decreasing the availability of tryptophan (the primary precursor of serotonin) and increasing the concentration of quinolinic acid, which has neurotoxic properties. In addition, recent data have shown that activation of the p38 MAPK cascade by proinflammatory cytokines, including IL-1, is associated with upregulation of the activity and expression of the serotonin transporter, thereby further decreasing serotonin availability in the synapse. Thus, by decreasing serotonin availability both at the level of its metabolism as well as its presence in the synapse, inflammatory processes can contribute to marked decreases in serotonin neurotransmission, a hallmark of the pathophysiology of depression. Indeed, the efficacy of serotonin reuptake inhibitors in cytokine (IFN-α)-induced depression is consistent with the relevance of serotonin pathways in the mechanism of cytokine-induced behavioral changes.

Cytokine effects on neuroendocrine function Probably the most studied of the effects of inflammation and proinflammatory cytokines on the nervous system are the effects on the neuroendocrine system. Proinflammatory cytokines have been shown in multiple studies in laboratory animals to activate the expression, production, and release of the neuropeptide, corticotropin-releasing hormone (CRH), a primary regulator of the stress response. Given the capacity of CRH to induce behavioral changes that overlap with sickness behavior, including altered locomotor activity, anorexia, and impaired sleep, it has been suggested that cytokine-induced increases in CRH may in part contribute to the behavioral effects of cytokines. Indeed, increased CRH activity has been a consistent finding in major depression as manifested by increased CRH in the cerebrospinal fluid, increased CRH mRNA and protein in the hypothalamus, and decreased CRH receptors in the prefrontal cortex (likely secondary to increased CRH production).

Another neuroendocrine alteration that can be induced by proinflammatory cytokines and may contribute to the pathophysiology of depression is glucocorticoid resistance. Glucocorticoid resistance, as manifested by nonsuppression of the hypothalamic-pituitary-adrenal (HPA) axis following administration of the synthetic glucocorticoid, dexamethasone (DEX) (determined in the DEX suppression test or the DEX/CRH test), is a reliable finding in patients with depression. In addition, glucocorticoid resistance is believed to contribute to the hypersecretion of CRH, which is normally under negative feedback regulation by glucocorticoids. Glucocorticoid resistance in depression is believed to stem from alterations in the expression and/or activity of the glucocorticoid receptor (GR). Indeed, transgenic mouse models of decreased GR availability have been associated with vulnerability to depressive-like behaviors, including learned helplessness. Regarding cytokines, a number of studies have demonstrated that activation of p38 MAPK pathways as well the STAT5 pathway is associated with decreased GR function. Activation of p38 signaling leading to glucocorticoid resistance has been posited as a major mechanism involved in steroid-resistant asthma. p38 appears to phosphorylate the GR, leading to disruption of GR nuclear translocation, whereas STAT5 has been shown to dysregulate the GR through direct protein–protein interactions. Thus, proinflammatory cytokines can not only stimulate CRH expression, production, and release, but also, through inhibitory effects on the GR, disrupt GR-mediated negative feedback pathways on CRH, all of which contribute to a feed-forward cascade of inflammation and activation of CRH.

Cytokine effects on synaptic plasticity Recent research has focused on the role of synaptic plasticity and related growth factors, including brain-derived neurotropic factor (BDNF) in the pathophysiology and treatment of depressive disorders. Data suggest that activation of cytokine pathways in the brain during stress may influence growth factors, thereby representing another mechanism by which stress via cytokines may contribute to depression. For example, IL-1 has been shown to mediate the inhibition of BDNF expression in the hippocampus of rats following social isolation stress. TNF-α and activation of NF-κB signaling pathways have also been associated with stress-induced production of nitric oxide within the CNS, which in turn may contribute to alterations in neuronal growth and survival through the induction of oxidative stress. Oxidative stress has been shown to alter promoter function for several genes central to synaptic plasticity. Consistent with these findings is that stress-induced neuronal cell loss in rodents has been linked to increased concentrations of TNF-α and NF-κB.

Cytokine effects on information processing Recent data indicate that another major pathway by which cytokines may influence behavior is through their effects on the activity and function of neurocircuitry relevant to cognition. Indeed, using functional magnetic resonance imaging (fMRI) and visuospatial attention task, investigators have demonstrated that patients chronically administered the innate immune cytokine, IFN-α, exhibit significantly greater activation of the dorsal anterior cingulate cortex (dACC) than do control subjects not undergoing IFN-α treatment. The dACC is a brain region that plays a fundamental role in conflict monitoring and error processing and participates in the allocation of mental resources for accomplishing tasks and reaching goals. Important interconnections also exist between the dACC and the striatum, which previous studies have shown is a target for cytokine activity in patients with HIV and in patients undergoing IFN-α therapy. Increased activation of the dACC may indicate cytokine-induced increases in mental effort or may reflect an increased sensitivity (decreased threshold) for processing negative events. Increased activity in the dACC has also been observed in subjects with high-trait anxiety, neuroticism, and obsessive–compulsive disorder, all conditions of increased sensitivity to environmental and interoceptive stimuli and all conditions associated with an increased vulnerability to the development of mood and anxiety disorders. Thus, altered dACC activity as a function of exposure to innate immune cytokines may represent a cognitive pathway to psychopathology.

Integrating Stress, Cytokines, and Depression

From the literature reviewed in the preceding sections, it is clear that stress activates the innate immune response and that an activated innate immune response can in turn contribute to many of the pathologies that characterize depression, including both biological and behavioral features. In addition, there is a rich literature demonstrating that stress is a reliable precipitating factor for the development of depression. Despite the logical connections which can be drawn from these individual relationships, it may be difficult to establish that all of these factors together conspire in some demonstrable linear fashion to lead to disease. More likely, stress effects on the immune system and the immune system's contribution to the pathophysiology of depression represent two of many convergent pathways which together contribute to a multi-determined disease endpoint. Nevertheless, from the standpoint of treatment and prevention, several translational implications are apparent. The first has to do with the role of the autonomic nervous system in regulating the immunologic response to stress. Research and interventional strategies that address the relative balance of sympathetic and parasympathetic outflow to the immune system are particularly relevant in this regard and require focus on the transmitters and signal transduction pathways involved. Special attention needs to be paid to the catecholamines and acetylcholine and to their signaling pathways, as well as to their interaction with inflammatory signaling pathways, including NF-κB and MAPK. As for the immune system, it has become increasingly apparent that further knowledge about inflammatory signaling molecules that are involved in reproducing pathologies that characterize depression (including p38 and NF-κB) may be particularly relevant regarding the identification of therapeutic targets, as well as in determining the full clinical implications of the immune system as it relates to behavior. Finally, further detailing of the neurocircuitry of cytokine effects on the brain may help identify brain regions that subserve cytokine effects on behavior, and thus represent circuits for therapeutic intervention through either somatic or psychotherapeutic means.

Summary

In conclusion, the data indicate that depression is not an isolated disease state of the brain; rather, it is a systemic illness invoking a complex interaction of the nervous, endocrine, and immune systems. As such, the innate immune response appears to be a potential pivotal mediator in the relationship between stress and depression. Further elucidation of the interactions between stress, cytokines, and depression may ultimately provide a novel conceptual framework with the potential to guide future developments in research and therapy as they relate to the multidimensional pathophysiologies that lead to psychiatric diseases such as depression.

Stress, Dopamine, and Puberty

Stress, Puberty, and Adolescence

A stressor is anything that is perceived by the individual to cause emotional, mental, or physical strain. This definition suggests that awareness of the stress is vital for its impact on both emotional and cognitive processing. Thus, what is considered stressful needs to be placed in developmental context when it is applied to immature systems. For example, conflict and missed deadlines are stressors for adolescents and adults, whereas neglectful parents or no friends are stressors for children. Relevant examples for adult animals in a species-specific context include choice conflicts or delay of reinforcement paradigms, whereas maternal deprivation or social isolation model childhood and young adolescent stressors. Age-appropriate stressors are important for correct interpretation of behavioral and neurochemical responses at different stages of development.

Development occurs in a series of phases, defined physiologically or socially. The term puberty refers to the achievement of reproductive fitness hailed by secondary sex characteristics and maturity of the reproductive systems. As part of this process, adolescence describes the period between the onset of puberty and adulthood when the individual defines and refines the sense of self in terms of social values, personal values, and future goals. The use of the terms puberty versus adolescence in this article will reflect whether the topic refers to physiological or social changes and the timing of the developmental period discussed. For example, stress during adolescence may depend more on social context than physiological deprivation given the importance of social development during this period. Adolescence will also be used to refer to the period of development that spans between puberty onset and adulthood.

As outlined in this article, understanding how the dopamine system develops during the transitions between childhood, adolescence, and adulthood sets the stage for framing the uniqueness of the impact of stress on behavior, neurochemistry, and neuroanatomy.

The Dopamine System

Neuroanatomy

The catecholaminergic dopamine system is more localized in its innervation patterns relative to many other neurotransmitter systems. Dopaminergic cell bodies, also known as A9 and A10, emanate from the ventral tegmental nucleus (VTA) and the substantia nigra, respectively. Smaller, less well-characterized dopamine terminals have been identified in the amygdala, hippocampus, and cerebellum. From the VTA, separate dopaminergic neurons project to either the nucleus accumbens and comprise the mesolimbic dopamine system, or the prefrontal cortex and comprise the mesocortical system. The substantia nigra sends projections to the caudate and putamen (collectively referred to as the striatum), and forms the nigrostriatal dopamine system.

Signaling Mechanisms in the Dopamine System

The signaling mechanisms of the dopamine system are associated with five main receptor subtypes, referred to as D1–D5 (Figure 1). The majority of these receptors are G-protein-coupled receptors (GCPRs). D1 and D5 are more excitatory in nature, are linked to stimulatory G-proteins, and classically increase the activity of the second messenger cyclic adenosine monophosphate (cAMP). In contrast, D2–D4 dopamine receptors are inhibitory in nature, couple with inhibitory G-proteins, and reduce cAMP activity. This is merely the beginning of the signaling cascade, as other second messengers (protein kinases) and the inositol triphosphate (IP_3) system are also involved.

Dopamine receptor signaling mechanisms, activated by environmental changes, can induce transcriptional regulating proteins, which ultimately leads to changes in gene transcription. Enhanced expression of cyclic AMP response element-binding protein (CREB) and delta-Fos subunit B (ΔFosB), have been extensively studied. It is believed that changes in these proteins signal the beginning of long-term alterations, or plasticity, that occur in response to drugs of addiction or stress. Changes in immediate early gene expression, notably the Fos and Jun genes, are among the most commonly reported. Their expression, in turn, increases the production of numerous proteins that produce the enduring actions of

Figure 1 Dopamine receptor signaling cascades. Dopamine acts at G-protein-coupled receptors to produce activational (via D1/D5 receptors) or inhibitory effects (via the D2 family (D2–D4)) overall. Dopamine acting at D1/D5 receptors predominantly activates the stimulatory G-protein-coupled receptors (Gs), which upregulate adenylyl cyclase activity, leading to an increase in cAMP. Higher levels of cAMP activate protein kinase A, which phosphorylates many proteins, including transcriptional activators, and membrane-bound ion pumps and channels. Phosphorylation of ion pumps/channels produce short-term alterations in the membrane potential, causing the cell to become more or less likely to fire. In contrast, longer-term effects are seen through the phosphorylation of transcription factors such as CREB and ΔFosB. These transcription factors ultimately increase the production of proteins, including *c-fos*, neurotrophins, and neuropeptides. Dopamine at D2–D4 receptors activates the inhibitory G-protein-coupled receptors (Gi), which decreases adenylyl cyclase activity. Dopamine can also act through a secondary D1/D5 pathway, via Gq receptors and the phosphatidylinositol pathway. In this pathway, dopamine binding increases phospholipase C activity, which produces inositol triphosphate and diacylglycerol from phosphatidylinositol. Increased levels of diacylglycerol activate protein kinase C, which phosphorylates other kinases such as mitogen-activated protein kinase, and transcription factors such as CREB. Higher levels of inositol triphosphate increase cytoplasmic Ca^{2+} levels, thereby activating calcium-dependent kinases, which further continue the process of protein phosphorylation and activation. AC, adenylyl cyclase; AGS3, activator of G-protein signaling 3; BDNF, brain-derived neurotrophic factor; cAMP, cyclic adenosine monophosphate; CREB, cAMP response element-binding protein; DA, dopamine; DAG, diacylglycerol; ΔFosB, delta-Fos subunit B; GTP, guanosine triphosphate; IEGs, immediate early genes; IP_3, inositol triphosphate; MAPK, mitogen-activated protein kinase; PIP_2, phosphatidylinositol; PLC, phospholipase C; TCF, transcription factor.

dopamine receptor activation. Most of this work has been performed in animals exposed to drugs of addiction. However, because stress and addictive agents often work by the same mechanistic cascades, the information from stimulant studies is likely to transfer to stress exposure. This represents an area that is tremendously understudied to date.

Brain Development and the Dopamine System

Overproduction and Elimination of Synapses during Puberty

Profound brain changes occur during the course of postnatal development and adolescence and represent the final phase of this transition. Cortical structures, including the prefrontal cortex, and subcortical structures, including the striatum and nucleus accumbens, undergo an exuberant overproduction of synapses and associated signaling molecules between childhood and adolescence. This is subsequently followed by the selective elimination, or pruning, of synapses before adulthood. This pruning is similar to what occurs with trees: branches (dendrites) are selectively cut back to optimize growth potential (or in the case of the brain, efficiency) to match the needs of the environment. In humans, cortical gray matter volume reaches peak density at 11.6 years in females and 12.2 years in males. In rats, similar changes in density are observed at approximately 40 days of age. For all mammalian species, the timing of these synaptic

density changes coincides with the onset of puberty. However, it is noteworthy that different brain regions have their own unique course of development. For example, the striatum reaches peak dopamine receptor density at pubertal onset, and prunes shortly thereafter. The later-developing prefrontal cortex attains maximum receptor density at the same age, but delays pruning until young adulthood. This differential time course has been used to explain why motor disorders (attention-deficit/hyperactivity disorder and Tourette's syndrome) affect children, whereas schizophrenia typically emerges during young adulthood. Different periods of vulnerability are associated with the individual trajectory of a given brain region. Thus, in order to understand the impact of stress exposure during development, it is imperative to appreciate the state of maturity of the underlying trajectory at the time of insult.

Functional Development of the Dopamine System

Striatum and nucleus accumbens The subcortical structures of the dopamine system, the striatum and the nucleus accumbens, demonstrate functional changes during the onset of puberty. Dopamine D1 and D2 receptors are overproduced in the striatum, but not in the nucleus accumbens. Extracellular levels of dopamine decrease modestly during puberty in these regions. Dopamine autoreceptors regulate the rate of dopamine synthesis and release much like a thermostat functions to control fluctuations in temperature. Despite this regulatory role, the sensitivity of the dopamine autoreceptors does not change during puberty. These data suggest that changes within other systems during puberty mediate the observed functional changes in subcortical dopamine structures.

The impact of acute stress on either the striatum or the accumbens is not well understood. The striatum is associated with motor patterns, including stereotypies, habit learning, and initiation of movement. The nucleus accumbens plays vital roles in activity and reward. During pubertal onset, spontaneous locomotor activity reaches its highest point (females are more active than males), and reward systems are vulnerable to the addictive effects of drug exposure. Animal handling prior to testing enhances cocaine-induced locomotion relative to adults, suggesting enhanced reactivity. These behaviors reflect changes within the dopamine system, but are not well characterized as they relate to acute stress *per se*. The effects of chronic, early life stress on this system are of interest and are discussed below.

Prefrontal cortex The functional activity of the prefrontal cortex does not come on-line fully until the onset of puberty. This increase in dopaminergic activity is important for understanding a number of adolescent transitions. Immunohistochemistry shows that dopaminergic innervation of the prefrontal cortex approaches adult levels during puberty. Along with the increase in innervation, functional rearrangements also occur that increase dopamine activity in response to external stimuli. Dopamine D1 and D2 receptor density peaks during this period before being pruned back in adulthood. Dopamine receptors increase by 38%, plateau during puberty, and are ultimately pruned 33% in adulthood in the rat. Cyclic AMP levels are 35% higher during adolescence than adulthood. This enhancement of dopamine function during puberty may be partly related to the simultaneous loss of regulatory processes. Although poorly understood, modulation of dopamine synthesis in the prefrontal cortex wanes during pubertal onset and is absent by adulthood. Taken together, the cortical dopamine system rapidly reaches an adultlike state during this time.

Circuitry within these regions becomes increasingly complex, as innervation from the dopaminergic cell bodies and other neurotransmitter systems continues during puberty. Connections between stress-related brain regions also become more adultlike during puberty. Once the perception of stress has occurred, activational systems, such as glutamatergic efferents to various emotional and cognitive brain regions, are responsible for the course of action.

Sex Differences in the Dopamine System during Puberty

Sex differences exist in the immature dopamine system. It is often the case that females overproduce (and prune) less than males. Dopamine receptors are overproduced in the striatum of males during puberty, whereas little change in either D1 or D2 receptor density is observed in females. The pruning of D1 and D2 receptors shows that density changes by 54% and 63%, respectively, in the striatum, and approximately 25% in the accumbens of males between 40 and 80 days of age. This is not to imply that females do not significantly reorganize during adolescence. For instance, signaling mechanisms, including cAMP, in females are elevated during this period before pruning in adulthood.

In preparation for reaching sexual maturity, levels of the gonadal hormones estrogen and testosterone rise in the prepubescent subject. However, their dramatic rise seems to have little impact on the neuroanatomy of the dopamine system. Given the profound sex differences that exist in the dopamine system, it is plausible to hypothesize that testosterone increases the overproduction of dopamine receptors or that

estrogen suppresses it. Neither seems to be the case. Estrogen in adults or cell cultures increases dendritic branching, yet neuroanatomical changes in female adolescents are not observed. Based on immunohistochemistry with tyrosine hydroxylase antibodies (a marker that stains the rate-limiting enzyme in dopamine production), dopaminergic innervation of the three major terminal fields does not change with age in females. In addition, removal of the gonadal hormones well before they surge does not alter dopamine expression. These data suggest that gonadal hormones are not involved in the activational phases of changes within the dopamine system. Rather, sex differences may be organized during the prenatal period.

Stress Reactivity during Puberty

The Hypothalamic–Pituitary–Adrenal Axis and Stress Response

In order to understand stress reactivity, it is necessary to step back and briefly discuss the maturation of the hormonal system of stress responses. The hypothalamic–pituitary–adrenal (HPA) axis is involved in the secretion of stress hormones. Activation of the paraventricular nucleus of the hypothalamus (PVN) is involved in the release of corticotropin-releasing hormone (CRH), which activates the cascade of stress-related changes at the hormonal level. The PVN receives dopaminergic innervation, and thus is modulated by higher-level processing of stressors. CRH travels to the pituitary, causing the release of adrenocorticotropin hormone, which ultimately signals the release of the stress effector hormone cortisol (human and nonhuman primates) and corticosterone (rodents) from the adrenal glands. Cort (abbreviated as such to capture both hormone versions) then travels back to the brain to signal stress-related changes.

The onset of puberty is a transition point in HPA reactivity. Cort activation following acute restraint stress is more pronounced and prolonged in adolescent than in adult rats. Adolescent rats secrete more Cort in response to acute restraint stress than adult rats. Moreover, the response is larger in female than male adolescent rats. The Cort response following chronic stress, however, differs between adolescents and adults. Adolescent rats with a history of chronic stress exposure return to baseline levels faster than adults.

Age differences in stress-related reactivity are observable with *c-fos* immunoreactivity in the PVN. *c-fos* is often used as a marker of neuronal activity and can be used to map where changes occur. Prepubertal male rats have increased *c-fos* immunoreactivity in CRH-containing neurons of the PVN relative to adults in response to an acute stressor. These findings suggest that the prepubertal rat is more sensitive to the effects of stressful events than adults. They also raise the issue of what is initiating this cascade of stress-related effects.

Dopamine Systems and Stress Responsiveness

Of the three primary ascending dopamine systems, the mesocortical dopamine system is the one commonly associated with stress responses. The prefrontal cortex has an abundant amount of glucocorticoid receptors, second only to the hippocampus, which makes the prefrontal cortex particularly vulnerable to stress and its cascade of effects. In adults, stressors including footshock, restraint, and hotplate preferentially increase dopamine release in the prefrontal cortex. The nucleus accumbens is also activated by these stressors, but to a lesser extent than the prefrontal cortex. The striatum is minimally activated in response to acute stressors, but may be more involved in long-term compensations involving habits.

Stress Reactivity in the Dopamine System Emerges with Age

It is during pubertal onset that the cortex becomes increasingly vulnerable to the acute effects of stress relative to younger and older ages. Evidence from a pharmacological stressor, the GABAergic antagonist FG-7142, demonstrates that neuronal activity within the three major dopamine systems shifts in dominance. In this study, changes in the immediate early gene *c-fos* were quantified following FG-7142 and converted to a percentage of total *c-fos* immunolabeled neurons to derive an index of maturation. The subcortical structures are significantly activated before puberty and may be more vulnerable to stress at this age. These younger animals do not show the adult-typical pattern of dominant prefrontal cortex activation. Not surprisingly, the adult-typical pattern matures between 18 and 45 days of age in the rat – coincident with the onset of puberty. Further, *c-fos* immunolabeling is enhanced in the prefrontal cortex at 45 days of age relative to adult rats, demonstrating that an acute stressor during adolescence has a greater impact on cortical structures than comparable exposure in adulthood. These findings offer a neurochemical explanation for why children are more likely to increase their activity levels in response to stress. In contrast, as cortically based stress reactivity emerges, adolescents and adults experience stress on a more cognitive basis.

Circuits Involving Dopaminergic Modulation of Stress

Prefrontal cortex The functional nature of the prefrontal cortex places it in a vulnerable niche. The cortex is involved in motivation and cognition, in part by integrating environmental and emotional information and deciding the next course of action. As an example, abnormality or immaturity of the system is associated with impulsive or inappropriate decisions for a given context.

The cortex, however, does not act alone. Connections to other brain regions play a critical role in stress responses during puberty. One such circuit loop is the prefrontal cortex to dorsal raphe. Here, the prefrontal cortex has the important role of differentiating controllable from uncontrollable stress (Figure 2). The learned helplessness paradigm models depressive-like behaviors in rats. This test was designed to parse controllable from uncontrollable stress effects, and relies on cortical modulation. Normal, pubertal female rats demonstrate a higher level of helplessness following one day of conditioning to a series of escalating tail shocks. This sex difference was reversed, however, following a 5-day social stressor that occurs immediately before the onset of puberty. After this subchronic stress exposure, males demonstrate increased learned helplessness, whereas females show some degree of improvement in this behavior.

Amygdalar Contributions to Stress

The amygdala also plays an important role in stress responses, but more at the level of mediating fear responses. Fear, by definition, is a reaction to a future,

Figure 2 Learned helplessness paradigm. The learned helplessness model of depression is based on the differential response of rats to (a) controllable shock, (b) uncontrollable shock, or (c) no shock. Controllable (escapable) shock rats can terminate the tail shock by completing a behavioral response (turning a wheel). Uncontrollable (inescapable) shock rats are yoked to the controllable shock rat, so they receive the same number and duration of shocks, but are unable to control the termination of each shock. No shock rats are restrained similarly to the other two rats, but receive no shock during the training phase. The latency to escape a footshock (out of 30 s) and the number of escape failures (out of 30 trials) are recorded in a shuttlebox the next day. Leaned helplessness is defined as longer latencies to escape (f) and a greater number of escape failures than the controllable shock animals (A) or no shock controls (C). The anatomical circuit involved in dissociating controllable from uncontrollable stress involves the prefrontal cortex (PFC) and dorsal raphe nucleus (DRN). (d) Following controllable stress, glutamatergic projections from the PFC act on GABAergic interneurons in the DRN to suppress activation of serotonergic neurons. (e) Following uncontrollable stress, there is an increase in activation of serotonergic (5-HT) DRN neurons that project to the PFC, which serves in part to inhibit the glutamatergic neurons projecting back to the DRN. In the case of either controllable or uncontrollable stress, dopamine (DA) from the ventral tegmental nucleus (VTA) serves to signal the presence of a stressor. This figure and description is based on the seminal work of Maier and colleagues: Amat J, Baratta MV, Paul E, Bland ST, Watkins LR, and Maier SF (2005) Medial prefrontal cortex determines how stressor controllability affects behavior and dorsal raphe nucleus. *Nature Neuroscience* 8: 365–371.

probabilistic event based on past, conditioned responses. As such, fear responses are highly dependent on the context. Dopamine, via innervation from the VTA, plays an important role in the plasticity that underlies the associations between the context and the unconditioned, fear-eliciting stimulus. Increases in cortical dopamine are correlated with increased anxiety that increases during puberty. How levels or innervation of the amygdalar dopamine system change in response to stress during puberty is not known and remains another area of future investigation.

More is known, however, on the innervation of fibers from the amygdala to the prefrontal cortex. The prefrontal cortex receives input from the amygdala to integrate environmental contextual information with emotional processing. This innervation occurs throughout postnatal brain development, but begins to plateau during the onset of puberty. Studies with systemic and microinjections of dopamine agonists, in addition to dopamine depletions, show that these effects are modulated by dopamine. Again, the developmental profile of this effect is not known.

Synthesis

Taken together, data from Cort changes, *c-fos* localization, and behavioral paradigms suggest that the responses to stressful events rapidly shift during puberty onset. Increased dopaminergic activity in the prefrontal cortex is likely to play a significant role in the processing of environmental events, and thus facilitate enhanced responsiveness to stressful events. Acute stress during puberty onset has a greater impact on females compared with males. However, chronic stress exposure immediately before testing changes this relationship. Males have increased responsiveness within the HPA axis and in learned helplessness following chronic stress exposure when challenged during the pubertal period. The effect on adolescents is short lived, and animals show a return to baseline faster than adult cohorts. Studies such as these further suggest that the stress system is programmed by previous experiences differently during development when compared with adults.

Programming of Immature Stress-Responsive Systems

Sensitive Periods of Development

As discussed above, the brain develops in a series of stages. Overproduction and pruning of synaptic connections and signaling mechanisms program the brain to match the demands of the environment. What this means is that stress responses are appropriate for the level of stress that one has experienced. The immature brain, in turn, encodes these demands by pruning appropriately. However, the timing of stress experiences significantly influences which brain areas are vulnerable. Brain areas undergoing the most change are likely to be affected by stress exposure to a greater degree than those that have yet to overproduce connections or have already pruned. These periods of selective vulnerability are known as sensitive periods. The impact of stressful events on the immature brain will depend on the sensitive period during which the stressor occurred.

Early Postnatal Stressors and Brain Development

In order for something to be perceived as stressful, it has to involve the manipulation of something that is highly relevant to the organism. During early postnatal life, one of the single most important variables is the level of parental (predominantly maternal) care. Therefore, it should not be surprising that manipulation of the level of maternal care significantly affects the maturation of stress-related systems. All mammalian species studied to date that have significant variations in maternal care experience changes in Cort responses later in life, although exceptions occur for individual differences.

Events set in motion early in life program the formation of brain anatomy and functional impact follows suit. While detailed timecourses of functional changes within the dopamine system have not been assessed during puberty, it is likely that the impact of early life events manifests during this period.

Rats have been the most-studied species in maternal deprivation paradigms, and the discussion here will be limited to rodent studies. Early maternal deprivation alters the overproduction of synapses that occurs during adolescence. The most vulnerable region affected is the hippocampus, which fails to overproduce synapses between puberty and adulthood in animals that were stressed early in life. Early stress, however, has little impact on the dopamine system in the prefrontal cortex.

The nucleus accumbens shell, on the other hand, fails to overproduce dopaminergic terminals between puberty and adulthood in maternally deprived animals. Dopamine D1 receptors are elevated in the accumbens, with no observable change in the striatum during puberty. The rest of the results that are discussed are based on adult outcomes of the deprivation. Maternal deprivation decreases the density of dopamine transporters in the accumbens. This may explain why cocaine-stimulated dopamine release is higher in these animals. To compensate, animals with a history of maternal deprivation will self-administer

more cocaine relative to controls in adulthood. As the propensity that stimulant abuse in humans emerges during the adolescent period, these changes most likely emerge during this period.

Late Postnatal Stressors and Brain Development

The alternative paradigm to early maternal deprivation involves social isolation beginning from the time of weaning (prepubertal) into adulthood. This paradigm produces a number of behavioral changes linked with reduced cortical dopamine that include deficits in sensorimotor gating of the acoustic startle response, increased locomotion in response to novelty, and enhanced dopamine levels in the prefrontal cortex. Since this paradigm spans across puberty into adulthood, it is difficult to speculate as to when this social stressor exerts its effects on the dopamine system.

Clinical Impact of Stress during Puberty

The transition between childhood and adolescence is a unique period of vulnerability. It is during this period that adolescents (males more so than females) engage in risky behaviors, novelty-seeking, and peer-directed behavior including the abuse of substances. Postpubertal changes also serve as a permissive factor for the expression of mental illnesses that are associated with stress, including schizophrenia and depression. For example, stressful events during adolescence often precipitate the first psychotic episode, which on average occurs in males an average of 6 years earlier than in females.

Traumatic stress also effects adolescent transitions in brain development, especially within the late-developing prefrontal cortex. Exposure to stress is associated with an increase or a decrease in the size of this region, if the timing of the exposure is before or after puberty, respectively. In clear-cut cases of significant, traumatizing, stress, males are affected more than females as cognition is often impaired. For females, the onset of puberty brings with it its own unique challenges. As social roles are defined, the emergence of mood disorders affects females 2.3-fold more than males and rises from 3% of the population to an estimated 8% during adolescence. It is possible that stress during puberty affects the amygdala/cortical development in females, which would increase depression and anxiety.

Part of the emerging role of the prefrontal cortex during this time is to modulate stress responses. Mentally healthy individuals are able to separate stressors into these two categories of controllable and uncontrollable and deal with them accordingly. In contrast, individuals with depression, anxiety, and schizophrenia perceive most stressors as uncontrollable and become overwhelmed (Figure 2). These disorders are associated with elevated levels of cortical dopamine activity in response to stress. The parallel timing of the significant rise in dopamine activity and the prevalence of these disorders during puberty is more than just coincidence. Although this has yet to be demonstrated conclusively, it is likely that increased cortical dopamine plays a role in the perceptual 'switch' between controllable versus uncontrollable stress.

On the other hand, the pubertal transition, dopamine, and its relationship to stress provide a window of opportunity for some. The waning of motor tics in Tourette's syndrome during puberty reflects the benefit of positive changes associated with enhanced dopamine activity in the cortex. Generally, tics are exacerbated in response to stress in Tourette's syndrome patients. The prevalence of tics (or their willful modulation) improves during adolescence.

Conclusions

Despite the universal nature of the stressful transitions that are associated with the onset of puberty, relatively little research has been conducted on this important topic. The emerging role of cortical dopamine increases the perception of stress during puberty. Whether this translates into more or less controllability over life's strife and stress most likely depends on genetic and stress history. What is becoming increasingly clearer, however, is that events that happen before this transition can drastically shape the ability to deal with stressful events later on. The occasion to intervene during this potential window of opportunity beckons more researchers to explore what this area may offer.

Stress, Sex and Adolescent Nicotine Response

F M Leslie and M K Park, University of California at Irvine, Irvine, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Epidemiological studies have shown that tobacco use begins primarily during adolescence. Adolescence is a period of major biological changes, including maturation of limbic brain regions that regulate emotional responding, and alterations in hormonal levels. It is therefore not surprising that cognitive and inhibitory control processes and stress responses continue to mature throughout this period. Active brain growth and plasticity during adolescence are important in that these processes permit teenagers to adapt their behavioral responses to the surrounding environment, at a time when teens typically leave the family and become independent, and to learn from new experiences. However, these processes also represent a period of high vulnerability to behavioral control disorders, including substance abuse.

Uniqueness of Nicotine-Induced Responses during Adolescence

Although it has long been believed that teen smoking is the result of social influences, recent studies have shown that adolescence is a time of heightened biological sensitivity to tobacco constituents. Many teenage smokers rapidly progress to dependence after they start to inhale, and have difficulty quitting smoking when they do. This is particularly evident in those who begin to smoke during their early teens.

Rodents, which have been used extensively as an experimental model to examine age differences in drug response, exhibit during their fifth and sixth weeks after birth (postnatal days (P) 28–42) many of the behavioral and hormonal changes evident in human teenagers. During this developmental period, defined as rodent adolescence, mice and rats exhibit altered behavioral and neuronal responses to nicotine, the major psychoactive component of tobacco. Moreover, there is greater sensitivity to nicotine during early adolescence as compared to late, indicating that dramatic developmental changes occur within this time frame. During early adolescence, but not later adolescence or adulthood, male rodents exhibit increased sensitivity to the rewarding effect of nicotine, as evidenced in conditioned place preference, two-bottle choice, and self-administration tests. They also show decreased sensitivity to the aversive effects of nicotine. Furthermore, there are differences in other behavioral effects of nicotine, including locomotor activation and anxiety reduction, and in patterns of drug-induced neuronal activation in limbic and sensory brain regions, as measured by expression of immediate-early genes.

Epidemiological studies have shown a developmental progression of drug use during adolescence, from tobacco and alcohol during early teens through marijuana to later use of cocaine, amphetamine, and heroin. Such findings have led to the suggestion that tobacco may act as a 'gateway' drug by altering the adolescent brain, making it more responsive to the effects of other addictive substances. Animal studies provide considerable support for the view that nicotine produces irreversible changes in adolescent brain structure and function. Brief treatments with low doses of nicotine during early adolescence produce long-term changes in a number of neurochemical systems, including monoamine, acetylcholine, glutamate, and peptide neurons. Neurotoxic effects, including cell loss in the hippocampus, result from treatment with higher doses of nicotine. Adolescent nicotine exposure also produces corresponding long-term changes in a number of behaviors, including locomotion, learning, emotional responding, and nicotine self-administration. In all of these reports, the consequences of adolescent nicotine treatment are very different from those of a similar treatment in adults. Thus adolescent nicotine exposure produces profound changes in brain plasticity during a sensitive period for limbic system development.

Recent brain imaging studies in humans have shown that some of the structural changes that occur during adolescence are sex specific. In particular, there are significant sex differences in the development of the amygdala and hippocampus. Whereas the growth of the amygdala is enhanced in males as compared to females, the opposite is true for the hippocampus. These sex-dependent changes in regional growth are consistent with the enhanced expression of androgen receptors in the amygdala and estrogen receptors in the hippocampus. Neurochemical and structural studies in animals have yielded similar findings, and show that the unique actions of nicotine on adolescent brain may differ in males and females. Although not all studies have systematically examined whether there are sex differences in adolescent responses to nicotine, in those that have, substantial sex differences have been found. Whereas self-administration of a mixture of tobacco constituents, nicotine and acetaldehyde, decreases with age in males, this age-dependent decline is not observed in

females. Sex differences have also been observed in the anxiolytic and locomotor sensitizing effects of nicotine. Many of the long-term teratogenic effects that result from nicotine exposure during adolescence also differ in males and females; in particular, the loss of hippocampal cells resulting from adolescent nicotine exposure has been shown to occur only in females. Such findings suggest that there are sex differences in factors that may be critical for initiating and maintaining smoking.

Nicotine Interaction with Stress Circuitry

The central and peripheral stress systems are critical for adaptation to environmental change, with their activation resulting in improved chances of survival for the individual. Although these adaptations are normally positive and time limited, the central stress system has been heavily implicated in addictive processes, and there is a high correlation between stress-related disorders and drug abuse. Both a stressful environment and subsequent activation of the hypothalamic–pituitary–adrenal (HPA) axis facilitates the acquisition and reinstatement of use of addictive drugs, including nicotine and tobacco. Indeed, recruitment of brain stress systems has been proposed to provide the negative motivational state that drives addiction, and produces the vulnerability toward relapse (Figure 1).

The physiological stress response system consists of two components – glucocorticoid release from the adrenal cortex via activation of the HPA axis and catecholamine release from the adrenal medulla via activation of the splanchnic nerve (Figure 1). Nicotinic acetylcholine receptors (nAChRs) play a critical physiological role in both systems. Activation of the HPA axis, and subsequent glucocorticoid release, are mediated by nAChRs on noradrenergic brain stem cell bodies within the nucleus tractus solitarius (NTS); these provide excitatory innervation to the hypothalamic paraventricular nucleus (PVN), the site of corticotropin-releasing factor (CRF) neurons that are crucial for the release of adrenocorticotropic hormone (ACTH). Excitatory nAChRs on chromaffin cells of the adrenal medulla also regulate circulating levels of catecholamines. Nicotine can increase both plasma glucocorticoid and catecholamine levels via activation of nAChRs in the NTS and adrenal medulla, respectively. However, animal studies have shown that nicotine-induced activation of the two components of the stress system is dependent on the contingency of drug delivery; whereas experimenter-administered nicotine activates both the adrenal medulla and the HPA axis, self-administered nicotine activates only the latter.

Figure 1 Schematic representation of the central and peripheral stress systems and their regulation by nicotine acting on nicotinic cholinergic receptors. ACTH, adrenocorticotropic hormone; CRF, corticotropin-releasing factor; E, epinephrine; GR, glucocorticoid receptors; NE, norepinephrine; NTS, nucleus tractus solitarius; PVN, paraventricular nucleus of the hypothalamus.

HPA axis regulation in adult rodents is sex specific, with males responding to acute nicotine injection with higher vasopressin release, whereas females respond with greater ACTH and glucocorticoid release. This finding is consistent with earlier reports from both clinical and preclinical studies that females respond to stressors with higher levels of ACTH and glucocorticoids than males do. This reflects an enhancement of HPA activation by estradiol and inhibition by testosterone. Although nicotine produces activation of the HPA axis when administered acutely, this effect diminishes over time with chronic exposure. Again, however, this decrease in the HPA-activating effects of chronic nicotine is sex specific, with some evidence from both clinical and preclinical studies that there may be less tolerance to chronic nicotine in females.

The interaction of nicotine and the stress system is dynamic and bidirectional. Whereas nicotine activates the HPA axis, glucocorticoids also modulate the physiological and behavioral effects of nicotine in a complex manner. Adrenalectomy potentiates a number of responses to nicotine, including heart rate, body temperature, and antinociception; such changes in nicotine sensitivity are prevented by glucocorticoid replacement. However, other effects of nicotine, such as locomotor activation, are attenuated by adrenalectomy. Glucocorticoids have also been implicated in the neural plasticity that results from repeated nicotine exposure, and which may contribute to tolerance and dependence. Whereas many studies have suggested that HPA activation promotes a form of learned tolerance to nicotine, glucocorticoids have also been shown to be necessary for the development of nicotine-induced locomotor sensitization, a form of behavioral plasticity that is implicated in addiction. There is some evidence to suggest that environmental context may be a critical determinant of whether tolerance or sensitization occurs. Further studies are needed to elucidate the underlying mechanisms.

The clinical literature indicates that there is a wide variance in individual response to the effects of tobacco, and that this may correlate, to some extent, with individual differences in stress reactivity. Preclinical studies have also shown that individual differences in sensitivity to both the rewarding and aversive effects of nicotine may reflect variations in HPA responsiveness to nicotine (Figure 2). In adult mice, there are strain differences in nicotine-induced glucocorticoid secretion, with the C57BL6 strain showing the lowest responsiveness. Conversely, this mouse strain exhibits the greatest propensity to self-administer nicotine, an effect which has been correlated with decreased sensitivity to the aversive effects of the drug. Similarly, Lewis and Fisher F344 inbred strains of rat exhibit substantial differences in HPA response to nicotine, with the F344 strain showing an enhanced drug-induced glucocorticoid secretion as compared to the Lewis rat. The Lewis rat is much more sensitive to the rewarding effect of nicotine, as determined in self-administration and conditioned place preference tests, and is less sensitive to nicotine-induced conditioned taste aversion. Lewis rats are also more sensitive to the discriminative stimulus properties of nicotine, and, unlike F344 rats, exhibit a substantial antagonist-precipitated withdrawal syndrome after chronic nicotine treatment. Although intriguing, these findings of an inverse association between nicotine reward and HPA activation are purely correlational. More direct experimental evidence will be required to determine whether this association reflects 'cause and effect.'

In this context it is of interest to note that, in clinical studies, attenuated HPA reactivity is associated with increased withdrawal symptoms. Cortisol levels are higher in smokers than in nonsmokers, and the HPA response to psychosocial stress is significantly blunted in chronic smokers of either sex. Upon quitting, there is a rapid and sustained decline in plasma cortisol levels, the magnitude of which is

Figure 2 Schematic model of the possible interrelationship between nicotine-induced hypothalamic–pituitary–adrenal (HPA) activation and the balance of rewarding and aversive effects of the drug.

associated with subsequent relapse. Significant individual variation is evident in withdrawal-induced changes in HPA response, with those who relapse quickly showing the most attenuated HPA responses to acute stress and the most exaggerated withdrawal symptoms. Thus, decreased stress response may predict increased vulnerability for smoking relapse. Further studies need to be undertaken to determine whether this absence of nicotine-induced HPA activation underlies the reduced aversive properties of the drug during adolescence.

A number of different mechanisms may underlie the influence of glucocorticoids on nicotine or tobacco-induced physiological and behavioral changes. Glucocorticoids have been widely shown to regulate the neural systems which mediate addiction, including dopamine pathways, amygdala, and prefrontal cortex. In this respect, the effects of stress are generalizable to many drugs of abuse and are not specific to nicotine or tobacco. Glucocorticoids also have some selective effects on nicotine signaling, however, via modulation of nicotinic receptors. Corticosterone not only acts as an acute allosteric modulator of nACHRs, but also induces downregulation of some nicotinic receptor types, particularly the $\alpha 7$ receptor, which has been implicated in brain plasticity and cognitive function.

Adolescent Development of Stress Circuitry

Whereas the HPA axis is the final common pathway for glucocorticoid secretion, there is an extensive network of higher order neural circuits that regulate stress hormone secretion. Adolescence is a period of active remodeling of many of the brain regions which modulate the HPA response, including prefrontal cortex, hippocampus, and amygdala. Remodeling of the adolescent limbic system involves the same proliferative and regressive events that are the hallmarks of earlier periods of brain development, including neurogenesis, apoptosis, axonal sprouting, synapse formation and elimination, and myelination. In addition to these morphological changes, there are dynamic alterations in monoamine inputs that regulate higher order stress circuits. Such neuronal changes occur in a regionally and time-dependent manner and, although they reflect an innate developmental program, they are actively modified by hormonal changes and environmental experience.

Adolescence is also characterized by substantial changes in circulating steroid hormone levels. Puberty results in elevated levels of sex steroids, which produce the peripheral manifestations of pubertal growth and development and which also have marked effects on brain function. Gonadal steroid actions during adolescence play critical roles in the maturation of brain circuitry underlying adult sexual behavior and modulate emotional responding and social behaviors, as well as stress responses. In contrast to the sex steroids, adolescence is not marked by dramatic alterations in corticosteroid secretion. As with adults, there is a normal diurnal variation in glucocorticoid secretion, with highest levels upon waking. However, upon closer examination, there are significant age differences in the regulation of adolescent glucocorticoid levels.

In clinical studies in which diurnal cortisol secretion patterns in adolescents have been observed in naturalistic settings, an age-dependent increase in basal cortisol levels has been observed. Although basal cortisol levels are elevated with increasing age, there is also a flattening of diurnal rhythms, with a smaller increase in hormonal secretion upon waking. In contrast to adults, cortisol levels are also elevated when teenagers are alone, suggesting that social interaction is a critical regulator of the adolescent stress response. Preclinical studies have also shown age differences in the regulation of the HPA axis. One common finding is that there is decreased negative feedback control of glucocorticoid secretion in adolescents, which results in a prolonged HPA activation in response to an acute stress, as compared to adults. There are also substantial age differences in response to chronic stress. Whereas repeated exposure to a stressor results in a habituation of the peak corticosterone response in adults, this is not the case in adolescents; however, the duration of the stress response following chronic stress in adolescents is much shorter than in adults. Since experience-dependent glucocorticoid secretion can induce substantial changes in brain structure and function, these age differences in HPA response may have important functional consequences. A prolonged release of glucocorticoids in an adolescent after a single stressful experience may facilitate learning and memory of the event. In contrast, the more rapid decline of hormonal responses following chronic stress in the young may protect them from the deleterious effects of chronically high levels of glucocorticoid exposure.

There is an important interaction between pubertal age and stress in the regulation of both the HPA and the hypothalamic–pituitary–gonadal (HPG) axes. Adolescent and adult rats exhibit strikingly different patterns of regulation of both gonadal and adrenocortical systems in response to chronic stress. It has been proposed that, when they are stressed, adolescents protect body growth at the expense of sexual function, whereas the opposite is true in adults. Evidence for this comes from studies in which stress has been shown to decrease testosterone secretion in

adolescent rats, but to increase it in adults; conversely, adolescent rats maintain body weight following repeated stress, whereas adults do not. Treatment of male rats with the testosterone receptor antagonist flutamide also alters ACTH responses to stress in an age-dependent manner; whereas no drug effect is observed peripubertal rats, flutamide increases ACTH response to repeated stress in adults. In addition, there are striking age differences in the interaction of flutamide and stress on the numbers of vasopressin and CRF neurons within various components of the central stress circuitry. Sex differences in both hormonal and neuronal responses to stress also emerge at puberty, with females becoming hyperresponsive in comparison to both adult males and adolescent females. Such findings add to a growing body of literature that suggests that there is a major reorganization of central stress circuitry during puberty, a process in which sex hormones have influential roles.

Given the substantial remodeling of stress circuitry that occurs during adolescence, it is not surprising that various psychopathologies associated with limbic dysfunction emerge during this developmental period. Many cognitive and emotional disorders, such as substance abuse, eating disorders, and schizophrenia, are rarely seen before adolescence. Others, such as major depression, anxiety, and bipolar illness, greatly increase in prevalence during the teenage years. There is substantial comorbidity between tobacco use and many psychiatric disorders, including anxiety, depression, and schizophrenia, which may reflect either common neural substrates or attempts at symptomatic relief through self-medication. However, in at least one report, there is evidence that tobacco use during early adolescence contributes to the etiology of panic attacks. These clinical data are consistent with the finding of preclinical studies that chronic nicotine treatment in adolescent rodents increases subsequent anxiety in adults. Thus, nicotine exposure during the sensitive period of adolescence may interfere with the remodeling of central stress circuitry.

Nicotine Interaction with Adolescent Stress Circuitry

A number of factors, including stress, have been identified as contributing to the uptake of smoking in teenagers. In longitudinal clinical studies, both higher basal HPA activity and decreased anticipatory response to stress have been associated with the subsequent initiation of smoking in adolescents. In preclinical studies, differences in adolescent stress responses can be induced by differential handling and housing conditions during the early postnatal period. An interaction between acute nicotine treatment and early handling has been found, such that those adolescents with a higher basal HPA activity tend to exhibit a decrease in corticosterone levels in response to nicotine. Interestingly, acute intravenous nicotine administration, which models the route of delivery in drug self-administration studies, and which most closely models human smoking, does not induce the same profound glucocorticoid release in adolescent rats as it does in adult rats. Thus, HPA axis response to acute nicotine exposure is quite different during the adolescent sensitive period than it is in adults (Figure 2). Although the exact mechanism of this age difference is not yet understood, anatomical studies have shown age differences in nicotine activation of immediate-early gene expression in the hypothalamic PVN.

In contrast to the absence of an acute drug effect on adolescent glucocorticoid release, chronic nicotine treatment during adolescence induces a long-term adaptation in HPA responding. Chronic adolescent nicotine exposure has been reported to increase basal ACTH and corticosterone levels in a dose-dependent manner, and to increase levels of CRF peptide immunoreactivity in both the hypothalamus and prefrontal cortex. Behavioral correlates of this elevated HPA activity include increased locomotor responding in a novel environment, increased anxiety, and increased depression as measured on a forced swim test. Social factors play an important role, however, both in the adolescent reorganization of central stress circuitry and in the effects of nicotine on adults. Social stress during adolescence influences locomotor sensitization to nicotine and nicotine-induced activation of the HPA axis in a sex-dependent manner. This finding of a critical influence of social factors during adolescence on subsequent drug sensitivity has important implications for the design and interpretation of both clinical and preclinical studies. Social factors must be carefully controlled for in order to reduce interpretational confounds.

Conclusions

Both clinical and preclinical studies have shown that nicotine activates the HPA axis in adults. As with other stressors, females are hypersensitive to the HPA-activating effects of the drug. In contrast to adults, both male and female adolescents exhibit minimal HPA activation in response to nicotine, which may influence the balance of rewarding and aversive effects of the drug (Figure 2). Thus, decreased activation of stress circuitry may be one mechanism that underlies the increased rewarding and decreased aversive effect of nicotine that has been widely seen in preclinical studies of adolescents.

Adolescence is a period of dynamic plasticity and reorganization of central stress circuitry. During this sensitive period, hormonal and environmental influences can have profound and long-term influences on stress responding. Nicotine exposure during this sensitive period results in long-term alterations of central stress pathways, with resulting adaptations in both endocrine and behavioral response. Such drug-induced adaptations in HPA regulation may underlie the long-term addictive effect of smoking in those who begin during early adolescence.

Stress, the HPA Axis and Depressive Illness

E Young, Molecular and Behavioral Science Institute, Ann Arbor, MI, USA
A Korszun, Barts and The London School of Medicine, London, UK

Depression can be conceptualized as a maladaptive, exaggerated response to stress. Stressful life events, particularly those related to loss, such as divorce and bereavement, have a strong causal relationship with depressive episodes. However, not all people who experience such events develop depression, and an individual's sensitivity to stress depends to a large extent on his or her genetic makeup. There is also compelling evidence that early life stress constitutes a major risk factor for depression in adult life, and thus the combination of genetic predisposition, early life stress, and ongoing stress determines an individual's susceptibility to developing depression. The main component of the physiological stress response is the stress hormone axis, the hypothalamic–pituitary–adrenal (HPA) axis, and it is now well established that abnormalities of the HPA axis play a major causal role in the development of depression.

HPA Axis Regulation

The HPA axis transforms stressful input into hormonal messages enabling the organism to adapt to environmental change and to maintain the body's homeostasis. Corticotropin-releasing hormone (CRH) is synthesized in the paraventricular nucleus (PVN) of the hypothalamus and secreted into the hypophyseal portal system via the median eminence. The stimulus for CRH secretion can be either 'physical' (e.g., exercise or starvation) or 'psychological' (e.g., perceived danger or stressful life events). The HPA axis is closely linked to the autonomic nervous system, and brain stem catecholamine systems are critical circuits involved in the 'activation' pathways for CRH release. The release of CRH stimulates secretion of pituitary adrenocorticotropic hormone (ACTH) which, in turn, results in the secretion of glucocorticoids by the adrenal cortex in a feed-forward cascade. Cortisol is the main glucocorticoid, and its secretion is tightly controlled by negative feedback effects of glucocorticoids at both pituitary and brain sites. Negative feedback on secretion can occur very rapidly, within 5–10 min, and this provides real-time inhibition to limit the stress response and prevents oversecretion of glucocorticoids. In addition to these rapid effects on secretion, glucocorticoids exert negative feedback effects on mRNA and subsequent protein stores for both CRH and the ACTH precursor, proopiomelanocortin (POMC). Regulation of gene transcription can occur directly via glucocorticoid responsive elements, as has been shown for POMC, or by transsynaptic influences and 'inhibition' circuits. There is strong evidence that these transsynaptic inhibition circuits are critical in regulating CRH mRNA levels in the PVN.

Stressful stimuli activate all levels of the HPA axis, causing increases in CRH, ACTH, and cortisol secretion. However, these increases are superimposed on an intrinsic circadian pattern of HPA activity driven by the suprachiasmatic nucleus (SCN). ACTH secretion is pulsatile in nature, with the trough of integrated secretion occurring in the evening and early night and the peak of secretion occurring just before awakening; active secretion continues through the morning and early afternoon. Even in the absence of corticosteroid feedback (e.g., adrenalectomy), ACTH continues to demonstrate a circadian rhythm which is believed to be secondary to the circadian rhythm of CRH production and results in a similar circadian pattern of cortisol secretion. There is evidence that intrinsic neural elements are responsible for both the initiation and the inhibition of the CRH/ACTH/cortisol circadian rhythm and that glucocorticoids act to dampen the overall amount of secretion. It is possible that glucocorticoids interact with neural elements to alter rhythm characteristics indirectly, although they are not themselves directly responsible for the inhibition of PVN CRH secretion during the quiescent phase.

HPA Axis Abnormalities in Depression

Overactivity of the HPA axis as manifested by an increase in cortisol secretion is a well-established phenomenon in depression. The original studies of Sachar and colleagues showed that up to 50% of depressed patients have higher mean plasma cortisol concentrations and an increased number and duration of cortisol secretory episodes, suggesting increased cortisol secretory activity. Numerous later studies have validated hypercortisolemia in depression; however, although it was expected that the increased cortisol would be accompanied by an increased level of plasma ACTH, this has proved more difficult to demonstrate. There are also conflicting reports of alterations in sensitivity to ACTH 1–24 in depressed patients. Also, it is unclear whether the hypercortisolemia of depression is due to excessive drive with increased ACTH secretion or to enhanced adrenal sensitivity to ACTH, although the balance of

Figure 1 HPA axis abnormalities in depression.

evidence points strongly to the brain as the source of HPA axis hyperactivity.

Enlarged adrenals and increased sensitivity to ACTH are both common consequences of chronic adrenal stimulation by ACTH and, thus, stress or depression-associated enhanced adrenal sensitivity may be secondary to increased central drive. Following the development of hypercortisolemia, feedback mechanisms may be engaged that attempt to limit the degree of excess cortisol secretion by decreasing ACTH secretion. It is possible that more than one pattern of abnormality exists, that is, increased ACTH secretion accompanied by increased cortisol secretion, and normal ACTH secretion accompanied by increased cortisol secretion. In both cases, glucocorticoid feedback acts to restrain CRH and ACTH secretion, thus blunting the true degree of CRH overdrive in depression, analogous to the blunted response to exogenous CRH administration seen in depression.

Thus, HPA overactivity in depression could be due to one or a combination of factors: increased CRH drive, decreased sensitivity to glucocorticoid feedback, altered secretory rhythms, and altered response to stress (Figure 1).

Increased CRH Drive

Early investigators reporting hypercortisolemia in depression hypothesized that it resulted from an increased central CRH secretion. The subsequent isolation and sequencing of CRH allowed further studies, including evaluation of both behavioral and endocrine responses to exogenous CRH, as well as radioimmunoassay measurement of CRH in several brain areas in chronically stressed animals and in postmortem samples from depressed patients. It had been noted earlier that central CRH administration produces behavioral effects similar to the symptoms of depression, including anorexia, weight loss, motor hyperactivity in familiar environments, freezing behavior in novel environments, increased awakenings during sleep, and decreased libido. Endocrine challenge studies with exogenous CRH administration in depressed patients demonstrated a blunted ACTH response to CRH, a finding compatible with CRH receptor downregulation. However, the interpretation of these studies is complicated by the higher baseline cortisol, which inhibits responsiveness to exogenous CRH. Strategies to equalize the degree of negative feedback between patients and controls have used metyrapone or dexamethasone, to inhibit cortisol production, plus CRH challenge. Because metyrapone stimulates the HPA axis differentially in patients and controls, this adds an additional confounding factor. However, studies using the administration of dexamethasone followed by CRH challenge show greater ACTH and cortisol responses to CRH, consistent with a CRH overdrive hypothesis.

Some studies examining CRH in the cerebrospinal fluid (CSF) of depressed patients and normal controls have also found increased CRH in the CSF in

depressed patients. Furthermore, increased POMC, the ACTH precursor, has been demonstrated in suicide victims with an indication of oversecretion of CRH from the PVN, although it should be noted that suicide victims are not necessarily all depressed. Raadsheer and colleagues reported increased CRH and increased numbers of CRH neurons in the PVN in postmortem samples from depressed patients; both findings are compatible with increased CRH drive. In addition, decreased CRH receptor binding in a number of brain regions has also been observed in suicide victims, again compatible with the hypothesis of increased CRH release. Interestingly, several basic science studies have also demonstrated that early trauma may lead to lifelong changes in stress responsiveness and CRH content in hypothalamic and extrahypothalamic brain nuclei.

Studies of metyrapone in major depression support the presence of increased central nervous system (CNS) drive in depression, at least in the evening, and it appears that there is increased CRF/ACTH secretion, which is likely amplified at the adrenal to lead to increased cortisol. These changes in cortisol secretion are commonly considered to be 'state' changes and resolve when the depression resolves. However, almost all studies of the HPA axis in major depression in euthymic subjects have examined patients on tricyclic antidepressants, which exert direct effects on the HPA axis. Three studies of epidemiological samples from the United States and one from the United Kingdom found that salivary cortisol is increased in subjects with lifetime major depression, most of whom had no current mood symptoms.

Despite this evidence, only approximately 30–50% of depressed patients manifest hypercortisolemia. Thus, although CRH overdrive in depression remains an attractive hypothesis, it has not been conclusively demonstrated. This may in part be due to compensatory increases in cortisol acting to turn off both CRH drive and ACTH secretion so that the true extent of CRH hypersecretion is obscured by the effects of negative feedback.

Decreased Sensitivity to Glucocorticoid Feedback

The failure of some depressed patients to suppress cortisol after dexamethasone is a well-accepted phenomenon, but its pathophysiology is not clear. Although an insensitivity to glucocorticoid negative feedback is the hypothesized defect, studies suggest that relatively low plasma dexamethasone concentrations may contribute to the failure to suppress cortisol. Although plasma dexamethasone concentrations may explain part of the variance, some individuals who do not suppress cortisol show adequate plasma dexamethasone concentrations. Also, because dexamethasone is presumably acting through intermediate and delayed feedback mechanisms, the concentration of dexamethasone bound to the receptors in the CNS and pituitary feedback sites may actually be the relevant physiological parameter, rather than the dexamethasone plasma concentration.

It was commonly assumed that cortisol nonsuppression reflected pituitary nonsuppression of ACTH. The majority of studies tested this hypothesis by comparing plasma ACTH values between cortisol suppressors and cortisol nonsuppressors. In most studies, the plasma ACTH measures were taken in the morning (8 a.m.), whereas the cortisol samples were drawn at 4 p.m.; the reason for this discrepancy in sample timing is not clear. The majority of these studies concluded that ACTH concentrations are higher in nonsuppressors than suppressors. Subsequent studies have demonstrated that depression is accompanied by an increased cortisol secretory response following ACTH 1-24 infusion and, consequently, cortisol nonsuppression to dexamethasone is not necessarily linked to ACTH hypersecretion. Because cortisol nonsuppression is defined by a 'cut-off' criterion, rather than a decrease from baseline secretion, it is possible that ACTH hypersecretion may not be accompanied by cortisol nonsuppression. Thus, cortisol hypersecretion or ACTH hypersecretion or both could be involved in the HPA axis disturbances demonstrated by the dexamethasone suppression test.

Evidence from several studies shows that more depressed patients demonstrate HPA axis dysregulation at the pituitary corticotroph level than at the adrenal level, and that cortisol plays an important role in regulating changes in negative feedback at the pituitary. These findings are in agreement with data from rats demonstrating that age and elevated glucocorticoid concentrations interact to lead to alterations in glucocorticoid negative feedback that is associated with decreases in hippocampal glucocorticoid receptors. This nonsuppression is associated with higher baseline cortisol, particularly in the afternoon, and advancing age or menopausal status in women. Even small elevations in cortisol concentrations can lead to alterations in negative feedback, and decreased sensitivity to negative feedback occurs in more than half of depressed patients and can be demonstrated above the level of the adrenal.

Altered Secretory Rhythms

Circadian dysregulation hypothesis Although the HPA axis is conceptualized as the 'stress' hormone axis, in the absence of stressful stimuli, its secretion is driven by the circadian oscillator – the SCN. In practice, it is difficult to distinguish between secretion

occurring as a response to stress and secretion driven by the intrinsic circadian pacemaker: disruption of either of these major inputs may affect the functioning of the other. Previous observations in depression of diurnal variation in mood and a seasonal pattern suggested abnormalities in the circadian oscillator and disruption in the circadian rhythm of cortisol in depressed patients. Sachar's early report of a phase advance in the circadian rhythm of cortisol was further supported by observations of early morning awakening and the altered distribution of rapid eye movement (REM) sleep (shortened REM latency and increased REM density in the first half of the sleep period), suggesting a phase advance of multiple circadian systems in depression. However, a newer understanding of circadian physiology revealed that studies carried out under normal day/night conditions do not take into account masking of the endogenous circadian rhythm by entrainment to multiple environmental Zeitgebers. Also, introduction of the constant routine conditions that are necessary for accurate endogenous pacemaker assessment leads to sleep deprivation that frequently improves depression, thereby making it difficult to evaluate completely the circadian dysregulation hypothesis of depression.

Later studies testing the phase advance hypothesis of cortisol secretion produced ambiguous results. Two studies failed to find evidence for phase advance of the cortisol rhythm in depressed subjects and normal controls undergoing 24 h cortisol sampling, but they did observe an earlier onset of the first cortisol secretory episode in depressed subjects compared to normal controls. Another study, using age, sex, race, and menstrual status-matched controls for depressed subjects, observed no change in the circadian rhythm or in the onset of the first secretory episode. Also, in these same subjects melatonin onset and offset times did not differ between depressed patients and controls. However, these studies were conducted under ambient room light rather than dim light, so light-induced suppression of melatonin onset may have occurred. In addition, in several of these studies, hypercortisolemic depressed patients were older than eucortisolemic depressed patients, suggesting a possible interaction between age and HPA axis dysfunction.

A meta-analysis by van Cauter and co-workers of the pooled cortisol data from the controls in these and additional studies demonstrated clear effects of age on the circadian rhythm of cortisol secretion, with an earlier onset of secretion in older subjects. This suggests that the absence of strict age matching of controls to depressed patients, which was the case in all but one of the studies, skews the analysis of circadian rhythm. In another meta-analysis of the depressed patient cortisol data from all these studies, van Cauter found clear evidence for an earlier onset of secretion but no evidence of a change in the timing of the acrophase or nadir. Taken together, these studies suggest that a shift or phase advance in the whole circadian rhythm of cortisol does not occur in depressed patients, but that the onset of circadian drive may begin earlier in these patients. To complicate matters further, studies demonstrate that partial sleep deprivation can lead to an increase in cortisol secretion during the nadir, raising the question of whether the reported earlier onset of secretion observed in depressed patients may be secondary to sleep disturbances. The earlier onset of cortisol secretion could also be explained by a change in set point for cortisol in the CNS of depressed patients that would result in relative cortisol insufficiency in the late evening and subsequent activation of the SCN-CRH drive at an earlier time in the circadian period.

Studies involving evening administration of metyrapone, a cortisol synthesis inhibitor, have found that blockade of cortisol in the late afternoon and evening (4–10 p.m.) leads to greater rebound in ACTH secretion in patients with major depression compared to matched control subjects. Whereas these data may suggest increased central CRH drive, studies conducted with metyrapone in the morning and early afternoon (8 a.m. to 2 p.m.) found a normal ACTH response to metyrapone in patients with major depression. This suggests that CRH drive in the evening is different from that in the morning and may represent an earlier onset of the active phase of secretion in the presence of diminished negative feedback. Longer-term studies with metyrapone blockade are necessary to determine if this finding supports a change in set point or an earlier onset of secretion.

Ultradian rhythms and pulsatile secretion In addition to a 24 h circadian rhythm in the HPA axis hormones, ultradian rhythms of ACTH and cortisol have been identified, most frequently 90–110 min. A similar rhythm has been demonstrated for ACTH in rats that disappears with CRH immunoneutralization, linking this rhythm to the CNS. Other studies have found a coupling between cortisol secretory activity and EEG ultradian rhythms during sleep, with a significant relationship between daytime EEG β activity and cortisol secretory activity. The frequency of 110 min for β activity and 117 min for cortisol, with a lag time of 10 min for cortisol by cross-correlation, suggests that this ultradian rhythm of cortisol is linked to central alertness/arousal mechanisms, and our own data demonstrate a strong ultradian rhythm of 120 min. In addition, a number of studies have found that the onset of sleep, during

both night and daytime, results in a decrease in cortisol secretion, and failure to inhibit cortisol secretion at sleep onset has been reported in depressed patients. Following identification of the pulsatile nature of ACTH and cortisol secretion, emphasis has shifted to identifying pulses and to performing time domain-based analyses rather than frequency domain-based analyses. Less is known about the physiology of pulse frequency in the HPA axis than in other hormone systems such as the reproductive axis. Of the four studies that have examined cortisol pulsatility in depression, there is only one report of an increased number of pulses in depressed patients. The overall evidence suggests that increased cortisol secretion is not due to increased pulse number but, rather, to either increased amplitude or increased baseline cortisol not secreted in a pulsatile manner.

Altered Response to Stress

Increased cortisol is found in only a proportion of patients, and there is evidence that there may be two different types of depression. One is characterized by increased basal circadian drive, decreased negative feedback, and normal stress reactivity (classic depression). The other is associated with early trauma and characterized by enhanced stress reactivity and enhanced negative feedback resulting in normal to low cortisol secretion.

The National Comorbidity Study found that childhood adversities were consistently associated with the onset (but not necessarily persistence) of mood disorders. Data from this survey indicated a significant association between childhood sexual abuse and mood disorders, and childhood adversity increased the risk for recent episodes of major depression. Another large population-based study found that multiple childhood adverse experiences increased the risk for lifetime depression disorders (odds ratio, 2.7), and there was a dose relationship between the cumulative events and probability of lifetime and recent depressive disorders, even after controlling for a mentally ill household member. A Finnish study also found a similar cumulative effect of adult traumas, with odds ratios for persistent depression of 6.0 for men and 6.99 for women with three or more traumatic experiences.

Childhood sexual abuse has also been found to sensitize women to the depressogenic effects of subsequent stressful life events and to be associated with an increased likelihood of suicide or self-harm attempts in depressed women. Heim and colleagues examined multiple HPA axis function in depressed subjects with or without a history of childhood abuse. They found an effect of early abuse and depression on stress reactivity, with increased ACTH and cortisol responses to the stressor compared to either controls or depressed patients without childhood abuse. In these same subjects, they found a blunted response to CRH challenge in depressed patients with or without childhood abuse but an increased response to CRH in abused individuals without depression. The abused subjects also showed a blunted cortisol response to ACTH 1–24. Thus, childhood abuse resulted in an "enhanced pituitary response with counter-regulatory adrenal adaptations" – changes compatible with low or normal basal cortisol. Furthermore, they found lower cortisol and enhanced feedback to low-dose dexamethasone in the same subjects. The abused groups also demonstrated lower baseline and stimulated cortisol in response to CRH challenge as well as following ACTH infusion. These same groups of women showed a significantly greater HPA axis response to the Trier Stress Test despite smaller responses to CRH.

Introduction and Historical Outline of Several Stress Concepts

Aristotle, Hippocrates, and the other Ancients were aware of stress and its adverse effects. However, Claude Bernard was the first to formally explain how cells and tissues in multicelled organisms might be protected from stress. One of the world's greatest physiologists, Bernard, working in Paris during the second half of the nineteenth century, first pointed out (1859) that the internal medium of the living organism is not merely a vehicle for carrying nourishment to cells. Rather, "it is the fixity of the *milieu intérieur* which is the condition of free and independent life." That is, cells are surrounded by an internal medium that buffers changes in acid-base, gaseous (O_2 and CO_2), and ion concentrations and other biochemical modalities to minimize changes around biologically determined set points, thereby providing a steady state. Fifty years later, Walter Bradford Cannon, working at Harvard, suggested the designation homeostasis (from the Greek *homoios*, or similar, and *stasis*, or position) for the coordinated physiological processes that maintain most of the steady states in the organism. Cannon popularized the concept of 'homeostasis' in his 1932 book, *Wisdom of the Body*.

Cannon also coined the term fight or flight to describe an animal's response to threat. The concept of fight or flight proposes that animals react to threats with a general discharge of the sympathetic nervous system, priming the animal for fighting or fleeing. This response was later recognized as the first stage (acute stress response) of a general adaptation syndrome (GAS) postulated by Hans Selye to be a universal stress response among vertebrates and other organisms.

Born in Vienna in 1907, Hans Hugo Bruno Selye, also known as the 'father of stress,' began his stress research while still a medical student in 1926. He observed that patients with a variety of illnesses had many of the same 'nonspecific' symptoms that were a common response to stressful stimuli experienced by the body. These clinical observations together with experiments on laboratory rats underpinned Selye's concept of GAS, which led Selye to assert that prolonged exposure to stress resulted in 'diseases of adaptation.' That is, chronic stress, by causing the overproduction of chemicals and hormones, produced gastroduodenal ulcers and high blood pressure. Although the GAS hypothesis was subsequently shown to be incorrect, it did put stress on the map and also highlighted the fact that stress had major effects on the immune system as well as on the adrenal glands.

In addition to providing the first clear definition of stress, Hans Selye was also the first to recognize that homeostasis could not by itself ensure stability of body systems under stress. He coined the term heterostasis (from the Greek *heteros*, or other) as the process by which a new steady state was achieved by treatment with agents that stimulate the physiological adaptive mechanisms. Heterostasis could be regarded as the precursor for the concept of allostasis, first advanced by Peter Sterling and Joseph Eyer in the 1980s. That is, homeostasis, which has dominated physiological and medical thinking since the nineteenth century, is thought to provide 'stability through constancy.' Allostasis, on the other hand, provides 'stability through change' brought about by central nervous regulation of the set points that adjust physiological parameters to meet the stress/challenge.

A different tack, focused on cognition, was taken by Richard Lazarus, the eminent and influential Berkeley University psychologist. At a time when psychology tried to understand human behavior by first understanding simple organisms engaging in simple behaviors learned by associations, rewards, or punishments, Lazarus instead emphasized the importance of studying cognition, which he extended into stress and coping.

Epidemiology has been and remains central to stress studies. Numerous epidemiological studies have tried to define the effects of social, workplace, and lifestyle on stress, health, and well-being. However, of the recent epidemiological studies that have generated new stress concepts, the most important perhaps is that of David Barker, which led to the hypothesis that fetal undernutrition in middle to late gestation programs later coronary heart disease. This concept was soon extended by Hales and Barker in their 'thrifty phenotype hypothesis.' The latter proposes an association between poor fetal and infant growth and the subsequent development of type 2 diabetes and the metabolic syndrome, which afflict communities in epidemic proportions. Poor nutrition in early life, it is postulated, produces permanent changes in glucose-insulin metabolism. These changes include insulin resistance (and possibly defective insulin secretion), which combined with effects of obesity, aging, and physical inactivity are the most important factors in

determining type 2 diabetes. Many studies worldwide have confirmed Barker's initial epidemiological evidence, although the strength of the relationships has varied between studies.

With advances in genomics, the concept of susceptibility genes that increase the vulnerability of individuals to stressful life events has attracted considerable research interest. Thus, for example, the work of Avshalom Caspi and associates suggests that a polymorphism in the monoamine oxidase A (MAOA) gene promoter, which reduces MAOA expression, influences vulnerability to environmental stress, and that this biological process can be initiated by childhood abuse. Furthermore, Caspi and associates, working at the Institute of Psychiatry, London, have demonstrated that a polymorphism in the promoter of the serotonin transporter gene can render individuals more susceptible to stressful life events. In addition to their disorder-specific value, these findings have heuristic value for further thinking and research on genetic–environmental interactions that determine the response to stress and the development of mental disorders.

In parallel with these stress concepts, neuroendocrine advances revealed the physiological substrate for homeostasis, allostasis, and the stress response mechanisms. The autonomic nervous and the hypothalamic–pituitary–adrenocortical (HPA) systems subserve the afferent and efferent limbs of the stress response in vertebrates and are also central to maintaining homeostasis and effecting allostasis. The term autonomic nervous system was coined in 1898 by the Cambridge physiologist John Newport Langley, who was also renowned for his development (in parallel with Paul Ehrlich) of receptor theory. Controlled by the brain, and utilizing as neurotransmitters epinephrine and norepinephrine (sympathetic nervous component) or acetylcholine (parasympathetic component), the role of the autonomic nervous system in fight-or-flight and homeostasis (especially cardiovascular) was clearly explained by Walter Cannon.

The story of our understanding of the HPA, and the concept of the neurohumoral hypothesis of anterior pituitary control, is tortuous. The pituitary gland had long been regarded, by luminaries such as the great Harvard neurosurgeon Harvey Cushing, as the autonomous controller of the adrenal cortex, the thyroid, and the gonads. That is, the anterior pituitary gland was considered to be the 'conductor of the endocrine orchestra.' This view was reinforced by the dramatic effects of experimental pituitary removal (hypophysectomy) in rodents made feasible by the parapharyngeal surgical approach to the pituitary developed by PE Smith in approximately 1930. However, at approximately the same time, experiments were in progress that would eventually prove that the anterior pituitary gland is not autonomous; rather, it is controlled by the brain. The first of these experiments, carried out by William Rowan working alone at −50 °C in Edmonton, Alberta, in the late 1920s, showed that migration in birds was controlled by the gonads, and that gonadal size in birds was increased many-fold by increases in day length. Day length and the effects of other exteroreceptive factors, such as stress, on endocrine function together with the effects of brain tumors and trauma in the human led to an acceptance of the then (1930s) revolutionary concept that the pituitary gland is under central nervous system (CNS) control.

The neural lobe of the pituitary gland is composed of nerve projections from the paraventricular and supraoptic nuclei of the hypothalamus: these projections terminate on systemic blood vessels into which they release the nanopeptide neurohormones, vasopressin and oxytocin. In contrast, the anterior pituitary gland receives no direct innervation from the brain. Rather, the CNS control of the anterior pituitary gland is mediated by neurohormones synthesized and released from hypothalamic neurons and transported to the anterior pituitary gland by the hypophysial portal vessels. Proof of the neurohumoral hypothesis of anterior pituitary control came, first, from the elegant pituitary stalk section and pituitary grafting experiments of Geoffrey Harris and Dora Jacobsohn; second, from the characterization of some of the neurohormones by Andrew Schally and Roger Guillemin, for which they were awarded the 1977 Nobel Prize for physiology and medicine; and third, from the demonstration, first by my group, that these neurohormones were indeed released into hypophysial portal blood. Corticotropin-releasing factor (CRF), a 41-amino-acid peptide that mediates neural control of adrenocorticotropic hormone (ACTH) release from pituitary corticotropes, was isolated and sequenced by Wylie Vale and associates in 1981. A series of physiological studies, including measurements of neurohormone release into hypophysial portal blood *in vivo*, have confirmed earlier views that arginine vasopressin acts synergistically with CRF to control ACTH release.

Finally, no outline of the history of stress concepts would be complete without mention of the characterization of the adrenocortical glucocorticoids and their function. The glucocorticoids are steroid hormones whose secretion by the adrenal cortex is controlled by ACTH. The hormones of the adrenal cortex were isolated, identified, and synthesized independently by Edward Kendall (at the Mayo Foundation) and Tadeus Reichstein (at Zurich) and their associates. The availability of large amounts of synthetic steroids

enabled their physiological effects to be studied. Ultimately, Philip Hench was able to test the glucocorticoid, cortisone, in the human and demonstrate that it is a powerful anti-inflammatory agent. Hench, at the Mayo Foundation, had previously observed that rheumatoid arthritis was sometimes relieved during pregnancy and in some patients with jaundice, leading him to conclude that the pain-alleviating substance was a steroid. Kendall, Hench, and Reichstein were jointly awarded the Nobel Prize for physiology and medicine for 1950, and synthetic glucocorticoids continue to be used to treat arthritis, asthma, autoimmune conditions, and other inflammatory disorders in humans.

Definitions of Stress

Stress has a different meaning for different people under different conditions. The first and most generic definition of stress is that proposed by Hans Selye: "Stress is the nonspecific response of the body to any demand." Selye repeatedly emphasized the fact that the continued use of the word stress as a nonspecific-response to any demand was most appropriate. Selye argued that stress is not identical to emotional arousal or nervous tension since stress can occur under or in response to anesthesia in man and animals, and it can also occur in plants and bacteria that have no nervous system. This point is elaborated later in the context of stress-induced heat shock proteins (Hsps) that play a key role in cytoprotection across all three phylogenetic domains of organisms on Earth. The word stress, as used by Selye, is accepted in all foreign languages, including those in which no such word existed previously.

Stress, Selye underscored,

> is not something to be avoided. Indeed, it cannot be avoided, since just staying alive creates some demand for life-maintaining energy. Even when man is asleep, his heart, respiratory apparatus, digestive tract, nervous system, and other organs must continue to function. Complete freedom from stress can be expected only after death.

There has been much controversy and debate about Selye's concepts and particularly Selye's view that stress is best regarded as a nonspecific response. Because of their heuristic value, these points will be further considered later.

Other definitions, reviewed in detail by Selye in his treatise *Stress in Health and Disease*, include the following:

1. In behavioral sciences, stress is regarded as the "perception of threat, with resulting anxiety discomfort, emotional tension, and difficulty in adjustment."

2. In the group situation, lack of structure or loss of anchor "makes it difficult or impossible for the group to cope with the requirements of the situation, and the problem of leadership and interpersonal behavior becomes one of evolving or supplying a structure or anchor and of supplying the expertness for coping with the demands of the situation."

3. Stress can also be defined in terms of pure neuroendocrinology. Eugene Yates, for example, defined stress as any stimulus that will provoke the release of ACTH and adrenal glucocorticoids. Presumably, the same might apply to the equally powerful sympathetic markers of stress, underscored earlier by Walter Cannon.

4. Finally, Selye also mentions Richard Lazarus, famous for his work in cognitive psychology and focus on the emotions. Lazarus underscores the difficulties of reaching a precise overarching definition of stress by setting out the following different meanings of the term: "In spite of consistent confusion about the precise meaning of the term, stress is widely recognized as a central problem in human life. Scientists of many disciplines have conceptualized stress but each field appears to have something different in mind concerning its meaning. For the sociologist, it is social disequilibrium, that is, disturbances in the social structure within which people live. Engineers conceive of stress as some external force which produces strain in the materials exposed to it. Physiologists deal with the physical stressors that include a wide range of stimulus conditions that are noxious to the body. In the history of psychological stress research, there has been no clear separation between physical stressors which attack biological tissue systems and psychological stressors which produce their effects purely because of their psychological significance."

Selye's Definition of Stress – A Further Consideration

Selye's definition and concept of stress has remained controversial. For some, his definition is too biological and ignores cognitive and psychological factors, a criticism that seems to stem from the mistaken idea that cognition is not a function of the brain (a reversion to Rene Descartes' outmoded doctrine that mind and body are separate). For others, Selye's definition is too general. This section reviews the basis for Selye's definition of stress and considers whether the criticisms leveled at Selye's stress concept are valid. Overall, our observations suggest that Selye fully understood so-called psychological or cognitive stress, and that the generality of Selye's stress definition has facilitated the molecular, genotypic and phenotypic analysis of stress and stress responses across all species from bacteria to man.

General Adaptation Syndrome

Selye first put stress on the map with GAS. In search of a new hormone, Selye injected extracts of cattle ovaries into rats. The injection caused the following characteristic triad:

1. The adrenal cortex became enlarged and discharged lipid secretory granules.
2. The thymus, spleen, lymph nodes, and all other lymphatic structures showed severe involution.
3. Deep bleeding ulcers appeared in the stomach and duodenum.

Selye at first thought that these effects were due to a new hormone in the extracts but soon found that all toxic substances – extracts of kidneys, spleen, and even toxicant not derived from living tissue produced the same syndrome.

Selye surmised that the response to the injection of toxic substance reflected his "classroom concept" of "the syndrome of just being sick." That is, adrenal enlargement, thymicolymphatic involution, and gastrointestinal ulcers were the omnipresent signs of damage to the body when under attack. The three changes thus became (for Selye) the objective indices of stress and the basis for the development of the entire stress concept.

First described in a note to *Nature* in 1936, GAS has three stages: alarm, resistance, and exhaustion. In the alarm stage, the body shows changes characteristic of the first exposure to the stressor; these changes generally coincide with the sympathetic discharge that enables the fight-or-flight phenomenon of Cannon. If the stressor continues and is compatible with adaptation, features of the alarm reaction disappear and resistance develops. Prolonged exposure to the stressor may result in exhaustion and finally death.

One of the most important findings of GAS is the stress-induced thymicolymphatic involution, which highlighted for the first time that stress has a major impact on the immune system. This concept preceded by more than 20 years the discoveries of lymphocyte recirculation by James Gowans and acquired immunological tolerance by MacFarlane Burnet and Peter Medawar. Selye's discovery began the field of neuroimmunomodulation.

Selye soon became aware of the fact that the adrenal enlargement of GAS was associated with increased secretion of glucocorticoids (cortisol or corticosterone) that

> induce glycogenolysis, thereby supplying a readily available source of energy for the adaptive reactions necessary to meet the demands made by the stressors. In addition, they facilitate various other enzymatically regulated adaptive metabolic responses and suppress immune reactions as well as inflammation, assisting the body to coexist with potential pathogens.

Selye asserted that glucocorticoids are needed for adaptation to stress primarily during the alarm reaction. Selye's view that glucocorticoids enhance and mediate the stress response has been upheld with the additional concepts that glucocorticoids play a permissive role that primes the body's stress response systems and also prevent overshoot of the defense systems. Overshoots in the body's defense system are perhaps most dramatically seen in major inflammatory cataclysms called cytokine storms and the consequent systemic inflammatory response syndromes that play a key role in the lethality of avian influenza and have also occurred in response to the injection of certain antibodies. Exogenous synthetic glucocorticoids such as methylprednisolone remain a mainstay of the treatment of cytokine storms.

Although GAS is sometimes manifest in extreme stress, the three components of GAS have not withstood the test of time as indices of stress as Selye had originally proposed. Rather, the main biological markers of stress have long been behavioral observations and tests and measures of sympathetic and HPA activation. In the case of the latter measurements of glucocorticoid concentrations in blood, either alone or in parallel with plasma concentrations of ACTH, have been used as the main biological indices of stress. So, despite its heuristic value, especially for stress-induced neuroimmunomodulation, the concept of GAS has lost scientific currency.

Stressors: Features of and Lack of Stressor Sign

In *Stress in Health and Disease*, Selye underscored the fact that

> stress is part of our daily human experience, but it is associated with a great variety of essentially dissimilar problems, such as surgical trauma, burns, emotional arousal, mental or physical effort, fatigue, pain, fear, the need for concentration, the humiliation of frustration, the loss of blood, intoxication with drugs or environmental pollutants, or even the kind of unexpected success that requires an individual to reformulate his lifestyle. Stress is present in the businessman under constant pressure; in the athlete straining to win a race; in the air-traffic controller who bears continuous responsibility for hundreds of lives; in the husband helplessly watching his wife's slow, painful death from cancer; in a race horse, its jockey, and the spectator who bets on them.

Selye went on to argue that "while all these subjects face quite different problems they respond with a stereotyped pattern of biochemical, functional, and structural changes essentially involved in coping with

any type of increased demand upon vital activity, particularly adaptation to new situations."

Selye also asserted that stressors have no sign as far as evoking the stress response. That is, the response will be the same "whether the agent or situation being faced is pleasant or unpleasant; all that counts is the intensity of the demand for readjustment or adaptation that it creates." Selye underscored this point with the following poignant example:

> The mother who is suddenly told that her only son died in battle suffers a terrible mental shock; if years later, it turns out that the news was false and the son unexpectedly walks into her room alive and well, she experiences extreme joy. The specific results of the two events, sorrow and joy, are completely different, in fact they are opposite to each other, yet their stressor effect – the nonspecific demand for readjustment to a new situation – is the same.

Nonspecificity of Stress Response

Selye seemed to have been driven to find specificity in the response to different types of stressors. Thus, again in *Stress in Health and Disease* he wrote,

> It is difficult to see at first how such essentially different things as cold, heat, drugs, hormones, sorrow, and joy could provoke an identical biologic reaction. Nevertheless this is the case; it can now be demonstrated by highly objective, quantitative biochemical and morphologic parameters that certain reactions are totally nonspecific and common to all types of agents, whatever their superimposed specific effects may be.

Criticism of Selye's definition of stress has been put to experimental test. Pacak, Palkovits, and associates, for example, demonstrated that different stressors activate different stress biomarkers and different regions of the brain. Thus, low blood glucose concentrations (glucopenia) or hemorrhage activate both sympathetic and HPA systems; hyperthermia, cold, and formalin injection selectively activate the sympathetic system. On the basis of these data, Pacak and Palkovits conclude that each stressor has its own specific neurochemical signature. However, since these stress indices are limited to just two neurohumoral systems, and since for most stressors there is at least some overlap in response, it is not clear that this approach invalidates Selye's definition, "stress is the nonspecific response of the body to any demand," which would probably be unassailable had Selye omitted the term 'nonspecific.'

Heat Shock (Stress) Proteins

Whatever the shortcomings of Selye's definition of stress for the human, it is probably appropriate for the vast majority of living organisms. Living cells are classified into three main evolutionary lines or phylogenetic domains: Bacteria (eubacteria), Archaea (formerly archaebacteria), and Eucarya (eukaryotes, which encompass all plants and animals through to man). The cellular response to stress in all three phylogenetic domains is represented at the molecular level by the stress-induced synthesis of stress or Hsps, of which molecular chaperones and proteases represent two well-characterized families. The heat shock response was discovered in 1962 by Ritossa, who observed a pattern of *Drosophila* salivary gland chromosome puffs that were induced in response to transient exposure to elevated temperatures. Since then, many studies have shown that the heat shock response is ubiquitous and highly conserved in all organisms from bacteria to plants and animals. It is an essential defense mechanism for protection of cells from a wide range of stressors, including heat shock, alcohols, ischemia, inhibitors of energy metabolism, heavy metals, oxidative stress, fever, or inflammation, which depending on amplitude and duration can all cause cell death by apoptosis or necrosis. The heat shock response can protect against stress-induced cell death by way of a cell-protective process known as thermotolerance or cytoprotection, in which exposure of cells to mild stress conditions, sufficient to induce the expression and accumulation of Hsps, protects against a subsequent challenge from another stress that is, by itself, lethal. Although their precise function remains to be determined, the high degree of conservation of these Hsps across species, coupled with their importance in cell survival in various conditions, suggests that Hsps are critical for both normal cellular function and survival after a stress. Several cytoprotective functions have been attributed to Hsps and, in particular, the HSP70 family. These include (1) the folding of proteins in various intracellular compartments, (2) the maintenance of structural proteins, (3) the refolding of misfolded proteins, (4) translocation of proteins across membranes and into various cellular compartments, (5) the prevention of protein aggregation, and (6) the degradation of unstable proteins. Hsps also serve as modulating signals for immune and inflammatory responses, and they may have a role in cytokine production.

So, for the heat shock response to stressful stimuli, Selye's "stress is the nonspecific response of the body [or cell] to any demand" would appear to be appropriate.

Concepts of Stress and Disease

There is a vast literature on the role or possible role of stress in the causation and/or exacerbation of disease in most organ systems of the body. Here, attention

is focused on mental disorders. The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) of the American Psychiatric Association recognizes two stress disorders: acute stress disorder and posttraumatic stress disorder (PTSD). For the diagnosis of acute stress disorder, the individual, while experiencing the trauma or after the event, must have at least three of several dissociative symptoms, such as a subjective sense of numbing, detachment, or absence of emotional responsiveness; reduction in awareness of surroundings; depersonalization; or dissociative-amnesia. Following the trauma, the traumatic event is persistently reexperienced, the individual avoids stimuli that may arouse recollections of the traumatic event, and he or she has anxiety or increased arousal. The trauma causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

PTSD is defined as a condition in which a traumatic event is persistently reexperienced in the form of intrusive recollections, dreams, or dissociative flashback episodes. Cues to the event lead to distress and are avoided, and there are symptoms of increased arousal. To meet the diagnostic criteria of the DSM-IV, the full symptom picture must be present for more than 1 month, and the disturbance must cause clinically significant distress or impairment in social, occupational, or other areas of functioning.

PTSD has only been accepted officially as a mental disorder since 1980, when it was included, amid considerable controversy, in the DSM-III. References to the aftereffects of psychological trauma date back as far as the third century BC; achieved prominence during the early period of the railroad in Britain when rail travel, then precarious and physically traumatic, gave rise to a syndrome called railway spine or postconcussion syndrome; and were regarded as the basis for hysteria at the turn of the nineteenth century by neurologists and psychiatrists such as Jean-Martin Charcot, Pierre Janet, and Sigmund Freud. Long before PTSD was included in any diagnostic system, Charles Dickens wrote *A Tale of Two Cities* (1859), which can be considered as an early case report of PTSD. Interest in PTSD increased dramatically during World War I: Charles Samuel Myers was the first to coin the term and report case histories of 'shell shock,' which described a condition that afflicted many troops who screamed and wept uncontrollably, froze and could not move, became mute and unresponsive, and lost their memory, sensations, and capacity to feel. Pat Barker's monumental trilogy, *Regeneration*, deals poignantly with the psychological traumas of war and the nature of shell shock. The condition occurred again in vast numbers of people as a consequence of World War II. However, it was the psychological trauma experienced by Vietnam veterans and their demand for compensation that led to the inclusion of PTSD in the DSM-III as a condition that occurred both in civilian (e.g., rape trauma syndrome, battered woman syndrome, and abused child syndrome) and in military trauma response syndromes.

Future Developments of Stress Concepts

This brief account of some of the definitions and concepts of stress shows that there is still much to be done in the area of stress research. Thus, with respect to gene–environmental interactions, work on susceptibility genes has just begun, and there is still much room for expanding our knowledge about the role in stress of epigenetic factors and other mechanisms of gene control such as RNA interference. On the basis of previous experience, it seems likely that Barker's 'fetal origins' hypothesis might be honed and revised and may lead to a robust understanding of the metabolic syndrome and diabetes type 2. New powerful computer analysis of brain imaging and electrical recording may help to resolve the many questions that surround consciousness and cognition. The vexed cause-and-effect questions regarding the influence of stress in mental disorders, cancer, and other diseases need to be answered. In the past 25 years, we have witnessed how Selye's cherished and widely accepted axiom that stress is the cause of gastric ulceration (one of the three components of GAS) was undone by the careful observations and courageous perseverance of Barry Marshall and Robin Warren, who demonstrated that, in fact, most gastroduodenal ulcers are caused by a microbe, *Helicobacter pyloris*, that is readily amenable to treatment with antibiotics. And yet, there is evidence that stress does play a role in gastric ulceration, so the stress – *H. pyloris* interaction needs to be worked out. These and other biological questions about stress are likely to be tractable – rational and rigorous biology will almost certainly win the day.

However, the causes of human stress, acute and posttraumatic, are commonly social and sociological, political and irrational (beliefs in religious and racial superiority). Our continuing strife and conflict reflect in part man's innate, often irrational (limbic-brain generated) drive for conquest, territory, acquisition, and reproduction of the species. Perhaps the fact that man is such a smart political animal works against us and could ultimately lead to our stressful self-destruction. It is not clear that anything can protect man from this fate.

Stress: Homeostasis, Rheostasis, Allostasis and Allostatic Load

B S McEwen, The Rockefeller University, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The brain mediates adaptation to changes in the physical and social environment through the autonomic, neuroendocrine, and immune systems as well as through behavioral responses that include fighting or fleeing, as well as health-promoting or health-damaging responses. Adaptation to stressful events or environmental changes is an active process that involves the output of mediators such as neurotransmitters and modulators, as well as many hormones and cytokines and chemokines of the immune system. The goal of this adaptation is to maintain homeostasis and promote survival of the organism. However, the process of adaptation also produces an almost inevitable wear and tear on the body and brain, and this wear and tear is exacerbated if there are many stressful events and/or if the mediators that normally promote adaptation are dysregulated, that is, not turned on when needed or not turned off efficiently when no longer needed. The description and analysis of this scenario has entailed the addition of some new terminology, such as allostasis, and the refinement of some classical terminology, such as homeostasis and stress.

Characteristics of Homeostatic Systems

Homeostasis refers to the ability of an organism to maintain the internal environment of the body within limits that allow it to survive. Homeostasis also refers to self-regulating processes that return critical systems of the body to a set point within a narrow range of operation, consistent with survival of the organism.

Homeostasis is highly developed in warm-blooded animals living on land, which must maintain body temperature, fluid balance, blood pH, and oxygen tension within rather narrow limits, while at the same time obtaining nutrition to provide the energy to maintain homeostasis. This is because maintaining homeostasis requires the expenditure of energy. Energy is used for locomotion, as the animal seeks and consumes food and water, for maintaining body temperature via the controlled release of calories from metabolism of food or fat stores, and for sustaining cell membrane function as it resorbs electrolytes in the kidney and intestine and maintains neutral blood pH.

Homeostasis also refers to the body's defensive mechanisms. These include protective reflexes against such things as inhaling matter into the lungs, the vomiting reflex as a protection to expel toxic materials from the esophagus or stomach, the eye blink reflex, and the withdrawal response to hot or otherwise painful skin sensations. There is also the defense against pathogens through innate and acquired immunity.

According to Walter B Cannon,

> Bodily homeostasis ... results in liberating those functions of the nervous systems that adapt the organism to new situations, from the necessity of paying routing attention to the management of the details of bare existence. Without homeostatic devices, we should be in constant danger of disaster, unless we were always on the alert to correct voluntarily what normally is corrected automatically. With homeostatic devices, however, that keep essential body processes steady, we as individuals are free from such slavery – free to enter into agreeable relations with our fellows, free to enjoy beautiful things, to explore and understand the wonders of the world about use, to develop new ideas and interests, and to work and play, untrammeled by the anxieties concerning our bodily affairs. (Cannon, 1929)

The body has a considerable redundancy, or safety margin, when it comes to many of these mechanisms. There are two kidneys and adrenal glands, in case one fails, and the digestive tract is able to function adequately in food absorption, even if intestinal length is shortened. Moreover, individuals are able to survive with one lung. Also, the cardiovascular system has a number of devices to maintain blood pressure after considerable blood loss. Finally, as Cannon notes, the body displays considerable resilience in the face of injury and after surgery, in order to compensate for lost function.

Need for Refocusing of the Concept of Homeostasis and Additional Terminology

Yet, there are paradoxes and problems with the notion of a set point that is always maintained. In discussing obesity, Cannon states "What leads to the storage of fat in large amounts – sometimes in grotesquely large amounts – in some persons, and in slight amounts in others, is not well-understood." This and other aspects of pathophysiology, particularly in response to stress, has forced a re-evaluation of the processes that reestablish homeostasis in the

face of a challenge and which, under some circumstances, exacerbate disease. This is one of the reasons why the terms allostasis and allostatic load (see below) have been introduced.

Another problem with 'homeostasis' is that, taken literally, it is a rather static concept, akin to the notion of equilibrium in classical thermodynamics, whereas, in real life, an organism experiences changing set points around which it maintains stability over a finite period of time. Moreover, unlike the closed systems of classical thermodynamics, a living organism is an open system in which energy and matter flow in and out, with equilibrium being replaced by steady state. Cannon recognized this and used the term steady state and even suggested that 'homeodynamics' might be a better term than 'homeostasis.'

The same problem was also recognized by a number of other authors. Nicolaides introduced the term homeorheusis, in which 'stasis' is replaced by 'rheusis,' meaning 'something flowing.' Mrozovsky introduced the term rheostasis to mean "a condition or state in which, at any one instant, homeostatic defenses are still present but over a span of time there is a change in the regulated level, or set point of a system." Mrozovsky considers this concept advantageous in explaining how organisms adjust to changing environments such as seasons of the year by storing body fat or changing reproductive physiology, and he believes that rheostasis allows for the kinds of physiological plasticity that is involved in evolution.

What Is Stress?

Stress may be defined as a real or interpreted threat to the physiological or psychological integrity of an individual that results in physiological and/or behavioral responses. In biomedicine, stress often refers to situations in which the adrenal glucocorticoids and catecholamines are elevated because of an experience. Stress is also a subjective experience that may or may not correspond to physiological responses, and the word stress is widely used in many languages as part of daily discourse. There is 'good stress' and 'bad stress,' and people talk about bad stress as 'being stressed out.'

Stress involves a stressor and a stress response. A stressor may be a physical insult, such as trauma or injury, or physical exertion, particularly when the body is being forced to operate beyond its capacity. Other physical stressors include noise, overcrowding, excessive heat or cold. Stressors also include primarily psychological experiences such as time-pressured tasks, interpersonal conflict, unexpected events, frustration, isolation, and traumatic life events, and all of these types of stressors may produce behavioral responses and evoke physiological consequences such as increased blood pressure, elevated heart rate, increased cortisol levels, impaired cognitive function, and altered metabolism.

Behavioral responses to stressors may decrease risk and get the individual out of trouble or involve health-promoting activities such as a good diet and regular exercise, but they may also include responses that exacerbate the physiological consequences of stress, for example, self-damaging behaviors like smoking, drinking, overeating, or consuming a rich diet, or risk-taking behaviors like driving an automobile recklessly. The physiological stress responses include primarily the activation of the autonomic nervous system and the hypothalamo–pituitary–adrenal (HPA) axis, leading to increased blood and tissue levels of catecholamines and glucocorticoids. It is these physiological responses that have both protective and damaging effects (see the sections on allostasis and allostatic load).

There are two important features of the physiological stress response: the first involves turning it on in amounts that are adequate to the challenge (see the section 'Allostasis'). The second is turning off the response when it is no longer needed. The physiological mediators of the stress response, namely, the catecholamines of the sympathetic nervous system and the glucocorticoids from the adrenal cortex, initiate cellular events that promote adaptive changes in cells and tissues throughout the body, which in turn protect the organism and promote survival. However, too much stress, or inefficient operation of the acute responses to stress, can cause wear and tear and exacerbate disease processes.

There are enormous individual differences in interpreting and responding to what is stressful, as well as individual differences in the susceptibility to diseases, in which stress may play a role. Genetic predispostions exist which increase the risk of certain disorders. In addition, developmental process, such as prenatal stress or nurturing postnatal experiences, contribute to the lifelong responsiveness of the behavioral and physiological responses to stressors. Furthermore, experiences throughout the life course resulting in memories of particularly unpleasant or pleasant situations combine with the genetic and developmental influences to produce large differences among individuals in how they react to stress and what the long-term consequences may be.

Allostasis

Allostasis means 'achieving stability through change'; it was introduced by P Sterling and J Eyer in 1988.

Allostasis refers to the process that maintains homeostasis, as defined above, and it recognizes that 'set points' and other boundaries of control may change with environmental conditions. There are primary mediators of allostasis such as, but not confined to, hormones of the HPA axis, catecholamines, and cytokines. Allostasis also clarifies the inherent ambiguity in the term homeostasis and distinguishes between the systems that are essential for life (homeostasis) and those that maintain these systems in balance (allostasis). Allostatic systems enable an organism to respond to its physical state (e.g., awake, asleep, supine, standing, exercising) and to cope with noise, crowding, isolation, hunger, extremes of temperature, physical danger, psychosocial stress, and microbial or parasitic infections. For example, blood pressure rises when we get up in the morning and fluctuates with exercise and other demands of the waking period, and these fluctuations make it possible for the individual to function in response to a changing social and physical environment.

Whether exposed to danger, an infection, a crowded and noisy neighborhood, or having to give a speech in public, the body responds to challenge by turning on an allostatic response, thus initiating a complex pathway for adaptation and coping, and then shutting off this response when the challenge has passed. Two primary allostatic responses involve the sympathetic nervous system and HPA axis. 'Turning on' these systems leads to release of catecholamines from sympathetic nerves and the adrenal medulla and the secretion of adrenocorticotropin (ACTH) from the anterior pituitary gland, which stimulates release of glucocorticoids from the adrenal cortex.

'Turning off' these responses leads to a return to baseline concentrations of cortisol and catecholamines, and this normally happens when the danger is past, the infection contained, the living environment is improved or the talk has been given. As long as the allostatic response is limited to the period of challenge, protection via adaptation predominates over adverse consequences. However, over weeks, months, or even years, exposure to elevated levels of stress hormones (an allostatic state) can result in allostatic load and overload, with resultant pathophysiological consequences.

Allostatic States

An allostatic state refers to the altered and sustained activity levels of the primary mediators, for example, glucocorticoids, that integrate energetic and associated behaviors in response to changing environments, challenges such as social interactions, weather, disease, predators, pollution, etc. An allostatic state results in an imbalance of the primary mediators reflecting excessive production of some and inadequate production of others. Examples are hypertension, a perturbed cortisol rhythm in major depression or after chronic sleep deprivation, chronic elevation of inflammatory cytokines and low cortisol in chronic fatigue syndrome, imbalance of cortisol, corticosteroid-releasing factor (CRF), and cytokines in the Lewis rat that increases risk for autoimmune and inflammatory disorders. Allostatic states can be sustained for limited periods if food intake and/or stored energy, such as fat, can fuel homeostatic mechanisms (e.g., bears and other hibernating animals preparing for the winter). If imbalance continues for longer periods and becomes independent of maintaining adequate energy reserves, then symptoms of allostatic overload appear. Abdominal obesity is an example of this condition.

Allostatic Load and Overload

Allostatic load and allostatic overload refers to the cumulative result of an allostatic state. For example, fat deposition in a bear preparing for the winter, a bird preparing to migrate or a fish preparing to spawn are examples of animals experiencing an allostatic load. This is a largely beneficial and adaptive condition and can be considered the result of the daily and seasonal routines which organisms use to obtain food and survive, and obtain the extra energy needed to migrate, molt, and breed. Within limits, they are adaptive responses to seasonal and other demands. However, if one superimposes on this additional load of unpredictable events in the environment, disease, human disturbance (for animals in the wild), and social interactions, then allostatic load can increase dramatically and become allostatic overload, which can become a pathophysiological condition.

There are two distinctly different outcomes of an allostatic state in terms of allostatic load or overload. First, if energy demands exceed energy income, and also exceeds what can be mobilized from stores, then type 1 allostatic overload occurs. For example, breeding birds use increasing food abundance in spring to reproduce and raise their young. If inclement weather then increases costs of maintaining homeostasis and the allostatic load of breeding, and at the same time reduces food available to fuel that allostatic load, then negative energy balance results in loss of body mass and suppression of reproduction. Another example is the mass movement of seabirds to islands in the face of a severe storm that limit access to food. Second, if energy demands are not exceeded and the organism continues to take in or store as much or even more energy than it needs, perhaps as a result of

stress-related food consumption, choice of a fat-rich diet, or metabolic imbalances (prediabetic state) that favor fat deposition, then type 2 allostatic overload occurs. Besides fat deposition, there are other cumulative changes in other systems that can result from repeated stress, for example, neuronal remodeling or loss in hippocampus, atherosclerotic plaques, left ventricular hypertrophy of the heart, glycosylated hemoglobin and other proteins by advanced glycosylation end products as a measure of sustained hyperglycemia, high cholesterol with low high-density lipoprotein (HDL), increased oxidative stress, elevated proinflammatory mediators, and chronic pain and fatigue, for example, in arthritis or psoriasis, associated with imbalance of immune mediators.

Types of Allostatic Overload

Four situations can lead to allostatic overload, resulting in overexposure to stress hormones over time. The first is frequent stress, for example, blood pressure surges can trigger myocardial infarction in susceptible persons, and experiments in primates have shown that repeated blood pressure elevations over weeks and months accelerates atherosclerosis, which increases the risk of myocardial infarction. Thus, the frequency of stressful events determines the degree of this type of allostatic load, leading to increased exposure to hormones and other allostatic mediators.

A second type of allostatic overload is the failure to habituate to repeated challenges, such as in some individuals' cortisol response during a repeated public speaking challenge.

The third type of allostatic overload is caused by an inability to shut off allostatic responses. This pertains to the termination of stress and also to the decline of these same hormones during the natural diurnal cycle. With respect to the stress response, blood pressure in some persons fails to recover after acute mental arithmetic stress, and hypertension accelerates atherosclerosis. Intense athletic training also induces allostatic load in the form of elevated sympathetic and HPA activity, which results in reduced body weight and amenorrhea and the often-related condition of anorexia nervosa. Regarding the diurnal cycle, women with a history of depressive illness have decreased bone mineral density because the allostatic load of chronic, moderately elevated glucocorticoid levels, especially at night, that are associated with depression cause chronic, reduced levels of osteocalcin.

The fourth type of allostatic overload is caused by inadequate allostatic responses that trigger compensatory increases in other allostatic systems. When one system does not respond adequately to a stressful stimulus, the activity of other systems is increased because the underactive system is not providing the usual counter-regulation. For example, if adrenal steroid secretion does not increase appropriately in response to stress, secretion of inflammatory cytokines (which are counter-regulated by adrenal steroids) increases. In Lewis rats, the failure to mount an adequate HPA response results in increased vulnerability to autoimmune and inflammatory disturbances; thus, an infection or wound that causes an inflammation will lead to an increased inflammatory response. Human counterparts of the state of HPA hyporesponsiveness include individuals with fibromyalgia and chronic fatigue syndrome.

Examples of allostatic states leading to allostatic overload include hypertension, reduced parasympathetic activity, increased levels of inflammatory cytokines and oxidative stress, elevated insulin and glucose, and triglycerides. In the brain, the remodeling of neurons in the hippocampus, amygdala, and prefrontal cortex, as a result of chronic stress, are examples of allostatic overload, which impair memory and enhance anxiety and aggression. For the immune system, acute stress enhances immune responses, whereas chronic stress has the opposite effect. Chronic stress is reported to shorten teleomeres and reduce telomerase activity on white blood cells (and possibly other cells, as well).

Early stress and neonatal handling influence the course of aging and age-related cognitive impairment in animals. Early experiences are believed to set the level of responsiveness of the HPA axis and autonomic nervous system. These systems overreact in animals subject to early unpredictable stress and underreact in animals exposed to the neonatal handling procedure. In the former condition, brain aging is accelerated, whereas in the latter, brain aging is reduced. Lifespan is also influenced by early-life differences in HPA reactivity: rats that show increased HPA reactivity as neonates to novelty have shorter life spans compared to rats with lesser HPA reactivity to novelty.

Role of Behavior in Allostatic Overload

Anticipation and worry can also contribute to allostatic overload. Anticipation is involved in the reflex that prevents us from blacking out when we get out of bed in the morning and is also a component of worry, anxiety, and cognitive preparation for a threat. Anticipatory anxiety can drive the output of mediators like ACTH, cortisol, and adrenalin; thus, prolonged anxiety and anticipation is likely to result in allostatic overload. For example, salivary cortisol levels increase within 30 min after waking in individuals who are under considerable psychological stress due to work or family matters. Moreover, intrusive

memories from a traumatic event (e.g., in posttraumatic stress disorder) can produce a form of chronic, internal stress and can drive physiological responses.

Allostasis, allostatic states, and allostatic overload are also affected by health-damaging behaviors such as smoking, drinking, excess calorie intake, or, on the opposite side, health-promoting behaviors such as a healthy diet and regular moderate exercise. These behaviors are integral to the overall notion of allostasis – how individuals cope with a challenge – and also contribute to increasing or decreasing allostatic overload by known pathways. For example, a rich diet accelerates atherosclerosis and progression to noninsulin-dependent diabetes by increasing cortisol, leading to fat deposition and insulin resistance; smoking elevates blood pressure and atherogenesis. Yet, regular, moderate exercise protects one against cardiovascular disease, prevents diabetes, and increases attention and other aspects of cognitive function.

The Physiological Function of the Striatum

The striatum is a part of the thalamocortical system, residing in a loop that connects the cortex to the thalamus. Inputs from nearly every part of the cortical mantle make connections in the striatum. The output of the striatum, after one connection in the basal ganglia output nuclei, influences neurons in some parts of the thalamus which project back to the cortex. There have been many proposed functions for this transcortical loop. Most of them have in common the idea that the striatum detects combinations of cortical inputs. Cortical areas can communicate directly, but they do so in a very limited way, through specific corticocortical projections. The striatum receives cortical inputs in a more general way, with some striatal cells receiving convergent input from a wide range of combinations of cortical regions. Cortical areas project to the striatum in a roughly topographical order, with some cortical areas projecting to widely separated regions of the striatum and others showing greater or lesser overlap. Within these broad domains, cortical inputs form complex, discontinuous innervation zones so that cortical areas that project to the same general region of the striatum may converge to a greater or lesser degree. In general, the patterns of convergence follow function-related rules. For example, the somatosensory cortex projections from multiple body maps converge in the striatum so that different body parts have nonoverlapping representations, but different cortical representations of the same body part overlap extensively. The axonal arborizations of individual corticostriatal axons are often very large, and the volume of striatum occupied by the dendritic field of a single striatal neuron is innervated by an enormous number of cortical cells located in widespread regions of the cortex. Thus, even cortical areas that project to mostly nonoverlapping regions of the striatum have some small region of convergence with some proportion of striatal cells receiving both inputs. Therefore, the striatum may be able to identify specific combinations of activity in functionally related cortical circuits that could not be detected in the cortex, or in the thalamus, where cortical afferents are also organized in a way that allows only limited overlap of cortical projections from diverse functional areas.

Of course, the simplest version of this combinatorial view of the striatum cannot be completely accurate. The striatum is smaller than the cortex and has fewer neurons, and there are many more combinations of activity in cortical cells than there are cortical cells. The striatum cannot be designed to detect and distinguish every possible arbitrary combination of activity in the cortex. To make a combinatorial idea credible, one must specify which combinations of cortical patterns the striatum is designed to detect and what combinations are disregarded or confounded with others. Possibly, the striatum extracts a low-resolution view of the cortex, detecting only the large-scale patterns that involve many neurons in each cortical region. This implies that single corticostriatal neurons are good, but low-resolution, representatives of the average activity signal for their cortical areas. Alternatively, the striatum may specifically detect some limited number of classes of coincident activity in cortical regions. If this second view is correct, and the striatum is selecting out some specific set of transcortical events, how are the correct convergent connections of the relevant cortical inputs onto specific striatal neurons specified so that each striatal neuron receives the correct set of synaptic connections? Perhaps the connections are established by exercise of a learning rule, and the large number of potential combinations of cortical activity patterns is the raw material from which the striatum would sculpt a representation of cortical activity based on some particular set of criteria. If these criteria could be discovered, they would constitute a compact description of the function of the striatum.

Afferents to the Striatum

Like most brain regions, the striatum has a large number of different sources of afferents, only a few of which have been studied in detail. The well-studied striatal afferents are the corticostriatal, thalamostriatal, and nigrostriatal pathways. Among the less studied are projections from the amygdala, the dorsal raphe nucleus, and a projection from the external segment of the globus pallidus.

The Corticostriatal Pathway

The corticostriatal pathway is enormous. It consists of at least two different projections, arising from different kinds of cortical neurons, located in different

cortical layers and with different axonal branching patterns. One corticostriatal pathway arises from collaterals of large pyramidal cells located mostly in layer V that project to the brain stem and perhaps even to the spinal cord. These cells have exclusively ipsilateral projections to the striatum. A second corticostriatal pathway arises from the collaterals of corticocortical cells, including those that form the callosal connections between the hemispheres. Bilaterally projecting corticocortical cells also project bilaterally to the striatum. Cortical efferents are diverse, so there may be a variety of subcategories of corticostriatal neurons that have very specific patterns of axonal collateralization. However, in any case, the corticostriatal neurons are not a unique kind of cortical cell with properties and connections specifically adapted for communication with the striatum. They are the same cells that carry cortical output signals to the brain stem and that subserve communication among cortical areas ipsilaterally and bilaterally.

The cortical projection neurons generally employ glutamate as their neurotransmitter, and glutamate serves this role in the corticostriatal projection. Stimulation of the cortex *in situ* or in slices (after eliminating complications due to inadvertent stimulation of other axons and polysynaptic pathways) produces brief, simple AMPA receptor-mediated excitatory postsynaptic potentials (EPSPs) in most striatal neurons. With removal of magnesium block (i.e., by depolarization), an NMDA receptor-mediated component is also seen. Cortically evoked glutamate release can also activate metabotropic glutamate receptors, for which a variety of effects have been reported.

The main target of the corticostriatal projection is the dendritic spine of the striatal spiny neuron. Approximately 90% of all corticostriatal synapses are made onto dendritic spines. Cortical inputs make a higher proportion of their synapses on spines than do other inputs, including those from the thalamus, which are also glutamatergic and often end on spines. Overall, approximately 80% of all asymmetrical synapses with round synaptic vesicles (the type of synapse formed by the corticostriatal projection) are formed on spines. Some neurons in the striatum are not strongly excited by stimulation of the cerebral cortex. For example, the aspiny cholinergic interneurons have been reported to respond weakly or not at all to cortical stimuli that were very effective at exciting spiny projection neurons located nearby. Another class of aspiny interneuron, the parvalbumin-positive fast-spiking interneuron, is strongly excited by cortical stimulation. This cell receives fewer synapses of cortical origin than the spiny cells; its strong response is probably due to the high input resistance and greater excitability of this neuron.

The Thalamostriatal Pathway

Like the corticostriatal pathway, the thalamostriatal projection is actually at least two separate pathways. One thalamostriatal projection, arising from the intralaminar nuclei proper (e.g., the central lateral nucleus), makes synapses on dendritic spines of spiny neurons and strongly resembles the corticostriatal projection. The other, arising from the parafascicular nucleus and center median, makes asymmetrical synapses, but mostly on dendritic shafts rather than on dendritic spines. The physiological responses to these two pathways have not been studied in isolation, but stimulation of the thalamus *in vivo* generates EPSPs that strongly resemble those of the corticostriatal pathway. The magnitude of the thalamostriatal projection is often overlooked. The maximal EPSPs evoked by stimulation of the cortex or thalamus are approximately the same size, implying approximate parity in effect on striatal neurons. However, the thalamostriatal projection must arise from a much smaller number of cells, so the rules governing convergence of thalamic inputs must be much different. The functions of the intralaminar thalamic nuclei are obscure. It has been difficult to incorporate the thalamostriatal projection into theoretical ideas about the function of the basal ganglia, despite its physiological prominence.

The Nigrostriatal Pathway

Because of its apparent importance in a wide range of functional disorders, from Parkinson's disease to schizophrenia, more effort has been expended on understanding the physiological function of dopamine in the striatum than on any other aspect. After decades of work, it is clear that dopamine does not directly control ligand-gated ion channels, at least on the spiny neurons of the striatum, and does not directly generate a change in their membrane potential that can control firing rate. On the other hand, dopamine has been shown to affect many other aspects of striatal cell function, including efficacy of corticostriatal synapses, spike threshold, calcium entry and disposition in the cell, and corticostriatal (perhaps also thalamostriatal) synaptic plasticity. Thus, it is difficult to discern a pattern in dopamine's effects in the striatum. Most work has focused on three general categories of dopamine effects: modulation of voltage-sensitive ion channels, presynaptic effects on transmitter release, and effects on synaptic plasticity.

It has been well demonstrated that dopamine can alter the voltage sensitivity or maximal conductance

of a host of voltage-sensitive ion channels on projection cells and interneurons in the striatum. What is missing from this information is an organizing principle that can help us to understand the net effect of all the dopamine-mediated modulations. For example, dopamine alters the voltage sensitivity of inactivation of sodium channels in spiny cells, shifting the spike threshold in the positive direction. Through the D1 receptor, dopamine can enhance activation of the voltage-sensitive L-type calcium channels in spiny cells possessing this receptor, whereas D2 receptors on other spiny cells have an inhibitory effect on L channels. Likewise, dopamine has a host of effects on release of neurotransmitters and other modulators, but the net effect of these modulations does not immediately suggest a single function for dopamine in the circuit. Dopamine is a prerequisite for synaptic plasticity of glutamate synaptic potentials in the striatum, which complement theoretical studies showing that the firing of dopamine neurons is very similar to that predicted for a critical part of the reinforcement–learning process.

The Striatal Spiny Projection Cell

Spiny projection cells outnumber all other types of striatal neurons by approximately 20 to 1. They receive the vast majority of afferent synapses, and their axon collaterals are the largest source of intrinsic synapses in the striatum. They are also the source of the efferent fibers of the striatum. Thus, the striatal network can be said to consist of the spiny cells, their afferents, and their interconnections. The spiny neurons are recognized in extracellular recordings by their phasic firing patterns. They have a low rate of background activity, often remaining silent for minutes at a time in an animal that is sitting quietly, and fire in brief episodes of activity that may be related to events of a motor, sensory, or cognitive nature. In many studies, investigators have attempted to characterize the nature of the circumstances that give rise to responses of spiny cells. These studies have identified striatal spiny cells that respond in nearly any kind of motor, sensory, or cognitive task, but the responses of single neurons are very specifically related to some distinct aspect of a task. This is consistent with the view, described previously, that individual striatal spiny neurons respond to some specific set of combinations of cortical activity, but that the striatum as a whole can represent a wide spectrum of cortical activity states.

The responses of spiny neurons apparently reflect the convergent activity of large numbers of cortical and thalamic afferents. In the absence of strong synaptic input, the cells are deeply hyperpolarized because of the action of a hyperpolarization-activated potassium conductance (KIR) that holds the cell near the potassium equilibrium potential. It is this ion channel that is primarily responsible for the low level of background firing among spiny neurons and also for the low input resistance of the spiny cell. To activate the spiny cell, synaptic input must be strong enough to overcome the KIR current, which requires depolarizing the cell by 10–15 mV, at which point the potassium channel deactivates and the cell enters a high-input resistance state in which it is very sensitive to excitation. If depolarized further, an additional set of depolarization-activated potassium channels are activated, which oppose synaptic excitation. The combination of excitatory synaptic inputs and depolarization-activated K^+ current creates another high-conductance state at approximately −50 to −55 mV, near but still slightly negative to the action potential threshold. Thus, the striatal spiny neurons spend most of their time in one of the two high-conductance states – the hyperpolarized 'down' state when the level of excitatory input is too low to overcome the KIR current, and the more depolarized 'up' state during sustained excitation. In the up state, action potentials may be evoked by strong excitatory inputs that drive the cell the remaining few millivolts to the spike threshold. The existence of the up and down states is determined by ionic conductances known to be present in the spiny neuron membrane, but the pattern of transitions between the states reflects the pattern of convergent synaptic input to the cells. In locally anesthetized, immobilized rats, striatal neurons remain in the down state for many seconds or minutes, and they have up state transitions that may last for 0.1 to several seconds. In rats anesthetized with barbituates, up and down state transitions are rhythmic at 5–7 Hz, corresponding to the spindles seen in cortical and thalamic neurons, including those that form the corticostriatal input. In rats anesthetized with urethane, up and down state transitions are rhythmic at a much lower frequency of approximately 1 Hz or less, corresponding to the slow oscillations seen in the cortex and thalamus under these conditions.

The dependence of spiny cell membrane potential fluctuations and firing patterns on the pattern of inputs suggests that the striatal cell is not directly responsible for any of these oscillations. That is, the cell's membrane potential is not bistable but, rather, has a single stable state, the down state; the up state is a driven state that requires synaptic input for its maintenance. This is demonstrably so, at least in urethane-anesthetized animals and in slices of the striatum (Figure 1). When forced into the membrane

Figure 1 Physiological properties and synaptic responses of spiny projection neurons. (a) Spontaneous membrane potential fluctuations and firing *in vivo* (urethane anesthesia). Note the large membrane potential fluctuations between a hyperpolarized down state and a depolarized up state. Firing only occurs in the up state, but not every up state evokes action potentials. (b) Response to thalamic stimulation (arrow) in the up and down states. The EPSP is followed by a transition to the down state, followed 250–500 ms later by an up-state transition. Responses to cortical stimulation are similar (not shown). (c) Responses to a range of intensities of local stimulation in striatal slices. Note that cells in the slice are in the down state. Local stimulation produces an EPSP that is finely graded with stimulus intensity. (d) Responses to a graded series of constant current pulses. Note the low input resistance in the hyperpolarizing direction from rest (the down state) and increasing membrane resistance in the depolarizing direction. Firing is accompanied by a slow ramp depolarization and can occur arbitrarily late. (e) Current–voltage curve generated from the traces in (d). Note the strong inward rectification.

potential range of the up state by an experimentally applied input, spiny neurons in the down state return to the down state immediately upon removal of the depolarizing influence. However, the powerful voltage-dependent ion channels in the membrane of the spiny neuron shape the membrane potential response to excitatory and inhibitory inputs, and they impose a requirement for cooperation among the excitatory inputs from the cortex and thalamus. An excitatory input that arrives by itself in the down state is completely overcome by the hyperpolarizing influence of the KIR current. The same input arriving

in conjunction with other excitatory inputs that drive the cell into the low-conductance region between the states may be empowered to trigger an up-state transition or even and action potential.

How many extrinsic inputs are required to trigger an up-state transition or action potentials in a spiny neuron? Each spiny neuron receives approximately 10 000 excitatory axospinous inputs from the cerebral cortex and thalamus. Anatomical studies suggest that these arise from a nearly equal number of different cortical and thalamic neurons. Computer simulations and studies of explant cultures of the striatum suggest that the number of coincident inputs required to drive the spiny cell to the up state may be as low as 100–300. If that proves to be the case *in vivo*, then there may be a very large number of different cortical and thalamic input combinations that are equivalent in driving the spiny striatal cell. Each cell may not be searching for just one transcortical combination of inputs but, rather, a huge number of such combinations, that are considered equivalent by the spiny neuron. Alternatively, the large number of input combinations might be viewed as a list of possible cortical patterns from which the spiny neuron should select a correct set by the exercise of a synaptic learning rule that disables all the other combinations.

Striatal spiny neurons are GABAergic and inhibitory in their effects on their target structures in the globus pallidus and substantia nigra. Before exiting the striatum, the axons of spiny neurons give rise to axon collaterals that arborize in the general vicinity of the cells of origin, forming a dense plexus of locally derived inhibitory synapses. Many of the synapses formed by these spiny cell axons are made onto the dendrites and dendritic spine shafts of neighboring spiny cells. These mutually inhibitory synaptic connections among spiny neurons were originally proposed to be the cause of the low background firing pattern of the spiny cells. However, extracellular recording studies of the effects of local GABA blockade on firing patterns of spiny neurons showed that inhibition was not responsible for either the low background rate or the phasic firing pattern of the cells. Firing rates during the episodes of firing (probably corresponding to up states seen in intracellular recordings) were increased by blockade of all striatal $GABA_A$ receptors in the vicinity of the recorded cells. These observations and others suggest that collateral inhibition (and other GABAergic synaptic inhibition in the striatum) is more effective in controlling the firing rate and patterns of cells in the up state than in sculpting the temporal patterns of up and down states. Studies employing intracellularly recorded pairs of cells have shown that within a neighborhood corresponding roughly to the dendritic field of the cells, spiny cells have a very high level of connectivity; each cell makes a synapse on approximately one of every six of its neighbors and receives a synapse from approximately the same proportion. Reciprocally connected pairs are relatively rare. The connections among spiny cells are very weak when viewed from the soma, largely because of their distal location. Like the excitatory synapses on the spiny neuron (which are similarly distributed on the cells), the strength of the inhibitory synapses depends critically on the conductance state of the spiny cell.

Direct and Indirect Pathway

There are two types of spiny striatal neurons that can be distinguished by their axonal projections and by a number of cytochemical markers. The cell subtypes are named according to their axonal projections. The cells that form the direct pathway are those whose axons project directly to the basal ganglia output neurons of the globus pallidus internal segment and substantia nigra pars reticulata, as well as the external segment of globus pallidus. The indirect pathway spiny neurons project to the external segment of globus pallidus but do not connect directly to the output nuclei. These cells differ in their cotransmitters, with the direct pathway releasing substance P as well as GABA, whereas the indirect pathway neurons employ enkephalin and dynorphin as cotransmitters. They also differ in dopamine receptors, with the direct pathway expressing the D1 receptor and the indirect pathway expressing the D2 receptor. The two types of spiny cells are similar in their overall physiological properties, and both receive cortical and thalamic excitation. The axon collaterals of both types of neurons make synapses on both direct and indirect pathway cells. There are some differences in cortical innervation of direct and indirect pathway neurons, with collaterals of brain-stem-projecting cortical cells preferentially innervating indirect pathway neurons, whereas the collaterals of bilaterally projecting cells preferentially innervate the direct pathway cells. A number of questions have been posed based on the differential distribution of dopamine receptors on direct and indirect pathway spiny neurons. Generally, both direct and indirect pathway neurons respond to D1- and D2-dependent processes. For example, corticostriatal long-term depression is exhibited by all spiny neurons, but it depends critically on D1 dopamine receptors. Spiny cell responses to dopamine in such cases are primarily mediated by interneurons that possess both receptors.

Striosomes and Matrix

Another categorization of spiny neurons arises from the spatial compartmentalization of the striatum into striosomes (patches) and matrix. These compartments can be distinguished on the basis of cytochemical markers, such as calbindin (the expression of which is much higher in the matrix spiny cells) and μ opiate receptors (the expression of which is much higher in the neuropil of the striosomes). The corticostriatal innervations of striosomes and matrix are also different, with each following a separate topographical scheme. Both compartments contain direct and indirect pathway neurons, so there are four different kinds of spiny neurons. No physiological differences have been discovered between striosome and matrix cells, but the dendrites and axons of the spiny cells observe the boundaries of these compartments, so the local inhibition among spiny cells is restricted to their respective compartments. Striosome and matrix neurons have been reported to differ in their axonal projections, with direct pathway striosomal neurons projecting preferentially to the substantia nigra pars compacta.

The Cholinergic Interneuron

Extracellular recording studies of the striatum have always included a sample of cells that fire continuously, in contrast to the phasic firing pattern of the spiny cells. These cells, called tonically active neurons, also have unusual responses in behaving animals. Their responses are much less diverse than those of spiny neurons. They respond to sensory stimuli of high salience, including strong or meaningful unconditioned stimuli, or stimuli which have acquired a high salience by association. Their responses consist of a long-lasting interruption of their background firing, often flanked by preceding and subsequent moderate rate increases. Intracellular recording of cells firing in this pattern has revealed them to be large cholinergic interneurons, one of the best-known interneurons of the striatum (Figure 2). Although few in number, these cells have extremely dense axonal projections that provide the striatum with one of the densest cholinergic innervations in the brain.

The background firing of cholinergic interneurons is autonomous. When isolated from inputs, they fire at approximately the same rate as (although more rhythmically than) they do *in situ*. In slices, their firing is driven by a combination of a persistent sodium current that turns on at approximately -60 mV, action potential-triggered calcium influx through N-type calcium channels, and a calcium-dependent potassium current that repolarizes the cell after each action potential and delays the depolarization that leads to the next spike. A hyperpolarization-activated inward current (HCN) ensures that the cell will depolarize into the range of the persistent Na^+ current when the calcium-dependent potassium current ebbs sufficiently because of removal of calcium from the cytoplasm.

The cholinergic interneuron is also seen to fire in irregular and rhythmic bursting firing patterns, both in slices and *in situ*. Cholinergic interneurons have two different bursting mechanisms, which can both act at the same time. The first is an unusual mechanism consisting of a regenerative hyperpolarization that interrupts ongoing firing. This occurs because of a hyperpolarization-activated potassium current (KIR) that at some membrane potentials is strong enough to drive the cell membrane to a deeply hyperpolarized level. At the bottom of this hyperpolarization, a strong HCN current is activated and restores the membrane potential. This mechanism, which is basically a very slow hyperpolarizing spike, can lead to rhythmic bursting or can amplify hyperpolarizations that are triggered in other ways. One such source of hyperpolarizations is a slow afterhyperpolarization that occurs after a period of sustained depolarization (or a burst of action potentials). The slow afterhyperpolarization is caused by an unidentified calcium-dependent potassium current that is linked to L-type calcium current and calcium release from intracellular stores. Although strong depolarizations are not required to activate this hyperpolarizing current, prolonged depolarizations (longer than 20 ms) are required so the current is not triggered by the individual action potentials during single spiking. Cholinergic cells fire in either the single spiking or bursting patterns, depending on the relative strength of the mechanisms described previously. These mechanisms are sufficiently fluid that cholinergic cells can switch between firing patterns in a matter of seconds. The synaptic mechanism of the pause response in cholinergic interneurons is not understood, but some hints are available from the *in vivo* literature. *In vivo* studies have shown that an intact dopamine innervation and an intact thalamic input are required. However, the most interesting aspect of this response is its ability to be conditioned to nearly any stimulus that is used as a signal, and it is unknown how this occurs.

Like dopaminergic synapses, cholinergic synapses on spiny cells do not produce any strong ionic currents in spiny cells but act mainly through muscarinic receptors that activate G-proteins and have a wide variety of effects on voltage-sensitive channels, synaptic transmission, and synaptic plasticity. Effects on synaptic plasticity have received much attention because of the similarity between the responses of

Figure 2 Physiological properties and synaptic responses of the cholinergic striatal interneuron. (a) The range of spontaneous firing patterns seen in slices. (b) Responses to constant current pulses. Note the strong time-dependent inward rectification and rebound in response to hyperpolarizing pulses and the slow afterhyperpolarization following depolarizing pulses. (c) Response to local stimulation in slices (arrow). Two traces are superimposed, one showing the spontaneous firing of a rhythmic single spiking neuron and one in which excitation evoked by local stimulation occurs approximately half way between two spontaneous action potentials. Note that the effect of synaptic stimulation is not primarily to evoke or prevent action potentials but, rather, to change their timing. The action potential occurs long after the synaptic potential is over, but it occurs earlier than it would have if the EPSP had been absent. In spontaneously active neurons such as the cholinergic cell, synaptic inputs can interact with the oscillation to change spike timing rather than to directly drive firing.

dopaminergic and cholinergic cells to reward and reward-related cues. Acetylcholine acts on a variety of striatal targets in addition to the spiny cell. Its effects on dopaminergic axon terminals, mediated via nicotinic receptors, may be important for the well-known interaction between cholinergic and dopaminergic drugs. Its effects on the fast-spiking interneuron may also be indirectly influential on spiny cells and the output of the striatum.

Fast-Spiking Parvalbumin-Positive Interneuron

Another striatal interneuron is easily recognized anatomically because of its strong expression of the calcium-binding protein parvalbumin. These cells are GABAergic and make their synapses mainly on the somata and proximal dendrites of the spiny projection cells. Physiologically, they can be recognized by their brief action potentials and ability to fire at high rates with minimal spike frequency adaptation. Because of these properties, which they share with parvalbumin-positive neurons in other forebrain regions, they are usually called fast-spiking (FS) interneurons (Figure 3). FS neurons are not spontaneously active, and they are quiet when isolated from excitatory inputs, as occurs in slices. Like spiny neurons, they receive a strong cortical (and probably thalamic) innervation, which causes them to fire phasically *in vivo*. FS cells are the most likely candidates for the inhibition that controls spiny cell firing in the up state. Although the total number of FS GABAergic synapses received by each spiny cell is less than that of the Sp→Sp synapse, individual synapses from FS cells are much more powerful than those formed by other spiny cells, and each FS cell makes more synapses on any one spiny cell. There are many fewer FS cells; thus, when a single FS cell fires (as these cells readily

Figure 3 Physiological properties, synaptic responses, and synaptic effects of the fast-spiking (FS) striatal interneuron. (a) Spontaneous membrane potential fluctuations and firing of an FS neuron *in vivo* (urethane anesthesia). Phasic synaptic excitation of the FS cell gives rise to episodes of firing but not to distinct up and down states of the membrane potential. (b) Responses to a graded series of constant current pulses. Note the absence of strong rectification. (c) Response to strong depolarizing current includes episodic firing. (d) Synaptic responses to excitatory inputs. (Top trace) EPSP response to cortical stimulation *in vivo* (urethane anesthesia). (Bottom trace) Excitatory postsynaptic current evoked by local stimulation holding at −70 mV, superimposed on the response to the same stimulus after treatment with glutamate antagonists DNQX and APV. (e) Inhibitory postsynaptic current evoked in a striatal spiny neuron (top trace) by a single action potential in a nearby FS cell (bottom trace). The spiny neuron was loaded with chloride to move the reversal potential to 0 mV, and the spiny (Sp) cell was held at −70 mV.

do when corticostriatal inputs are active) it exerts a powerful effect on all spiny cells in its vicinity. FS cell axons do not extend over very large volumes of the striatum, so their influence can be spatially discrete. However, FS cells are interconnected by gap junctions that are likely to promote synchrony among those cells and which may sometimes allow for coordinated inhibition over large portions of the striatum.

Somatostatin/Nitric Oxide Synthetase-Containing Low-Threshold Spike Interneuron

The physiological properties of one other interneuron have been described. Like the other striatal interneurons, our knowledge of the low-threshold spike (LTS) neuron derives mostly from the studies of Kawaguchi and associates, who used immunochemical identification to establish the correspondence between physiological properties and the morphological and cytochemical cell types. Although they do not contain a high level of somatic GAD or GABA, the somatostatin-containing interneurons are GABAergic and make many of their synapses on the dendrites of spiny cells. The physiological properties of these cells are known only in outline. Their most striking feature is the presence of a large regenerative posthyperpolarization rebound (low-threshold spike) resembling that seen in thalamic relay neurons. At least some of these cells also demonstrate membrane bistability – that is, self-sustaining plateau potentials that can be triggered by depolarizations but long outlast the triggering stimulus. Like the FS cell, these neurons exert powerful inhibitory effects on spiny neurons within their axonal fields.

Conclusions

The striatum is fundamentally a feed-forward single-layer network consisting of the spiny neurons and their afferents. Because there are four categories of spiny neurons, the direct and indirect cells in the matrix and striosomes, the striatum should be considered as four such networks. The topographical arrangement of both cortical and thalamic afferents imposes a diversity of information on these striatal networks according to location within the striatum and also among cells at a given location. Cross-talk among spiny neurons is weak, and there are no long-range collaterals of spiny neurons, so the internal structure of the spiny cell network does not impose strong spatial intrinsic patterns on the output of the nucleus. Powerful feed-forward inhibitory interactions arise from the activity of GABAergic interneurons. Dopaminergic and cholinergic inputs act indirectly on the spiny cells, modulating synaptic plasticity and altering the excitability of inhibitory interneurons.

Stroke

D Leifer, Weill Cornell Medical College; and New York Presbyterian Hospital–Weill Cornell Medical Center, New York, NY, USA

Definition

Strokes are acute focal injuries to the brain that have a vascular cause and occur because of interruptions to the blood supply of the brain (ischemic strokes) or because of bleeding in or around the brain (hemorrhagic strokes). Approximately 85% of strokes are ischemic, and the others are hemorrhagic. Sometimes, the word stroke is used with a more limited definition that includes only ischemic events.

Epidemiology

Stroke is a major public health problem throughout the world. In the United States, there are more than 700 000 strokes per year. Stroke is the third leading cause of death after heart disease and cancer, and it is a leading cause of disability as well. Of those who survive a stroke, 90% have a deficit. Stroke is usually considered a disease of the elderly, and in the United States approximately two-thirds of strokes occur in people older than the age of 65 years, but strokes can occur at any age and their consequences in terms of lost productivity are even greater in younger patients than in older ones.

Stroke versus Transient Ischemic Attack

Strokes are distinguished from transient ischemic attacks (TIAs), which are traditionally defined as events that occur when there is a transient interruption of the blood supply to a part of the brain with focal deficits that resolve within 24 h. TIAs defined in this way were thought not to cause any permanent damage to the brain, but magnetic resonance imaging (MRI) with diffusion-weighted imaging has demonstrated that as many as half of all so-called TIAs are actually small strokes. Permanent damage is more likely the longer that symptoms persist. True TIAs that are not associated with any permanent damage mostly resolve within a few hours or less and may last for only a few minutes. A new definition of TIA has been proposed that classifies transient events with MRI evidence of damage as strokes.

In any case, the same processes that cause strokes also cause TIAs, and clinically, TIAs should be evaluated with the same rigor as strokes to identify their causes because there is a significant risk of a stroke after a TIA, especially within the first few days after the TIA.

Hemorrhagic Strokes

There are two major categories of hemorrhagic stroke: intracerebral hemorrhages within the brain and hemorrhages in the space around the brain. Intracerebral hemorrhages occur because of bleeding from small blood vessels within the brain, or less frequently from vascular malformations, in which there are tangles of abnormal blood vessels with direct connection from small arteries to veins. Small blood vessels may bleed because of chronic damage from hypertension or because they have been weakened by amyloid deposition, which is particularly a problem in elderly people older than approximately 80 years.

Intracerebral hemorrhage can also result from bleeding into an ischemic stroke. Such bleeding may be petechial in nature with only tiny patches of blood that are sometimes only visible at autopsy but can sometimes be seen on computerized tomography (CT) or MRI. Larger areas of hemorrhage are referred to as areas of hemorrhagic conversion, and even more extensive bleeding into an ischemic infarct may result in the formation of a cavity filled with blood (i.e., a hematoma) that can damage surrounding brain by compressing it.

Hemorrhages can also occur in the subarachnoid, subdural, or epidural spaces. Subarachnoid hemorrhages most commonly result from rupture of an aneurysm – a balloon-like protrusion from one of the main arteries around the base of the brain. Aneurysmal hemorrhages may recur with catastrophic or fatal bleeding within the first few days after an initial bleed, so rapid imaging to identify an aneurysm and then emergent treatment to obliterate the aneurysm are critically important. Aneurysms can be treated by surgically clipping the so-called neck that connects them to the artery from which they arise or by angiographic procedures in which they are filled with tiny metal coils delivered through a special catheter threaded into the artery. In addition to repeat bleeding, aneurysmal hemorrhages can also lead to vasospasm that causes constriction of arteries primarily near the skull base and may lead to ischemic strokes. Vasospasm is treated by aggressive hydration and the use of vasopressor drugs that elevate blood pressure to improve perfusion through the constricted arteries. Sometimes, it is also treated by intra-arterial vasodilating drugs or by angioplasty.

Subarachnoid hemorrhage can also occur spontaneously in the absence of an aneurysm; such hemorrhages may be venous in origin, are typically perimesencephalic in location, and have a benign prognosis. Subarachnoid hemorrhage can also occur if a parenchymal hemorrhage ruptures through the surface of the brain or if there is head trauma.

Bleeding may also occur into the subdural and epidural spaces. Bleeding into these spaces usually results from trauma, in which case it is usually not considered a stroke, but is occasionally spontaneous. These types of hemorrhage often require surgical drainage.

Treatment of acute hemorrhages involves the use of medications to reverse any abnormal bleeding tendency and to reduce reactive swelling around the hemorrhage, when appropriate, and surgical drainage or resection if the hemorrhage excessively compresses adjacent parts of the brain.

Ischemic Strokes

Approximately 85% of strokes are ischemic. Ischemic strokes are the focus of the remainder of this article. Several different mechanisms lead to the interruptions in blood flow that cause ischemic strokes.

Arteries that supply the brain may become blocked because of atherosclerotic plaques in which cholesterol is deposited. These plaques gradually narrow the artery. Often, blood clots form on top of the plaque and may completely close off the artery. In addition, these clots may break off (or, in other words, embolize) and travel into smaller arteries until they ultimately lodge in an artery that is too small for them to go any further.

Cholesterol deposition can also occur in small arterioles and leads to progressive narrowing with lipohyalinosis, in which there is not only formation of lipid clefts in the vessel walls but also hyalinosis, which may reflect chronic stresses to the vessel from hypertension.

Arteries may also become blocked if a clot forms in the heart and travels through the great vessels and then into progressively smaller arteries until it lodges in one that is too small for it to pass through. The most common cause for clot to form in the heart is atrial fibrillation, an arrhythmia in which the atria do not contract normally. Left ventricular thrombus, which forms when parts of the heart do not contract properly, for example, after a myocardial infarction, can also embolize and cause a stroke. In addition, in patients who have endocarditis, an infection of the heart valves, infected material or vegetations can develop on the valves and can also embolize to cause a stroke.

Uncommon Causes of Ischemic Stroke

Atherothrombotic and cardioembolic mechanisms are by far the most important causes of stroke, but several other causes of stroke, although rare, are worth noting.
