Strokes are also caused by vasculitis with inflammation that is limited to the cerebral circulation in primary central nervous system (CNS) vasculitis or that is part of a systemic vasculitis. CNS vasculitis was originally defined in 1959. Pathologically, there are mononuclear infiltrates and fibrinoid necrosis of small leptomeningeal and parenchymal vessels. Granulomas are present in approximately 85% of patients. It is rare, with an incidence of less than 1:2 million. Headache is the most common presenting feature and is present in two-thirds of patients. Patients may also present with a diffuse encephalopathy and, less frequently, with a focal stroke. The diagnosis should particularly be considered when a patient presents stroke on a background of encephalopathy.

There is typically some lymphocytic pleocytosis and often an elevated cerebrospinal fluid (CSF) protein, but the CSF may be normal. CNS vasculitis is sometimes associated with infections, including mycoplasma, varicella-zoster, arboviruses, HIV, fungal, syphilis, and Lyme disease. It is also sometimes associated with lymphoma, malignant histiocytosis, and hairy cell leukemia.

CNS vasculitis may also be part of a systemic vasculitis, such as polyarteritis nodosa, Churg–Strauss syndrome, Wegener's granulomatosis, giant cell arteritis, hypersensitivity vasculitis, Behest's disease, systemic lupus erythematosus, Sjogren's syndrome, sarcoidosis, rheumatoid arthritis, scleroderma, mixed connective tissue disease, dermatomyositis, ulcerative colitis, and celiac disease.

Other strokes may be caused by paradoxical emboli that form in leg veins or in pelvic veins and travel through a patent foramen ovale or through a pulmonary arteriovenous malformation.

Strokes can also be caused by arterial dissection, in which the inner part of the arterial wall lifts up like a flap from the outer wall. The flap may occlude the artery or clot may form between the flap and the exposed inner surface of the outer wall, and pieces of this clot may embolize to block more distal arteries. Dissections of the carotid or vertebral arteries are the most likely to cause stroke, but aortic dissections can also cause stroke if they extend into origins of the carotids or vertebrals or if embolization occurs. In addition, dissections can also involve the large intracranial vessels. Dissections are often caused by trauma, although for some patients no definite precipitant can be identified. Certain connective tissue abnormalities, particularly Ehlers–Danlos syndrome

type IV and Marfan's syndrome, are associated with an increased risk of dissection. Dissections often heal with antithrombotic therapy, and the dissected artery may return to having normal or nearly normal flow as the flap reattaches to the outer wall.

Although most ischemic strokes result from a blocked artery, thrombosis of cerebral veins or sinuses can occasionally lead to a stroke. Such thromboses are more common in people who are hypercoagulable – that is, those who have an underlying tendency of the blood to clot excessively. Hypercoagulability may contribute to arterial strokes, but it seems to be more important in venous strokes.

Among the factors that are usually tested when hypercoagulability is searched for are anti-cardiolipin antibodies, PTT, protein C, protein S, factor V Leiden, and antithrombin III. There are also tendencies toward hypercoagulability late in pregnancy, in the postpartum period, and in association with systemic malignancy.

Despite intensive evaluation to classify ischemic strokes into one of these groups, it is not possible to assign every stroke to one of the categories, and most studies find that the cause cannot be identified definitively for approximately 30% of patients. As more potential risk factors are identified, it is anticipated that the number of cryptogenic strokes will decrease.

Stroke Syndromes

The symptoms that a stroke causes depends on its location in the brain. The most common finding in stroke is weakness on one side of the body. Weakness may involve the face, arm, or leg separately or in combination. For example, strokes affecting the portion of the posterior frontal primary motor cortex in the middle cerebral artery territory preferentially cause weakness of the face and arm and, to a lesser extent, weakness of the leg, which is sometimes spared entirely. In contrast, strokes involving the anterior cerebral artery preferentially affect the leg, and strokes that damage the internal capsule or pons where all motor fibers are close together tend to involve the face, arm, and leg equally.

Strokes affecting the language areas, which are in the frontal, temporal, and parietal regions around the Sylvian fissure and are usually in the left hemisphere, produce different forms of aphasia. Strokes affecting the corresponding areas in the right hemisphere tend to produce problems with attention and left-sided neglect. Strokes affecting the occipital cortex and the optic radiations produce partial or complete visual field defects. Strokes affecting the cerebellum and the fibers connecting with it tend to produce ataxia. Similar ataxia sometimes also results from damage to sensory areas in the parietal lobe. Double vision occurs in strokes that affect the brain stem. Slurred speech and swallowing difficulties are common after strokes in many areas of the brain.

Imaging Evaluation of Stroke

The initial tool of evaluation of stroke patients is CT scan. CT does not generally provide as much detail as MRI, but it is faster than MRI and generally more accessible. It is easier to monitor patients during a CT scan than during an MRI. The main disadvantage of CT is that acute strokes are generally not visualized and may not become visible until the infarcted tissue becomes sufficiently edematous or necrotic, and some small strokes are never seen on CT. In contrast, MRI is extremely sensitive for small acute strokes when diffusion-weighted imaging is used, which can detect acute strokes within 1 h from onset.

CT and MRI can also be used to visualize the arterial supply of the brain from the aortic arch to the second- or third-order branches inside the skull in procedures known as CT angiography (CTA) and MR angiography (MRA). These tests help to identify any fixed stenoses that may have caused the patient's stroke and may put the patient at risk for another stroke.

Carotid ultrasound and transcranial Doppler tests are also used to assess blood flow in the arteries that supply the brain. They provide information that complements the results of CTA or MRA.

It is also important to search for cardiac causes of stroke. In this regard, most stroke and TIA patients are studied by transthoracic echocardiography to search for intracardiac thrombus, to assess left ventricular function, and to search for valvular abnormalities. Telemetry or Holter monitoring are used mainly to search for atrial fibrillation, which is the leading cause of cardioembolic stroke, but also to monitor for other arrhythmias because many stroke patients also have cardiac disease.

Laboratory Evaluation of Stroke

Blood tests that are important specifically for risk factor evaluation include a fasting lipid panel and fasting glucose. Hemoglobin A1c levels, which measure the glycosylation of hemoglobin and provide a measure of the average blood glucose over the approximately 60-day half-life of red blood cells, may also be advisable in some patients with diabetes mellitus or suspected diabetes. Blood cell counts are also important because extremely high red cell counts may make blood viscous and predispose to thrombus formation. Elevated platelet counts

may also lead to increased risk of thrombosis. Coagulation parameters are also assessed routinely in stroke patients.

Acute Ischemic Stroke Treatment

The only approved treatment for acute stroke in the United States is intravenous tissue plasminogen activator (TPA), also known as alteplase. It is approved for use within the first 3 h after the patient was last known to be at baseline. A study sponsored by the National Institutes of Health demonstrated that 34% of patients treated with TPA had excellent outcomes compared to only 21% of control patients ($p < 0.002$). The benefits come with an increased risk of hemorrhage. A total of 6.4% of TPA-treated patients had a symptomatic intracerebral hemorrhage within the first 36 h compared to only 0.6% of the control patients ($p < 0.001$); however many of these hemorrhages occur in patients with large strokes who would do poorly.

Other options for acute treatment of stroke are available at specialized centers. Intra-arterial delivery of thrombolytic drugs such as TPA can sometimes dissolve clots that are resistant to intravenous TPA, and this is used for patients who have not responded to intravenous TPA or are outside of the 3 h window but still within 6 h from the time when they were last normal.

Sometimes, special corkscrew-like catheters can be inserted into a blocked artery and used to pull the clot out. These devices are used up to approximately 8 h after onset. Another intra-arterial option for opening occluded or stenotic arteries is angioplasty, which is usually followed by stenting.

At many centers, decisions to proceed with intra-arterial procedures are made only after MRA and CTA, and frequently these studies are performed in combination with perfusion imaging to measure delivery of blood to the brain parenchyma. Perfusion studies can identify tissue that is at risk but not yet infracted. Development of algorithms to use perfusion and other imaging data to identify those most likely to benefit from intra-arterial procedures is the subject of ongoing research.

Another option for patients who are not eligible for intravenous thrombolysis or for intra-arterial procedures is the use of hypertensive therapy. Its rationale derives from the existence of tissue at risk in the periphery of an infarct. The goal is to improve perfusion of this tissue by raising blood pressure with hydration and/or pressers. Anecdotal evidence suggests that this approach can stabilize patients with fluctuating deficits that worsen when blood pressure is lower.

In addition, some very large strokes may produce dangerous amounts of swelling that compress adjacent parts of the brain and necessitate surgical decompression.

Neuroprotection for Acute Ischemic Stroke

Numerous drugs have been found to reduce the size of acute ischemic strokes in animals by so-called neuroprotectant mechanisms that interfere with the generation of toxins as a result of the initial ischemic injury. The basic premise behind neuroprotection is that ischemia leads to a cascade of events that results in increases in intracellular calcium, which triggers the release of excitatory neurotransmitters that in turn lead to generation of more intracellular calcium. Increases in intracellular calcium lead to generation of free radicals and activation of proteases and lipases that cause additional damage. The processes of necrosis and apoptosis (programmed cell death) are triggered and lead to damage to additional cells.

Unfortunately, a growing list of clinical trials have failed to demonstrate any benefit for stroke patients from neuroprotectants. There are several possible reasons for this failure. Some trials have had overly long windows for treatment so that patients had already suffered too much irreversible damage for the drugs to work. In addition, human strokes are heterogeneous and may not all respond to the same neuroprotectants, but trials have generally included all types of stroke; for example, patients with strokes primarily involving white matter have been included in trials of drugs acting at synapses in gray matter structures. In addition, most drugs have been tested only in rodents with small brains, which may differ in important ways from the human brain. Also, studies have included patients with severe deficits who simply may have had too much damage to be helped by any treatment and other patients with mild deficits who recover too well without treatment for an effect to be detectable. Additional trials with other neuroprotectants are still in progress, and their designs have been modified because of the experiences with previous unsuccessful trials.

Secondary Prevention of Ischemic Stroke

After the acute event, one major goal of treatment is to reduce the risk of recurrent stroke and other ischemic events. The main therapeutic approaches are antithrombotic drugs and treatment of risk factors that increase stroke risk. With regard to antithrombotic

therapy, the two options are anticoagulation – usually with warfarin – and antiplatelet therapy. Numerous studies have shown that warfarin is the treatment of choice in patients who have atrial fibrillation. Other cardiac sources of emboli are sometimes also treated with warfarin. For other stroke patients, antiplatelet therapy is used. The Warfarin–Aspirin Recurrent Stroke Study showed several years ago that warfarin is not better than aspirin for stroke patients who do not have a definite cardioembolic explanation for their symptoms, and there is a significant increase in the rate of bleeding with warfarin.

Options for antiplatelet therapy include aspirin at doses of 81–325 mg day^{-1}, clopidogrel 75 mg day^{-1}, and the combination of aspirin 25 mg and dipyridamole combination 200 mg twice daily. Clinical trial data suggest that the aspirin/dipyridamole significantly reduces stroke risk compared to aspirin alone. There is also evidence that clopidogrel is slightly more effective than aspirin. An ongoing trial is comparing the combination of aspirin and dipyridamole to clopidogrel. Currently, there is no solid data to rely on in choosing among these alternatives.

The other important issue in stroke prevention is rigorous control of risk factors. Hypertension, hyperlipidemia, and diabetes mellitus need to be treated aggressively, and patients who smoke must be counseled about techniques for smoking cessation. Throughout the years, the goals of therapy have been progressively tightened. Systolic blood pressures below 160 were once considered acceptable; the usual standard now accepts blood pressures below 140/90, but there is evidence that especially for diabetic patients, there is added benefit in getting the pressure below 130/80, and systolic pressures below 120 may confer additional protection. Similarly, the target for low-density lipoprotein (LDL) cholesterol has been lowered; in recent years, guidelines have suggested keeping the LDL below 130, but data suggest a target of 100 for patients with significant atherosclerosis, including many stroke patients, and there is evidence from the coronary literature that plaque may actually regress if the LDL is below 70.

Rehabilitation after Stroke

Another goal of treatment after stroke is optimization of recovery. In this regard, the first step is the prevention of medical complications, such as infection, deep venous thrombosis, and bedsores. Intervention by trained therapists can help to reduce the risk of these problems and also help to maximize recovery of function. Depending on the deficits of stroke patients, they may need physical and occupational therapy, speech therapy, and swallowing therapy. Rehabilitation has long been thought to benefit stroke patients by helping them to regain strength and learn to compensate for their deficits, but until recently there has been little scientific foundation for rehabilitation.

Some justification for rehabilitation therapy comes from functional imaging studies that have visualized changes in brain activity as patients recover from a stroke. Additional areas that are not normally used for simple motor and language tasks are activated in stroke patients. In some cases, activity patterns tend to return more toward normal as patients recover. These changes in neuronal activity over time suggest that even the adult brain has some degree of plasticity and they provide motivation for developing therapeutic modalities that enhance recovery.

One promising approach is constraint-induced therapy, in which patients who are partially paralyzed on one side receive intensive physical therapy for the affected arm while the unaffected arm is immobilized to force them to use the affected limb more. Another new approach is the use of robotic devices that can guide a weakened limb in practice sessions. This may aid in recovery by helping to teach the movement to a patient in a different way from the help that a therapist gives and also by simply providing more repetitions of a task than therapists have time to do in standard therapy.

Current research is also investigating the role of stimulant drugs in promoting recovery when given prior to therapy sessions. Such drugs are being studied clinically and in experimental models of stroke. Growth factors that may enhance formation of new neuronal connections are also being studied in experimental models.

Finally, ongoing research is also studying electrical stimulation of the brain with implanted electrodes or with scalp electrodes as an adjuvant to physical therapy.

Introduction

Stroke is a clinical syndrome of sudden-onset neurological deficits resulting from vascular etiology. Ischemic stroke accounts for 80% of all strokes; hemorrhagic stroke accounts for the remaining 20%. Brain injury after stroke results from sudden cessation of blood flow, leading to impaired delivery of oxygen, glucose, and other nutrients to brain cells, triggering a cascade of ultimately lethal cellular events.

Several mechanisms of stroke-induced cell death have been delineated, the most important of which include glutamate excitotoxicity, acidotoxicity, oxidative/nitrative stress, apoptosis, inflammation, and peri-infarct depolarization. These fundamental pathways are interdependent, overlapping, and evolve over minutes, hours, or days to mediate injury in neuronal cells, glial cells, and vascular structures. The individual contribution of individual mechanisms toward the net stroke-related injury (Figure 1) is dependent on the degree and duration of ischemia, the timing of reperfusion, the type of brain tissue affected, physiological variables such as brain temperature, and genetic influences. For example, excitotoxicity has a dominant role in the 'core' of the ischemic territory where the reduction in blood flow is severe (less than 20% of baseline, typically 10–12 ml $100\,g^{-1}\,min^{-2}$). In peripheral zones termed the 'ischemic penumbra,' where the blood flow reduction is abnormal but not as severe (20–60 ml $100\,g^{-1}min^{-2}$), cell death occurs relatively slowly via mechanisms such as inflammation, apoptosis, and peri-infarct depolarization. In these penumbral regions, brain electrical activity ceases, but the cells remain viable for an extended time period, constituting a target for stroke therapy.

In addition to the severity of ischemia, stroke-related injury is dependent on the type of brain tissue involved. Gray matter and white matter have different susceptibilities to ischemic injury. Among neurons, CA1 hippocampal pyramidal neurons, cortical projection neurons in layer 3, neurons in dorsolateral striatum, and cerebellar Purkinje cells are particularly susceptible. Among cell types comprising the white matter, oligodendrocytes are more vulnerable than are astroglial or endothelial cells. White-matter ischemia is typically severe, with rapid cell swelling and tissue edema because there is little collateral blood supply in deep white matter. Cell death mechanisms such as excitotoxicity have a different pathophysiology in white-matter ischemia, as compared to gray-matter ischemia. It is important to note that 'global' cerebral ischemia (which occurs after cardiac arrest) and 'focal' cerebral ischemia (which occurs due to thrombosis or embolism to a brain artery) result in different histological and behavioral outcomes and have different molecular mechanisms and treatments.

While restoration of blood flow can salvage penumbral brain regions, pharmacological interruption of one or more pathways of cell death can also mitigate stroke-related brain injury. Indeed, a major goal of uncovering pathways of cellular injury is to uncover targets for treatment. Numerous drugs have proved effective in reducing infarct size and functional deficits in animal stroke models. Although no neuroprotective drug to date has proved efficacious in humans, much knowledge has been gained. There is now a better understanding of factors such as the therapeutic time window and optimal patient selection, which are critical for success. Rapid advances in neuroimaging have made it possible to estimate the degree of ischemia and quantify penumbral tissue within minutes after symptom onset. These advances raise hope that successful stroke neuroprotection is imminent. In the following sections we review the major mechanisms of neuronal injury after stroke, emphasizing targets for intervention.

Excitotoxicity and Ionic Imbalance

Glutamate, the main excitatory neurotransmitter, promotes the activity of virtually every neuron within the brain and spinal cord. It is synthesized within neurons, stored in presynaptic vesicles, released in a calcium-dependent manner to bind with specific receptors, and inactivated after release by high-affinity reuptake mechanisms. Glutamate flux is tightly regulated by its receptors and transporters. There are two categories of glutamate receptors: ionotropic *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxalleprionate (AMPA), and kainate receptors, and metabotropic glutamate receptors (mGluRs). In the context of stroke-related injury, NMDAR and AMPAR activation mechanisms have been extensively studied.

Stroke-induced reductions in oxygen and glucose supply lead to the failure of energy-dependent processes such as that involving Na^+, K^+-ATPase,

Figure 1 Contribution of individual mechanisms toward the net stroke-related injury.

processes which normally maintain cellular homeostasis. This causes an abrupt cessation in the exchange of Na^+, K^+, and other ions across cell membranes; release of excitatory neurotransmitters such as glutamate; and inhibition of glutamate-reuptake mechanisms. Excessive glutamate binding to ionotropic NMDA and AMPA receptors promotes the deleterious influx of calcium into the cytoplasm and mitochondria, with activation of downstream phospholipases and proteases that degrade membranes and proteins.

Ca^{2+} influx leads to activation of intracellular proteases such as calpains, which are involved in pro-death pathways such as those involving free radical-mediated mitochondrial damage, activation of Bad and subsequent release of cytochrome *c*, and cleavage of the Na^+/Ca^{2+} exchanger, leading to further Ca^{2+} influx. Calpains activate several caspases that in turn promote apoptosis, demonstrating the overlap between excitotoxic and apoptotic cell death mechanisms. Glutamate excitotoxicity and calcium influx also directly or indirectly influence intracellular signaling pathways. Three mitogen-activated protein kinase (MAPK) signaling pathways have been characterized: the extracellular signal-related kinase (ERK) MAPK pathway, the p38 MAPK pathway, and the c-jun N-terminal kinase (JNK) MAPK pathway. Growth factors, cytokines, and free radicals released after stroke all stimulate the MAPK pathways, providing further evidence for the overlap between the different fundamental pathways. ERK pathway activation is known to be neuroprotective; however, emerging data show that the ERK pathway is involved in mitochondrial cytochrome *c* release, activates caspase-3, and interacts with mGluRs to make them more susceptible to excitotoxic injury.

Because the endoplasmic reticulum (ER) participates in redistributing Ca^{2+} ions within the cells, Ca^{2+} influx also contributes to ER stress, which further exacerbates cell death. With regard to the mitochondria, Ca^{2+} overload leads to the opening of the nonspecific mitochondrial permeability transition pore, which allows protons and other small molecules to cross the mitochondrial membrane, resulting in ATP depletion and cell death via necrosis or apoptosis. Whether necrosis or apoptosis dominates is determined by the duration of pore opening. If the pore reseals quickly, ATP production may be rescued, resulting in apoptotic death via cytochrome *c* release rather than necrotic cell death. In addition to the aforementioned processes, glutamate-dependent processes include the activation of transcription factors cAMP response element-binding protein (CREB) and nuclear factor-kappa B (NF-κB), trophic factor signaling, and regulation of Bcl-2. Ionotropic glutamate receptors also promote ionic homeostasis perturbations that play a critical role in cerebral ischemia. Glutamate receptor activation is not uniformly deleterious, since different subtypes of receptors have prosurvival and proapoptotic effects. As explained next, this leads to a new level of complexity in finding suitable pharmaceutical agents for stroke.

Pharmaceutical agents that block the glutamate, NMDA, AMPA, and metabotropic subfamily receptors have been shown to attenuate infarct volumes in animal stroke models. However, these approaches were effective within a narrow 1 h time window, and a short therapeutic time window might explain the failure of several glutamate antagonists to show efficacy in clinical trials. Drugs that have failed clinical testing include lubeluzole, the competitive NMDA-antagonist selfotel, and several noncompetitive NMDA antagonists (dextrorphan, gavestinel, aptiganel, and eliprodil). The failure of these drugs is also attributable to drug toxicity, possibly due to inhibition of excitatory neurotransmission, and the fact that the NMDA receptor has variable functions depending on its location (synaptic or extrasynaptic), so that nonselective blockade of NMDA receptors may not be fruitful. For example, the activation of synaptic NMDA receptors promotes cell survival via mechanisms such as inactivation of the proapoptotic protein Bad, and the activation of CREB and expression of its target genes such as brain-derived

neurotrophic factor (BDNF). Activation of extrasynaptic NMDA receptors causes inactivation of the CREB pathway and counters the increase in BDNF expression, leading to a proapoptotic effect. Therefore, the challenge for the future is to uncouple the essential excitatory neurotransmitter functions from deleterious effects – for example, by blocking downstream neurotoxic signaling pathways without blocking the receptors.

Acidotoxicity

As compared to cell types in other organs, neurons are more vulnerable to ischemic injury. Experimental research has shown that the metabolic acidosis accompanying stroke can exacerbate neuronal death via excitotoxic mechanisms that are distinct from glutamate- and Ca^{2+}-mediated excitotoxicity. Neuronal acid-sensing ion channels (ASICs) have recently been characterized in the brain as ligand-gated channels belonging to the epithelial Na^{+} channel superfamily. ASICs have at least six subunits, which form voltage-insensitive, amiloride-sensitive channels on the surface membrane. In contrast to other neurotransmitter-receptor channels that are inactivated with acidosis, these multimeric channels become activated when pH falls below 7.0, and their activation is half-maximum at a pH of 6.2, which is consistently achieved within ischemic regions. ASIC activation is also increased by arachidonic acid and lactic acid production, as well as membrane stretching and decreased extracellular Ca^{2+} (all processes that routinely occur after stroke). The major role of ASICs is to gate amiloride-sensitive Na^{+} currents. However, some subunits facilitate a glutamate-independent influx of Ca^{2+} in the presence of acidosis. In experiments utilizing cell culture, patch clamp, and *in vivo* rodent stroke models, the tarantula toxin PcTX1 (an ASIC1a-specific antagonist) and amiloride have been shown to inhibit excitotoxic Ca^{2+} currents via the ASIC1a ligand-gated ion channel. Moreover, ASIC1a channel inhibition has been documented to decrease infarct volumes by over 60%, acid-mediated toxicity is shown to be absent in mice lacking the ASIC1 gene, and ASIC transfected cells show increases in intracellular Ca^{2+} following acidosis. These and other data indicate that ASIC1 causes a significant acid-dependent increase in excitotoxic cell death and that the ASIC1a subunit represents a promising stroke therapeutic target.

Apoptosis

Apoptosis is an evolutionarily conserved process of programmed cell death. It is characterized histologically by nuclear and cytoplasmic condensation, nuclear fragmentation, and cell shrinkage. Apoptotic cells are terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL)-positive cells that exhibit DNA laddering. Cell type, age, and brain location render them more or less resistant to apoptosis or necrosis. Since apoptotic pathways require energy in the form of ATP, apoptosis predominantly occurs in the ischemic penumbra that sustains milder injury, rather than in the core, where ATP levels are rapidly depleted. Nevertheless, ionic imbalances can also trigger apoptosis under certain conditions, suggesting a close mechanistic interrelationship between glutamate-mediated excitotoxicity and apoptosis. The normal human brain expresses caspases 1, 3, 8, and 9, apoptosis protease-activating factor-1 (APAF-1), death receptors, P53, and a number of Bcl-2 family members, all of which are implicated in apoptosis.

Caspases are protein-cleaving enzymes (zymogens) that belong to a family of cysteine aspartases constitutively expressed in adult and newborn brain cells, particularly neurons. Apoptosis occurs via caspase-dependent as well as caspase-independent mechanisms. Caspases are sequentially cleaved and activated via two pathways: an extrinsic pathway dependent on death receptors, and an intrinsic mitochondrial pathway. With regard to the extrinsic pathway, several apoptotic triggers of have been identified. These include oxygen free radicals, Bid cleavage, death receptor ligation, DNA damage, and lysosomal protease activation. The tumor necrosis factor (TNF) superfamily of death receptors, most importantly Fas, powerfully regulates upstream caspase processes. Emerging data suggest that the cell nucleus is involved in releasing signals for apoptosis, and that the mitochondrion plays a central role in mediating apoptosis. At least four mitochondrial molecules mediate downstream cell death pathways: cytochrome *c*, secondary mitochondria-derived activator of caspase (Smac/Diablo), apoptosis-inducing factor (AIF), and endonuclease G. While cytochrome *c* and Smac/Diablo mediate caspase-dependent apoptosis, AIF and endonuclease G mediate caspase-independent apoptosis. Cytochrome *c* binds to Apaf-1, which combines with procaspase 9 to form the 'apoptosome' that activates caspase 9 in the presence of dATP. In turn, caspase 9 activates caspase 3. It is important to note that formation of the apoptosome complex is inhibited by Bcl-2, which becomes upregulated very early after stroke. Smac/Diablo binds to inhibitors of activated caspases and causes further caspase activation. After activation, caspases 3 and 7 (the executioner caspases) attack and degrade various substrate proteins, ultimately leading to DNA fragmentation and irreversible cell death. Over 30

proteins can be cleaved, including the DNA-repairing enzyme poly(ADP-ribose) polymerase (PARP), the cytoskeletal protein gelsolin, actin, presenilins, and other caspases. Caspase 3, the most prominent cysteine protease, is present in the infarct core as well as in the penumbra and is cleaved acutely after stroke. Subsequent caspase cleavage occurring after hours or days leads to delayed cell death.

Caspase-independent apoptosis has been shown to develop in cultured neurons by NMDA-receptor induced activation of PARP-1, and in fibroblasts exposed to oxidative stress. AIF is implicated as a key molecule in this cascade. AIF is released from mitochondria after PARP-1 activation, then relocates to the nucleus, where it binds DNA, promotes chromatin condensation, and leads to cell death via incompletely understood mechanisms. The exact significance of caspase-independent apoptosis remains to be determined.

Overexpression of Bcl-2, deletions of genes for Bid or caspase-3, and the use of caspase-3 inhibitors, peptide inhibitors, and antisense oligonucleotides that suppress the expression and activity of apoptosis-promoting genes have been shown to reduce infarct volume or decrease neurological deficits after stroke. A single intracerebroventricular injection of zDEVD-FMK, a relatively selective caspase-3 inhibitor, is shown to be neuroprotective when administered up to 9 h after transient focal stroke. However, caspase inhibitors do not reduce infarct size in all brain ischemia models. This variable effect may be attributable to different severities of ischemia, to limited potency or inability of caspase inhibitors to cross the blood–brain barrier, to the relatively minor impact of apoptosis as compared to excitotoxicity or other mechanisms on stroke outcome, and to upregulation of caspase-independent or redundant cell death pathways.

Oxidative and Nitrosamine Stress

Free radicals subserve an important role in virtually all fundamental cell death pathways. Under resting conditions, mitochondria produce reactive oxygen species, such as superoxide and hydroxyl radicals, during electron transport. Oxidative and nitrosamine stresses are routinely modulated by endogenous antioxidant enzyme systems such as superoxide dismutase (SOD) and the nitric oxide synthase (NOS) family. Moreover, toxic free radicals are normally scavenged by SOD, catalane, and glutathione (GSH), and antioxidant vitamins (e.g., α-tocopherol and ascorbic acid). Ischemia-induced accumulation of intracellular Ca^{2+}, Na^{+}, and ADP stimulates excessive mitochondrial oxygen free radical production, which overwhelms endogenous scavenging mechanisms. Reoxygenation during reperfusion provides large amounts of oxygen as a substrate for numerous enzymatic oxidation reactions in the cytosolic compartments, subcellular organelles, and mitochondria. There is a burst of oxygen free radicals from enzymatic conversions, including the cyclooxygenase-dependent conversion of arachidonic acid to prostanoids and degradation of hypoxanthine, the superoxide-mediated reduction of iron, and the generation of nitric oxide. Substantial amounts of free radicals are also generated during the inflammatory response after ischemia.

Oxygen radicals and oxidative stress facilitate mitochondrial transition pore (MTP) formation, which dissipates the proton-motive force required for oxidative phosphorylation and ATP generation. As a result, mitochondria release apoptosis-related proteins and other constituents within the inner and outer mitochondrial membranes. Free radical-mediated mechanisms signal the release of mitochondrial cytochrome *c* by mechanisms probably related to Bcl-2 and translocation of Bax. After its release, cytochrome *c* binds to Apaf-1 followed by caspase-9 to form the apoptosome complex that subsequently activates caspase-3 and other caspases. Activated caspase-3 goes on to cleave several nuclear DNA repair enzymes, culminating in apoptosis. Another major signaling pathway of oxygen radicals involves NF-κB, an important transcription factor. NF-κB activation results in its translocation into the nucleus and binding to the NF-κB site of inducible genes such as cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (iNOS), matrix metalloproteinases (MMPs), intercellular adhesion molecules (ICAM-1), and cytokines. Furthermore, after ischemia, the activation of NMDA receptors and formation of oxygen free radicals and nitric oxide by neuronal nitric oxide directly signal the mitochondrial release of cytochrome *c* or formation of peroxynitrite. Subsequent hydroxyl radical production results in lipid peroxidation and directly damages proteins, carbohydrates, and DNA, ultimately leading to necrotic cell death.

The significant contribution of free radical-mediated injury is apparent from studies showing reduced stroke-related tissue injury in mice overexpressing SOD, and in mice with reduced expression of the neuronal and inducible NOS isoforms. Treatment with free radical scavengers such as *N-tert*-butyl-α-phenylnitrone (α-PBN) is also shown to attenuate stroke-related injury. However, in clinical trials, free radical scavengers such as NXY-059 have failed to show any benefit.

Inflammation

Inflammation is intricately related to atherosclerosis and stroke onset, as well as subsequent stroke-related tissue damage. Elevated stroke risk has been linked to high blood levels of inflammatory markers, such as C-reactive protein, interleukin-6 (IL-6), TNF-α, and soluble intercellular adhesion molecule (sICAM). Arterial thrombosis associated with plaque ulceration is triggered by multiple processes involving endothelial activation and proinflammatory and prothrombotic interactions between the vessel wall and circulating blood elements. Ischemic stroke-related brain injury itself triggers inflammatory cascades within the parenchyma that further amplify tissue damage. Within a few hours after the onset of ischemia, the expression of several cytokines (including TNF-α and IL-1β) is upregulated in brain. By 24 h, brain microglia become activated. Adhesion molecules (including ICAM, and P- and E-selectins) are expressed in vascular endothelial cells, facilitating the attraction, rolling, and entering of blood-borne inflammatory cells into the ischemic brain – first neutrophils, at 24–48 h after ischemia, followed by lymphocytes and macrophages, peaking at 5–7 days after ischemia. Lymphocytes express inflammatory cytokines and chemokines (including TNF-α and IL-8), while macrophages participate in the scavenging of necrotic cell debris. The enzymes iNOS and COX-2 are also upregulated after cerebral ischemia, contributing to the formation of nitric oxide and oxygen free radicals.

There is evidence that the inflammatory cascade occurring after cerebral ischemia contributes to acute and delayed cell death. Blocking inflammatory cell infiltration or blocking or deleting the genes for various cytokines, adhesion molecules, or other inflammatory mediators reduces cell death in animal models of cerebral ischemia. On the other hand, infiltration of blood-borne cells following ischemia likely includes hematopoietic and other stemlike and progenitor cells, which may play a role in the repair of brain injury following stroke.

Peri-infarct Depolarizations

Research in mouse, rat, and cat stroke models has shown that neurons and astrocytes in ischemic penumbral regions exhibit waves of spreading depression, detected as spreading negative slow-voltage variations. These waves, termed peri-infarct depolarizations (PIDs), exacerbate tissue damage due to the increased energy requirements for reestablishing ionic equilibrium in metabolically compromised ischemic tissues. In the initial 2–6 h after experimental stroke, PIDs result in a stepwise increase of core-infarcted tissue into adjacent penumbral regions. The frequency and total duration of spreading depression correlate with infarct size. Recent evidence suggests that PIDs contribute to the expansion of the infarct core throughout the period of infarct maturation. The significance of PIDs to human stroke pathophysiology is unclear; however, a recent study of patients with subarachnoid hemorrhage showed strong correlation between periods of spreading electrocorticographic depression and delayed ischemic neurological deficits and brain infarcts. These results suggest that spreading depolarizations with prolonged depressions may be a promising target for stroke treatment with pharmaceutical agents such as NMDA antagonists, or with physiological approaches such as hypothermia and hyperoxia.

Contemporary Views on Stroke Pathophysiology: A Clinical Perspective

While each step in every cell death pathway provides an opportunity for pharmaceutical intervention, no drug has proved effective in clinical trials. Agents that have failed clinical testing include the lipid-peroxidation inhibitor tirilazad mesylate, the ICAM-1 antibody enlimomab, the calcium channel blocker nimodipine, the γ-aminobutyric acid (GABA) agonist clomethiazole, the glutamate antagonist and sodium channel blocker lubeluzole, the competitive NMDA antagonist selfotel, and noncompetitive NMDA antagonists such as dextrorphan, gavestinel, aptiganel, and eliprodil. The lack of efficacy can be related to diverse factors, including inadequate preclinical studies, inclusion of patients without evidence for salvageable tissue on brain imaging, and deficiencies in clinical trial methodology, particularly the use of crude 'global' outcome measures rather than outcome measures designed to assess specific modalities of neurological function, which may be more sensitive. From a basic science standpoint, the failure of clinical trials has exposed the shortcomings of traditional approaches that relied on targeting a single cell death pathway.

The overlapping features and interactions between pathways are now better appreciated, and newer approaches have focused on combining or adding drugs in series so as to target distinct pathways during the evolution of ischemic injury. Neuroprotective combinations that have shown success in animal models include the coadministration of an NMDA receptor antagonist with GABA receptor agonists, citicoline, free radical scavengers, cyclohexamide,

and caspase inhibitors. While growth factors such as basic fibroblast growth factor (bFGF) have shown promise in promoting recovery after stroke, recent studies indicate that growth factors also exert powerful neuroprotective effects via downstream mechanisms, including upregulation of free radical-scavenging enzymes and antiapoptotic proteins. Therefore, it is not surprising that synergy is observed when combining citicoline with bFGF, and that caspase inhibitors given with bFGF or an NMDA receptor antagonist extend the therapeutic window with lower effective doses. Since early reperfusion with tissue plasminogen activator (tPA) has proved efficacy, attention is also being paid to neuroprotective strategies that decrease reperfusion injury, reduce postischemic hemorrhage, and inhibit downstream targets in cell death cascades. In animal models, thrombolysis has shown synergistic or additive effects with oxygen radical scavengers, AMPA receptor antagonists, NMDA blockers, MMP inhibitors, citicoline, topiramate, antileukocytic adhesion antibodies, and antithrombotics. Clinical trials have reported the feasibility and safety of tPA used in combination with clomethiazole or lubeluzole. However, in recent major clinical trials, the combination of the free radical scavenger NXY-059 with tPA showed no benefit.

Given the importance of targeting multiple pathways, more attention is being paid to physiological approaches such as modulation of brain temperature, optimizing blood glucose levels, improving brain oxygenation, and enhancing cerebral blood flow. While less specific, these approaches offer potential to interrupt nearly all deleterious biochemical and molecular pathways. For example, a reduction in brain temperature reduces cellular physiological processes and metabolic demands, as well as slows the rate of pathological processes such as lipid peroxidation and reduces the activity of certain cysteine or serine proteases. Hyperoxia favorably alters the levels of glutamate, lactate, Bcl-2, manganese SOD, and COX-2, and inhibits cell death mechanisms such as apoptosis. These physiological interventions are now being carefully tested in ongoing clinical trials.

Finally, it is now recognized that stroke-related injury is not simply restricted to cellular elements, but also involves the endothelial and vascular smooth muscle cells, the astro- and microglia, and the associated tissue matrix proteins – the integrated concept of the 'neurovascular unit.' Endothelial/astrocyte/matrix interactions are considered vital in protecting the integrity of brain tissue, and it is recognized that disruption of the neurovascular matrix, which includes basement membrane components such as type IV collagen, heparan sulfate proteoglycan, laminin, and fibronectin, upsets cell matrix and cell–cell signaling mechanisms that maintain neurovascular homeostasis. Emerging data show important linkages between tPA, MMPs, and brain edema and hemorrhage. The potential efficacy of MMP inhibitors in mitigating ischemic damage after stroke is being actively investigated.

Summary

The current pathophysiological understanding of stroke is substantially based on experimental studies. Brain injury after cerebral ischemia results from a complex signaling cascade that evolves in a spatiotemporal pattern and differentially affects gray and white matter. Excitotoxicity leads to acute cellular necrosis predominantly in the core of the infarction. The surrounding ischemic penumbra suffers milder insults, with excitotoxic and inflammatory mechanisms leading to delayed cell death showing characteristics of apoptosis. Research to date has led to an improved understanding of the importance, timing, and functional relationships of individual mechanisms, and to a better understanding of the differences between humans and the animal models in which these cell death mechanisms were discovered. Despite advances in the knowledge of individual injury mechanisms and despite intense efforts to translate this knowledge to effective stroke treatments, no therapeutic strategy has proved successful. The traditional 'neurocentric' approach is quickly yielding to a modern strategy of targeting neurons and glial cells, in particular astrocytes, as well as the neurovascular unit. It is anticipated that advances in basic science research and molecular neuroimaging, combined with advances in the fields of genomics and proteomics – as well as refinements in patient selection, improved methods of drug delivery, use of more clinically relevant animal stroke models, and use of combination therapies that target the entire neurovascular unit – will soon make stroke neuroprotection an achievable goal.

Stroke: Neonate vs. Adult

A M Comi and M V Johnston, Kennedy Krieger Institute, Johns Hopkins University, Baltimore, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Definition

Stroke is defined as brain injury occurring as a result of insufficient glucose and oxygen delivery to meet the needs of the involved brain tissue. Ischemic stroke is defined as brain injury resulting from blockage or other impairment of arterial blood delivery. The causes, molecular pathways, available treatments, and clinical outcomes are age dependant. This article focuses on contrasting neonatal arterial ischemic stroke with that in adults (see Table 1). Venous and hemorrhagic causes are not included. Neonatal arterial ischemic stroke is defined in this article as an arterial stroke presenting either (1) in the term infant during the first month of life, or (2) in the first year of life with early handedness and magnetic resonance imaging (MRI) evidence of a stroke presumed to have occurred in the neonatal period.

Epidemiology

Overall, stoke is the third leading cause of death and the leading cause of disability in the United States. Although the incidence is highest in the elderly, about one-fifth of all strokes occur in individuals younger than 65 years. Recently, data have demonstrated that neonatal stroke occurs in approximately 1 in 4000 term live births. About 33% of children with cerebral palsy have the hemiplegic form affecting the motor functions of one side of the body. In many children, the hemiplegic cerebral palsy results from a stroke in the pre-, peri-, or postnatal period. Overall, the costs of stroke are projected to be in the tens of billions of dollars per year. Stroke in the developing brain is also an important cause of neurologic impairment that often persists into adulthood.

Presentation

When recognized in the neonatal period, the most common presentation of stroke is seizures. Other less common presenting signs are lethargy or asymmetric limb movements. Other evidence of encephalopathy may also be seen, including poor suck, apnea, and hypotonia. In addition, pediatric patients with stroke often present with seizures. Children with ischemic middle cerebral artery stroke who present with seizures may be at increased risk for poor neurologic and functional outcome. When neonatal stroke presents later in the first year of life, the most common presentation is early handedness or other evidence of hemiparesis, with or without other developmental delays.

Stroke in adults is much less likely (compared with neonates) to present with acute seizures. Adult stroke is much more likely to present with the acute onset of a neurologic deficit such as a motor paresis (weakness of a limb), aphasia (inability to speak), alexia (inability to read), or apraxia (the inability to perform a previously learned motor task despite normal strength and coordination). The precise deficit in adult stroke is dependent on the location of the stroke and severity of the ischemic insult. Elegant localization of the stroke in an adult is often possible based on the constellation of neurologic deficits. This is usually not the case in neonates. Small vessel ischemia may also present with slowly evolving dementia and/or motor impairments in older adults.

Location, Etiologies, Workup, and Management

The most common site of neonatal arterial stroke is in the distribution of the middle cerebral artery and on the left side. Less commonly, neonatal ischemic stroke may occur in a watershed distribution. Stroke in the adult is more variable and depends on the age and risk factors of the individual, and whether it is secondary to large or small vessel disease or embolism.

In elderly adults, the most common causes of ischemic stroke are cardiovascular, resulting in thrombotic, lacunar, or embolic strokes that may involve the cortical, subcortical, or brain stem structures. Diagnostic workup often includes an MRI (including diffusion and perfusion) of the brain, carotid ultrasound, and cardiac echo, depending on the location and type of stroke. In adults younger than 65 years, underlying causes of ischemic stroke are generally more diverse and include thrombophilias, infection, dissection, autoimmune and inflammatory causes, and malignancy. Workup in these younger adults therefore more often includes testing such as magnetic resonance angiogram (MRA) or computerized tomography angiogram (CTA) of the neck, a thrombophilia workup, a lumbar puncture, and testing for sources of autoimmunity or cancer.

Ischemic stroke in the neonate deserves a workup as well, although a specific etiology is less often found. Inherited thrombophilias may be sought, although a recent study of candidate gene polymorphisms in genes regulating thrombosis and thrombolysis did

Table 1 Differences between neonatal and adult stroke

	Neonate	*Adult*
Frequently presents with seizures	Yes	No
Frequently presents with focal deficits	No	Yes
Sex-related differences	Yes, but different from adults	Yes, but different from neonates
Prolonged prominent apoptosis after stroke	Yes	Not so much
Oxidative reserves	Less	More
Specific treatment available	No	Yes: tissue plasminogen activator (TPA) in some cases
Recurrence risk	Very low	Generally much higher

not identify any variant allele more common in newborns with stroke than in the normal controls. An MRI/MRA with diffusion imaging is needed to determine the location and nature of the stroke and extent of brain damage. Infection should be excluded and an echocardiogram considered as well. Maternal medical issues and placental pathology also have important roles in the etiology of neonatal stroke.

Recurrence risk for ischemic stroke is related to the underlying etiology and ongoing risk factors for stroke. The recurrence risk for neonatal stroke overall is very low. It is likely that in most neonates the stroke occurs as a result of a convergence of factors related to the process of transitioning from the intranatal state to the postnatal state. As a result, these children are not likely to experience recurrence of stroke. It is not clear to what extent this recurrence risk is modified by the existence of one or more thrombophilias. Major congenital cardiovascular anomalies do carry a substantial risk for stroke recurrence. In young adults, the recurrence risk depends on whether the underlying cause is ongoing but in general is higher than in neonates. Ischemic stroke in the elderly is most often caused by multivessel disease, and overall recurrence risk is high.

The acute management of ischemic stroke in adults includes supportive measures such as preventing fevers, managing intracranial pressure and edema, and ventilation if required. Specific treatment is available in the form of tissue plasminogen activator (TPA) given either peripherally or intravascularly to break up the clot producing the ischemia. TPA is limited to the subset of patients presenting in the first few hours after stroke with no contraindication, but in this setting can be very helpful in reducing the morbidity from stroke. Aspirin is another antithrombotic treatment shown to be beneficial for the acute treatment of stroke in adults. No randomized clinical trials have addressed the acute management of perinatal stroke. Supportive care is also provided to neonates after a stroke, but anticoagulation is generally not used except for treatment of a known cardioembolic stroke.

Gender Differences

Clinical ischemic stroke has long been recognized to be sexually dimorphic in adults; most studies have shown that while women have lower stroke incidence relative to men, early outcome may be more favorable in men. This difference has been largely attributed to a protective estrogen effect in women; the risk in postmenopausal women equals that in age-matched men. Until recently, little data were available from clinical trials in adults regarding gender and response to treatment. Female sex is a mildly unfavorable prognostic factor in rehabilitation outcome after stroke.

In the pediatric population, neonatal arterial ischemic strokes are more commonly diagnosed in boys. Boys are at higher risk for all stroke types than girls. In addition, male gender may be a prognostic factor for poor outcome after stroke. Little attention, however, has been given to whether or how clinical interventions for neonatal or pediatric stroke should be tailored for patient gender.

Very recent studies suggest that sex may influence the response to treatment of ischemic brain injury. The impact of animal sex on susceptibility to brain injury has recently been examined *in vitro*. Du and colleagues studied sex-segregated neuronal cultures and found that XX and XY cultures responded differently to cytotoxic and pharmacological manipulation. They reported that XY neurons were more sensitive to nitrosative stress and excitotoxicity than XX neurons. After $ONOO^-$ treatment, XY neurons demonstrated apoptosis-inducing factor (AIF)-mediated programmed cell death, but XX neurons underwent predominantly caspase-dependent apoptosis. Sex-related differences in response to hypoxia-ischemia have also been shown experimentally *in vivo*. Results of experiments with hypoxia-ischemia in 7-day-old mice showed that knocking out Parp-1 protected males but not females. These sex-related differences could be related to differences in expression of genes known to be on the X chromosome, such as AIF or X-linked inhibitor of apoptosis (XIAP). Poly(ADP-ribose) polymerase-1 (PARP-1) is a nuclear enzyme activated by DNA strand breaks that participates in DNA repair and

replication. On the other hand, a similar experiment in adult Parp-1 knockout mice demonstrated that female adults sustained worse injury rather than less injury. Recently, Zhu et al. showed that in P9 C57/BL6J mice, neuronal death after hypoxic-ischemic injury proceeded predominantly via an AIF-mediated pathway in males versus a caspase-dependent pathway in females. These findings support the conclusion that the pathways mediating ischemic brain injury and neuroprotection may differ in males and females. This sex-related difference is relevant to both adults and neonates, but manifests differently in these two age groups.

Mechanisms of Neuronal Injury

Both adult and neonatal animal models for stroke have been developed, and the basic pathways involved are similar. Broadly speaking, a core of severely injured tissue is formed at the epicenter of the ischemia that develops into pan-necrosis. Surrounding this core is an area of underperfused tissue, the penumbra. The penumbral tissue is at risk of becoming included in the infarcted core. Cerebral ischemia triggers the release of the excitatory neurotransmitter glutamate, and the energy uncoupling produced by ischemia prevents the active removal of glutamate from the synaptic cleft. Excess glutamate overstimulates postsynaptic receptors, thereby opening the associated ion channels. This allows sodium and calcium ions to enter the cell, while potassium flows outward. Excessive calcium influx initiates a cascade of energy-consuming and ultimately lethal intracellular events.

However, *in vivo* models have revealed important differences in the immature brain as compared to the adult brain exposed to ischemic injury. In the neonatal animal, apoptosis evolves over the week following the initial ischemic insult or longer. This contrasts with a much shorter period of apoptosis following ischemic injury in the adult brain. A range of morphologies from necrosis to apoptosis is more common in the neonatal brain. The oxidative reserve of the neonatal brain, in terms of its high oxygen demand and low concentration of antioxidants, is also less compared to that in the mature animal. This in conjunction with the high concentrations of unsaturated fatty acids and bioavailable iron suggests that the neonatal brain is more susceptible to oxidative damage compared with the mature brain. In the neonate, activation of the Cl^- permeable γ-aminobutyric acid type A ($GABA_A$) receptors is excitatory and has been linked to a higher propensity for seizures. The immature brain also differs greatly from the mature brain in terms of the ion channel subunits expressed, leading to important differences in excitation and patterns of regional vulnerability to ischemic injury. These important differences make it essential that developmentally appropriate models are used for mechanistic and preclinical studies and emphasize the need for clinical trials in neonates as well as adults with stroke.

Seizures induced by global hypoxia, global ischemia, or hypoxic-ischemic injury have been noted in adult and immature rats. Studies examining interactions between seizures and hypoxic-ischemic brain injury in developing rats have produced various results. Status epilepticus induced by the GABA antagonist bicuculline after hypoxia-ischemia did not exacerbate brain damage in postnatal day 7 (P7) rats. On the other hand, in P10 rats subjected to unilateral carotid ligation and brief hypoxia, seizures induced by kainate significantly exacerbated brain injury. It is controversial and difficult to determine, however, whether seizures occur only secondary to the injury or in fact contribute to the ischemic brain injury.

Outcome

Outcome in neonatal stroke is variable. Although the majority of children survive their stroke, about 75% have sequelae including cerebral palsy. In one study, 46% of children followed after neonatal stroke developed cerebral palsy. The assessment of motor movements in the weeks following birth can be useful in the early identification of hemiparesis. A delayed presentation is associated with the developmental of cerebral palsy, as are the radiologic findings of large stroke size and injury to Broca's area, the internal capsule, Wernicke's area, or the basal ganglia. Other long-term complications include epilepsy and learning disabilities. Outcome in adults depends on the age, associated medical comorbidities, type of stroke, and recurrence risk of the individual involved but is generally less good than in neonates. Nevertheless, the potential for lifelong neurologic impairments makes stroke in the neonate an important national health issue.

Prevention

Prevention of stroke in adults is aimed at decreasing or treating the risk factors for stroke such as hypertension or hypercholesterolemia, eliminating sources of embolic clots such as the heart or carotid artery, and anticoagulation. In contrast, prevention of neonatal stroke risk factors (such as preeclampsia, extracorporeal membrane oxygenation (ECMO), maternal diabetes, chorioamnionitis, placental pathology, trauma, infection, or polycythemia) is often currently not possible and recurrence risk is low in most cases. No randomized clinical trials have been done to address the issue of primary or secondary prevention

in neonatal stroke. Maternal thromboprophylaxis for maternal thrombophilia remains speculative, and aspirin use is generally not recommended after neonatal stroke.

Future Directions

More rigorous preclinical study and clinical trial design may produce future success in neuroprotection. Other promising future approaches include enhancing the endogenous regenerative response with growth factors. A recent pilot trial with granulocyte colony-stimulating factor (GCSF), given to adults after stroke, reported that CD34+ cells were mobilized and the treatment was safe and well tolerated. Recent genetic studies have identified loci that confer susceptibility to stroke and have future application in the management of ischemic stroke patients. Advances in the treatment of stroke in adults will require careful study in developmental models and neonatal trials before they can be applied in neonates.

Substance Abuse and Dependence

J A Brewer and M N Potenza, Yale University School of Medicine, New Haven, CT, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Addiction involves compulsive substance use despite negative consequences and incorporates components of both substance abuse and dependence, as defined by the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) and the *International Classification of Diseases*.

The DSM-IV diagnostic criteria for substance abuse require the presence of a "maladaptive pattern of substance use leading to clinically significant impairment or distress" as manifested by recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home; situations in which it is physically hazardous; related legal problems; or continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance.

The DSM-IV diagnostic criteria for substance dependence incorporate a combination of three or more of substance-related manifestations including tolerance, withdrawal, larger amounts of drug taken for longer than intended, a persistent desire or unsuccessful attempts to quit, a large amount of time/activity spent obtaining, using, or recovering from the substance, important activities given up or reduced due to substance use, and continued use despite knowledge of adverse consequence.

Generally speaking, ingestion of a psychoactive substance leads to a pleasurable feeling and/or body sensation (the 'high' of cocaine or the 'buzz' of alcohol, for example). As with other goal-directed or rewarding behaviors, memory of drug-related pleasurable experiences leads to the desire for their repetition, giving these substances reinforcing properties.

On a molecular level, psychoactive substances have diverse mechanisms of actions (see specific classes below) but typically share a common final pathway: increased synaptic dopamine within the basal ganglia. Specifically, projections from the ventral tegmental area release dopamine in the ventral pallidum, nucleus accumbens, prefrontal cortex, and amygdala, all part of a 'motivational' or reward circuit. Dopamine activity within this circuitry facilitates the learning of associations between behavior and perceived sensations.

Repeated drug use induces reorganization in the motivational circuit leading to the establishment of patterns of behaviors characteristic of addiction, namely 'cravings,' persistent use despite negative consequences, and a perceived 'loss of control.' These patterns are startling in their power to supplant most other goals.

Additionally, repetitive use of many drugs leads to the development of tolerance, in which larger amounts need to be ingested to produce the desired effects. This may be due to induction of liver enzymes that break down the drug, thus increasing drug metabolism, the downregulation of receptors on which the drug works, leading to a decrease in sensitivity, and/or other mechanisms, such as changes in the expression patterns of intracellular proteins.

With this as an introduction, the following sections briefly review the major classes of commonly abused drugs. Estimates of prevalence of use, abuse, and dependence related to these drugs are found in Tables 1 and 2.

The Opioids

The opioid agonists include both naturally occurring alkaloids (e.g., codeine, morphine, and opium), the semisynthetic derivatives (e.g., hydromorphone, hydrocodone, and heroin), and the synthetic compounds (fentanyl, tramadol, methadone, meperidine). There exist partial agonist (agonist–antagonist) opioids as well, for example, butorphanol, nalbuphine, and buprenorphine. Opiates may be ingested orally, inhaled, injected intravenously or intramuscularly. Additionally, they are commonly taken in combination with other psychoactive substances (e.g., heroin mixed with cocaine and injected intravenously, aka a 'speedball'). Rapid elevations in blood levels correlate with the associated 'high' or degree of intoxication. Once in the blood, opiates travel to the brain where they bind to opioid receptors (of primary importance is the mu-opioid receptor (reclassified as OP3) which modulates euphoria and analgesia) in the brain and other organ systems such as the gastrointestinal (GI) tract. In the brain, opioids activate the mesolimbic reward system generating signals in the ventral tegmental area, causing release of dopamine in the nucleus accumbens and feelings of pleasure. Binding to the mu-opioid receptor in the locus coeruleus suppresses norepinephrine (noradrenaline) release to other parts of the brain where its normal function is to stimulate wakefulness, breathing, and general alertness, among other functions.

Clinically, acute opioid intoxication manifests as euphoria (the acuity of which depends on the drug and route of administration), relaxation, drowsiness, pupillary constriction (miosis), motor retardation,

slowing of the GI tract, and decreased pulse, blood pressure, and respiratory rate. Overdose can be fatal if untreated, with the three hallmark signs being central nervous system (CNS) depression (ranging from drowsiness to coma), miosis, and respiratory depression.

Continued or repeated exposure to opioids leads to tolerance and dependence in part via decreased receptor responsiveness. Importantly, abrupt cessation of these drugs or the administration of an opioid antagonist such as naloxone in dependent individuals leads to a withdrawal state, characterized by anxiety, muscle cramping, nausea, vomiting, diarrhea, pupillary dilation (mydriasis), diaphoresis, and yawning. Physiologically, this withdrawal state is thought to be mediated in part by increased noradrenergic output in the locus coeruleus. The onset of a withdrawal state is dependent upon the pharmacological half-life of the opioid involved: the longer the half-life, the later the onset of withdrawal. Typical withdrawal from heroin (half-life ~2 h), for example, begins 6–12 h after its last use, whereas that from methadone (half-life 15 h) begins 36–72 h after last use. Whereas withdrawal symptoms are generally uncomfortable, they are typically not life threatening (exceptions include at-risk vulnerable groups like newborns, older adults, and medically compromised individuals), and can be alleviated by administration of an opioid (the most common being the long-acting methadone). In the hospital or other treatment settings, if further opiate administration is tried to be avoided, withdrawal symptoms are typically treated with the alpha-2 agonist clonidine. Clonidine activates the locus coeruleus and is thought to dampen the overactive noradrenergic output that occurs during withdrawal. Clonidine may be augmented with lorazepam (or other anxiolytics), immodium, and tramadol for symptomatic relief of anxiety, diarrhea, and pain, respectively.

Current pharmacologic treatments for opiate addiction include methadone, buprenorphine, buprenorphine/naloxone combinations, and naltrexone. Methadone, a long-acting synthetic opiate (see above), is a schedule II controlled substance used to reduce opiate use and retain patients in treatment. In the United States, methadone is administered via federally licensed 'methadone clinics,' where it is provided in liquid form and ingestion is generally observed by a clinician. It is currently the mainstay of treatment and has been shown to reduce both mortality and morbidity. Buprenorphine, an opioid receptor partial agonist, was approved by the United States Food and Drug Administration (FDA) in 2002 for the management of opiate dependence. It is administered sublingually due to significantly reduced availability when taken orally due to first-pass effects. Additionally, it is available as a combination pill with naloxone (an opioid antagonist) to reduce its abuse potential: naloxone is poorly absorbed through the GI tract, thus has little to no effect when taken orally as intended, but if crushed and injected, it blocks binding of the buprenorphine to the opiate receptors. Naltrexone, another opioid antagonist which can be taken orally, can block opiate effects at the opiate

receptor for over 24 h, but is typically not abused because it lacks the positive effects afforded by opioid agonists or partial agonists. It is generally used in settings of teenage or newly narcotic addicted or within highly motivated groups (e.g., professionals such as doctors or nurses with licensing privileges at stake), with the hope of avoiding the need for methadone (which is often a more chronic therapy). A long-acting depot form of naltrexone appears safe and efficacious and was recently approved by the FDA for alcohol dependence (see below).

Nonpharmacological approaches include individual and group drug counseling, self-help groups, contingency management techniques ('earning' money for drug-free urines or the opportunity to receive take-home medications in return for prolonged abstinence), and therapeutic communities. Therapeutic communities are often long-term (6–18 months) residential settings where residents share responsibilities such as cooking, cleaning, and leading group therapy.

CNS Depressants

The CNS depressants include alcohol, benzodiazepines, barbiturates, and sedative hypnotics. As the class depressant implies, this group of drugs induces sedation or sleep. These drugs can be administered orally or intravenously, and once in the bloodstream, act on various receptors in the brain.

Benzodiazepines are relatively lipid soluble, with their degree of solubility determining their relative onset (more lipophilic = faster onset). They are thought to act at the benzodiazepine receptor complex which includes the γ-aminobutyric acid (GABA) receptor and a chloride channel. When bound, they increase the sensitivity of the GABA receptor complex to GABA, an inhibitory neurotransmitter, either by increased affinity for the receptor or increased coupling with its associated chloride channel. Neurotransmission at this receptor complex and associated GABA pathways leads to characteristic sedation, anxiolysis, and striated muscle relaxation. Benzodiazepine overdose is generally not fatal in otherwise healthy adults, unless combined with other drugs or taken parenterally.

Ethanol acts at a variety of sites in the brain. Specifically, it facilitates $GABA_A$ receptor function, inhibits *N*-methyl-D-aspartate (NMDA) receptors, and may influence voltage-sensitive calcium channels, serotonin receptors, and dopamine release. Intoxication is characterized by a wide range of behavioral and cognitive effects including sedation, clouded memory and judgment, slowed information processing and reaction time, ataxia, and slurred speech. Alcohol overdose or 'poisoning' often manifests as coma and respiratory depression, and can lead to death (often by coincident aspiration or trauma).

Barbiturates are largely absorbed in the stomach and small intestine, and generally act by facilitating GABA transmission at the GABA receptor. Additionally, they may act by inhibiting calcium-mediated excitatory neurotransmitter release. Intoxication is similar to alcohol and benzodiazepines, with overdose manifesting in stupor to coma. Additional signs of overdose include hypothermia, respiratory depression, and hypotension.

CNS depressants all have the propensity for tolerance and dependence. Due to a shared mechanism of action on the GABA receptor, there is a degree of cross-tolerance that can also develop between groups (alcohol and benzodiazepines most commonly).

Mild withdrawal from alcohol in dependent individuals manifests as anxiety, irritability, nausea, vomiting, tremor, anorexia, and diaphoresis. More serious effects include hallucinosis (often characterized by tactile and/or visual hallucinations), delirium tremens (disorientation, autonomic instability, fever, agitation), and seizures. Withdrawal generally begins 6–36 h after cessation, followed by hallucinosis and delirium tremens (at 3–5 days, but lasting up to 10 days). Seizures usually peak at 1–3 days after the last drink, but have been reported out to 14 days. Benzodiazepine and barbiturate withdrawal shows similar symptoms, but the timecourse may be different depending on the half-life of the agent involved.

Treatment of acute withdrawal from CNS depressants is usually undertaken in a hospital or acute detoxification facility. Initially, patients are provided supportive treatment (vitamin, electrolyte, and fluid repletion), while a taper or cross-taper (e.g., given chlordiazepoxide for alcohol dependence) of the class of drug is initiated. Anticonvulsants have also been used for alcohol withdrawal.

Pharmacological relapse prevention strategies for alcohol dependence include disulfiram, opioid antagonists, and acamprosate. Disulfiram has been available since the 1950s and works by inhibiting the liver enzyme aldehyde dehydrogenase, causing the buildup of acetaldehyde, a byproduct of alcohol, and leading to a variety of unpleasant physiological effects, including nausea and flushing. It is often suboptimal in maintaining abstinence due to treatment nonadherence. Naltrexone, an opioid receptor antagonist (see 'The Opioids'), is also used, and this medication is thought to reduce cravings and substance use as an anticraving medication. Naltrexone has been shown in a majority of trials to be superior to placebo in preventing relapse, but adherence is variable. A depot formulation has been developed, tested, and approved by the FDA in 2006. Acamprosate has

multiple actions in the brain, including decreased presynaptic glutamate release, decreased NMDA receptor excitability, and decreased calcium flux through the voltage-dependent calcium channels. Approved by the FDA in 2004, it (in combination with naltrexone, due to their theoretically different and complementary mechanisms) is currently undergoing a large clinical trial in the United States.

Behavioral treatments and self-help approaches that are used for relapse prevention include inpatient rehabilitation programs, self-help groups (most notably the '12-step' program Alcoholics Anonymous), cognitive behavioral therapies, social skills training, stress management, and community reinforcement, among others. Some evidence suggests that in an outpatient setting, 12-step programs are as effective as cognitive behavioral treatments. However, 12-step programs and behavioral therapies also show high rates of early dropout, suggesting that compliance is a concern across treatment modalities for individuals with alcohol dependence.

CNS Stimulants

CNS stimulants include cocaine, methylphenidate, amphetamine, methamphetamine, and methylenedioxymethamphetamine (MDMA). Most are injected, swallowed, smoked, or snorted depending on the compound. Methylphenidate and amphetamine, when prescribed by physicians, are often used to great therapeutic benefit for attention-deficit hyperactivity disorder (ADHD). They are also used to treat narcolepsy. Cocaine is derived from the leaves of the *Erythroxylon cocais* plant and used medically as a local anesthetic. On the street, cocaine is available in two forms: the water-soluble powder compound formed by dissolving the alkaloid in hydrochloric acid, and the 'free base' compound produced by alkalinization with sodium bicarbonate or ammonia (crack).

Cocaine acts peripherally by activating α- and β-adrenergic receptors, causing vasodilation. Additionally, it activates sigma receptors and blocks the formation of nitric oxide resulting in vasoconstriction. In the brain, it acts by blocking dopamine, norepinephrine, and serotonin reuptake at their respective transporters. Chronic abuse is thought to induce relative dopamine hypofunction, changing the functional coupling of GABA receptors and $GABA_A$ receptor subunit composition. Amphetamine increases extracellular catecholamine and serotonin concentrations via vesicular depletion, reuptake inhibition, enhancement of dopamine synthesis, and monoamine oxidase (MAO) inhibition. MDMA acts similarly to amphetamine, though it causes greater serotonin release than dopamine release. Additionally, it induces vasopressin (ADH) release from the hypothalamus.

Stimulant intoxication may manifest as hyperarousal, hypervigilance, psychomotor agitation, and hypersexuality. Increased amounts and/or length of ingestion can lead to confusion and even stimulant-induced psychosis, characterized by paranoia, delusional thought processes, and compulsive behavior (seen more commonly with amphetamines than cocaine). Due to its vasoactive properties, as well as influences on platelets, cocaine ingestion can lead to ischemic cardiomyopathy and associated chest pain, myocardial infarctions (heart attacks), strokes and other vascular problems. MDMA ingestion can initially cause agitation, time distortion, and diminished thirst, followed by euphoria and a sense of well-being. Additionally, intoxication can lead to diaphoresis, tremor, hypertension, and even serotonin syndrome (characterized by mental status change, autonomic hyperactivity, and neuromuscular abnormalities).

Abrupt cessation after continued use of a stimulant can produce a wide range of dysphoric symptomatology, commonly known as a 'crash.' During this time, anxiety, agitation, intense craving, and depressive symptoms can manifest, although controlled studies have often shown minimal withdrawal symptoms.

A number of medications from stimulants to antidepressants have been evaluated in relapse prevention studies, but none have shown substantial efficacy and currently there are no FDA-approved medications for the treatment of cocaine dependence. In targeting dopaminergic systems, among the most promising drugs for treatment of cocaine dependence has been disulfiram, a drug that inhibits dopamine β-hydroxylase (DBH), the enzyme that converts dopamine to norepinephrine. Novel therapeutics are currently being evaluated and include drugs that act on the GABA system (tiagabine, gabapentin, baclofen) and immunotherapies (cocaine vaccine).

Psychotherapies that have been employed for cocaine and other stimulant abuse include cognitive behavioral therapy, drug counseling, and contingency management procedures (presenting rewards or incentives for abstinence and withdrawing privileges for continued drug use).

Hallucinogens

The hallucinogens include lysergic acid diethylamide (LSD), mescaline, and psilocybin. LSD is swallowed or absorbed through oral mucosa, mescaline is smoked or swallowed, and psilocybin is generally swallowed. Once ingested, hallucinogens act as

agonists at the postsynaptic serotonin (5-HT_2)and NMDA receptors, among others.

Hallucinogens can produce an altered state of perception including synesthesia (mixing of sensory modalities; e.g., "I feel orange"), distortion of time, increased body temperature, pulse and blood pressure, loss of appetite, numbness, weakness, nervousness, panic, and paranoia. Visual disturbances, such as hallucinations, are also common. After-imagery, geometric pseudo-hallucinations, and halos can sometimes persist for years after drug use, and this effect may be due to an unusual sensitivity of the visual system compared to other cortical pathways. Studies of LSD administration also show an incidence of subsequent psychosis in up to 5% of samples studied.

There is little evidence for documented hallucinogen withdrawal. Benzodiazepines are used for treatment of panic induced by acute intoxication, and neuroleptics are used for psychotic components of ingestion.

Marijuana

Marijuana is the most commonly used illegal drug in the US. It is commonly swallowed or smoked. Its active ingredient is delta-9-tetrahydrocannabinol (THC), with an average joint containing between 5 and 20 mg of THC, although the concentrations may be increasing with new varieties of marijuana being grown. Inhalation provides a more rapid rise in plasma THC levels than does ingestion.

Acutely, marijuana has peripheral, as well as central effects. THC is thought to act at the cannabinoid receptors (thus far, there have been three subtypes identified: CB1, CB2, and CB3), which are prominent in the hippocampus, thalamus, brain stem, and basal ganglia. Although further characterization is required, activation of these receptors produces blockade of voltage-activated calcium channels, and activation of adenylyl cyclase via G-protein coupling. CB1 and CB3 receptors regulate GABA, glutamate, dopamine, norepinephrine, serotonin, and acetylcholine release in the brain. THC can produce mild euphoria, relaxation, perceptual distortions, and enhancement of ordinary sensory experiences. It can also impair short-term memory, motor skills, and reaction time. It is commonly known to stimulate appetite, and medicinal THC preparations are used to varying degrees of efficacy for anorexia associated with chronic diseases such as AIDS. Peripherally, THC can cause tachycardia and, at high doses, orthostatic hypotension. Although controversial, evidence also suggests an association between cannabis use and psychosis. This association has biological support from studies, suggesting that multiple actions are mediated through CB receptor activation.

With chronic use of marijuana, evidence suggests the development of tolerance, including decreases in autonomic functions, increased intraocular pressure, and mood changes. Abrupt cessation does not result in severe withdrawal, although subjective symptoms can include increased irritability and restlessness, insomnia, anorexia, and mild nausea. Signs can also include tremor, increased body temperature, and weight loss. Some studies estimate the risk of dependence is up to 30% with use over five times.

Relapse prevention strategies for marijuana dependence have only recently been studied. Cognitive behavioral therapy, motivational enhancement therapy, and case management have been demonstrated to be efficacious in reducing use in a limited number of controlled trials, with fewer data available about the efficacy of pharmacotherapies, although some drugs (antidepressants, anxiolytics) have shown potential in open-label trials.

Club Drugs and Dissociative Anesthetics

This group of drugs includes ketamine, phencyclidine (PCP), MDMA (see 'CNS Stimulants'), and gamma-hydroxybutyrate (GHB). Ketamine is taken intravenously, snorted, or smoked, PCP is injected, swallowed, or smoked (often dissolved in formaldehyde and soaked into marijuana, known as 'illy' or 'wet'), and GHB is swallowed.

PCP was first synthesized in the 1950s and marketed as a surgical anesthetic, but withdrawn from the market 15 years later due to associated behavioral disturbances including dysphoria, paranoia, hallucinations, rage, and violence. The psychotic symptoms from PCP anesthesia were noted to persist for more than a week in many patients. It acts as a noncompetitive antagonist at the NMDA receptor, a cholinergic antagonist centrally, and dopamine 2 receptor antagonist peripherally. Additionally, it increases dopamine release from synaptic vesicles. These actions manifest, as noted above, in a mixture of anesthetic, stimulant, depressant, and hallucinogenic effects. At low doses, anticholinergic symptoms are prominent (red dry skin, amnesia, disorganization), and, at high doses, dopaminergic effects predominate (paranoia and hallucinations). In susceptible individuals, PCP may 'induce' a permanent psychosis impossible to distinguish from schizophrenia, although it is often difficult to differentiate direct causality versus precipitation of an underlying psychotic illness by the drug.

Ketamine, a less potent structural analog of PCP introduced into the pharmacological armamentarium

about 30 years ago, is a dissociative anesthetic and continues to be used clinically for a number of applications (mainly in pediatric populations due to often intolerable side effects in adults, including nightmares). Arguably, its best-known action is as an NMDA receptor antagonist (binding to the same site as PCP), and it continues to be used in clinical studies as a model of induced psychosis. Additionally, ketamine binds to mu- and kappa-opioid receptors, blocks monoamine reuptake, and influences muscarinic receptors and voltage-sensitive calcium channels. When used clinically or as a club drug, ketamine produces dissociative anesthesia (floating outside of one's body), a 'dream-like' state, analgesia, perceptual changes (including hallucinations), delusions, impaired memory, increased pulse, and increased blood pressure.

GHB was sold until 1991 and used for fat reduction and muscle building. Structurally similar to GABA, GHB acts through the $GABA_B$ receptor complex, on second messenger pathways and through dopamine signaling blockade. Effects of GHB ingestion are dose dependent, ranging from amnesia, somnulence, and hypotonia to dizziness, confusion, respiratory depression, hypotension, bradycardia, seizures, loss of consciousness, and even coma at higher levels. As the effects of GHB generally subside in a few hours, treatment of GHB intoxication is typically supportive, although physostigmine has also been used.

There is some evidence of development of withdrawal symptoms with extended use of ketamine, and, in some severe cases, detoxification may be warranted. Chronic use of GHB may produce dependence and a withdrawal syndrome that includes anxiety, insomnia, tremor, and, in severe cases, treatment-resistant psychoses.

Tobacco

Tobacco is available as snuff, chewing tobacco, cigars, and cigarettes, although the majority is consumed as cigarettes. The main active ingredient is nicotine, a widely distributed plant alkaloid found in highest concentrations in the species *Nicotinia tobacum* and *Nicotinia risticum*. Once it enters the bloodstream, nicotine, a tertiary amine similar to acetylcholine, binds to nicotinic cholinergic receptors in the brain and elsewhere. In the brain, its sympathomimetic activity enhances release of dopamine, norepinephrine, acetylcholine, serotonin, vasopressin, glutamate, and GABA, among other neurotransmitters. In this respect, it acts as a CNS stimulant. With tobacco use, people report improved concentration, elevated mood, and reduced anger, stress, and tension, although it is sometimes difficult to differentiate intrinsic effects on the brain from those related to relief from abstinence. However, nicotine administration improves attention, reaction time, and problem solving, suggesting the former is at least contributory.

With repeated exposure to nicotine, tolerance and dependence develop which are likely mediated physiologically by regulation of the nicotinic acetylcholine receptor and psychologically by the mesolimbic dopamine system (described above). Abstinence leads to symptoms of lethargy, irritability, restlessness, inability to concentrate, and dysphoria.

When asked, about 70% of smokers would like to quit and most adults require four or more attempts before being successful. Nicotine replacement therapies (NRTs), in the form of patches, gum, nasal spray, and inhalers, have been shown to be effective in enhancing smoking cessation by twofold compared to placebo, although up to 90% of attempts to quit fail despite NRT. Bupropion has also shown benefit and is FDA approved for smoking cessation, and, when combined with NRT, has been shown to be more effective than NRT alone. Most recently, varenicline, a partial nicotinic receptor agonist, has received FDA approval for smoking cessation.

Aversion therapies, acupuncture, hypnotherapy, and exercise have been used, but further studies need to be done to determine their efficacies.

Conclusions

In sum, substance abuse and dependence exact a tremendous toll economically, socially, and personally on individuals around the world. Although drugs of abuse vary widely in their effects, research into the neurobiological basis of addiction has revealed some striking commonality in their action which leads to addiction. Additionally, new knowledge of specific mechanisms of action of drugs continues to lead to novel, targeted therapies that may prove to be more efficacious than those currently available. Just as importantly, as the neurobiological underpinnings of addiction continue to be elucidated, it is coming to be understood as a disease rather than just a social problem.

Tachykinins: Genes, Peptides, and Their Receptors

Tachykinin Peptides

Substance P (SP), neurokinin A (NKA), and neurokinin B (NKB), the first peptides of the family of mammalian tachykinins (TKs) to be characterized, were initially found to be specifically expressed in the neurons of the peripheral districts and central nervous system (CNS) and therefore were included in the broad definition of neuropeptides. Nowadays, it is unanimously agreed that TKs are not exclusively localized in neuronal cells; nevertheless, the peripheral nervous system (PNS) and CNS are the districts in which the effects of TKs have been more extensively investigated. Another mammalian TK has been recently discovered. This was termed hemokinin-1 (HK-1) because it was initially localized in the hematopoietic tissue; however, it soon became clear that HK-1 was also expressed into the CNS. Unlike the other TKs, the sequences of mouse and rat HK-1, on the one hand, and human HK-1, on the other, are not identical; however, no striking pharmacological differences have been detected between these two peptides.

SP, HK-1, NKA, and NKB are short peptides containing 11, 11, 10, and 10 amino acids (aa), respectively; elongated forms of NKA (neuropeptide K with 36 aa and neuropeptide γ with 21 aa) and of HK-1 (endokinin A with 47 aa and endokinin B with 41 aa) have also been identified (Table 1).

Tachykinin Genes

All these TKs are encoded by three genes, termed TAC1 (or preprotachykinin-A, PPT-A, or PPT-I), TAC3 (or PPT-B or PPT-II), and TAC4 (or PPT-C). TAC genes are transcribed into primary mRNAs which are subjected to alternative posttranscriptional splicing, and the derived peptides are then subjected to posttranslational processing. This process produces different phenotypes from just one genotype (Table 2).

As with other peptides that are released extracellularly, TKs are synthesized in the rough endoplasmic reticulum as prepro-TKs (prepropeptide); large peptide sequences directly derived from the translation of exons contained in the mRNAs are listed in Table 2. The cleavage of a signal sequence in the prepro-TKs leads to the pro-TKs (propeptide), which is now stored in the Golgi apparatus; this process occurs in the soma of neurons. The maturation of the Golgi vesicles into secretory vesicles occurs during their transport along axons and parallels a further proteolytic cleavage of the peptide precursor (the propeptide) into the mature peptide that is now ready to be released from the axon terminals. In a subclass of TK-expressing primary afferent neurons (termed capsaicin-sensitive), this process is bidirectional; that is, the release of TKs (together with their co-transmitters) occurs at both the axonal (in the spinal cord) and dendritic (at the peripheral level) pools of the neuron.

All TKs, except endokinin C and D, share a common C-terminal amidated amino acid region, Phe-X-Gly-Leu-Met-NH_2, which is the minimal sequence for exerting biological activity at the TK receptors and therefore for exerting the function of neurotransmitters. Indeed, a truncated form of NKA, NKA(3–10), has been detected in some tissues, and it retains activity at the TK receptors (at NK2, in particular). The N-terminal part of SP also exerts several biological effects, especially at the CNS level; however, these effects are not mediated by known TK receptors. The receptor involved in the effect of the N-terminal fragment of SP (e.g., SP(1–5)) has not been identified yet; however, the recent finding that the SP domain contained in the protachykinin peptide (derived from β-preprotachykinin, or β-TAC1) interacts with δ-opioid receptor to regulate its trafficking at nerve terminals renders this receptor the likely target accounting for the biological effects exerted by SP(1–5).

Tachykinin Receptors

TKs exert their biological effect by acting at three different G-protein-coupled receptors, termed TK NK1 (coded by the TACR1 gene), NK2 (coded by the TACR2 gene), and NK3 (coded by the TACR3 gene). The NK1 receptor can be expressed in two different forms due to alternative TACR1 splicing; these forms have been defined as long and short because of the different lengths of the intracellular C-terminal domain. The short isoform of the NK1 receptor is less prone to desensitization and internalization than the long isoform, and it has been recently shown that the activation of the short isoform is a much more efficient signal for an autocrine induction of β-TAC1 than the stimulation of the long isoform. NK2 receptor is also expressed in two different isoforms: the α-isoform is the classic NK2 receptor, whereas the β-isoform is not a functional TK receptor because it lacks an amino acid sequence forming an extracellular (EC3) loop, an intracellular (IC2) loop, and a transmembrane domain (TM4) and so cannot be activated by TKs.

Table 1 Peptide sequence of mammalian tachykinins[a]

[a]The common C-terminal amino acid sequence required for exerting activity at tachykinin receptors is shown in bold: endokinin C and D lack the C-terminal Met and are almost devoid of affinity at these receptors; because of this they have been termed as tachykinin-related peptides. Red indicates the sequence of neurokinin A, of which neuropeptide-γ and neuropeptide-κ are elongated forms; blue indicates the sequence of human hemokinin-1, of which endokinin A and B are elongated forms.
[b]Rat and mouse sequence.

Table 2 Tachykinin genes, tachykinin-encoding messenger RNAs, and tachykinin peptides[a]

TK gene	*TK mRNA*	*TK peptides*
TAC1	α-TAC1	Substance P
	β-TAC1	Substance P, neurokinin A, neuropeptide K
	γ-TAC1	Substance P, neurokinin A, neuropeptide-γ
	δ-TAC1	Substance P
TAC3	α-TAC3	Neurokinin B
	β-TAC3	Neurokinin B
	γ-TAC3	None
TAC4	α-TAC4	Hemokinin-1, endokinin A, endokinin C[b]
	β-TAC4	Hemokinin-1, endokinin B, endokinin D[b]
	γ-TAC4	Hemokinin-1, endokinin B
	δ-TAC4	Hemokinin-1, endokinin B

[a]TK, tachykinin.
[b]TK gene-related peptides (see **Table 1**).

All TKs act as full agonists at the NK1, NK2, and NK3 receptors, although with different estimated affinities. The potency orders of TKs at the receptors are:

- NK1: SP = hHK-1 > NKA > NKB
- NK2: NKA > NKB > SP > hHK-1
- NK3: NKB > NKA > hHK-1 > SP

However, significant deviations to these rankings can occur, mainly depending on (1) the animal species investigated (large species-related differences in the affinity of nonpeptide TK receptor antagonists are well known, but smaller differences are also present among peptide agonists) and (2) the kind of bioassay (if more than one TK receptor is expressed or is in any way involved in the response measured, the kind of signal transduction activated, or the presence of peptidases). Selective TK receptor agonists (peptides only) and antagonists (both peptides and nonpeptides) are also available. These selective ligands have been fundamental tools in the characterization of the receptors involved in a given function. However, there are several studies in which a response is mediated by more than one TK receptors, so that the application of only one selective receptor antagonist might not be sufficient to block, or even to reduce, the studied function unless other TK receptors are blocked.

Knockout mice lacking the TAC1 or TACR1 gene have been produced. These knockout mice have also been instrumental in clarifying several aspects of the neurophysiological processes mediated by TKs; however, the possibility of developmental remodeling to compensate for the lack of function in the system can never be excluded when adopting this strategy. Indeed, as with other neurotransmitter systems, the tachykinergic system must not be thought of as static; there are several examples showing that developmental and environmental changes affect the pattern of expression of TKs and their receptors in both neurons and glia. Finally, the importance of TKs in neurophysiological processes regulating sensory, emotional, and neurovegetative functions is highlighted by a large number of preclinical studies.

Tachykinins and Their Receptors in the Central Nervous System

All the TAC genes described so far are expressed in the CNS; however, it is uncertain whether TAC4 is expressed exclusively in the glia or in both the glia and neurons. β- and γ-TAC1 mRNAs are the most abundant TAC1 transcripts in the CNS and have been quantified as appearing in a ratio of 1:3; α-TAC1 is expressed at a low level in the olfactory bulb and striatum (approximately 1% of the total transcripts). The most conspicuous source of TAC1 products in the CNS is represented by neurons located in the extra-pyramidal (mainly basal ganglia), limbic (mainly accumbens), thalamic (hypothalamus), and brain stem autonomic areas (mainly the raphe nuclei, periacqueductal gray matter, and lateral dorsal tegmentum). The substantia nigra and dorsal horns of the spinal cord contain a high density of SP- and NKA-positive fibers. Numerous NKB-positive neurons have been detected in the bed nucleus of stria terminalis, olfactory areas, and hypothalamic nuclei; the two latter areas also contain a dense network of NKB-positive fibers.

All the TACR genes described so far have been found to be expressed in the CNS. Despite the species-related variations in the distribution of TK receptors, a general pattern of TK NK1, NK2, and NK3 receptor expression can be discerned. NK1 receptors, of which the long isoform preponderates in the brain, are well represented in the olfactory system and related cortical areas, hippocampus, septum, amygdala, pons, and medulla. NK2 receptors are expressed at low levels in the limbic area of the cortex, hippocampus, thalamic nuclei, and substantia nigra (although only TACR2 mRNA was found, functional evidence for the expression of NK2 receptors is available). NK3 receptors are particularly dense in the deep cortical layers; hippocampus; amygdala; and selected hypothalamic, mesencephalic, and medullary nuclei. The dorsal horns of the spinal cord mainly express NK1 and NK3 receptors; NK2 receptors have also been described, although at a low level of expression. CNS NK2 receptors have described as developmentally regulated because autoradiographic studies have described a moderate expression in newborn animals but low, if any, expression in adult animals. Despite this, functional evidence clearly indicates that the adult brain expresses NK2 receptors in the same areas as newborn animals.

NK1, NK2, and NK3 can be expressed in glial cells which also express all the four TAC1 mRNAs during development. This expression is again turned on in the case of infection or injury, and SP acting through NK1 receptors can support the cytokine-mediated proliferation of glia. This mechanism is also important for the growth of gliomas; in these tumors, TAC4 mRNA expression was also detected. Recently, it has been shown that spinal glial cells can play a role in nocifensive behavior induced by intraplantar carragenan or intrathecal SP, whereas the SP-induced loss of dopaminergic neurons is mediated by the activation of microglial nicotinamide adenine dinucleotide phosphate (NADPH) oxidase.

Several drugs targeting CNS NK1, NK2, and NK3 receptors have been tested in clinics. Promising results have been obtained with an NK3 antagonist in schizophrenia, whereas the same antagonist was ineffective in a pilot trial on levodopa-induced dyskinesia. Likewise, results from large trials on NK1 receptor antagonists in pain and depression have been disappointing; however, aprepritant has been approved for the treatment of nausea and vomiting associated with chemotherapy or surgery. Most of the anatomical and functional information available derives from animal studies, the rat being the most extensively investigated. The main nerve TK pathways in the rat brain are shown in Figure 1 in more details on the distribution of TK peptides and their receptors in the CNS are presented in Table 3.

Rhinencephalon

In macrosomatic animals, the olfactory areas are involved in social behavior, reproduction, and emotional and aggressive behavior, but in microsomatic species, other brain areas are much more important for the regulation of these functions. Because of this, numerous species-related differences have been found in the cytoarchitecture and neuronal chemical coding of this area.

In invertebrates (*Drosophila*), TKs are involved in the modulation of olfactory perception, and a correlation between the degree of anosmia and the loss of SP-positive trigeminal neurons has been observed in a rodent model. However, no major deficits in odor perception have been detected in mice lacking the TAC1 gene. In the rat olfactory tubercle, TAC1 levels are modulated by sodium depletion, alcohol preference, and aging. Olfactory bulbs have also been implicated in the modulation of aggressive behavior; bulbectomy increases aggressions and locomotor activity, effects which are antagonized by antidepressants. Interestingly, bulbectomy-induced hyperactivity was not observed in TAC1 knockout mice, whereas cage-residents NK1 knockout mice displayed reduced aggressions against intruders. However, these effects could also be dependent on other brain areas (the accumbens, ventral pallidum, substantia nigra, or hypothalamus).

Figure 1 Drawing of main tachykinin (TK) pathways in a sagittal section of the rat brain. (1) Medium-size TK-containing neurons in the striatum, also termed as caudate putamen (CPu), send collaterals within the caudate putamen and project to the substantia nigra (SN). Striatal TK-containing neurons also send axons to the entopeduncular nucleus (EP), which is the rodent equivalent of the internal segment of the primate globus pallidus (GP). (2) TK-containing neurons in the ventromedial hypothalamic nucleus (VMH) send axons to the medial preoptic area (MPO), and those in the area between anterior hypothalamic nucleus (AH) and lateral hypothalamus (LH) project to the lateral septal nucleus (LS). The amygdala (Amg) contains a number of TK-containing neurons, which give rise to an intrinsic plexus in the amygdala and also project via the stria terminalis to the bed nucleus of this bundle (BST) and LH. TK-containing neurons in the medial part of the central nucleus of amygdala, together with those in the ventral bed nucleus of stria terminalis, project to dorsal motor nucleus of the vagus nerve (NX), and solitary tract nucleus (Sol). (4) TK-containing neurons in medial habenula (MHb) project via habenulointerpeduncular tract to the lateral subnuclei of interpeduncular nucleus (IP) and ventral tegmental area (VTA). Those in lateral habenula (LHb) project to dorsal raphe nucleus (DR). (5) TK-containing neurons found in rostral subnucleus of interpeduncular nucleus project to dorsal tegmental nucleus (DTg) and laterodorsal tegmental nucleus (LDTg) and to the rostral extension of dorsal raphe nucleus. (6) A group of cholinergic TK-containing neurons in laterodorsal tegmental nucleus projects via the medial forebrain bundle to the lateral septal nucleus and to medial parts of the frontal cortex (FC). (7) TK-containing neurons in the Edinger–Westphal nucleus (EW) project to the facial nucleus (FN) and spinal cord. (8) TK- and cholecystokinin-positive neurons in the periaqueductal central gray matter (PAG) send descending axons to the facial nucleus and spinal cord. (9) TK-containing neurons also co-expressing serotonin and thryrotropin-releasing hormone in raphe pallidus (RPa), raphe obscurus (ROb), and possibly raphe magnus (RMg) send axons to the facial nucleus, solitary tract nucleus, and spinal cord. (10) Raphe magnus receives TK projections from a number of brain stem nuclei including the cuneiform nucleus (Cnf), superior colliculus (SC), median raphe nucleus (MnR), paragigantocellular reticular nucleus (PGi), and solitary tract nucleus. (11) TK-containing primary afferent neurons in the ganglion of the trigeminal nerve (V) receive inputs from various tissues of the orofacial region and terminate in the caudal part of the spinal trigeminal nucleus (SpV). (12) The solitary tract nucleus is innervated by TK-containing primary afferent fibers from the facial (VII), glossopharyngeal (IX), vagal (X), and trigeminal nerves. Acb, nucleus accumbens; LC, locus coeruleus; VP, ventral pallidum. Adapted from Otsuka M and Yoshioka K (1993) Neurotransmitter functions of mammalian tachykinins. *Physiological Review* 73: 229–308.

Telencephalon

The expression of TKs in cortical areas is sparse in rodents but more prominent in other species, including humans. In the rat neocortex, TAC1 and TAC3 are expressed in separate populations of γ-aminobutyric acid (GABA)egic neurons, NKB often co-localizes with acetylcholine, vasointestinal peptide, colecystokinin (CCK), and corticotropin-releasing hormone (CRH). In the enthorinal cortex, bicuculline-induced epileptiform activity was reduced by the activation of NK1, whereas NK3 receptor-mediated enhancement of this activity was due to glutamtergic mechanism. In primates, both NK1 and NK3 receptors are distributed throughout all cortical areas; however, unlike in

Table 3 Tachykinin-positive neurons, fibers, and receptors in CNS areas

Area	*TK-positive neurons*	*TK-positive fibers*	*TK receptors*
Rhinencephalon			
Olfactory bulbs	SP-, NKA-positive mitral and granule cells NKB-positive perigranular cells	SP-, NKA-, NKB-positive fibers. Trigeminal SP and NKA-positive sensory fibers	NK1, NK3
Accessory olfactory bulbs	SP-, NKA-positive granule cells. NKB-positive neurons projecting to the amygdala	SP and NKA-positive sensory fibers	NK1, NK3
Olfactory tubercles	SP-, NKA-positive neurons projecting to the ventral pallidum. NKB-positive neurons projecting to the striatum	SP-, NKA-, NKB-positive fibers	NK1, NK3
Piriform cortex	SP-, NKA-positive neurons	SP-, NKA-, NKB-positive fibers	NK1, NK2, NK3
Telencephalon			
Neocortex	SP-, NKA-positive nonpyramidal cells of layers 4-6. SP-, NKA-positive pyramidal cells projecting to subcortical targets. NKB-positive neurons in layers 2, 3, and 4	SP-, NKA-, NKB-positive fibers. SP, NKA-positive fibers from the medial forebrain bundle (cell bodies in the dorsolateral tegmentum and from septal nuclei)	NK1, NK2, NK3
Nucleus accumbens	SP-, NKA-positive neurons co-express CART peptide and project to the ventral pallidum. Other SP-, NKA-, NKB-positive neurons project ventral tegmental area (some contain GABA). NKB- and mu opioid receptor-positive neurons project to the substantia innominata	SP- and NKA-positive fibers originate from solitary tract nucleus and from the periaqueductal gray area. NKB-positive fibers	NK1, NK2, NK3
Globus pallidus		SP- and NKA-positive fibers (contain dynorphin) from the striatum	NK1, NK3
Entopeduncular nucleus	SP-, NKA-positive neurons (some contain somatostatin) project to the lateral habenular nucleus	SP- and NKA-positive fibers from the striatum	NK1, NK3
Ventral pallidum		SP- and NKA-positive fibers from the accumbens	NK1, NK3
Striatum: matrix	SP-, NKA-positive neurons (contain GABA) project to the substantia nigra pars reticulata, the ventral tegmental area, the entopeduncular nucleus, and to the striatum itself	SP-, NKA-, NKB-positive fibers. NKB-positive fibers from olfactory tubercles	NK1, NK2, NK3
Striatum: striosomes	SP-, NKA-, NKB-positive neurons (contain GABA, dynorphin, and D1 receptors, some also met-enkephalin) project to the substantia nigra pars compacta and to globus pallidus NKB-positive neurons (contain mu opioid receptors) project to the substantia innominata	SP-, NKA-, NKB-positive fibers	NK1, NK2, NK3
Amygdala	SP-, NKA-, NKB-positive neurons project to the bed nucleus of stria terminalis and hypothalamus. SP- and NKA-positive neurons project to the periaqueductal gray	SP-, NKA-, NKB-positive fibers. SP-, NKA-positive fibers from lateral parabrachial and lateral dorsal tegmental nucleus and NKB- from the accessory olfactory bulbs	NK1, NK3
Bed nucleus of the stria terminalis	SP-, NKA-, NKB-positive neurons project to the periaqueductal gray, motor nucleus of vagus, and solitary tract nucleus	SP-, NKA-, NKB-positive fibers from hypothalamus and amygdala	NK3
Hippocampus	SP- and NKA-positive neurons in pyramidal layer and stratum oriens (CA1). NKB-positive neurons in dentate gyrus neurons (CA3)	SP-, NKA-, NKB-positive fibers from the hyothalamus, septo-hippocampal nucleus and local circuitries	NK1, NK2, NK3
Septum and cholinergic forebrain nuclei	SP, NKA-, and NKB-positive neurons, some projecting to the cortex some to the hippocampus	SP- NKA-, and NKB-positive fibers from the hypothalamus and lateral dorsal tegmental nucleus and from local circuitries	NK1, NK2, NK3
Diencephalon

Area	*TK-positive neurons*	*TK-positive fibers*	*TK receptors*
Thalamus	SP-, NKA-, and NKB-positive neurons in habenular nuclei projecting to the midbrain interpeduncular nucleus, dorsal raphe, ventral tegmental area, and the pineal gland	SP-, NKA-, and NKB-positive fibers in habenular nuclei from the entopeduncular nucleus. SP-, NKA-positive fibers in paraventricular thalamic nucleus from Edinger–Westphal and medullary raphe nuclei and mesopontine tegmentum. SP-, NKA-positive fibers in somatosensory thalamic nuclei from spinal cord neurons. SP-, NKA-positive fibers in the intergeniculate leaflet from dorsal raphe. SP-, NKA-, and NKB-positive fibers in the geniculate nucleus from superior colliculus. SP- and NKA-positive fibers in the medial and posterior part of the thalamus from the parabrachial nucleus	NK1, NK2, NK3
Hypothalamus	SP- and NKA-positive neurons in dorsomedial, ventromedial, dorsolateral, lateral, posterior hypothalamus, mammillary nuclei projecting to the hippocampus, preoptic, suprachiasmatic and arcuate, nuclei. NKB-positive neurons in anterior hypothalamus mammillary, arcuate, parabrachial nuclei, dorsal motor nucleus of the vagus, median eminence, and dorsal part of the hypothalamus	SP- and NKA-positive fibers in suprachiasmatic nucleus from retinic afferents. SP-, NKA-, and NKB-positive fibers from the bed nucleus of stria terminalis, the pedunculopontine and the laterodorsal tegmental nucleus (both cholinergic) and medullary cathecolaminergic nuclei (C1, C2, C3, A1, A2)	NK1, NK3
Mesencephalon			
Substantia nigra (A9) pars reticulata		SP- and NKA-positive fibers from ipsilateral striatum matrix area	NK1, NK2, NK3
Substantia nigra (A9) pars compacta		SP-, NKA-, and NKB-positive fibers from ipsilateral striatum striosomal area	NK1, NK2, NK3
Ventrotegmental area (A10)	SP- and NKA-positive neurons	SP-, NKA-, and NKB-positive fibers from habenular and accumbens nuclei	NK1, NK2, NK3
Interpeduncular nucleus	SP- and NKA-positive neurons projecting to the dorsal and laterodorsal tegmentum	SP-, NKA-, and NKB-positive fibers from the habenular nuclei	NK1, NK2, NK3
Superior and inferior colliculi	SP-, NKA-, and NKB-positive neurons projecting to raphe magnus (B3) and to geniculate nuclei and pulvinar	SP- and NKA-positive fibers from retinic ganglionic cells	NK1, NK3
Periaqueductal gray matter	SP- and NKA-positive neurons project to the thalamus, hypothalamus, accumbens, nucleus of tractus solitarius and the spinal cord. NKB-postive neurons project to the facial nucleus	SP-, NKA-, and NKB-positive from bed nucleus of stria terminalis	NK1, NK2, NK3
Edinger–Westphal nucleus	SP- and NKA-positive neurons project to the paraventricular thalamic nucleus, cerebellum, trigeminal motor nucleus and spinal cord	SP- and NKA-positive fibers from the suprachiasmatic nucleus	
Dorsal raphe (B7)	SP- and NKA-positive neurons project to thalamic nuclei intergeniculate leaflet	SP-, NKA-, and NKB-positive fibers from thalamic and habenular nuclei	NK1, NK3
Metencephalon			
Parabrachial nuclei	SP- and NKA-positive neurons project to the amygdala, bed nucleus of stria terminalis, and thalamic nuclei	SP-, NKA-, and NKB-positive fibers from the spinal cord, nucleus of tractus solitarius the reticular formation, the laterodorsal tegmental nucleus, hypothalamic nuclei, bed nucleus of stria terminalis, and amygdala	NK1, NK3
Dorsal and laterodorsal tegmental nuclei	SP- and NKA-positive neurons (some acetylcholine and CRH or ANP) project to the thalamus, hypothalamus, septum, and prefrontal cortex via the medial forebrain bundle	SP- and NKA-positive fibers from the interpeduncular nucleus	NK1, NK3
Pontine raphe nuclei (B5, B6)	SP- and NKA-positive neurons project to NTS	SP- and NKA-positive fibers from medulla (reticular formation, trigeminal, cuneate nuclei, NTS), peduncolopontine tegmental nucleus, other raphe nuclei, and PAG	NK1, NK3

5-HT, serotonin; ANP, atrial natriuretic peptide; CART, cocaine- and amphetamine-regulated transcript; CNS, central nervous sytem; CRH, corticotropin-releasing hormine; GABA, γ-aminobutyric acid; NKA, neurokinin A; NKB, neurokinin B; NTS, nucleus of tractus solitarius; PAG, periaqueductal gray; SP, substance P; TK, tachykinin; TRH, thyrotropin-releasing hormone.

rodents, NK1 exceeds NK3 density. The highest expression of NK3 receptors occurs in the prefrontal cortex. In local circuitries, NK1 receptors are located on neurons expressing nitric oxide, GABA, and glutamate, whereas NK3 sites are specifically linked to glutamatergic transmission. NK3 receptors are also expressed on fibers of GABAergic neurons located in the substantia innominata. The relatively dense expression of NK3 receptors in the prefrontal cortex could be related to the promising results obtained in clinical trial of osanetant, a selective NK3 receptor antagonist, in schizophrenia. Modulatory effects on the TK system have been reported following various conditions such as ischemia, alcohol preference, schizophrenia, and depression. Interestingly, the systemic administration of NK1 or NK2 receptors attenuates stress-induced cortical noradrenaline release; however, these effects could be exerted at the locus coeruleus. NK1 receptor blockade also reduces stress-induced cortical dopamine release by acting putatively at the ventral tegmental area.

TKs and their receptors are expressed in the basal ganglia, such as the nucleus accumbens, globus pallidus, entopeduncular nucleus, and striatum (caudate putamen). The nucleus accumbens is the projection area of the mesolimbic dopaminergic pathway originating in the ventral tegmental area and also receives glutamatergic inputs from cortical areas. The accumbens is believed to serve as interface among emotions, motivation, and movements. Intra-accumbens injection of selective NK1 or NK3 receptor agonists induce a naltrexone-resistant analgesia in the tonic phase of the rat formalin test, suggesting that TKs activate a midbrain dopaminergic component of stress- or pain-induced analgesia. Local stimulation of the NK1 receptor

produced an haloperidol-sensitive increase in locomotor activity, further highlighting the interaction of these receptors with dopaminergic mesolimbic pathway.

The globus pallidus and the entopeduncular nucleus contain a high density of TK fibers, mainly originating from the striatum and creating part of a corticofugal pathway regulating motor activity. Reduced levels of TKs have been described in the postmortem brains of patients affected by Parkinson's and Huntington's diseases.

An increased locomotor activity was observed following NK1 receptor stimulation in the ventral pallidum, a region receiving tachykininergic input from the accumbens. The ventral pallidum is one of the brain areas that has been associated with reinforcing effects mediated by the stimulation of NK1 receptors. Although the injection of C-terminal fragments of SP into the rat ventral pallidum induces an NK1-mediated anxiolytic-like effects in the rodent plus-maze test, the possibility of an unspecific effect due to an increased locomotion cannot be ruled out. Indeed, a large body of evidence indicates that the stimulation of NK1 receptors induces an anxiogenic effects, whereas their blockade induces anxiolytic effects in several animal models.

The striatum is part of the extra-pyramidal motor system that is also involved in the regulation of motivational and cognitive functions. The striatum is the projection area of the mesostriatal dopaminergic pathway; it can be divided into morphologically (but not topographically) distinct areas: the matrix and striosomes. Striatal TK-containing neurons appear to be intimately connected with nigral dopaminergic neurons; dopamine mimetics acutely increase and antagonists decrease striatal TK release, whereas the chronic administration of dopaminergic drugs regulates the expression of TAC1 through a D1 receptor-mediated effect. On the other hand, TKs enhance striatal dopaminergic transmission. In the matrix, NK1 receptors are localized on cholinergic neurons and on somatostatin–nitric oxide synthase-positive neurons, whereas NK3 receptors are probably expressed on both these and dopaminergic neurons. In fact, NK3 receptor stimulation produces a tetrodotoxin (TTX)-resistant dopamine release, whereas that induced by NK1 and NK2 receptor stimulation is totally and partially TTX resistant, respectively. In contrast, in the striosomal area, NK1 receptor stimulation produces a TTX-resistant dopamine release, whereas NK2 receptors control the release of acetylcholine in which the modulation can be positive or negative depending on the viability of the dopamine receptors. The intrastriatal injection of a selective NK1 or NK2 receptor agonist induces atropine-sensitive controlateral rotations in mice, whereas NK1 or NK2 antagonists reduced rotations evoked by the striatal stimulation of D1 receptors. Likewise, the blockade of striatal NK1 receptors reduces amphetamine- or cocaine-induced dopamine release and protects striatal dopaminergic fibers from the toxic effect produced by amphetamine. Alterations in the striatal TK system have been associated with movement disorders in Parkinson's and Huntington's diseases. Reduced SP levels were observed in the striatum of Parkinson's patients, and the degree of reduction of TAC1 expression has been associated to the severity of motor impairment in a model of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridire (MPTP)-induced Parkinsonism. Reduction of SP in the striatal projection to the substantia nigra pars reticulate has been detected in Huntington patients.

As with other brain areas, amygdala is involved in a number of vital functions such as memory, emotions, sexual (one amygdaloid nucleus is more conspicuous in males than females) and aggressive behaviors, and neuroendocrine and autonomic regulations. In this area, NK3 receptors are abundant in rodents but relatively scarce in primates, whereas NK1 receptors predominate. The release of TK acting at the NK1 receptors in the amygdala has been associated with phobias and anxiety in both humans and rodents, and it is an important site where NK1 antagonists exert their anxiolytic effect. NK1 receptors have also been implicated in stress-induced hypertension. Accordingly, SP expression was increased in the medial amygdaloid nucleus (and lateral hypothalamus) in a rodent model of chronic mild stress. NK1 receptor-expressing (i.e., GABAergic) neurons have also been involved in opiate reward because the selective ablation of these neurons prevents morphine-induced conditioned place preference. Local activation of NK3 receptors suppresses salt intake in sodium-depleted rats.

The bed nucleus of the stria terminalis, which is also sexually dimorphic, is the area with the densest network of NKB-positive fibers. Local injection of NKA or its elongated forms suppresses male copulatory behavior. The local stimulation of NK3 receptors suppressed alcohol, water, and food intake in deprived rats. Altogether, these effects suggest that TKs exert a potent rewarding effects at this level.

The hippocampus is associated with memory generation and processing. The role of local NK1, NK2, and NK3 receptors in the regulation hippocampal circuitries is uncertain. It is known that the blockade of NK2 or NK3 receptor reduces the hippocampal release of acetylcholine induced by stress or CRH; however, these effects are likely to be exerted at the cholinergic basal forebrain nuclei such as the septal nuclei and/or nucleus basalis of Meynert rather than locally. Systemic administration of a selective NK1 receptor antagonist produces a dose-dependent increase of

hippocampal acetylcholine release and facilitates inhibitory avoidance learning and open field habituation. However, NK1 receptor antagonists also block SP-induced long-term potentiation, and decreased hippocampal SP levels have been observed following chronic β-amyloid infusion, suggesting that the stimulation of these receptors could elicit both pro- and anti-amnestic effects. Long-term treatment with NK1 antagonists enhances hippocampal serotonin (5-HT) transmission; this effect is believed to underlie the effect of these antagonists in animal models of depression. Hippocampal TKs have also been related to the development of epilepsy; status epilepticus increased hippocampal levels of both SP and NKB, and NK1 antagonists offered some protection against seizures.

The basal forebrain and septal cholinergic nuclei are part of the limbic system regulating a variety of behavioral (cognitive and emotional) and autonomic (cardiovascular, osmoregulation, and thermoregulation) functions. Stimulation of NK1, NK2, and NK3 receptors located on these nuclei elicits hippocampal acetylcholine release; however, NK2 antagonists reduced it only when elicited through CRH or behavioral stimulation. Local stimulation of NK1 receptors produces anxiogenic effects and increases blood pressure; however, given the results discussed so far, it is likely that this area is involved in the anxiolytic effects of NK2 but not of NK1 antagonists.

Diencephalon

The thalamus integrates somatosensory and motor information from both the spinal cord and brain stem nuclei and projects to the basal ganglia and cerebral cortex. In addition, an area close to the geniculate nuclei is part of the pathway regulating circadian rhythms. Systemic administration of a NK2 antagonist selectively reduces the firing of rat posterior thalamic neurons induced by thermal but not mechanical stimuli; however, this effect could be exerted at the spinal cord level. Systemic administration of NK1 antagonist inhibited light-induced phase advancement of locomotor activity in hamsters, indicating that NK1 receptors are the targets of retinic input; however, this effect could involve hypothalamic or mesencephalic, in addition to thalamic sites.

The hypothalamus, the first structure from which SP was isolated, controls endocrine functions through the pituitary, but it is also an important relay for autonomic (cardiovascular and thermoregulatory) and emotional (aggressive-defensive and ingestive) responses. Application of NK1 antagonists in the medial hypothalamus reduces aggressive behavior induced by amygdaloid stimulation.

Several neurohormonal effects are mediated by TKs acting through NK1 and/or NK3 receptors, although it should be pointed out that TKs can act at all levels of the hypothalamic–pituitary–gonadal or hypothalamic–pituitary–adrenal axes to produce neurohormonal effects. A dense network of TK-containing axon terminals are close to the blood vessel in the median eminence. SP acts on the suparoptic nucleus to release both vasopressin and oxytocin through the stimulation of both the NK3 and NK1 receptors. Interestingly, prolonged hypotension alters the dynamics of NK3 receptors at this level, supporting the involvement of NKB in the CNS control of cardiovascular homeostasis. NK3 receptors also control the secretion of gonadotropin-releasing hormone. NK1 receptors are involved in the control of luteinizing hormone and follicle-stimulating hormone release with direction of effects which depend on the follicular phase. Prolactin secretion can also be modulated by TKs. They exert a direct stimulatory effect on the pituitary gland, but at hypothalamic level TKs interact with both inhibitory and stimulatory mechanisms. SP, acting through NK1 receptors, tonically inhibits both the release and the synthesis of CRH by acting on the rat paraventricular nucleus. An NK1 receptor-mediated control of growth hormone secretion has also been postulated. In turn, as a feedback mechanism, a variety of hormones or releasing factors (CRH, ghrelin, TRH, testosterone) exert a regulatory effect on the expression of TK peptides and receptors.

Mesencephalon

The substantia nigra has been traditionally associated with disorders of the extra-pyramidal motor system, but this area also plays an important role in regulating autonomic, neuroendocrine, and emotional processes. Dopaminergic neurons of the substantia nigra (A9) pars reticulata and pars compacta receive direct excitatory input from ipsilateral striatal TK-containing neurons from the matrix and striosomes, respectively. Nigral TK fibers also target nondopaminergic (possibly GABAergic) neurons. In rodents, NK3 receptors, which are located on dopaminergic neurons, are the most abundant; in humans, dopaminergic neurons express NK1, but not NK3, receptors, and the formers are the most represented. The intranigral administration of nonselective TK agonists reproduces several electrophysiological, neurochemical, and behavioral effects of dopaminergic drugs; however, the dissection of the role of each TK receptor has revealed an unexpected complexity of the regulation of mesostriatal dopamine system by TKs. In rat studies, the unilateral intranigral infusion of NK1 receptor antagonists induced ipsilateral rotations, whereas NK1 agonists had no effect on locomotion but elicited vacuous oral movements, an effect enhanced by the chronic blockade of dopamine D2 receptors that suggests

that this mechanism is linked to tardive dyskinesia. Indeed, the infusion of an NK1 agonist in the pars reticulata induced a short-term (1–20 min) decrease of striatal dopamine release followed by a long-term (60–180 min) increase, suggesting that NK1 receptors can either inhibit or excite A9 dopaminergic neurons. However, when locomotor activity was increased by striatal D1 receptor stimulation, this effect was reduced by the nigral blockade of both NK1 and NK3 receptors. The stimulation of NK3 receptors in the substantia nigra compacta elicited locomotion, rearing, and sniffing; these receptors are located on A9 cell bodies, as determined by tyrosine hydroxylase co-localization and selective neurochemical lesions. A similar dopaminergic activation was elicited by uni- or bilateral stimulation of NK2 receptors in the substantia nigra reticulata that was paralleled to an increased metabolism of dopamine in the striatum. Interestingly, the selective stimulation of nigral NK1, NK2, or NK3 receptors elicits tachycardia in normotensive rats, whereas the blockade of these receptors decreases blood pressure in spontaneously hypertensive animals.

The ventral tegmental area (VTA) is the origin of dopaminergic neurons (A10) of the mesolimbic and mesocortical systems, which project to the nucleus accumbens, amygdala, olfactory tubercle, and prefrontal cortex. VTA has been associated with the regulation of locomotion, stress, reward, and the cardiovascular system. There is evidence that NK3 and possibly NK1 receptors are expressed on dopaminergic neurons because selective NK3 and NK1 agonists increase dopamine metabolism in the prefrontal cortex and nucleus accumbens and activate olfactory tubercle neurons. These neurochemical effects are associated with hyperlocomotion in the open field or, when tested in a familiar environment, with a characteristic stereotypic behavior consisting of sniffing, digging, face washings (NK1-mediated), head scratching (NK2-mediated), rearings, and wet-dog shakes (NK3-mediated). A parallel NK1 or NK3 receptor-mediated increase in blood pressure and heart rate has been also reported, whereas the stimulation of NK2 receptors increased heart rate only. These autonomic effects have been postulated to be the cardiovascular component of the defensive reaction. VTA NK1 receptors are also critical for the stress-induced analgesia because the reduction in the tonic phase of the formalin test induced by foot shock stress was prevented by VTA injection of NK1 antagonist. Furthermore, VTA stimulation of TK receptors induces analgesia that was reduced by the blockade of dopamine receptors in the nucleus accumbens, implying that TKs are the key mediators for the activation of the mesolimbic dopaminergic pathway during pain- or stress-induced analgesia. Like in the VTA, stress affects the TK system in the interpeduncular nucleus. The stimulation of NK1 receptors in the VTA has been associated with reinforcement properties of drugs of abuse in rodents, whereas in primates this effect has been attributed to the stimulation of NK3 receptors.

The periaqueductal gray matter (PAG) is another brain area involved in behavioral and autonomic manifestations related to stress, pain, and defense. PAG SP release has been observed following noxious stimuli, and the stimulation of PAG NK1 receptors, which are located on glutamatergic neurons, produces analgesia, produces anxiogenic-like effects, and increases fear-related behavior. NK1 receptor blockade in the nucleus of tractus solitarius (NTS) also prevents baroceptor reflex inhibition elicited by the electrical stimulation of the PAG, indicating that TK-positive neurons in this latter area integrate cardiovascular control exerted through the NTS.

The midbrain dorsal and medial raphe nuclei (B7 and B8) contain both TK-containing fibers and neurons which largely co-express SP and 5-HT in primates but not in rodents. In the dorsal raphe, NK1 receptors are located on glutamatergic neurons, which in turn excite 5-HT neurons (B7). The released 5-HT acts at the somatodendritic 5-HT1A receptors to provide inhibitory feedback. The fact that in some animal species (mouse and guinea pig) the acute administration of NK1 antagonists increase the neuronal activity of 5-HT neurons suggests that the described mechanism is tonically active. In contrast, the administration of NK2 (but not NK1) antagonist decreases the firing of rat 5-HT neurons. Dorsal raphe 5-HT neurons, which project to the hippocampus, are believed to be involved in the antidepressant/anxiolytic properties of NK1 receptor antagonists because hippocampal 5-HT transmission is enhanced following the chronic administration of NK1 antagonists as well as other antidepressant treatments. Activation of NK2 receptors in the median raphe increases rat locomotor activity, an effect dependent on the integrity of 5-HT neurons, whereas the stimulation of NK3 receptors increases locomotor activity and induced straub-tail, hindlimb splaying, and oral movements, suggesting that these receptors control the activation of the mesolimbic and mesostriatal dopaminergic pathways.

Metencephalon

In the pons, the highest density of TK-positive fibers (including NKB) is observed in the parabrachial nuclei, which are important centers for the integrating afferent inputs, including gustatory and visceral nociceptive stimuli, to the thalamic nuclei for the regulation of autonomic functions. Interestingly, the local blockade of NK1 receptors reduces nociception-induced

tachycardia, indicating that the supraspinal sympathetic drive is regulated by TKs.

Noradrenergic locus coeruleus neurons (A6) are activated by SP via NK1 receptors; NK1 antagonists do not acutely affect the spontaneous firing of these neurons, although they can prevent the inhibitory effect of adrenergic α-2 agonists. An increase in the spontaneous firing of A6 can be elicited following the chronic blockade of NK1 receptors. Stimulation of NK3 receptors also activate A6 neurons, and, at least in guinea pigs, these receptors have a permissive role on the NK1-mediated stimulation because noradrenaline release in the prefrontal cortex induced by NK1 agonists can be blocked by selective NK3 antagonists. The blockade of NK2 receptors also reduces stress-induced firing of A6 neurons and noradrenaline release in the prefrontal cortex, suggesting the expression of these receptors on these neurons. Locus coeruleus is involved in a number of physiological responses related to stress, including arousal and associated autonomic manifestations. The main center regulating the micturition reflex is also located close to the locus coeruleus; NK1, NK2, and NK3 receptors exert a supraspinal modulation of this reflex, but it is uncertain whether TKs act in this area.

The cerebellum contains only a few TK-expressing neurons and fibers. NKA and NKB are expressed in granule cells, and the stimulation of either NK2 or NK3 receptors can enhance glutamate neurotoxicity, whereas SP is more abundantly expressed in the glial cells. Dynamic changes in the cerebellar TK system have been observed in models of epilepsy.

Myelencephalon

TKs have been involved in the regulation of a number of autonomic functions at the medullary level, such as the regulation of cardiovascular reflexes (the baroceptor reflex, in particular), respiratory drive, and gastric motility (emesis) and secretions. SP- and NKA-positive afferent fibers from baroceptors and carotid body chemoceptors project to the NTS and ventrolateral medulla and are released during hypoxia; TKs applied at these sites evoke both respiratory and cardiovascular responses. The selective stimulation of either NK1, NK2, or NK3 receptors in the NTS produces bradypnoea, whereas the stimulation of either NK1 or NK3 receptors increases only the tidal volume. Exposure of neonatal rats to hypoxia produced an increase in respiratory frequency, an effect that was prevented by blocking NK1 receptors in the ventrolateral medulla. In adult rats, the hypoxia-induced hyperventilation of NK1 receptor knockout mice was attenuated compared to wild-type counterparts, indicating that TKs acting at these receptors modulate but are not essential for respiratory reflexes, at least in adulthood.

Baroceptor activation also induces the release of TKs in the NTS, where NK1 receptors are also involved in the modulation of baroceptor sensitivity following emotional noxious stimuli or physical exercise because the blockade of NK1 receptors differentially affects the symapathetic and parasympathetic arms of the vascular and cardiac components of the baroceptor reflex.

Medullary TKs are involved in the regulation of motility and secretions of the upper gastrointestinal tract (GI). CNS-acting NK1 antagonists block the emetic reflex induced by a wide array of chemical or physical stimuli in selected animal species. The stimulation of NK1 receptors in the dorsal motor nucleus of the vagus inhibits gastric motility; however, other medullary centers, such as the NTS and area postrema, could also participate in the anti-emetic effects of NK1 antagonists. C-fos expression in the NTS and area postrema induced by acid challenge into the stomach is modulated in a complex manner by excitatory amino acid and NK1 and NK2 receptors; the CNS blockade of these latter receptors prevents stomach acid secretion evoked by the CNS stimulation of transient receptor potential cation channel subfamily V (TRPV)1 receptors, the capsaicin receptors. Interestingly, the stimulation of CNS NK2 receptors can also evoke antisecretory effects (possibly through a dopaminergic mechanism) when gastric secretion is induced by pylorus ligation.

Finally, beyond the amygdala, hypothalamus, and PAG, the medullary areas receiving sensory TK inputs, such as the rostroventral medulla, provide a descending inhibitory control on noxious afferent processing in the spinal cord. This inhibitory control is disrupted in NK1 knockout mice or by blocking NK1 receptors in wild-type counterparts; however, it is still unclear whether spinal or supraspinal NK1 receptors play a pivotal role in this effect.

Spinal Cord

Most of the TK content in the spinal cord originates from fibers of the bulbospinal descending pathways and primary afferent neurons, which mainly project to the dorsal horn and autonomic areas. TK-positive spino-thalamic neurons, some of which co-express enkephalin, have also been detected. Capsaicin-sensitive (TRPV1-expressing) primary afferent fibers contain SP and NKA but not NKB, and they co-localize glutamate and calcitonin gene-related peptide (CGRP). The quantity of TK-positive sensory fibers is much higher in visceral than in somatic districts, so that TKs were postulated to play a more important role in the transmission of noxious information from the former than the latter domains. The vast majority of these fibers are unmyelinated (C fibers), whereas

fewer SP- and NKA-positive fibers are thinly myelinated (A-δ), with small or medium-size cellular bodies (respectively) located in the dorsal root ganglia (DRG). Most of these fibers project to the dorsal horn neurons located in lamina I and II; fewer in laminae III, IV, V; along the central canal (lamina X); and in autonomic areas. These capsaicin-sensitive neurons have been classified as polymodal nociceptors because they are preferentially stimulated by chemical and thermal stimuli and are also involved in encoding mechanosensitivity. Indeed, a certain deficit in encoding the intensity of paw pressure and colonic or bladder distension has been observed in NK1 or TAC1 knockout mice, respectively. Despite this, chemically induced but not hot- or pressure-induced nociceptive behavior was consistently reduced in either TAC1 or NK1 knockout mice, indicating that mechanical and thermal sensitivities were not altered despite the mentioned deficit in the electrophysiological coding of these stimuli. Interestingly, the enhancement of activity of the dorsal horn neurons induced by the repetitive stimulation of C fibers, a phenomenon defined as wind-up, was reduced in NK1 knockout mice, supporting an important role of TKs released from afferent fibers in central sensitization. NK1 receptors are expressed throughout all levels of the spinal cord, and their density exceeds that of NK2 and NK3 in both the dorsal (laminae I, III, IV, V) and ventral (lamina VII, VIII, IX, and X) parts and in the autonomic areas, whereas fewer receptors were found in the outer part of lamina II. NK3 receptors are denser in superficial laminae (I and II), where they co-localize with NOS and are scattered in other regions. A few NK2 receptors were detected in the spinal cord; these are mainly located in lamina I, V, and X and could be expressed by astrocytes rather than neurons.

There is massive electrophysiological and neurochemical evidence that TKs are released in the spinal cord upon peripheral noxious stimulation when NK1 receptors play a prominent role in the excitation of spinal cord nociceptive projection neurons. Despite this, the antinociceptive (or antihyperalgesic) activity of NK1 antagonists is restricted to a few animal models and is absent in humans. Several hypotheses, which are not mutually exclusive, have been put forward to explain this discrepancy.

1. The blockade of NK1 receptors alone is not sufficient to block the transmission of noxious signals, whereas the ablation of NK1 receptor-expressing spinal neurons is an effective antihyperalgesic treatment.
2. NK1 receptors are also located on inhibitory GABAergic neurons located in lamina V, whose excitation provide a strong and a long-lasting (feed-forward) inhibition to nociceptive projection neurons (i.e., SP-induced antinociception).
3. The excitation of NK1-expressing spinal cord nociceptive projection neurons activates supraspinal dopaminergic systems, which, in turn, activate a descending inhibitory control on nociceptive projection neurons (i.e., stress-induced analgesia).

Beyond the processing of nociceptive inputs, spinal cord TKs regulate neurovegetative functions. At the thoracolumbar level, NK1 and NK3 receptors affect preganglionic sympathetic neurons differently and evoke cardiovascular effects in spontaneously hypertensive rats which are qualitatively different from those observed in normal counterparts. Stimulation of NK1 receptors inhibits natriuresis and diuresis by enhancing sympathetic nerve activity. At the lumbosacral level, NK1 antagonists modulate the micturition reflex induced by bladder distension or irritation, whereas the stimulation of NK3 receptors produces an inhibitory effect on this reflex and affects urethral motility, probably through a direct action on Onuf's nuclei. The expression of TKs and TK receptors in CNS areas is detailed in Table 3.

Tachykinins and Their Receptors in the Peripheral Nervous System

In the PNS, TKs are expressed in peripheral branches of a subpopulation of capsaicin-sensitive afferent neurons, enteric neurons, and, under certain circumstances (i.e., axotomy), also in postganglionic sympathetic neurons. Peripheral branches of TK-positive capsaicin-sensitive afferent neurons, which originate from the DRG and trigeminal ganglia (which express TAC1 but not TAC3), are ubiquitous, although represented more in the visceral than somatic regions. Although the three TK receptors can be potentially expressed on the soma of DRG neurons, evidence for their expression on sensory fibers and terminals is scanty. In contrast, TK receptors are located on sympathetic and parasympathetic postganglionic neurons both in their soma within ganglia and in terminals regulating the activity of viscera. Likewise, NK1 and NK2 receptors are expressed by several cell types in peripheral tissues innervated by capsaicin-sensitive sensory neurons; the activation of these receptors mediates part of the an inflammatory response that has been defined as neurogenic inflammation. Several cell types express TAC1 in the enteric nervous system, and TAC3 expression has also been detected, although the amount of NKB was much less than the amount of SP and NKA at this level. NK1, NK2, and NK3 receptors have been found to be expressed on enteric neurons or nerve fibers, in addition to

effector cells. At the peripheral level, TAC4 expression has been shown to occur in nonneuronal cells (mainly leucocytes and reproductive cells).

Peripheral Branches of Afferent Fibers

TK-positive capsaicin-sensitive afferent neurons, which co-express glutamate and CGRP, terminate as free nerve endings in the skin and in the cardiovascular, bronchopulmonary, GI, genitourinary, and hematopoietic systems. The action of capsaicin on these nerve terminals is twofold in that an early excitatory effect is followed by a late neurotoxicity with a consequent depletion of TKs in innervated organs. These peripheral nerve terminals, which can be considered dendrites of the DRG, have the unique property of producing an antidromic release of both SP and NKA (and other mediators) on their stimulation (Figure 2).

The activation of NK1 receptors by peripherally released TKs can induce vasodilatation, promote plasma leakage and glandular secretions, and target a number of inflammatory/immune cells such as mast cells, neutrophils, macrophages, and lymphocytes. The stimulation of NK2 receptors has been associated with smooth-muscle contraction and increases the intraluminal permeability of hollow organs. Fewer effects have been associated with the stimulation of NK3 receptors by TKs released from sensory nerves. At the bronchopulmonary level, they have been shown to modulate parasympathetic outflow, whereas the source of TKs capable of evoking NK3-mediated contraction of the portal vein is still uncertain. Although peripheral terminals of sensory neurons represent an important source of tachykinins in the periphery, note that the role of nonneuronal TKs from inflammatory, epithelial, and neuroendocrine cells has been recently exploited.

In several animal models, the release of TKs at the bronchopulmonary level occurs following stimuli of chemical (irritants such as capsaicin, acrolein, and pollutants), physical (acid and cold), or biological

Figure 2 Drawing of a tachykinin-expressing capsaicin-sensitive sensory neuron and its targets at the peripheral and spinal cord level. Tachykinin NK1 receptors are located on (1) blood vessels, where they mediate vasodilatation and plasma leakage; (2) inflammatory cells such as lymphocytes (where they induce the expression of Th1-type cytokines), dendritic cells, macrophages; and neutrophils (where they promote respiratory bursts); (3) epithelial cells, where they favor proliferation; (4) epithelial secretory cells (i.e., globet cells), where they elicit mucous secretion; and (5) the spinal cord, where they participate in the transmission of nociceptive signals. Tachykinin NK2 receptors are located on (1) smooth muscle cells, where they elicit contraction; (2) epithelial cells, where they favor luminal permeability; (3) macrophages, where they favor respiratory burst; and (4) the spinal cord, where they participate in the transmission of nociceptive signals. NK3 receptors are rarely found at the peripheral level in the field of innervation of capsaicin-sensitive sensory neuron, but they can be stimulated at the spinal cord level. NK, neurokinin; TK, tachykinin.

(allergens, viruses, and products of bacterial metabolism) origin. In some animal species (guinea pigs and rabbits) but not in other ones (rats and mice), TKs induce bronchoconstriction through a direct stimulation of NK1 and NK2 receptors located on bronchial smooth muscle, promote airway hyperreactivity, and enhance motor responses driven by parasympathetic nerves (this latter effect is also promoted by NK3 receptors). An important role of NK1 receptors in eliciting mucus secretion and globet cell hyperplasia has also been demonstrated. Although bronchial inflammation (both plasma protein extravasation and recruitment of inflammatory cells) has been largely attributed to the stimulation of NK1 receptors, a minor NK2-mediated component has also been highlighted (intraluminal permeability of airways and recruitment of inflammatory cells). NK1 receptors are also expressed on airway epithelium, fibroblasts, and myoepithelial cells. In humans, the density of TK-positive fibers is much lower than in animals, and exploratory short-term clinical trials with NK1 or NK2 antagonists failed to show a significant TK-mediated component of asthmatic bronchoconstriction.

Only a minor component of the TK content in the GI tract originates from extrinsic capsaicin-sensitive afferent neurons. This applies also for salivary glands in which SP originates from both trigeminal (capsaicin-sensitive) and otic ganglia, in which it is co-expressed with acetylcholine in parasympathetic neurons (capsaicin resistant).

Primary afferent neurons provide the main source of SP and NKA in the urinary tract organs such as the kidney, ureter, urinary bladder, and urethra, and in associated peripheral ganglia (the pelvic and inferior mesenteric ganglia). The stimulation of these nerve terminals produces local motor effects in which NK2 receptors located on smooth muscle play a prominent role in most species, whereas NK1 receptors mediate spasmogenic effects mainly in rats (bladder and urethra) and in guinea pigs (ureter, bladder, and urethra). The stimulation of NK3 receptors can also elicit contractile responses in the rat ureter and urinary bladder; however, in the last organ the response is mediated by the release of TKs from nerve terminals which act through NK1 and NK2 receptors located on smooth muscle. Although this result provides evidence for the expression of NK3 receptors on peripheral terminals of capsaicin-sensitive neurons, the source of the endogenous-preferred agonist for these receptors (e.g., NKB) remains elusive. A role for both the NK1 and NK2 receptors in the enhancement of contractile effects mediated by the parasympathetic nerves has also been demonstrated. Because it occurs in the airways, the stimulation of NK1 receptors produces prominent proinflammatory responses such as vasodilatation, plasma leakage, leukocyte infiltration, mast cell degranulation, production of reactive oxygen species, and the expression of adhesion molecules. A role of NK1 receptors in promoting inflammatory responses in animal models of chemical cystitis has been demonstrated, whereas NK2 receptors play a role in bladder overactivity in models of bacterial cystitis and detrusor dyssinergia that follows spinal cord transection. Again, the contribution of these mechanisms in human diseases is uncertain because TK-positive nerve fibers are more prominent in animals than humans.

Primary afferent neurons provide a source of SP and NKA in both the male and female reproductive systems, although placenta and cumulus granulosa cells, blastocysts, and oocytes represent an alternative source of TKs (including products of the TAC3 and TAC4 genes) at this level. The effects of TKs include the enhancement of uterine and fallopian tube contractility, cervical dilatation, vasodilatation and plasma leakage of uterine vasculature, electrolyte transport across the endometrium, and secretion of steroids from the corpora lutea. The receptors involved in these effects are subjected to both species- and ovarian cycle-dependent variations. TKs have been implicated in stress-induced abortion, but a role in physiological pregnancy can also be postulated because capsaicin pretreatment or chronic treatment with an NK3 antagonist reduces rat litter size.

Enteric Nervous System

In the GI tract, most TKs (SP and NKA) are expressed by several classes of intrinsic neurons which are resistant to the neurotoxic effect of capsaicin. Evidence for the presence of NKB in the GI tract is scanty; its expression overlaps that of SP and NKA. A schematic representation of GI neurons expressing TKs is shown in Figure 3.

From a functional point of view, TKs provide inputs to smooth-muscle cells, interstitial cells of Cajal, myenteric and submucous neurons, glands, and secretory cells. Both NK1 and NK2 receptors mediate a noncholinergic excitatory component to muscular transmission and provide a prejunctional enhancement of cholinergic drive. The relative role of NK1 and NK2 receptors can vary depending on the intestinal segment and the species examined, but in humans the latter receptors play a pivotal role in the postjunctional effects mediated by endogenous TKs. In contrast, in all species examined so far, NK1 receptors are expressed on the interstitial cells of Cajal; these cells are believed to play dual motor and sensory roles because both are involved in the generation of slow waves and could behave also as stretch-sensitive

Figure 3 Schematic summary of the most important classes of TK-containing neurons and their polarized (oral-aboral) projections within the guinea pig small intestine. Extrinsic afferent neurons (in green) expressing calcitonin gene-related peptide (CGRP) arise from the dorsal root ganglion (DRG) and on their way to the gut pass through the prevertebral ganglion (PVG). Intrinsic neurons arise from the myenteric plexus (MP) and the submucosal plexus (SMP). Intrinsic primary afferent neurons (in light blue) express cholineacetyltransferase (ChAT) and calbindin (CB); long-projecting ascending excitatory motor neurons (in red) to the circular muscle (CM) express ChAT, neurofilament protein (NF), and enkephalin (ENK); and short-projecting ascending excitatory motor neurons (in red) to the circular muscle express ChAT, ENK, and γ-aminobutyric acid (GABA). Excitatory motor neurons (in red) to the longitudinal muscle (LM) express ChAT and calretinin (CR); ascending interneurons (in red) express ChAT and CR. MM, muscularis mucosae; MU, mucosa; TK, tachykinin. structures. NK1 and NK3 receptors are expressed on the soma of descending motor neurons, where their activation produces relaxant effects on smooth muscle. TK-mediated motor effects can also be regulated through an effect on myenteric neurons. NK3 receptors are involved in (slow) excitatory inputs between intrinsic primary afferent neurons, whereas NK1 receptors mediate slow excitatory inputs from intrinsic primary afferent neurons to interneurons. The cell body of ascending interneurons expresses both NK1 and NK3 receptors, whereas both varicosities and the cell body of descending inhibitory interneurons express NK2 receptors. A schematic representation of the GI expression of TK receptors is shown in Figure 4.

This complexity is well reflected in the variety of functional effects exerted by TK antagonists which depend on the species, the intestinal segment examined, and the experimental setting. Despite this, the general role of TKs in the regulation of GI tract physiology can be outlined. Peristalsis of isolated small or large intestine induced by distension is not consistently affected by NK1, NK2, or NK3 antagonists, but inhibitory effects can be observed when more than one TK receptor is blocked. A synergism between muscarinic and NK2 antagonists blocking peristalsis was observed in both the small intestine and colon of several species, whereas a similar inhibitory synergism between NK3 and nicotinic antagonists has been observed in the colon. These results indicate that TKs acting through NK1 and NK2 receptors (the latter is more important in humans) act as co-transmitters of acetylcholine at the neuromuscular junction, and NK3 receptors facilitate cholinergic transmission at synapses. Together the excitatory effects and the selective stimulation of each TK receptor can elicit inhibitory effects on intestinal motility. This effect could have pathophysiological relevance because the selective blockade of NK1, NK2, or NK3 receptors rescued an inhibited motility in rat models of postoperative ileus. Dilatation of mucosal arterioles induced by distension or mucosal stroking is partly mediated by TKs acting at NK3 receptors.

Figure 4 Schematic summary of the cellular expression of tachykinin NK1, NK2, and NK3 receptors in the guinea pig, rat, mouse, and human gut, based on immunocytochemical and pharmacological evidence. Filled circles depict neuronal cell bodies. Neurons in light blue are intrinsic primary afferent neurons. Ascending/descending motor neurons, interneurons, secretomotor, and vasomotor neurons are in red. Green ovals represent tachykinin NK1 receptors, violet triangles represent NK2 receptors, and yellow rectangles represent NK3 receptors. TKs also activate secretory processes through NK1, NK2, and NK3 receptors. NK1 or NK3 receptors exert this control through secretomotor neurons, whereas NK2 receptors are expressed on effector cells. All TK receptors have been involved in the peripheral modulation of visceral sensitivity; however, the precise mechanism through which TKs sensitize visceral afferents remains to be elucidated. As in other visceral organs, NK1 receptors mediate most of proinflammatory effects induced by TKs; these include vasodilation, promotion of plasma leakage, leukocyte recruitment, mast cell degranulation, stimulation of phagocytosis, and immunoglobulin and cytokine (especially T-helper (Th1) type, those linked to innate immunity) production. NK1 receptors have also been associated with enterocyte proliferation.

A few clinical studies have described the role of TK receptors in humans. NKA switches the small intestine motility from a fasted to a fed pattern through the stimulation of NK2 receptors. These receptors could be also involved in colonic urgency and in stress-induced inhibition of bowel movements, whereas the stimulation of NK1 receptors increases small intestine blood flow. Several drugs targeting the NK1, NK2, and NK3 receptors are being developed for GI diseases such as inflammatory bowel disease and irritable bowel syndrome.

Suicide

Incidence and Epidemiology

There are approximately 30 000 completed suicides per year in the United States and approximately 1 million worldwide. No one knows the actual number of attempts annually, but a conservative estimate is seven attempts per every completion – hence, at least 200 000 in the United States and 7 million in the world. Suicide ranges between the eighth and twelfth leading causes of death in the United States annually and it occurs at the rate of approximately ten per 100 000 in the United States (combined for both genders, all ages and races). The aftereffects of completed suicide extend far beyond the immediate family, leaving devastated relatives, colleagues, and friends. When studying suicide, comparing various groups, it is helpful to compare rates of completions or attempts per 100 000 of a given population at risk. For example, the fact that suicide is the second or third leading cause of death for college-age students is tragic, but this does not mean that their rate of suicide is higher than the average rate for all ages combined; it means that most young adults in such a healthier young population are not dying of heart disease, cancer, etc., so the number of deaths in this 'healthier' population will rank higher as a cause of death for this subpopulation than for a less healthy population. It is important to keep in mind that age-adjusted data are more reliable than crude death rates when comparing populations (unless one is studying rates for specific ages). Finally, when the International Classification of Diseases (ICD) was changed from ICD-9 to ICD-10 in 1997, slight differences in the classification of suicide ensued, making comparisons of pre-1997 data to post-1997 data not entirely comparable.

Gender Differences

Males complete suicide more than 3 times as frequently as females despite the fact that females attempt suicide 3 times more frequently than males. This appears to hold true for all countries throughout the world with the exception of China, where female completions equal or exceed male rates. Female completion rates peak in the middle years, resulting in a convex curve.

Racial and Ethnic Differences

White completion rates are greater than black rates; Hispanic rates are intermediate (except that young Hispanic women have particularly high attempt rates). Native Americans and Alaskan natives have the highest completion rates. South Asian completion rates vary along religious lines: Muslim's have remarkably low completion rates, whereas Hindu rates are relatively high.

Age Effects

Completed suicide is rare in children before puberty. Regarding US rates, from age 15 years through old age, in white males, rates are almost directly proportional to age with the exception that the slope is mildly biphasic – with an initial peak at approximately age 30–45 years and then slightly dipping before continuing to increase. In old age, rates are highest of all. Black US male rates are roughly comparable to white male rates until approximately age 35–40 years, after which black rates level off or decrease, whereas white male rates continue to increase. Female attempt rates are much greater than male attempt rates, especially in younger women (15–40 years old), and the white/black disparity is also seen in female attempt rates (Figures 1–3).

Religious and Socioeconomic Effects

Aside from the low rates in Muslims, religious and socioeconomic effects are not profound. In the United States, Protestants and Jews have slightly higher completion rates per 100 000 of a given at-risk population than do Catholics. Lower socioeconomic status is slightly more associated with completed suicide than is higher status.

Theories Possibly Accounting for These Differences

Very young children lack the means to kill themselves and may also lack the will and despair which accompany suicide. Furthermore, their dependence on their parents for their happiness and survival may also mitigate against suicide, as may their cognitive immaturity vis-à-vis existential matters. Women are more likely to choose suicide methods which are less lethal, less painful, and less disfiguring than those chosen by males (however, both sexes use guns as the most frequent method in the United States, but men choose guns more, proportionately). Thus, the use of pills is greater in females and this allows a larger margin of safety. Another explanation which has been put forth is that

Figure 1 2003 suicide rates by age, race, and gender. Data from www.cdc.gov, Morbidity & Mortality Data, Wisqars program, September 2006.

the greater amount of alcohol abuse and dependence in males accounts for the differences (so that controlling for alcohol use makes male and female completion rates much more comparable). Comorbid alcoholism has also been used to explain the inordinately high completion rates in Native Americans and Alaskan natives. Why women in China have rates comparable to or exceeding male rates may relate to the fact that completed suicide primarily occurs in rural China, where guns and tall buildings are not readily available but agrarian poisons are, and this represents a highly lethal method favored by women. (Furthermore, the male/female disparity in alcohol abuse is probably less in China than in the West.) Explaining lower female rates in general by a focus on methodology is unsatisfactory (i.e., women die by suicide less often because they opt for methods of lower lethality) since questions remain regarding why they opt for such methods. Since rates of depression in general appear to be higher in women than men, and since women make many more suicide attempts than men, the higher male completion rates are all the more remarkable.

There are multiple theories regarding white/black disparities, none of which are very convincing; nor are there satisfactory arguments explaining why black male rates are essentially level or decrease from midlife on, whereas counterpart white male rates continue to increase throughout the life cycle.

Trends during the Past Century

Although the overall rate of completed suicide in the United States has remained remarkably stable since 1900, there have been some dramatic shifts within subgroups. Rates dropped significantly during both World Wars and increased significantly during the Great Depression. For 15- to 24-year-olds, US rates increased 300% for white and black males and for black females and 200% for white females during the period 1950–80 (the rates increased from approximately 8 to 24×10^{-5}, 4 to 12×10^{-5}, 2 to 6×10^{-5}, and 4 to 8×10^{5}, respectively). Overall rates (i.e., rates for whites and blacks and males and females and all ages combined) changed very little during that same period, however, due to a comparable decrease (although less dramatic since it was spread out over a larger age range than the 10-year adolescent/young adult period) in elderly (i.e., 55–85+ years) rates. The cause of this marked adolescent increase in the United States is unknown (guns, drugs, alcohol, and a breakdown in family and religious values were all postulated), but a disproportionate number of adolescents vis-à-vis the remainder of the population engendered by the postwar US baby boom, which disadvantaged these children once they became adolescents, appears to some to be a more plausible explanation. Conversely, the growing population of elderly was advantaged by the advent of Social Security and better

physical and mental health, which may have improved their quality of life sufficiently to favorably impact their suicide rates.

The 1990 US rates were generally higher than ever, and by 2000 the rates had returned to 1980 levels. Since then, completion rates have continued to fall by approximately 15–35% (up to 2003, the most recent year for which US data are available). Explanations abound for this also; for example, the baby boomers have grown up and no similar disproportionately large bolus of adolescents is moving through the life cycle, or the increased use of antidepressant medications has impacted favorably on suicide rates (supported also by studies of US county-by-county and international country-by-country utilization of such medications revealing inverse correlations between those counties and countries using the most antidepressants having lower completion rates than those that used less such medication). Rates have fallen more for the young and elderly, leading some to question the selective serotonin reuptake inhibitor (SSRI)/serotonin–norepinephrine reuptake inhibitor (SNRI) hypothesis accounting for decreasing rates. Since overall rates are essentially driven by white male rates and, for at least the past 30 years, the white male versus age rates have shown a biphasic pattern with a slight dip in early midlife, this may be a relatively lower risk period which might make this age group less sensitive to antidepressant/antisuicidal effects of SSRI/SNRIs. A similar argument may help explain the smaller decrease in female completion rates.

Etiology

It is helpful to view suicide as a symptom, like fever, rather than a disease. As such, one still may view it from a biopsychosocial perspective. Biologically, although no definitive gene or genes have yet been discovered which are uniquely linked to suicide, there are a number of studies which indicate that there may be significant genetic contributions to suicide. These genetic predispositions are independent from the genes resulting in depression, as suggested by Roy's finding of a concordance rate for completed suicide of 13.2% for monozygotic twins compared to 0.7% for dizygotic twins. Psychological explanations for suicide focus on internalized aggression and/or states of hopelessness, helplessness, desperation, etc., which often accompany depression. Socially, there are marked differences in the frequency of suicide across ethnic and religious boundaries (e.g., very low suicide rates in Muslims and very high rates in Chinese women and Native Americans). More than 90% of those who complete suicide meet criteria for *DSM-IV* axis I or axis II disorders, and of those who do, 80% or more meet criteria for one of the depressive disorders. Consequently, effective treatment of depression is the primary focus for suicide reduction efforts. Bipolar depressive disorders carry the highest lifetime prevalence of death by suicide (15–20%), followed by major depression (10–15%) and schizophrenia (10%). Comorbidities, particularly alcohol and substance abuse, and also various axis II disorders raise these risks markedly.

Two hypotheses utilize stress–diathesis models which combine nature and nurture effects regarding suicide. Both posit a predisposition to impulsivity as the genetic diathesis (alternatively, very early traumatic life experiences such as an infant's prolonged separation from his or her mother can become the underlying diathesis). When such a predisposed individual becomes stressed later in life, this stress, coupled with the tendency to

impulsivity, is more likely to result in suicide. John Mann and colleague at Columbia focus on biogenic–amine deficiencies as the primary pathway mediating this, whereas Charles Nemeroff and associates at Emory University view cortical-hypothalamic axis dysregulation as the primary pathway.

The Suicide Assessment

Every patient who presents with signs or symptoms of depression needs to be asked about suicide (this includes patients who deny depression yet present with vegetative signs of depression – sleep or appetite or other autonomic or hormonal changes – in the absence of clear medical etiology). The clinician should be alert for opportunities to tactfully inquire about suicidality. For example, if the patient complains of feeling sad, one might ask, "Does it get so bad you wish you were dead?" If the patient says he or she does, one might then ask directly, "Have you been thinking about hurting yourself?" A positive response requires further inquiry about a method and the means to implement it: is the patient afraid that he or she might actually harm him- or herself? Although a positive response to that question is clearly of immediate concern, a negative response is only reassuring if the clinician is convinced that the patient is 'not concerned' because he or she has decided to end it all and is relieved by finally making such a decision.

Even if the apparently depressed patient denies being suicidal, a thorough family history (of depression and suicide attempts/completions) is needed and a careful investigation of the patient's past history of depression and suicide is warranted. For patients who have made prior suicide attempts, in addition to questions regarding any current attempt, the following questions should be addressed: how lethal were any past attempts? how likely was the possibility of rescue each time? what were the precipitants of each or did they appear completely inexplicable and impulsive? what was the most serious of the attempts? was the intention really to die?

A patient may deny that he or she is suicidal but the patient's presentation or past history may concern the clinician sufficiently to require contact with family members or close friends in order to ascertain if the patient has expressed suicidal wishes to them (which is more likely than the patient expressing them to the clinician). Should a patient present in a clinically sufficient alarming manner but deny suicide, the clinician may (and should) waive confidentiality if the patient refuses permission to contact the family, in order to obtain history and/or to help protect the patient from harming himself or herself.

Suicide assessments need to be performed as often as clinically indicated on a given patient (e.g., for the hospitalized psychiatric patient, particularly during the first few months of antidepressant administration).

'Why now in and why now out?' provides a useful reminder when evaluating patients for inpatient status and when one is considering them for discharge. That is, what precipitated a patient's need for admission? Also, when evaluating the safety of discharging such a patient (assuming he or she had been admitted), what has now changed enough to make discharge reasonable?

Inpatient psychiatric staff, especially nurses, have come increasingly to rely on 'no-suicide' or 'safety contracts' whereby the patient verbally or orally contracts with staff to notify them if he or she begins to feel acutely suicidal. Staff feel more confident about patient safety with these contracts because they provide quick, often written, documentation that the patient has been asked about suicide and indicated that he or she is not suicidal and promises to notify staff if he or she becomes so. They do not take the place of a suicide risk assessment. Psychiatrists and other mental health professionals should be wary of these since they lull staff into thinking the patients are safe, misleading them into feeling that a more meaningful risk evaluation is unnecessary and consequently may do more harm than good. I believe they are only useful in the negative – that is, when a patient refuses to 'contract,' it should be viewed as a red flag warning of elevated risk.

Prevention

Universal prevention strategies include generally improving the quality of people's lives, thereby reducing stress and unhappiness (cf. decreased rates in the elderly), and decreasing the availability of lethal means, such as control of guns, placing barriers on bridges, and limiting the amounts of acetaminophen per packet. Selective strategies include gatekeeper training at schools and institutions so that depressed and suicidal individuals can be identified and treated before they harm themselves and focusing on high-risk groups such as bereaved individuals or publicly shamed individuals in positions of high trust, such as disbarred attorneys, defrocked clergy, and de-licensed physicians. Indicated prevention refers to treating those already diagnosed as depressed and suicidal or those who have already made an attempt in order to minimize morbidity and prevent death. A roughly comparable schema divides prevention efforts into primary (i.e., changing the conditions which give rise to the disease), secondary (treating the disease), and tertiary (minimizing the progression of the

disease). Suicidologists often match these to prevention, intervention, and postvention.

It is useful to remember that the profile of the typical completer is male, white, older, and with an axis I diagnosis. For attempters, being younger, female, and having an axis II diagnosis are more characteristic. However, attempters and completers clearly overlap: one cannot dismiss a young woman with borderline personality disorder as not seriously suicidal merely because she does not fit the completer profile. It is estimated that 8–10% of attempters do ultimately complete suicide.

It is impossible to prevent all suicides and impossible to expect psychiatrists to predict all suicides. The standard of care for psychiatrists (and for non-psychiatrist physicians treating such patients for their psychiatric conditions) is for them to appropriately evaluate the degree of suicidal risk for a patient and to act accordingly.

Risk Factors and Warning Signs

A working group of the American Association of Suicidology has published a consensus set of warning signs for suicide. These signs, in contrast to risk factors, are more subjective, clinically derived, and imply imminent risk (risk factors being more objective, empirically derived, and less proximate in terms of time). The main warning signs are someone threatening to hurt or kill him- or herself; seeking ways (means) to hurt him- or herself; and talking or writing about death, dying, or suicide. These warrant the witness calling 9-1-1 or seeking immediate help from a mental health provider. Other warning signs overlap with many of the following risk factors: hopelessness, angry, recklessness, trapped feelings, increased alcohol or drug use, withdrawal, anxiety or agitation, sleep changes, dramatic mood changes, and no reasons for living.

Although the greater the number of risk factors, the greater the risk, risk factors are not simply additive – not all risk factors are equally risky. For example, a history of a prior attempt has the greatest predictive value, whereas a diagnosis of a major depression or bipolar depression and comorbid substance abuse also substantially increase the risk, but slightly less than a prior attempt. Hopelessness has traditionally been viewed as the best affective predictor of suicide, but other intense affects, especially desperation but also marked anxiety and agitation, may be equally, if not more, predictive. Asking about guns in the home should be an essential part of any evaluation of a depressed patient.

Risk factors can also be classified as static (e.g., race, gender, and past and family history of depression and suicidal behavior) as opposed to dynamic (e.g., degree of depression and the presence of psychosis). Another classification is based on the likely proximity to a suicidal act occurring (e.g., desperation, hopelessness, extreme agitation, and anxiety are viewed as requiring immediate steps to protect the patient; having suicidal ideation without a specific plan and having coexistent physical health problems are viewed as indicating less proximate risk). These distinctions are approximate and a careful interview of the patient and family members is essential when appraising risk. The examiner's subjective sense of how much psychic pain the patient is experiencing is another important indicator (with two exceptions: the patient who has made up his or her mind and feels calmed by having decided to die, and a retarded, rather than an agitated, depression, where the actual degree of internal distress may be masked).

Treatment

As with the previous discussion of etiologies, treatments are best via a comprehensive, biopsychosocial approach, but for simplicity we consider the biological and the psychological separately.

Suicidal behavior viewed as a symptom mandates that we treat the underlying disease. However, since the suicidal patient is at risk to act on his or her feelings, we need to ensure his or her safety during the period required before a serious depression can be brought into remission by medication and/or psychotherapy. Aside from physically protecting the patient via inpatient or partial hospitalization or charging the family with protecting the patient, as appropriate, there are two critical, simple interventions which can provide prompt relief to the agitation/anxiety and insomnia from which such a large proportion of suicidally depressed patients suffer. Liberal prescribing of antianxiety agents, such as clonazepam or other benzodiazepines, can quickly diminish anxiety (and they, or other agents, may also be prescribed to help the patient sleep). Manic or hypomanic patients can benefit enormously from relief of insomnia. A number of second-generation antipsychotics (SGAs) have begun to be used for rapid relief of anxiety as well. Furthermore, some SGAs have been approved as first-line treatments of bipolar depressed patients. Psychoses also generally respond fairly quickly to SGAs.

The pharmacological treatment of depressions, *per se*, is via antidepressants, generally SSRIs or SNRIs with or without a mood stabilizer such as lithium, valproate, carbemazepine, or lamotrigine. For bipolar depressed patients, caution regarding the use of antidepressants is advised since they may result in a switch to a manic state. More detail regarding pharmacological or other treatments for treatment-resistant patients

can be found in other articles in this encyclopedia. It should be noted, however, that there are few treatments for suicidally depressed individuals which have a convincing evidence basis, but two that do are clozapine for schizophrenic patients and lithium for bipolar patients. Long-term lithium use greatly reduces (up to sevenfold) the rate of completed suicide in such patients (but suicide rates markedly increase if lithium is abruptly discontinued, necessitating a gradual tapering of this agent when it is to be discontinued).

The major controversy in the pharmacological treatment of depression centers on the dilemma of possibly increasing suicidal behavior by the use of SSRIs/SNRIs. In the United States, the Food and Drug Administration mandated black box warnings on SSRI/SNRI labels indicating that suicidal behaviors may be increased in children and adolescents taking such medications. This was broadened to include anyone younger than 25 years of age in December 2006. In almost all of the studies leading up to the warnings, the suicidal behaviors which increased referred to thoughts or attempts, not completions. One study followed children and adolescents who had been hospitalized for depression and compared suicidal behaviors subsequent to discharge in subjects who had taken or not taken SSRIs/SNRIs. The study found a significant difference for attempts and a less robust, although possibly still significant, difference for completed suicides. There were nine completed suicides and this small number resulted in a confidence interval from 1.65 to infinity. As discussed previously, increased use of these agents correlates dramatically with lower completion rates both nationally and internationally, and since the black box warnings were instituted, the completed suicide rates for children and adolescent have begun to rise again – apparently substantiating fears that the warnings would dissuade parents and others from using these medications and reverse the downward trend in suicide rates for which these medications were probably responsible. A Finnish study replicated the finding of markedly lower completion rates in patients treated with antidepressant coupled with markedly higher attempt rates in such patients. All authorities agree that parents, physicians, and adults taking these medications should be alert to the possibility that these medications may have this paradoxical effect so that patients need to be closely monitored for the emergence of such feelings, particularly in the early phases of therapy.

Psychological approaches to suicidally depressed patients encompass the usual modalities of individual, group, and family approaches and various schools of therapy (e.g., psychodynamic, interpersonal, supportive, and cognitive–behavioral). Of these approaches, only cognitive–behavioral therapy (CBT) has clearly demonstrated effectiveness in reducing suicide attempts (and, possibly, completions) in depressed patients. Dialectical behavior therapy (DBT) has also demonstrated effectiveness in decreasing suicide attempts in borderline patients.

Most mental health professionals subscribe to the view that combined psychotherapy/pharmacotherapy represents the optimal approach for suicidal patients. In depression, either approach results in a 50–60% improvement rate which can be increased to approximately 60–70% when the two are combined. There are also reports that CBT improvements in depression may last longer than those resulting from medication. This may also be true for other psychotherapies (e.g., (interpersonal therapy)).

Special Populations

Adolescents

Depressed adolescents may not present with the same symptoms as do adults. Changes in behavior, friends, or grades may be more likely; irritability rather than sadness is typical; and increased or decreased alcohol and drug use is not uncommon. A refusal to comply with parental requests to see a psychiatrist or psychologist is far more likely than agreement (so that parents often need to insist on compliance and, if indicated, continued treatment). It is not 'cool' to be in such treatment, but it is less uncool to say 'my parents are making me' and most such coerced adolescents later express gratitude for having been so pressed. Adolescents appear more vulnerable to imitative or copy-cat suicidal behavior, resulting in various national organizations publishing guidelines for how the media should report suicide (e.g., do not romanticize the event, do not memorialize the decedent in the school, and do not describe the methods used) and for how schools should intervene following a suicide in order to hopefully prevent additional suicides.

Elderly

The elderly also may not manifest depression in the classical depressed manner. For example, they may simply become more withdrawn or may develop vague somatic concerns for which no apparent organic cause can be found. Although the elderly comprise only 12% of the population, they constitute 19% of the total number of annual completed suicides, making them the group with the highest rate. In addition, they have the lowest number of attempts per completion of any group. This means that they provide the fewest warnings of their suicide (via nonfatal

attempts) of any group and also that when they do attempt, it is more likely to be an attempt of high lethality. An additional problem confronting the depressed elderly is that their depression too often gets dismissed by their physicians and caretakers as to be expected in the old or as untreatable because 'it's depressing to get old.'

The Medically Ill

Those with axis III *DSM* disorders, especially those with chronic, painful, crippling, or lethal illnesses, are at greatly increased risk of suicide, particularly if they are also suffering from depression. Central nervous system (CNS) diseases, such as multiple sclerosis, Huntington's disease, AIDS dementia, head injuries, and malignancies, appear to carry very high risk, compounded by any accompanying CNS disinhibition.

Survivors

'Survivors' of suicide refers to the families and close friends of those who have completed suicide (not to people who have attempted and survived, although this is a population which receives insufficient support as well). It is generally believed that due to the guilt and stigmatization borne by such survivors, grieving a suicidal death is the most prolonged and painful of all. Among such survivors, the grief of parents over a child lost by suicide may be the most intense of all. Parents feel responsible for their children's health and happiness and believe they have failed; they have also lost a part of themselves. Groups such as Survivors of Suicide exist in most US cities, where survivors provide support to others so bereaved. These are usually, although not universally, lay led.

Psychiatrists, psychologists, and other mental health professionals constitute another group who often become survivors of their patients' suicides and who are in need of support (which they rarely receive) following such tragic professional events.

Future Directions

With 30 000 deaths per year (2001) by suicide (compared to 20 000 per year via homicide), suicide is clearly a public health problem and should be addressed in public health terms. Former US Surgeon General David Satcher accordingly issued *Preventing Suicide: A Call for Action* in 2002, in which he set down specific goals for suicide reduction. Since depression is found in 70% or more of suicide decedents and since most depressions are treated by primary care physicians rather than psychiatrists, it makes eminent sense to better educate such physicians to more accurately recognize depression and suicide risk and to treat such depression more adequately than they typically do. Reviews have revealed that of patients receiving antidepressant treatment by their primary care physicians, less than 25% receive adequately aggressive pharmacotherapy. Additionally, better educating the public and gatekeepers about the signs of suicide and how to respond to them should be useful. Similarly, educating the media about the need to not romanticize articles about suicide or publishing details about the methods used may help to decrease the number of imitative or copy-cat suicides. Surely, more effective antidepressants than the current SSRIs and SNRIs will be developed (current ones appear no better than tricyclics, although they are safer and better tolerated). Preliminary data suggest that faster treatments (e.g., intravenous ketamine or scopolamine hydrobromide) or newer approaches (vagal nerve stimulation and transcranial magnetic stimulation) may yet prove effective. Also, the increased use of CBT and DBT by increasingly larger groups of providers should have very beneficial effects on suicide rates. Pooling of data from larger collection sources (e.g., National Institute of Mental Health/American Foundation for Suicide Prevention's Developing Centers on Interventions for the Prevention of Suicide at large universities and medical centers) may finally enable us to have a large enough population base to allow for randomly controlled, prospective, placebo versus treatment arm studies of completed suicides so that we can actually learn what works the best, the fastest, and the safest.

Superior Colliculus

R H Wurtz, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

The superior colliculus (SC) is a structure in the midbrain that is part of the brain circuit for the transformation of sensory input into movement output. Its major function is orienting the animal, particularly with eye movements, to objects of interest in the outside world. This article first summarizes the basic functional architecture of the SC, then considers how the activities of neurons in the SC lead to the generation of eye movements, and finally addresses questions about the role of the SC in primates, including its role in providing information about impending movements to the cerebral cortex.

Functional Structure of the SC

The SC lies on the roof of the midbrain of the brain stem (Figure 1(a)). In mammals it has six layers and is the direct homolog of the optic tectum of birds, fish, reptiles, and amphibians. In these lower animals it is the major center in the brain for the receipt of the output of the retina. In mammals, and particularly in primates which we concentrate on here, the SC continues to receive retinal inputs but it also receives massive inputs from cerebral cortex and subcortical structures such as the basal ganglia.

The monkey SC has six alternating gray and white layers with an additional small fiber layer on its surface (the stratum zonale). These layers have different characteristics and distinguishing them is critical to describing and understanding the functional organization of the SC. The superficial layers consist of a gray and a deeper white layer (the superficial gray and the optic layers) followed by the intermediate gray and white layers and the deep gray and white layers (Figure 1(b)).

These layers have different inputs and outputs as well, and Figure 1(c) indicates the major ones. The input to the neurons in the dorsal part of these superficial layers is directly from the retina, but with increasing depth in the superficial layers the visual responses are more and more dependent upon the input from visual cortex: ablation of the primary visual cortex greatly reduces the visual responses of the neurons. While the terms gray and white layers imply pure neuronal and fiber layers as is the case in cerebral cortex, there are neurons scattered in the white layers as there are fibers of passage in the gray layers.

A major output of the visual layers is the descending one onto the intermediate layers below, which has recently been demonstrated in slice preparations of the rodent SC. The major ascending projections are up to the cerebral cortex after a synapse in the pulvinar nucleus (Figure 1(c)). One possibility is that the superficial layers of the SC lie on a second pathway from retina to cortex in addition to the prominent retina, lateral geniculate, visual cortex pathway. An alternative view is that the SC to pulvinar to visual cortex pathway provides a combination of sensory–motor information that provides a modulator input to the cerebral cortex rather than a purely visual input.

The major inputs to the intermediate layers of the SC are from the superficial layers, from regions of cortex beyond the primary visual areas such as the lateral intraparietal area of parietal cortex and the frontal eye field of frontal cortex. A major subcortical input is from the substantia nigra pars reticulata of the basal ganglia. A major output of the intermediate layers is a pathway, which crosses from one side of the brain to the other (the predorsal bundle) that conveys the collicular output to neurons in the deeper midbrain and pons. The critical point is that the pathway crosses the midline at this point so that activity in and above the SC is related primarily to saccades made toward the visual field contralateral to the side of the brain of the neuron, whereas neuronal activity below the SC is related to saccades made to the ipsilateral side. A major ascending output is to frontal cortex through the medial dorsal nucleus of the thalamus.

Neurons in the superficial gray and optic layers give a short latency (about 40 ms) response to the onset of a visual stimulus (Figure 2). The optimal stimulus is usually a small spot or object in one part of the visual field contralateral to the SC in which the neuron is located. Neurons in the intermediate gray and white layers also show a brief burst of neuronal activity after the onset of a visual stimulus, but in addition show increased activity beginning before the monkey makes rapid or saccadic eye movements. Many neurons in the deeper layers of the SC (deep gray and white layers) have properties similar to those in the intermediate layers, and they also frequently respond to sensory modalities other than vision such as auditory and somatosensory stimuli. The multimodal nature of these neurons indicates that a movement initiated by activity in the SC may result from input other than the visual or in conjunction with the visual. Less is known about the detailed organization

Figure 1 Anatomical structure of the superior colliculus (SC). (a) Location of the SC in the brain. The SC lies on the roof of the midbrain which is covered by the overlying cerebral cortex. The red vertical line indicates the plane of section through the SC (frontal or coronal) shown in (b). (b) Layers of the SC shown on the coronal section. The two sides of the SC are symmetrically placed across the midline. (c) Major inputs and outputs of the SC layers.

Figure 2 Visual activity in the SC superficial layers and movement-related activity in deeper layers. Histograms of activity on the right show the visual response (top) aligned on the onset of a visual stimulus and the saccade-related activity aligned on the saccade onset. Cartoon on the left shows the visual stimulus and saccade to it that led to this activity. The current fixation is indicated by a crosshair, the onset of the stimulus by the black spot, and the ensuing saccade to it by the arrow.

of these deep layers in relation to movement, and consequently the four intermediate and deep layers are frequently grouped together as the deep layers. We will concentrate primarily on the intermediate layers since this is the layer where the sensory to motor transition is most prominent. The samples of neuronal activity in Figure 2 indicate why the superficial layers are usually referred to as the visual layers and the deeper layers are referred to as the movement layers.

The final and probably most critical point regarding the SC structure is the presence of a retinotopic map of the visual field spread out on its surface and extending down in register through the lower layers. As shown in Figure 3, the contralateral visual hemifield is represented in the SC on one side of the brain, as is the case in primary visual cortex. This map is a nonlinear one with the central visual field represented in more detail than the peripheral field; hence, the map is compressed toward the peripheral edge of the visual field. Visual stimuli close to the center of the visual field are represented rostrally in the SC (black circle in Figure 3) and targets in the periphery are represented caudally (black triangle).

Each neuron in the superficial layers of the SC has a visual receptive field restricted to one part of the visual field, with the response of the neurons strongest in the field center, and with that center located on the map as predicted by the overall visual field map shown in Figure 3. The neurons in the intermediate layers of the SC also have receptive fields that map onto the same map as the neurons in the superficial layers. But in addition, these neurons become active before saccades made to just one region of the visual field, their movement field. There is a gradient of activity within each movement field just as in the visual receptive field (Figure 4), and a neuron's maximum discharge is associated with saccades to the

Figure 3 Projection of the visual field onto the SC. The projection of the right visual is to the left SC. The color code indicates the eccentricity. Courtesy of Nakahara, Morita, Wurtz, Optican (2006).

center of this field which conveys information about the specific amplitude and direction of an impending saccade. A neuron's optimal saccadic vector is usually closely aligned with the center of its visual receptive field. Different neurons have different vectors and the neurons are organized in a highly regular fashion to produce a neural map of saccadic vectors covering the contralateral visual field. On this map, large saccades are represented in the caudal SC, small are in the rostral SC, upward are more medial, and downward are more lateral, just as was the case for the visual map.

A key point of this map is that it is registering differences. For the visual responses, neurons with receptive fields 10° of arc away from the center of gaze (the center of the fovea), will indicate with their maximal response that the target is 10° away in a particular direction. Similarly for a saccade target at the same location, the activity of the saccade-related neurons with maximal activity for this point indicates that the change in the eye position to bring the eye to

Figure 4 Two-dimensional plot of a SC movement field showing the gradient of activity of neurons at one SC recording site. The color scale indicates the activity in spikes per second, but because the color indicator saturates, the contour lines indicate the higher frequencies in steps of 100 spikes/second with a small center frequency of 600 spikes/second. The map extends out horizontally and vertically to 30° of visual angle.

the target is 10° in that direction. Both indicate the distance from the fovea of the retina and are thus both retinotopic maps.

A second key point is that activity on this map produces eye movements not by the action of a few localized neurons but by a large population of neurons centered on one region of the map. If we consider neurons along one meridian, one estimate is that during fixation approximately 15% of the neurons (those centered on the rostral pole) are active and that during a saccade about 25% of the burst neurons and 40% of the buildup neurons are active.

Neuronal Activity for Saccades and Fixation

Activity leading to the generation of a saccadic eye movement is centered in the intermediate layers because it is here that neurons are active before the generation of saccades, where electrical stimulation generates them, and where inactivation leads to their disruption. The same logic holds for the control of the fixation between these movements. Not all intermediate layer neurons, however, are the same, and it is useful to consider these neurons as falling into three groups even though they almost certainly form a continuous distribution of neuronal types.

Burst neurons are the saccade-related neurons that have been most extensively studied in the SC, and are the ones that first flagged the SC as related to the generation of saccades. Their defining feature is a brief burst of firing time locked to saccades made into their movement fields (Figure 5, right). The burst neurons are found throughout the rostral to caudal extent of the collicular map, and their activity indicates an impending saccade with a vector coded by the position of that neuron on the SC map. They also frequently have a visual response time locked to the onset of the visual target.

Buildup neurons are similar to burst neurons in having visual responses and usually increased activity just before the saccade, but their distinctive characteristic is an increase of activity during the period between the visual response and the saccadic burst (the delay period – Figure 5, middle). Because of this delay in activity, they have also been referred to as long lead neurons or prelude bursters, and because the activity tends to increase as the time of the saccade approaches, they are referred to as buildup neurons. Like the burst neurons, the buildup neurons are found throughout the collicular map and represent the amplitude and direction of impending saccades related to that region of the map. The working hypothesis is that their buildup or delay activity represents the preparation to make a saccade, and their activation may facilitate saccade generation.

The neurons usually referred to as fixation neurons lie at the rostral pole of the SC. They are tonically active when the monkey fixates its eyes on a visual target (Figure 5, left) They are not dependent on the presence of the target, however, because the firing persists when the target is briefly removed, as long as fixation persists. There is a decrease in the discharge rate when a saccade occurs. All these characteristics led to referring to these rostral neurons as fixation neurons although further investigation suggests that they are a rostral extension of the buildup neurons (see below).

Saccade Generation

The elements in the SC show activity in an orderly sequence before the onset of saccadic eye movements. While the monkey is looking at a point and not moving its eyes, the fixation neurons are tonically active. During this period of fixation, when a target appears in the visual receptive field of a burst or buildup neuron, there is brief visual activity followed by a gradual increase in activity in buildup neurons that is taken to indicate preparation to make a saccade to the target. At some point the activity becomes strong enough to produce the high-frequency burst in the buildup and the burst neurons, and their output provides a strong drive on the saccade-related neurons in the lower midbrain and pons. These brain stem neurons receive what is essentially a retinotopic signal, and over a series of steps they provide a signal

Figure 5 Examples of histograms for burst, buildup, and rostral neurons all aligned on the onset of the target (start of each record) for the saccade (indicated by the deflection of the eye position traces above the histogram). The location of each neuron is indicated on the SC map with the fixation neurons being at the rostral pole and the burst and buildup neurons being more caudal in the SC.

appropriate for the pulling direction of the six eye muscles so that the eye moves to direct the fovea to the target that has led to the activation of the SC neurons. The output of the SC also acts to move the head to the target as well; most shifts to a new target involve the coordinated movement of both eyes and head and is referred to as a shift in gaze.

The SC is the last step where the active neurons on a retinotopic map indicate the amplitude and direction of the impending movement. In contrast, neurons below the SC indicate which muscles should contract and how much and for how long they should do so. Thus the signal to move the eyes is transformed from a spatial code on a map where the vigor of the activity is secondary to their place on the map to one in which there is no longer any map and it is a frequency code where the frequency and duration of the activity determines the eye movement.

What leads to the activity within the SC? From the frontal eye field region of the frontal cortex (refer to Figure 1(b)) the direct projection centered on the intermediate layers provides an excitatory drive to the SC. The frontal cortex provides a similar drive through the basal ganglia to the SC, but the output via this route through the substantia nigra pars reticulata is inhibitory. The substantia nigra input to the SC has a tonic high discharge rate and a pause at the time of the saccade just the opposite of that from the frontal eye field which has a relatively low discharge rate and a burst of activity. Thus these two inputs act as a push–pull control on the saccade-related activity of the SC. These two inputs exert a major effect on the SC. The input from parietal cortex, particularly lateral intraparietal area (LIP), is also a major excitatory input to the SC. Thus the activity in the SC related to saccades is shaped by these excitatory and inhibitory inputs.

Fixation

While it is critical for saccades to move the eye to different parts of the visual field to examine areas of interest, most of our useful vision occurs in the periods of fixation between the saccades. There is a continual interaction between periods of fixation for viewing one scene and saccades to shift from one view to another. This alteration of fixation and saccades forms the very root of our visual perception. It should

Figure 6 Schematic of the interaction between neurons at the rostral pole of the SC and buildup neurons in the caudal SC. Activity of each population on the other is inhibitory.

not be surprising that there are neuronal mechanisms that insure visual stability during these periods, the SC neurons that are critical are the neurons in the rostral SC, those referred to as fixation neurons.

The action of these rostral neurons has been demonstrated by showing that saccades are suppressed by their activation by either electrical stimulation or injection of bicuculine, a γ-aminobutyric acid (GABA) antagonist, that frees these rostral neurons from tonic inhibition. In contrast, saccades are facilitated by the inactivation of the rostral neurons by injection of the GABA agonist muscimol. Both activation and inactivation experiments show that the rostral SC alters when saccades are generated. Figure 6 shows schematically the interaction between fixation and saccadic mechanisms in the SC. The interpretation is that when the rostral neurons are active they inhibit all other SC neurons including the burst and buildup neurons in the caudal SC, and when these later neurons are active during a saccade they inhibit the rostral SC neurons.

Simplifying the SC Neuron Categorization

A possible continuity between the rostral neurons (the fixation neurons) and buildup neurons substantially simplifies the categorization of the SC neurons. Both neuron types have delay activity between the time of target presentation and the saccade; for the buildup neurons this is the buildup before the saccade and for the rostral neurons it is the continuing activity during fixation. Both types also have movement fields, that is, they have a burst of activity just before a saccade to the target as described for the buildup neurons but which applies equally well for the rostral neurons which show this burst before very small saccades (consistent with their position in the rostral pole of the SC). More importantly, the increase in activity of the rostral neurons occurs whether a saccade is made or not. This makes the rostral neurons just like the buildup neurons because they show increased activity long before saccade onset even if the saccade is not actually made. But the key point is that both these rostral neurons and the buildup neurons indicate an error between where the eye is now and where it should be. For the buildup neurons the error can be large depending on their location on the SC map, and the buildup or delay activity indicates this error (Figure 6). The same is true of the rostral neurons, but their activity indicates a small error, frequently only a fraction of a degree and too small to make a saccade. The working hypothesis is that the activity of these rostral and buildup neurons indicates an error between where the eye is and where the target is, and the size of the error represented by the neuron depends upon the location of the neuron on the SC movement map. This does not change the functional interaction between rostral and buildup neurons described above, nor the role of the rostral neurons in maintaining fixation, but instead provides a mechanism for the interactions. The hypothesis also raises the possibility that this error signal can be used for movements other than saccades, particularly for the generation of pursuit movements.

SC Determines Movement Goal, Not Metrics

The organization of the SC, its relationship to other structures, and the sequence of activity preceding saccadic eye movements form the core of our knowledge of the SC, for which there is little dispute. More recent experiments, however, have shown that the SC is as closely related to selecting the goal of a saccade as it is to determining the metrics of the impending saccade.

The first point is that even the earliest experiments on the primate SC showed that, although short-term SC inactivation largely eliminates saccade generation, ablation limited to the SC does not. This only serves to emphasize that while we are considering the SC, it is the brain that generates the saccade, and to develop a viable model of saccades other areas such as the cerebellum must be included. In addition, while the SC neurons provide the amplitude and direction information required to bring the fovea onto a new target of interest, knowing this does not allow prediction of the metrics of the saccade actually made. For example, by using an adaptation procedure, monkeys can be made to make saccades that are shorter than that required to get the eye to the visual target, but the peak activity in the SC remains centered on the region representing the target not the saccade actually made.

In contrast, SC activity is modulated by shifting the goal of a saccade. The importance of the goal first became apparent when it was recognized that the visual responses of SC superficial layer neurons were enhanced when the monkey attended to the stimulus

that was to be the goal of the impending saccade. More recent experiments have shown that when monkeys are given two visual targets in rapid succession, the monkey can shift its goal from one target to the other and make a strongly curved saccade from one target to the other. The SC activity is consistent with the successive selection of the two targets rather than the shape of the saccade executed. In addition, there are substantial modulations of the SC activity related to the selection of the target itself. If the probability of one of several visual stimuli becoming the target for the next saccade is varied, the activity in the SC changes long before the burst of activity related to a specific saccade. Therefore, the SC is providing an error that indicates the goal of the saccade, and via the fixation neurons, when the saccade will occur, but it is only part of the system determining the metrics of that movement.

Corollary of Impending Saccades

Everything considered so far summarizes the extensive information on the SC contribution to the generation of movement. But it has long been known that the SC not only has downward projections to the regions of the oculomotor nuclei for eye movement and the spinal cord for head movement but that it has projections that ascend upward through the thalamus to the cerebral cortex. Recent experiments have begun to indicate the signals carried by these pathways and the possible functions for them.

One prominent pathway extends from the SC (primarily from the intermediate layers) to the medial dorsal nucleus of the thalamus and from there to the frontal cortex including the frontal eye fields (Figure 7). The specific medial dorsal neurons that receive information from SC and relay it to the frontal eye field (FEF) have been identified by using the classic physiological techniques of antidromic and orthodromic stimulation, and they have been found to convey the visual and presaccadic activity described for the SC. One obvious possibility is that these neurons are providing a signal for the guidance of saccades, but this has been rejected because inactivation of the medial dorsal neurons does not significantly alter saccades. The other salient possibility is that the activity is conveying information for keeping track of the movement rather than generating it, that is, it is carrying a corollary discharge or efference copy of the intended movement. This turns out to be the case; inactivation of the medial dorsal neurons impairs saccadic accuracy in a task (the double step task) that requires the internal knowledge of the preceding saccade that would be provided by a corollary discharge. This sparing of guidance and disruption of registration is clearly what would be expected if this path from SC up to frontal cortex carried a corollary discharge and provides strong evidence that the SC provides information back up to the cerebral cortex, as well as receiving information from the cortex.

A corollary discharge is not the only type of information that the SC provides to cerebral cortex. Recent experiments have shown that visual spatial attention can be produced by stimulating oculomotor regions of the brain including the SC. Electrical stimulation of the SC improved performance on a visual motion task in ways consistent with a covert shift of attention. Because visual motion perception is largely a result of cortical processing, its modulation implies that the action of the SC is on cortex. Whether this effect reaches cortex via the pathway connecting SC and the frontal eye field or via the pathway from the SC through the thalamic pulvinar nucleus and then directly to motion areas in cortex remains unknown.

Figure 7 Comparison of the two major SC outputs, one for the generation of saccadic eye movements and the other to convey a corollary of these movements to cerebral cortex.

Conclusion

The SC is one of those structures in the brain whose function has shifted over evolution. In the primate, it still has activity related to the reflex movements made to the sudden appearance of a target in the visual field. But it is also a key way station in the oculomotor circuits that descend from the visual and premotor areas of the cerebral cortex to the movement centers in the brain stem. It is the last node where instructions for movement are represented as an error on a spatial retinotopic map before being broken up into instructions related to muscles. It provides information back to the cortex on the movement to be executed, the long sought corollary discharge. While it is embedded in the larger visual and oculomotor control system, it

has provided a superb model to study sensory–motor integration for both the control and the registration of movement.

Supplementary Eye Fields

M A Sommer, University of Pittsburgh, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

The supplementary eye fields (SEFs) were discovered in 1985 by John Schlag and Madeleine Schlag-Rey, who were informed by prior findings spanning the preceding century. In 1885, David Ferrier demonstrated that frontal cortex near the midline in monkeys is electrically excitable. By stimulating there, Ferrier evoked movements of the head and eyes toward contralateral space. Homologous sites in the human brain were reported by the neurosurgeons Foerster and Penfield. A breakthrough was provided by Woolsey, who carefully mapped the supplementary motor area in many animals and showed that it had a regular topography that included rostral eye representation. Brinkman and Porter qualitatively explored this zone in 1979. Unlike all of the prior studies, Schlag and Schlag-Rey explored the region in a highly quantitative manner using accurate and precise eye movement measurements. After their seminal work, studies on the function of SEF went in surprising directions.

Early work on the SEF first tested the hypothesis that it is important for generating eye movements, particularly the fast ones known as saccades. This hypothesis quickly fell by the wayside. In its place, other intriguing ideas about SEF function have been promoted and supported. It now appears that the SEF is unnecessary for generating eye movements but is important for higher-order control of eye movement behavior. The SEF might be likened to the foreman of a construction crew for assembling behavior; the SEF does not do the work but guides it.

The unveiling of the SEF as a distinct region in 1985 had special impact due to another landmark set of results published the same year by Bruce and Goldberg that formally delineated the nearby frontal eye field (FEF). Since then, a useful tactic in the field has been to analyze the SEF in relation to its historical twin, the FEF. The present article follows this comparative approach.

Anatomy

The SEF is located in dorsomedial frontal cortex (Figure 1(a)) and represents the ocular extension of the body map in the supplementary motor area (Figure 1(b)). The exact boundaries of the SEF have been a subject of debate. The functionally defined SEF corresponds roughly to a zone (F7) delineated by Matelli, Luppino, and Rizzolatti using cytoarchitectonics, but associating functional regions with cytoarchitectonic zones is not always straightforward. The FEF, for example, straddles two distinct cytoarchitectonic zones (Walker's 8A and 45) even though its functions seem continuous across them. It is generally accepted that eye-movement-related neurons can be found throughout a large swath of peri-midline cortex, leading some laboratories to select this entire region as their focus of study (using the term dorsomedial frontal cortex rather than SEF). Other laboratories are guided by the principle of studying the zone where eye movements can be elicited with least current threshold using trains of electrical current pulses. In the FEF, a criterion of <50 μA was established, and in an effort to make a fair comparison between SEF and FEF the same criterion was transferred to SEF. The location of SEF in humans is homologous to that in monkeys – in dorsomedial cortex at the rostral end of the supplementary motor area. In terms of connections, the SEF is very similar to the FEF. Both receive projections from, and send efferents to, a plethora of visual- and saccade-related areas with minor differences, such as slightly different patterns of thalamic connections. Functionally, however, the SEF seems more distantly connected than the FEF to the final saccade-generating circuits because the ability to evoke saccades from the SEF requires, in general, relatively higher currents, longer train durations, lower frequencies, and more care in minimizing behavioral obstacles such as intense fixation.

Function

Generating Saccades and Fixations

Schlag and Schlag-Rey proposed that the SEF was a distinct eye field because stimulating it elicited saccades and recording from it revealed vision- and saccade-related activity. Follow-up studies established that it also contains many fixation-related cells. Hence, the first hypothesis about SEF was a simple one: perhaps it helps to generate saccades and fixations. At the outset, however, this hypothesis seemed doubtful. A lesion study by Schiller had shown already that when other major oculomotor structures were ablated (the FEF and superior colliculi), animals were permanently devastated in generating saccades even though the SEF remained intact. It may have been that the SEF was indirectly damaged in that study, or that the SEF is important but needs the FEF or superior colliculus to transfer its signals downstream. Later experiments seemed to refute these possibilities, however. Stimulation in the

Figure 1 Location of the SEF. (a) Frontal, lateral perspective of monkey brain with general location of SEF and FEF shown in cutaway view at right. As, arcuate sulcus; Ps, principal sulcus; Ss, sagittal sinus. Anatomical directions are shown in orange. (b) Range of SEF recording and stimulation sites (blue) as reported by Schlag and Schlag-Rey. Data from two hemispheres (the two polygons) are superimposed. The SEF lies in the rostral supplementary motor area (SMA), in the head part of the body map. SEF and SMA are functional terms; the anatomical term for the region is the dorsomedial frontal cortex. Location of the FEF is shown for reference to the right. (a) Adapted with kind permission of Springer Science and Business Media from *Experimental Brain Research* 58, 1985, pp. 208–211, 'Unit activity related to spontaneous saccades in frontal dorsomedial cortex of monkey,' Schlag and Schlag-Rey, fig. 1, © Springer-Verlag 1985. (b) Modified and used with permission from *Journal of Neurophysiology* (Schlag J and Schlag-Rey M (1987) Evidence for a supplementary eye field. *Journal of Neurophysiology* 57: 179–200).

SEF evokes saccades after lesions of FEF or superior colliculus, implying that the SEF independently accesses saccadic-generating circuits. More to the point, reversible inactivation of the SEF has no discernible effect on saccades and fixations (even though inactivation of the FEF or superior colliculus causes enormous deficits). A study of SEF lesions by the Schiller group found deficits only in an extremely sensitive test of visuosaccadic behavior. The impairments were weak and short-lasting. It is safe to say that the SEF has little or no influence on the basic generation of saccades and fixations.

Stimulating the SEF also elicits head movements and smooth eye movements. No studies have silenced the SEF to test whether it is needed for these actions.

Providing Frames of Reference

If the SEF is inconsequential for fundamental oculomotor behaviors, then why is it so packed with visual- and eye-related neurons? Why does electrical

stimulation of it evoke saccades and fixations? These have been the salient questions driving SEF research in the past decade. The mystery is whether the SEF does something important even if it is unconcerned with the details of making individual movements.

From the first studies of Schlag and Schlag-Rey it was recognized that the SEF might play a special role in providing frames of reference. Electrical stimulation of the FEF, superior colliculus, and most other eye movement areas evoke vectors of saccades (i.e., constant displacements regardless of initial eye position). Schlag and Schlag-Rey showed that stimulation of the SEF, in contrast, may evoke goal-directed saccades. Such movements travel to a 'termination zone' in space that stays constant regardless of where the eyes initially fixate (**Figure 2(a)**). A debate ensued between Tehovnik and colleagues, who confirmed the goal-directed findings and extended them by describing a topographic map of termination zones across the SEF and surrounding dorsomedial frontal cortex, and Bruce and colleagues, who explained the appearance of goal-directedness as natural variation, whereas vector saccades were the norm (**Figure 2(b)**). The topographic stimulation map of Tehovnik was matched by a topographic map of tuning in SEF fixation-related neurons; similarly, the vector coding of Bruce was matched by the vector coding of SEF saccade-related neurons. It is possible that Tehovnik preferentially activated fixation neurons and Bruce saccade neurons, but this is speculative. On a related note, two laboratories (the Crawford and Schlag groups) showed that some SEF sites produce vector saccades and other SEF sites goal-directed saccades when stimulated, and that vector-to-goal-directed representations in SEF may be organized in a rostral–caudal gradient. The debate about coordinate frames in the SEF has spilled over into a nearly identical controversy regarding whether goal-directed or more limited movements are encoded in primary motor cortex.

A goal-directed or craniotopic (referenced to the head) representation is not the only type of nonstandard coordinate frame encoded by the SEF. Single neuron recording studies by Olson and colleagues found that many SEF neurons use an object-centered frame of reference (**Figure 2(c)**). Such neurons fire preferentially for saccades made to a particular part of an image (e.g., the left end of a small bar) regardless of where that image is presented. As argued by Olson, object-directed frames of reference are especially critical for us in everyday life as we survey, handle, and inspect the items that surround us. It is unknown to what extent object-directed frames of reference are unique to the SEF.

The bottom line is that there is broad support that the SEF plays a special role in representing frames of reference that are not directly extractable from the retinal image but which require further information: the location of eye in head for craniotopic frames of reference and the segregation of image clutter into distinct entities for object-centered frames of reference.

Supervising Behavior

The paradox of the SEF – that it seems so saccade related but is so blatantly unnecessary for generating saccades – and the early findings on multiple coordinate systems in the SEF inspired a new generation of experiments that have been very informative. This nascent research posits a higher level function for the SEF. The premise is that the SEF is well poised for controlling saccadic behavior due to its variety of neuronal signals as revealed by recording, its tight linkage to other saccadic centers as revealed by stimulation, and its fluency in multiple ways of spatially encoding visual stimuli and eye movements. The first fundamental question about an executive role for SEF logically would be the following: Can the SEF turn on and off saccades, even if it cannot generate them by itself?

Schall and colleagues studied this question using a task in which a monkey is instructed to make a saccade but then, randomly, may be instructed to cancel it. Nimble supervision of the saccadic system is necessary in this 'countermanding' task, and SEF neurons carry signals that may reflect this supervision. When errors of commission are made (saccades are made when they should have been canceled), many SEF neurons burst vigorously just after the movement (**Figure 3(a)**). Neurons in FEF, in contrast, seem to have a more proactive function: their activity is well suited to cause saccade generation or cancellation but is poor at representing task outcome.

Whether the error-related activity in SEF influences behavior cannot be answered by neuronal recordings and requires, instead, causal experiments. Schall and Stuphorn performed such a study, electrically stimulating the SEF in the countermanding task. In support of the role of SEF in supervising behavior, activating it with low currents lengthened saccadic reaction times in the countermanding task so that monkeys had more time to cancel their movements (**Figure 3(b)**). Outside of the countermanding task, however, in a visually guided saccade task, reaction times were made shorter instead of longer. This combination of neuronal recording and stimulation provides complementary evidence for a supervisory role of SEF in controlling whether a saccade is made.

Figure 2 Reference frames in the SEF. (a) Head-centered coordinate frame. Saccades (arrows) evoked by stimulation of the dorsomedial frontal cortex (DMFC) including the SEF (top) compared with saccades evoked from the FEF (left). In the DMFC, stimulation-evoked saccades go to a termination zone (gray circle) as a function of stimulated site. Long durations of stimulation cause a single saccade (inset). In FEF, stimulation-evoked saccades exhibit a constant displacement regardless of initial eye position. Long durations of stimulation cause similar saccades to occur repeatedly. (b) Eye-centered coordinate frame. In the core of the SEF, brief train durations evoke directions of saccades (*y*-axis) that match the directional tuning (*x*-axis) of visual, movement, or visuomovement neurons found at the stimulated site. Little evidence for termination zones was found in this experiment. (c) Object-centered coordinate frame. Activity of an SEF neuron is strong for saccades made to the left side of a bar (left) but not the right side (right), regardless of the instruction that cues the monkey (square on bar, top; color, bottom). (a) Adapted and reprinted from *Behavioral Research Reviews*, vol. 32, Tehovnik et al., 'Eye fields in the frontal lobes of primates,' pp. 413–448, © 2000, with permission from Elsevier. Figure 3 Supervisory function of SEF. (a) Average activity of an SEF neuron is shown for saccades made to the left (into ipsilateral space; inset) when the movement was appropriate (dotted line) and when it was errant because it should have been withheld (solid line). The SEF neuron fired vigorously after the error. The same effect occurred for rightward saccades. (b) Improvement in performance when stimulating the SEF (white circles) relative to not stimulating (black circles). Stimulation allowed the monkey to wait even longer – that is, nearer to the last possible moment (rightward shift to longer stop signal delays) before canceling the movement. Signaling Conflict

An effective foreman not only gives instructions but also makes wise judgments in the face of conflicting information. So it is with the saccadic system. The visual world provides little information about where to look next, and the signals that are available can provide mixed messages. A traffic light 'walk' signal is good to notice for an instant, but its continual illumination (and sudden change to a flashing 'don't walk' signal) provides a conflict for behavior by demanding your attention when you should, instead, maintain a vigilant watch to the left and right. SEF neurons seem to play a special role in dealing with visuosaccadic conflicts so that one looks in the correct direction, not just the attention-grabbing direction.

One form of visuosaccadic conflict was described previously: in the countermanding task, there is a conflict between the sudden need to fixate and the ongoing plan to make a saccade. Indeed, Schall and colleagues found that a second major cell type in SEF, in addition to the error-encoding type described previously, signaled conflict defined as the successful recognition of a stop signal when saccades were inhibited.

A particularly influential study on visuosaccadic conflict was performed by the discoverers of the SEF, Schlag and colleagues. In their task, a visual stimulus appeared in the periphery but then monkeys had to look away from it. The conflict was between the stimulus location and the required saccadic endpoint. SEF neurons had significantly higher activity in such 'antisaccade' trials than in control trials in which they were allowed to look toward the stimulus (Figure 4(a)). In addition, this antisaccade-related activity was higher in the SEF than in the FEF, providing a rare situation in which signals in the SEF are stronger than those in its more lateral neighbor. One problem in interpreting the results was that the higher activity may have been related to monitoring the conflict, to the different rules implicit in making a saccade toward a target versus away from it, or to other more subtle factors.

To tease apart the reason for elevated SEF activity in the antisaccade task, Olson and colleagues created a task in which the color of a cue, regardless of where it appeared in the visual field, informed the monkey of what vector of saccade to make (left, right, up, or down). The cue was placed randomly to the left, right, up, or down relative to initial fixation. The result was that rules were held constant (color–vector association never varied) but conflict changed from trial to trial (saccades might be made toward, away from, or at right angles to the visual stimulus). In another version of the task, the rule changed so that the monkey simply looked at the stimulus wherever it appeared. The end result was that SEF neurons fired more actively when conflict was high (saccades away from, not toward, stimuli) and rules were difficult (saccades determined by stimulus color, not location; Figure 4(b)). This explains the intense activity in antisaccades versus prosaccades, because in the former conflict is higher and the rule is harder.

Predicting Events

A common type of neuronal activity found throughout the cerebral cortex is predictive or anticipatory signals. The activity of many neurons ramps up if task context implies that an event, such as visual stimulus onset or a cue to move, is imminent. The SEF seems to

Figure 4 Conflict and rule functions of SEF. (a) SEF activity during antisaccade task. Considering only the trials in which the saccade (arrow) enters the receptive field (dotted circle), the SEF neuron fires more strongly when the saccade is an antisaccade (orange box) than when it is a prosaccade (blue box). The yellow circle shows visual stimulus. Other data show permutations of the task when saccade goes away from the receptive field. (b) The antisaccade task varies from the prosaccade task in that it involves conflict and a harder rule. To tease apart the influence of each factor, conflicts and rules can be varied independently. Both factors are important: SEF neurons fire more strongly for harder rules than easier ones (left) and more strongly for stimulus-response conflict than agreement (right). (a) Adapted by permission from Macmillan Publishers Ltd: *Nature* 390: 398–401, © 1997. (b) Adapted and reprinted from *Physiology & Behavior*, vol. 77, Olson and Gettner, 'Neuronal activity related to rule and conflict in macaque supplementary eye field,' pp. 663–670, © 2002, with permission from Elsevier.

be especially predictive in nature, exhibiting more prevalent anticipatory activity than the FEF or an oculomotor region of parietal cortex (the lateral intraparietal area), as shown in a comparative study by the Hikosaka laboratory. The predictive capacity of the SEF was studied in most detail by Heinen and colleagues in relation to smooth pursuit movements. The smooth pursuit system is exquisitely sensitive to regularities in motion and seems to promote prediction avidly. The result is to keep the fovea centered as much as possible on an object of interest rather than having it lag behind due to afferent visual delays. Heinen took advantage of this feature of the smooth pursuit system to quantify the predictive nature of the SEF. In agreement with its other higher-order functions, the SEF was found to be highly active when anticipatory pursuit occurred, and electrical stimulation in SEF promoted anticipatory pursuit. The predictive activity, like the other signals in SEF, seems to be sensitive to rules and other supervisory factors, as shown in a clever task by this group that required monkeys to judge whether a pursuit target would

cross a 'strike zone'; in this ocular baseball task, anticipatory activity was stronger for strikes than balls. The ability to modulate one's anticipation as a function of context – the point of their findings – clearly is important not only for baseball but also for many everyday tasks (e.g., driving a vehicle).

Learning

Little is known about learning at the neuronal level in the SEF. The only detailed study was performed by Chen and Wise, who demonstrated remarkably strong activity modulations as monkeys learned pairings between foveal-presented stimuli (arbitrary symbols) and direction of saccade required (right, left, up, or down) on a daily basis. For comparison, the monkeys also performed stimulus–saccade pairings that were constant from day to day. One type of neuron seemed to be a 'surprise' detector or learning selective, having activity at the start of learning that disappeared once learning was achieved (Figure 5(a)). Such neurons were not simple error detectors as described by Schall and colleagues because the modulation could occur at any time during the trial – for example, immediately after stimulus onset and not just after an incorrect response. Another type of neuron was learning-dependent, changing its activity in correlation with the learning curve as if mediated by long-term plasticity (Figure 5(b)). Such neurons could in principle store the new stimulus–response association. A striking consequence of their change in activity was that their directional tuning curves shifted during learning. This ties together with the flexibility in spatial coordinate frames represented by SEF neurons, and it raises the question of whether the SEF could represent any coordinate frame with enough training. Whereas learning-related neurons were prevalent in the SEF, they were significantly less common in the FEF.

Learning is a function of many variables, such as detection of stimuli, resolution of conflicts between looking at stimuli and places instructed by stimuli, trial-and-error attempts at finding responses that yield reward, and detection of reward or punishment. The SEF has activity related to sensory input, oculomotor response, conflict resolution, and supervisory control

Figure 5 Components of learning in the SEF. (a) For some neurons, activity surges and then disappears as learning progresses (learning-selective neurons). (b) For others, such as the one depicted in this summary graph, activity is correlated with behavioral improvement and then remains at a new level once learning is achieved (learning-dependent neurons). (c) A necessary signal for learning is acknowledgment of reward, and many SEF neurons fire for reward as shown by this example. (a,b) Adapted and used with permission from *Journal of Neurophysiology* (Chen and Wise, 73: 1101–1121, 1995). (c) Adapted with permission from *Journal of Neurophysiology* (Amador et al., 84: 2166–2170, 2000).

of actions. What about reward? Results have been mixed. During a trial, some SEF neurons seem to anticipate reward delivery, but Olson and colleagues suggest that this is uncommon and may be related primarily to motivational state rather than to reward *per se*. After the behavior necessitated by a trial, and at the time of reward delivery, many SEF neurons do seem to be unambiguously sensitive to detection of reward, as demonstrated by the Schlag laboratory (**Figure 5(c)**). In summary, the SEF seems to have essentially all of the apparatus necessary to accomplish the learning of visuomotor associations. Still needed are causal experiments to test the necessity of SEF for learning.

Planning Sequences

The only oculomotor deficit found after reversible inactivation of the SEF and its surrounding cortex has been a mild but significant impairment in performing sequences of saccades, as shown by Sommer and Tehovnik in the Schiller laboratory. In lesion studies, Chou and Schiller demonstrated that damage to the area results in mild, short-term impairments in the ability to process and respond normally to the presentation of multiple visual stimuli. In both studies, saccades to single targets were affected barely or not at all. As with learning, the ability to react correctly when faced with multiple stimuli is the product of many underlying factors. An integrative hypothesis would be that the SEF is necessary for the correct coordination of sequences because of the underlying operations that it performs, such as supervisory control.

An alternative view is that the SEF plays a special role in overseeing the production of sequences. This is supported by further evidence. Hikosaka and colleagues showed that many SEF neurons become strikingly selective for various segments of complex saccadic sequences ('hypersets' of five sequential, learned binary choices). Similar results were found by Tanji and colleagues. Transcranial magnetic stimulation of human SEF reorders saccades of sequences as shown by Tobler and Müri, and Histed and Miller showed that electrical stimulation causes a similar effect in monkeys. In the latter study, reordering of sequences favored a final termination location in contralateral space, thus linking the effect with the coordinate frame results discussed previously.

Coordinating Limbs and Eyes

By definition, the SEF is an eye field. But how absolute is this eye specificity? The SEF represents the rostral end of a topographic map of the body that extends through the entire supplementary motor area. Edges are blurred everywhere in this map, and it is well documented that skeletomotor representation extends into the oculomotor zone and vice versa. This suggests a supramodal role for the SEF: simply stated, perhaps it is involved in hand–eye coordination. As noted by Tehovnik in a review on the topic, neurosurgeon Penfield and colleagues found that stimulating the area around human SEF caused "the impression that the contralateral hand is raised … and that meanwhile the gaze is directed by movement of head and eyes toward the hand." By comparing the gross anatomy of where eye-related neurons and arm-related neurons were found in monkey dorsomedial frontal cortex, Tehovnik concluded that overlap is extensive (**Figure 6(a)**).

Specific studies of eye- and arm-related interactions in neuronal activity were performed by Tanji and colleagues. They had monkeys look at visual targets, reach to them, or look and reach. Exploring the entire dorsomedial frontal cortex, they concluded that eye-specific activity was largely confined to SEF and arm-specific activity to more caudal supplementary motor regions, but that there was appreciable overlap (**Figure 6(b)**). Approximately 7% of neurons outside of SEF proper were eye-specific, and approximately 14% of neurons within SEF proper were limb-specific. Other neurons showed complex contingencies (e.g., firing for eye movements if limb movements were withheld but going silent if eye and limb movements co-occurred). In contrast, the FEF was overwhelmingly eye-specific. More work needs to be done to explore multimodality of the SEF and its environs, but the concept that the area plays a special role in hand–eye coordination has received preliminary support.

Conclusion

The SEF has proven to be one of the more challenging cortical areas to study. Investigators have had to resort to intricate, psychologically based tasks in order to describe SEF activity, but the results have been fruitful. In parallel with the monkey work described here, studies on humans (using metabolic imaging, electroencephalograms, and studies of lesions) have arrived at comparable conclusions regarding human SEF. The human work has been neglected for brevity here, but it is just as important. Much of the progress in understanding the SEF has arisen from systematic application of simple tasks (countermanding and antisaccade tasks) to both the FEF and SEF and comparing the results. Findings from these simple tasks then inspired more complex ones specific to interpreting the functions of the SEF. This slow and steady approach has changed the

Figure 6 Overlapping limb and eye representation in and around the SEF. (a) Summary maps from a review on eye and forelimb fields in dorsomedial frontal cortex. The left column shows ranges of cortex within which eye-related or forelimb-related neurons were found in several studies. The right column shows ranges within which eye movements or forelimb movements were evoked by electrical stimulation. There is considerable overlap between the eye and forelimb fields, particularly as defined by neuronal activity. (b) Example map from one study that distinguished eye-related neurons from forelimb-related neurons. Color map (left) represents density of each type of neuron (number of neurons recorded per mm^2) as a function of cortical space. Orientation and layout of the map is explained by the anatomical diagrams at right. Although there is noticeable segregation, there is overlap as well. (a) Adapted and reprinted from *Behavioral Brain Research*, vol. 67, Tehovnik, 'The dorsomedial frontal cortex: eye and forelimb fields,' pp. 147–163, © 1995, with permission from Elsevier. (b) Adapted and used with permission from *Journal of Neurophysiology* (Fujii et al., 87: 2158–2166, 2002).

general view of the SEF from a frustrating area of study to a rather beautiful, intriguing area. The downside is that hypotheses about SEF function have sprouted wildly. A necessity in future work will be the rigorous application of causal tests, especially reversible inactivation, to establish the functions for which the SEF is truly needed.

Swim Oscillator Networks

A H Cohen and T Kiemel, University of Maryland, College Park, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

We begin our discussion of modeling swim oscillator networks with a brief review of the uses to which models of such networks are put. After this overview, we examine some types of models in the context of the central pattern generator (CPG) for locomotion of the lamprey. We also mention models of other swim networks.

Models of the lamprey swim network differ in the level or granularity of their description. Biophysical models focus on the specifics at the level of the membrane channel currents and details of the intra- and intersegmental connectivity. Such models have multiple variables per cell or cell type. (Often, one model neuron represents all neurons of a given type in each hemisegment.) Connectionist models have a single variable for each cell type and focus primarily on intra- and intersegmental connectivity. Phase models have a single variable for each segment and focus on intersegmental connectivity.

The choice of level of description for a model depends on both the research question being addressed and the trade-off between detail and simplicity. For example, a biophysical model is required to fully understand the impact of neuromodulators on the CPG. On the other hand, any model type can be used to investigate the production of intersegmental phase lags. Developing a biophysical model can be considered the ultimate goal since it accounts for the CPG's behavior on multiple levels of description. However, using a biophysical model requires estimating many parameters, only some of which can be directly estimated. Connectionist and phase models have fewer parameters, which simplifies both parameter selection and understanding of the resulting model. Given the lack of detailed empirical information, a model will not necessarily reproduce aspects of the CPG's behavior that were not considered when selecting its parameters. For example, all models are tuned to reproduce correct intersegmental phase lags. However, only some models reproduce correct functional intersegmental coupling strength or the details of the functional anatomy of the coordinating system.

The behavior to be captured by the models of swim networks is relatively simple. All swim oscillator networks produce some form of rhythmic output produced by a CPG. The rhythmic output of any swimming network is alternation among the muscles that move the body left/right or up/down, as well as a feature such as a traveling wave to aid in propulsion. In lamprey, the behavioral components of the motor output pattern are clearly defined as alternation between left and right muscles within a single spinal segment and a constant phase delay among the muscles along the side of the body (Figure 1). The traveling wave generated by this pattern typically forms a single wavelength along the body, which has been shown to be most efficient for this eel-like body form .

Modeling the Oscillator

We begin with the rhythm generation, or the mechanism for the oscillation between off and on states that accompany the oscillation of the membrane potential seen in the output elements of the CPG, the motor neurons. The oscillatory mechanism is often included with the mechanism for the alternation between the two sides of a single segment, but the two need not be linked. In modeling the oscillator, the first issue is whether the system depends on a single pacemaker or a number of distributed oscillators. The second issue is whether or not the oscillation is a function of membrane properties that generate the periodic changes in the membrane potential or whether it is a function of network connections. Indeed, most often it is a function of both membrane potential mechanisms and network connections, as has been found in the stomatogastric ganglion of Crustacea and the heart ganglia of the leech. In the lamprey, the evidence appears to support this double method as well. There are clearly membrane oscillations that appear in response to NMDA, and there are also network connections that are capable of forming an alternating output in combination with sufficient channel properties that are highly common.

It is also known that the CPG responsible for the oscillation is a distributed system, with each segment, hemisegment, or small group of segments capable of producing a rhythmic discharge of its own motor neurons. The exact minimal unit is still under debate, but there is evidence that it could be a hemisegment. On the other hand, the frequency appears to be a product of the ensemble of oscillators and apparently is not governed by any single oscillator.

Thus, any model of the lamprey swim network must account for rhythm generation in a single segment or hemisegment. There are several models for the network

Figure 1 Neural activity recorded from the motor nerves of an isolated 50-segment piece of lamprey spinal cord. Activity from the left and right motor nerves of the same segment exhibits alternation (L03 and R03). Activity from different segments exhibits a rostrocaudal traveling wave. Numbers indicate the segment numbers.

Figure 2 Known (solid lines) and presumed (dashed lines) connections in the lamprey CPG. Cell types are motor neurons (MN), excitatory interneurons (EIN), lateral inhibitory interneurons (LIN), crossed caudal interneurons (CCIN), small ipsilateral inhibitory interneurons (SiIN), and small crossing inhibitory interneurons (ScIN). (a) Connectivity scheme of Buchanan and Grillner based on pairwise recordings from different segments. (b) Segmental network if the LIN and CC interneurons are removed, based on the argument that these neurons provide primarily intersegmental coupling. (c) Evidence of intrasegmental connections. Figure provided by David Parker.

of the segmental unit CPG. The simplest was the original proposed by Buchanan and Grillner based on the experimental evidence of single cell recordings. The current network includes some additional neurons, again based on recordings of single neurons during rhythm generation by the isolated spinal cord, or what has been called 'fictive locomotion.' The basic oscillator model adds channel currents and some modulation. Such a model will almost certainly be missing some important elements of the oscillator, such as neuronal connections and/or channel currents. Nor can it include currents that have not yet been found that are either ligand gated or voltage gated. The current model does include some rather novel currents, such as potassium-dependent sodium channels.

There are many ways to model even a simple system such as the lamprey spinal cord. The issues are the neuronal composition and its connectivity. We present here, for comparison, the model put forth by David Parker, shown in Figure 2. The dashed lines represent those connections that are presumed to exist but for which there is no direct evidence. The solid lines represent those for which there is direct evidence. The inference of the connections from the large interneurons, such as the lateral interneurons and crossed caudal interneurons (CCINs), has been based on recordings between segments some distance apart. Although there have been attempts to prove that the large neurons do or do not have connections within their own segment, such evidence is very difficult to obtain directly. It is unclear how the

model will be affected by whether or not the inhibitory connections are from the larger CCINs or from the smaller crossed inhibitory interneurons. Unfortunately, answering these questions requires obtaining good recordings of each of the small interneurons in combination with their posited target neurons within a single segment; that task is very difficult. Obtaining the parameter values for the channel currents for each neuron throughout the dynamical changes that are likely to occur within a single cycle is even more difficult. Thus, although the model is a useful way to keep track of the latest view of the oscillator, one must be cautious of strong conclusions based on this or, indeed, any model.

The biophysically based model, in its current configuration, could be used to test the role of a variety of modulatory currents, such as those proposed by Parker and colleagues. This analysis would require that one perform a sensitivity analysis of those currents using perhaps two parameter values simultaneously. Unfortunately, there are far too many parameters in the current model for this kind of analysis to be practical. However, an abstracted form of the model could be developed in which such an analysis could be performed. The results of such a study would suggest which currents and modulators to vary in order to determine more accurately their roles in the development of the rhythm.

The oscillator networks have been modeled in several model systems, including the tadpole of *Xenopus* and the salamander. There are also examples among the invertebrates, including the leech. In some cases, the issues relate to the development of the network, whereas in others they relate to the rhythm generation alone.

In summary, a major difficulty with biophysically detailed models in which the parameters values are not fully known is that there are many 'free' parameters. That is, there are many parameters whose values during the motor behavior are dynamically changing but are known only from static experiments, at best. When one tweaks the parameters to achieve the desired motor output pattern, one can relatively easily change enough parameters to obtain the desired behavioral regime.

We demonstrate this with a discussion of a totally different kind of modeling by Jung and colleagues for the oscillator which used a bifurcation analysis to illustrate the range of potential output patterns that can be assumed by the simple six-neuron network of Williams. The model we consider makes no claims to realism. It has few parameters except the weights of the connections among the classes of the neurons and the descending drive strength that serves as the excitation to the network. In this simple network, we found that a parameter unnecessary for the oscillation was the connectivity of the excitatory neurons. Experimental evidence from the Grillner group has since been presented to counter this possibility, but the results of the model do suggest that one can, with a simple network, produce a relatively large range of behaviors. One must be cautious about any conclusions one draws from any model because the realm of its possible behaviors is manyfold and typically largely unexplored.

Modeling the Traveling Wave Motion

In modeling the traveling wave motion, there are other fundamental issues that must be addressed besides rhythm. The first is the necessity of sensory feedback. Does sensory feedback produce the sequential activation of the segments? In the lamprey CPG and several other CPGs (e.g., leech and *Xenopus*), it has been shown that the traveling wave among the segments appears in the absence of sensory feedback. Sensory feedback may contribute to the traveling wave motion, but it is not necessary for the motion to occur. The next question is whether the delays among the segments are a constant phase of the cycle duration or a constant delay. If they are a constant delay, the mechanism can be relatively easily explained, potentially, as due to conduction delays along the axons connecting the segmental oscillators. However, in most systems the delays are a constant phase angle of the cycle and not a constant delay. Thus, they are due to a computation wherein the delay is changed for each frequency at which the oscillators burst. In the lamprey, for example, this has been shown to be the case. The delays among the segments are a constant phase of the cycle regardless of the frequency even in the complete absence of sensory feedback. That is, in the case of 'fictive swimming,' the delays are roughly appropriate for the frequency seen that is elicited by the addition of excitatory amino acids to the bath holding the isolated spinal cord. The mechanism for the computation of the constant phase delay has been the focus when modeling the intersegmental coordination of the segmental oscillators.

Modeling the traveling wave motion began in 1982 with a paper by Cohen et al. Their model was a phase approximation of a chain of coupled stable limit cycle oscillators. A stable limit cycle oscillator has the property that, following a perturbation, the trajectories of the oscillator's variables return to their original waveforms; the only lasting effect of the perturbation is a phase shift. If stable limit cycle oscillators with similar frequencies are weakly coupled, then it is possible to derive a phase model that approximates the behavior of the system. The state of each oscillator is described by a single variable, its

absolute phase, and coupling between oscillators depends only on the relative phases of the oscillators. The behavior of a phase model is determined by the uncoupled frequency of each oscillator and the relative phase coupling functions. There can be a different coupling function for each pair of pre- and postsynaptic oscillators, although typically the coupling function is assumed to depend only on the relative position of the two oscillators in the chain.

Use of a phase approximation simplifies the understanding of intersegmental coordination by dividing the problem into two parts: (1) understanding how the details of the neural dynamics and neural circuitry affect uncoupled oscillator frequencies and the relative phase coupling functions and (2) understanding how the properties of the oscillator frequencies and coupling functions relate to intersegmental coordination. Cohen et al. addressed the second part of the problem. They assumed that coupling functions were sine functions. An important property of a coupling function is its preferred phase, the relative phase that would be produced by unidirectional coupling between two oscillators with equal uncoupled frequencies. The preferred phase of a sine coupling function is either in-phase or anti-phase, depending on the sign of the sine wave's coefficient. Cohen et al. showed that a traveling wave could be produced in two ways: (1) by a gradient of uncoupled oscillator frequencies and nearest-neighbor in-phase coupling and (2) by equal uncoupled oscillator frequencies, nearest-neighbor in-phase coupling, and anti-phase coupling between the first and last oscillator in the chain. These two examples correspond to the two basic mechanisms for producing a traveling wave in a chain of coupled oscillators: a systematic variation in oscillator frequencies (the oscillator frequency mechanism) or non-in-phase coupling functions (the coupling function mechanism). For the lamprey CPG, experimental evidence supports the coupling function mechanism as the source of the traveling wave. For example, when a piece of spinal cord is cut into smaller parts, the relative frequencies of these parts do not show a systematic pattern.

Work by Ermentrout and Kopell has provided a general understanding of the coupling function mechanism for phase models with short-distance coupling. Allowing preferred phases to take on any value, not just in-phase or anti-phase, they showed that the relative strength of ascending and descending coupling plays a critical role in determining intersegmental phase lags. For example, in the case of nearest-neighbor coupling with ascending coupling stronger than descending coupling, phase lags between adjacent oscillators are close to the preferred phase of the ascending coupling, except near the rostral end of the chain. This coupling dominance can be seen in certain swim models, such as the lamprey CPG models of Williams and Ekeberg.

Although the behavior of many swim models can be understood using a phase approximation, there are two important limitations. First, a phase approximation is only guaranteed to be valid in general if coupling is weak. For strong coupling, a phase approximation will be valid only in very restrictive special cases. Second, swim models only exhibit certain properties, such as coupling dominance, if long-distance coupling is absent or very weak. To test whether these two assumptions, weak and predominantly short coupling, hold for the lamprey CPG, we developed a method of estimating functional coupling strength based on recordings from two motor nerves. The method is based on estimating parameters in a model of two coupled phase oscillators and gleans information from cycle-to-cycle variation in cycle periods and intersegmental phase lags. Functional coupling strength is quantified by the measure β, which varies from 0 (no coupling) to 1 (infinitely strong coupling). For a 50-segment piece of spinal cord, functional coupling between the rostral and caudal ends is very strong (Figure 3). Also, by inhibiting 20 middle segments, we found that long-distance connections provided substantial coupling. Therefore, as summarized in Figure 3, coupling in the lamprey CPG is neither weak nor predominantly short.

The functional coupling strength measure β can be estimated for any model by adding noise to create cycle-to-cycle variations in cycle periods and intersegmental phase lags. We have estimated functional coupling strength for three models: the connectionist model of Williams; the model of Ekeberg, which was

Figure 3 Comparison of experimental estimates of coupling length and function strength to those of various models.

intended as a simplified version of the more-detailed biophysical models of Grillner and colleagues; and the phase model of Mellen et al. Figure 3 shows β for each model along with its maximum connection length. Note that the Williams model, which has only nearest-neighbor connections, exhibits weak functional coupling, whereas the other two models, which contain longer-distance connections, exhibit strong functional coupling.

The traveling wave of muscle activation along the body is a necessary element of the behavioral motor pattern underlying swimming. A full model for swim behavior should include the known properties of the intersegmental coordinating system fiber anatomy and physiology. Most models have focused on reproducing intersegmental phase lags, not functional intersegmental coupling strength.

Conclusion

It is critically important that models are never mistaken for truth. Regardless of how realistic they appear, they are unlikely to ever include all critical parameters, cells, and connections, at least until new methods for determination of neurons, their channels, and currents as well as their connections can be found. Until then, one can only state that a model contains sufficient anatomical and physiological elements for the generation of the behavioral features of swimming motor output. This holds true for both the rhythmic oscillations and the traveling wave.

One important conclusion from modeling work on the lamprey CPG is that it is advantageous to simultaneously model the system at different levels of description. For systems consisting of coupled oscillators, such as the lamprey and salamander spinal cords and leech nerve cord, phase models can provide insight into how factors such as frequency differences, coupling length, and coupling asymmetry lead to the system's observed behavior. For example, phase models of the lamprey CPG suggest the importance of long connections, but not frequency differences, in setting phase lags. In contrast to phase models, more-detailed models allow us to understand the underlying basis for frequency differences and coupling properties. More-detailed models also potentially allow us to check the validity of a phase model approximation. Thus, the complementary use of detailed models and high-level models often offers the best chance of gaining insight into a complex system's behavior. This should remain true regardless of the details of the underlying physiology of the system. Such systems are notoriously difficult to understand intuitively. Modeling often offers the only sensible approach, as has been shown by a robotic implementation of a salamander by Auke Ijspeert and colleagues in which they demonstrated a potential mechanism for changing gaits in tetrapods.

Swimming: Neural Mechanisms

Swimming is a mode of locomotion in most aquatic animals. In the case of microscopic planktonic animals, swimming is performed through the rhythmic beating of body cilia. Larger animals swim using periodic muscle contractions, which are controlled by the nervous system. Swimming is usually adapted to the environment. Particularly when swimming, animals are oriented in space. Like other automatic rhythmic movements, swimming is controlled by ensembles of neurons – central pattern generators (CPG) – which are capable of producing the basic spatiotemporal motor output in the absence of sensory feedback. Therefore, the neural mechanisms underlying swimming can be studied in terms of the activity of single neurons and neuron-to-neuron interactions using *in vitro* preparations (*in vitro*-generated swimming-like rhythmic activity is called fictive swimming). These studies have shown that invertebrates and vertebrates share some general principles of swim control, regardless of the mode of organization and the complexity of their nervous systems.

Generation of Rhythmic Swimming Activity

To understand the basic neural mechanisms that underlie swim movements, it is important to answer two main questions:

- What is the source of rhythmic activity?
- What mechanisms shape the pattern of motor output (i.e., determine the number of phases in a cycle and the transitions from one phase to another)?

These two aspects of swimming CPG activity are closely interconnected and, in general, are determined by the endogenous properties of generator neurons and their interactions. However, the relative importance of cellular and network mechanisms in generating a swimming rhythm, and in shaping the motor output, is different. The patterning of the motor output is mainly determined by interactions between the neurons. In contrast, experiments with physical and functional isolation of neurons show that the decisive role in rhythm generation is played by specific groups of interneurons (INs) that are endogenous pacemakers. Unlike rhythmic movements (e.g., heartbeat and respiration) that continue throughout the life span and are controlled by constitutive pacemakers, swimming is an episodic movement. Therefore, swimming rhythms are generated by conditional pacemakers, which are transferred from a nonactive to a rhythm-generating state by command signals. *In vitro*, pacemaker activity can be initiated by applying the neurotransmitters that are used by command inputs. Several examples of swim control systems are described for illustration.

Jellyfish Swimming

Jellyfish swim by periodically contracting the musculature. Jellyfish's musculature is composed of myoepithelial cells whose contractile processes form a circular sheet. Due to the jellyfish's radial symmetry, their nervous system has annular organization. It includes pacemaker neurons that continue to generate a swimming rhythm after isolation of a small part of the nerve ring. Putative command neurons are nitrergic neurons that initiate pacemaker activity through the NO/cGMP signaling pathway. The pacemakers form excitatory synapses on motor neurons (MNs), which innervate circular musculature.

Swimming cycles in jellyfish have only one active phase of muscle contraction, followed by passive relaxation. Therefore, jellyfish exhibit the simplest mode of interneural interactions. Pacemaker neurons interact via electrical synapses, as well as via unique bidirectional chemical excitatory synapses, where both synaptic terminals can serve as pre- and postsynaptic elements; inhibitory interaction between neurons is absent. This mode of neuron interaction performs two functions. First, it synchronizes the activity of generator neurons and therefore (along with electrical connections between the myoepithelial cells) allows the simultaneous contraction of circular musculature. Second, the frequency with which individual pacemakers fire is variable, and in the system of neurons with bidirectional connections there is a constant shifting of the leading function between pacemakers; each following cycle is triggered by the fastest element. Thus, interneural interactions raise both the frequency and the regularity of the generator output.

In addition to regular (slow) swimming, the stimulation of sensory cells evokes a fast escape reaction. This reaction involves the giant ring axon, which in turn excites MNs, producing fast, strong muscle contractions. The different strength of muscle contractions during regular and escape swimming is due to the ability of MNs to conduct two types of

spikes. Pacemaker neurons produce low-threshold calcium spikes of a small amplitude, whereas the giant axon produces high-threshold sodium spikes. The two types of impulses propagate independently because the peak of the calcium spike is below the threshold of the sodium spike.

Pteropod Mollusk

The pelagic marine mollusk *Clione limacina* (**Figure 1(a)**) swims by rhythmically moving its two wings. Each swim cycle consists of two phases, dorsal and ventral wing flexions, which are produced by alternating contractions of antagonistic wing muscles (**Figures 1(b) and 1(d)**). The swimming CPG is located in the pedal ganglia that give rise to the wing nerves. Two antagonistic groups of INs (INs 7 and 8 in **Figures 1(c) and 1(d)**) play the decisive role in rhythm generation. The INs generate prolonged (~100 ms), tetrodotoxin-resistant action potentials; there is one potential per cycle (**Figure 1(c)**). These action potentials determine the duration of the cycle phases. In young mollusks that have a higher frequency of wing oscillations (due to biomechanical reasons), the duration of IN action potentials is much shorter than in adults.

The INs of both groups are endogenous pacemakers. After extraction from the ganglion, they continue (under the influence of serotonin) to generate periodic action potentials with the frequency typical of wing beating (**Figures 1(e) and 1(f)**). Each neuron discharge is preceded by a pacemaker potential (**Figure 1(e2)**, arrowhead). Extraexcitation of the isolated IN shifts the phase of rhythmic activity (**Figure 1(f)**). One of the command systems, which transfers these pacemakers to a rhythm-generating state, is formed by serotonergic neurons located in the cerebral ganglia. The initiation or acceleration of swimming activity induced by the serotonergic neurons are not accompanied by the depolarization of pacemaker INs (**Figure 1(g)**). This suggests that the effect of serotonin is realized through metabotropic receptors. Simultaneously, the serotonergic neurons depolarize MNs, which results in an increase of their spike discharges in the proper phases of the cycle (**Figure 1(g)**). The serotonergic mechanisms, in addition to swim activation, enhance wing muscle contractility and accelerate the heartbeat. Therefore, these mechanisms perform both command and integrative functions.

The other command system is formed by the hunting neurons located in the cerebral ganglia. During *Clione* hunting, these neurons initiate the activity of different motor systems, including the swim control system. The putative transmitter used by the hunting neurons is acetylcholine because *in vitro* fictive hunting behavior can be evoked by the cholinesterase inhibitor. In addition to excitatory command neurons, there are inhibitory command neurons producing an abrupt halt of the swimming rhythm (e.g., in response to *Clione* head stimulation).

The pacemaker INs of each group are electrically interconnected and inhibit antagonistic INs (**Figure 1(d)**). A system of neurons with this type of interconnections generates biphasic output with synchronous excitation of synergetic neurons and a half cycle shift between phases (**Figures 1(b) and 1(c)**). Mutual inhibition of antagonistic INs not only determines their alternating excitation but also, due to postinhibitory rebound, assists the transition from one phase to another and, therefore, enhances the reliability of the rhythm generation. The rebound phenomenon facilitates the beginning of each following phase of the cycle through the hyperpolarization-activated inward current (I_h) occurring in the INs after the termination of the inhibitory postsynaptic potentials.

An additional mechanism contributes to the reliable transition from one phase of the cycle to another. The swimming CPG includes one more group of INs (INs 12 in **Figure 1(c)**). They are nonspiking cells that generate long-lasting plateau potentials. INs 12 are not endogenous oscillators, and their rhythmical activity is determined by inputs from the pacemaker INs. They receive an excitatory input from the ventral phase INs and an inhibitory input from the dorsal phase INs (**Figure 1(d)**). When excited, INs 12 produce a slight recurrent inhibitory effect on the ventral phase INs and an excitatory effect on the dorsal phase INs. Thus, INs 12 promote the termination of the ventral phase and initiation of the dorsal phase of the cycle.

The pacemaker INs control the activity of wing muscle MNs. They excite the synergetic MNs and inhibit the antagonistic ones (**Figure 1(d)**). Simultaneous excitation of synergetic MNs is determined by both their common inputs from INs and electrical interconnections.

Unlike *Clione*, rhythm generation in the other marine mollusk, *Tritonia*, is solely based on interneural interactions. The main reason for this difference is the fact that this benthos mollusk does not demonstrate sustained swimming. When *Tritonia* are touched by the ambulacral feet of a predatory starfish, this contact initiates a short series of alternating dorsal/ventral flexions of the body, which cause it to rise up from the substrate and be carried away by water current.

Medicinal Leech

To swim, a leech flattens itself by contracting its dorsoventral muscles; it then undulates by alternating contractions of dorsal and ventral longitudinal

Figure 1 Neural mechanisms controlling swimming in the pteropod mollusk. (a) Photo of *Clione* during swimming. W, wings. (b and c) Fictive swimming recorded in preparations of the isolated nervous system; simultaneous intracellular recordings from two antagonistic MNs active in the ventral (V) and dorsal (D) phases of the cycle (b) and from the generator INs 7, 8, and 12 (c). (d) Organization of the swimming CPG; arrows, filled circles, and resistor symbols show chemical excitatory and inhibitory connections and nonrectifying electrical connections, respectively. (e, f) The INs 7 and 8 are conditional pacemakers. An IN extracted from the pedal ganglion does not generate rhythmic activity, spontaneous or in response to prolonged depolarization (horizontal line in e1), but is transferred in a rhythm-generating state by serotonin application (e2). Extraexcitation of the isolated IN by current injection shifts the phase of rhythmic activity (f). (g) Intracellular stimulation of a cerebral serotonergic command neuron (horizontal line) results in an acceleration of the ongoing rhythmic activity and an increase of MN discharges; dotted lines indicate initial levels of the membrane potential. muscles, which produce quasi-sinusoidal, rearward-traveling waves, pushing the animal forward through the water. When the frequency of the undulations increases, the velocity of wave spreading also increases. As a result, there is no change in intersegmental phase lag and, therefore, in wavelength. The swimming CPG is distributed throughout the segmental nerve cord (Figures 2(a)–2(c)).

Rhythmic activity can be generated by single ganglia (Figure 2(d)). Each ganglion includes one unpaired and six paired putative oscillator INs (Figure 2(e)). There is no direct evidence that oscillator INs are endogenous pacemakers. Indirectly, the suggestion that at least some of them are endogenous oscillators is supported by the fact that intracellular injections of current shift the phase of the cycle (Figure 2(f)), which is typical of pacemakers (Figure 1(f)).

Figure 2 Neural mechanisms controlling swimming in the medical leech. The segmentally organized nervous cord (a) can generate fictive swimming after isolation (b, c). (b) Extracellular recording from the nerves supplying dorsal (DN) and ventral (VN) longitudinal muscles (the numbers of the segments are indicated in parentheses). (c) Activity in DNs from two segments (intersegmental lag is indicated by the dotted line). (d) Rhythmic activity generated by a single segment that had been isolated for 25 days; the upper trace indicates the time of occurrence of impulses in MN3 supplying a dorsal muscle. (e) The main groups of neurons involved in the swimming control; only one unpaired and three paired generator INs are shown; all homologous of INs are electrically coupled (not shown).

Interactions between oscillator INs within a ganglion are very complex (Figure 2(e)). All paired neurons are electrically connected. They communicate through inhibitory and rectifying electric synapses. The unpaired IN is an excitatory one. Some INs participate in the control of alternating activity in segmental antagonistic MNs (Figure 2(e)). In addition to excitatory MNs producing muscle contractions (dorsal and ventral excitors), there are output neurons designed as dorsal and ventral inhibitors. These MNs both inhibit the antagonistic excitors and reduce muscle contractions induced by the excitors. Thus, inhibitory MNs promote alternating contractions of antagonistic muscles. In addition, the inhibitors produce recurrent inhibition of some oscillator INs and, therefore, may be involved in the rhythm generation.

Unlike MNs that demonstrate biphasic activity (Figure 2(b)), phases of activity in INs are more dispersed. This is related to the fact that the oscillator INs not only control MN activity but also perform an additional function. They send axons either rostrally or caudally, and these intersegmental interactions determine the travel of the waves of excitation in the rostrocaudal direction (Figure 2(c)). Along with these central mechanisms, stretch receptors (which are embedded in the longitudinal muscles) also play an important role in organizing undulatory movements with proper intersegmental phase lags.

Command neurons initiating leech swimming have a two-level organization (Figure 2(e)). Neurons of a higher level (triggers) are located in the head ganglion. They receive inputs from body receptors, whose stimulation initiates swimming. The trigger neurons activate segmental command neurons (gaiting neurons) and, to some extent, oscillator neurons. The transmitters used by command neurons are glutamate and serotonin. Brief stimulations of command neurons initiate prolonged swimming bouts (Figures 2(g) and 2(h)). This suggests that they act through metabotropic synapses, although there is no direct evidence. Some command neurons perform integrative functions. In addition to activation of the swimming CPG, they excite flattener MNs. The command system in the leech, as in *Clione*, includes not only excitatory but also inhibitory neurons.

Swimming in Vertebrates

Among vertebrates, the lamprey's neural mechanisms of swimming have been studied in greatest depth. Lampreys swim by alternating contractions of antagonistic lateral muscles, which produce rearward-traveling undulatory waves. As in the leech, the undulatory waves spread with a constant intersegmental phase lag. The swimming CPG is distributed throughout the spinal cord. It is activated by the glutamatergic reticulospinal pathway – the main command system activating locomotion in all vertebrates. Rhythmic activity is generated due to intrinsic membrane properties of excitatory INs. Synchronous activity of the unilateral INs is determined by their mutual interconnections. These INs excite ipsilateral MNs and, through commissural INs, inhibit neurons of the contralateral side. This contralateral inhibition leads to alternating activity of right/left MNs. Although an inhibitory interaction is not necessary for rhythm generation, it may promote a transition from one phase to another due to postinhibitory rebound. In addition to central mechanisms, reliable rhythm generation is supported by signals from the stretch receptors located at the lateral margin of the spinal cord. The rostrocaudal travel of the waves of excitation is mainly determined by a higher inherent frequency of the rostral segmental CPGs. There is a similar organization in the swim control system in teleost fish swimming due to undulatory movements.

In addition to regular swimming, both Cyclostomata and teleosts exhibit startle/escape reactions that occur during prey capture or in response to threatening stimuli. These reactions are realized through the specific reticulospinal command system, including the giant Mauthner cells with high-diameter axons. Descending signals activate trunk MNs, which produce a unilateral bend of the body, followed by its fast straightening and, thus, by a propulsive tail stroke. Spinal circuits

(f) Current injection into the generator IN28 shifts the phase of rhythmic activity of the whole system. (g, h) Short stimulations of trigger (command) neurons SE1 (g) and Tr1 (h) initiate prolonged bouts of fictive swimming as monitored by rhythmic activity of MNs and generator INs. involved in regular swimming and escape behaviors partly overlap but are not identical. In particular, the activation of red muscles is dominant during regular swimming, whereas the escape reaction involves massive activation of fast, white muscles.

The neural mechanisms of swimming in amphibians were mainly studied on tadpoles, including the *Xenopus laevis* embryo released from the egg before normal hatching. As in the lamprey, the propulsive force arises from lateral body undulations, produced by alternating contractions of right/left muscles (**Figures 3(a) and 3(b)**). Neural organization of the swimming CPG in tadpoles (**Figure 3(c)**) is similar to that in *Clione* (**Figure 1(d)**) and in the lamprey. The core role in rhythm generation is played by excitatory INs that, together with ipsilateral commissural INs and MNs, form two antagonistic half-centers. The generator INs excite each other and, via commissural INs, inhibit neurons of the contralateral half-center, which provides a half-cycle shift between right/left efferent discharges (**Figure 3(b)**). As in *Clione*, synchronous activity of homonymous MNs is determined not only by the common input from the generator INs but also by their electrical coupling.

A swimming-like rhythm can be generated by a surgically isolated longitudinal half of the rostral (but not caudal) spinal cord taken from the *Xenopus* embryo (**Figure 3(d1)**). This suggests that generator neurons located in the rostral part of the spinal cord, and probably in the caudal hindbrain, are endogenous pacemakers capable of rhythm generation in the absence of inhibitory interactions between antagonistic neurons. Due to the rostral localization of the pacemaker neurons, an intersegmental delay of the wave of excitation underlying undulatory movements does not depend on the cycle period (as it does in the leech and lamprey). An additional mechanism which contributes to rhythm generation is reciprocal right/left inhibition followed by a postinhibitory rebound. An important role of the postinhibitory rebound follows from the fact that the glutamate agonist NMDA initiates rhythmic activity in the isolated hemicord only in the presence of Mg^{2+}, whereas the rhythmogenic effect of NMDA on the intact spinal cord does not depend on Mg^{2+}.

The decisive role in transferring the pacemaker INs from a passive to a rhythm-generating state is played by the glutamatergic command input(s) from higher centers. The application of the glutamate antagonist to the isolated hemicord blocks generation of swimming activity (**Figure 2(d2)**). Glutamate is also used as a transmitter by the excitatory generator INs. Therefore, mutual interactions between the excitatory INs not only lead to their synchronous activity but also strengthen the command signal. In addition to glutamatergic mechanisms, serotonergic mechanisms participate in transferring the conditional pacemakers into a rhythm-generating state. The application of NMDA combined with serotonin to the tadpole's spinal cord, which was treated with tetrodotoxin (which blocks spike activity and, therefore, disconnects synaptic interactions), produced rhythmic oscillations of the membrane potential in swim-control neurons (**Figure 3(e)**). This supports the idea that the generator neurons are endogenous oscillators.

As in other animals, the swimming CPG in tadpoles receives not only excitatory but also inhibitory command signals. These signals are transmitted through the GABAergic reticulospinal pathway that produces prompt termination of swimming in response to bumping into an obstruction.

Small tadpole embryos demonstrate a high frequency of undulations (up to 25 Hz). Correspondingly, an embryo's spinal neurons generate only one spike per cycle (**Figure 3(b)**). The mechanism preventing the neurons from repetitive discharges is a slowly inactivating increase of K^+ conductance, which maintains prolonged membrane refractoriness (**Figure 3(f1)**). After hatching, membrane properties start to change, and the neurons gain the ability to generate bursts of spikes (**Figure 3(f2)**). This leads to a decrease in the frequency of undulations in a growing tadpole (**Figure 3(g)**).

Thus, even the relatively simple neural networks that control swimming in both invertebrates and lower vertebrates have a redundant organization. All the important aspects of the network activity (rhythm generation, synchronous activity of synergetic neurons and alternating activity of antagonistic ones, transition from one phase of the cycle to another, etc.) are performed by multiple mechanisms that complement each other. This ensures a high reliability of swim control.

Spatial Orientation during Swimming

Many species actively stabilize a particular body orientation in space during swimming. Analysis of the systems for postural orientation and equilibrium control has been performed at behavioral and network levels in two animals, mollusk *Clione* and lamprey. It was shown that both actively maintain a specific body orientation due to gravitational reflexes driven by signals from the vestibular organs (lamprey) or from their functional analogs in invertebrates, the statocysts (*Clione*).

Figure 3 Neural mechanisms controlling swimming in tadpoles. (a) Tracing of swimming movements of a *Xenopus* embryo (intervals between traces are 3.3 ms); arrowheads indicate waves of bending, which progress toward the tail. (b) Fictive swimming in an embryo immobilized with *d*-tubocurarine; simultaneous recordings from a left spinal MN (LMN), right IN (RIN), and two symmetrical ventral roots (VR). (c) Organization of the swimming CPG; eIN, excitatory INs; iIN, inhibitory commissural INs. (d) A longitudinally split rostral part of the spinal cord isolated with a caudal part of the hindbrain generates swimming-like rhythmic activity as monitored by recordings from the sixth and eighth ventral roots in response to hindbrain stimulation (d1); the NMDA antagonist, 2-amino-5-phosphonovaleric acid (AP5), blocks the rhythm generation (d2). (e) Application of NMDA and serotonin to the tetrodotoxin-treated spinal cord of a *Rana temporaria* tadpole produces rhythmic oscillations of the membrane potential in spinal neurons. (f) Injection of depolarizing current of different strength into a spinal neuron of the *Xenopus* embryo evokes only single spikes (f1), whereas current injection into a neuron of the tadpole (24 h after hatching) can produce a burst of impulses (f2). (g) An episode of rhythmic activity evoked in an immobilized *R. temporaria* tadpole by electrical stimulation of the skin; the transition from the generation of bursts of impulses to the generation of single impulses is accompanied by an increase in the frequency of the swimming rhythm. Postural Neural Mechanisms in *Clione*

Normally, *Clione* maintains a vertical, head-up orientation (**Figures 1(a) and 4(a)**). Deviation from this orientation evokes postural correcting response. The tail is bent upward in the plane of deviation and the wing oscillations become asymmetrical, with the increased amplitude in the down-directed wing and retraction of the up-directed wing (**Figures 4(b) and 4(c)**, arrows). These postural reflexes lead to turning of the animal toward the vertical. The reflexes are driven by the gravity-sensing organs, the statocysts, that send signals to two types of cerebropedal

Figure 4 Control of spatial orientation in *Clione* (a–g) and lamprey (h–n). (a) The most common orientation of the swimming *Clione* is vertical, with the head up. L and R, the left and right aspects of the body, respectively. (b, c) Corrective motor responses to deviations from vertical in the frontal plane (arrows show directions of tail bending as well as increased activity of the down-directed wing and retraction of the up-directed wing). (d) The main groups of neurons involved in gravitational reflexes. CPB2 and CPB3, cerebropedal neurons; SL, statolith; SRC, statocyst receptor cell; TMN, tail MNs; WMN, wing MNs. (e) Neuronal network controlling *Clione* orientation in the frontal plane. Solid and interrupted lines are connections at lower and higher temperatures, respectively. (f and g) Operation of the network at lower temperature (f) and higher temperature (g). Due to a switch of connections from SRCs to CPB3 shown in d, the equilibrium point of the system changes from 0° (head-up orientation) at 10 °C (f) to 180° (head-down orientation) at 20 °C (g). The black and white arrows show directions of *Clione* rotation caused by the right and left TMNs, respectively. (h–j) Lamprey spatial orientation and its stabilization in the sagittal (pitch) plane (h; lateral view), transversal (roll) plane (i; frontal view), and horizontal (yaw) plane (j; dorsal view). Deviations from the stabilized orientation in these planes (angles α, β, and γ, respectively) evoke corrective motor responses (large arrows) aimed at restoration of the initial orientation. Symmetrical small arrows in (i) show directions of locomotor body undulations. (k) Main components of the brain stem orientation-controlling system. RS, reticulospinal neurons. (l) Organization of the roll-controlling network. Two groups of RS neurons, RS(R) and RS(L), receive inputs from the labyrinths (V) and eyes (E); they affect the spinal networks to evoke rolling of the

neurons, CPB3 and CPB2. The cerebropedal neurons, in turn, control the tail and wing muscle MNs (Figure 4(d)). After removal of the statocysts, *Clione* is not able to maintain any definite orientation in space.

The tail has the main role in stabilization of the body orientation. For example, deviations of the body in the frontal plane activate right or left statocyst receptor cells that excite the contralateral cerebropedal neurons (Figure 4(e), solid arrows). As a result, the contralateral tail MNs are excited and the tail bends up. The antagonistic gravitational reflexes driven by right and left statocyst receptors usually compensate for each other at the vertical head-up orientation (the equilibrium point of the control system in Figure 4(f)). Interneural interactions within the orientation-controlling network can change in relation to different behaviors. For example, the strength of the antagonistic gravitational reflexes can change asymmetrically. This will lead to a shift in the equilibrium point of the control system and, therefore, to a change in the swimming direction. This mechanism can be used during hunting behavior. A radical change in the interneural interaction occurs with an increase of water temperature. At higher temperature, statocyst receptors excite not the contralateral but, rather, the ipsilateral cerebropedal neurons (Figure 4(e), dashed arrows). This leads to a change in the equilibrium point in the system at 180° (from the head-up to the head-down orientation), which allows *Clione* to leave the superficial warm-water layers (Figure 4(g)).

Postural Neural Mechanisms in Lamprey

When swimming, the lamprey stabilizes the body orientation in the transversal (roll), sagittal (pitch), and horizontal (yaw) planes. Any deviation from the stabilized orientation causes corrective responses. In the pitch and yaw planes, the corrections occur due to the body bending in the corresponding plane (Figures 4(h) and 4(j)). In the roll plane, the corrections occur due to a change in the direction of locomotor body undulations from lateral to oblique (Figure 4(i)). These different types of motor responses are caused by four motor neuron pools in each spinal segment that innervate the dorsal and ventral muscles on the two sides.

The system for stabilization of orientation is mainly driven by vestibular input (Figure 4(k)). Deviation of the body from the stabilized orientation activates a specific group of vestibular afferents that, through neurons of vestibular (octavomotor) nuclei, affect contralateral reticulospinal (RS) neurons. These neurons, which constitute the main descending pathway in the lamprey, transmit commands for changing body orientation. In response to RS commands, the spinal cord forms output motor signals producing corrective movements (Figures 4(h)–4(j), bottom panels).

In addition to vestibular signals, RS neurons receive an ipsilateral visual input through pretectal neurons (Figure 4(k)). Visual signals exert a modulatory influence on RS neurons and thus can modify effects of the vestibular input. Natural sunlight assists in maintaining the normal dorsal-up orientation, whereas unilateral illumination causes a roll tilt toward the source of light (Figure 4(n)). Similar postural reactions to visual signals have been described in teleosts (the dorsal light response). Unlike the lamprey, some vestibuloectomized bony fish can maintain the dorsal-up orientation solely due to visual signals.

As in *Clione*, operations of the control systems, which stabilize orientation of the lamprey in each of the three planes, are based on the interactions between antagonistic vestibular reflexes mediated by two groups of RS neurons (Figures 4(l)–4(n)). The reflexes causing animal rotations in the roll plane are determined by the right and left RS neurons. Due to the vestibular input, the activity of the right and left RS neurons and, therefore, the activity of corresponding MNs depend on the animal orientation (Figure 4(m)). The antagonistic vestibular reflexes usually compensate for each other at the dorsal side-up orientation (the equilibrium point in Figure 4(m)). Unilateral eye illumination affects the two antagonistic groups of RS neurons differently and causes a shift in the equilibrium point of the system, which leads to a change in the stabilized orientation (Figure 4(n)). In the pitch control system, the stabilized orientation also corresponds to the equal activities in two bilateral antagonistic groups of RS neurons sensitive to the nose-up and nose-down tilt, respectively. The

lamprey. (m) Operation of the roll-controlling system when driven only by vestibular inputs. Ordinate, activity in RS(L) and RS(R) neurons; abscissa, angle of right and left roll tilting. Directions of rolling caused by activity of RS(L) and RS(R) neurons are indicated by the black and white arrows, respectively. The system has an equilibrium point at 0° (dorsal-side-up orientation). (n) Operation of the system when the right eye is illuminated. The visual input causes a shift of the equilibrium point to the left and the corresponding tilt of the animal. (a–d) Adapted with permission from Deliagina TG, Orlovsky GN, Selverston AI, and Arshavsky YI (1999) Neuronal mechanisms for the control of body orientation in Clione I: Spatial zones of activity of different neuron groups. *Journal of Neurophysiology* 82: 687–699. stabilized angle can be changed by increasing the water temperature, which affects the two groups differently and thus shifts the equilibrium point toward the nose-down orientation. Similarly, in the yaw control system, the stabilized orientation corresponds to the equal activity in the two antagonistic groups of RS neurons sensitive to the left and right lateral turn, respectively.

A control system for lamprey spatial orientation described previously at a functional level (Figures 4(h)–4(n)) has been analyzed in detail, with characterization of both sensory inputs and motor effects of individual RS neurons. A strong correlation has been found between vestibular inputs to individual RS neurons and effects on an efferent spinal output exerted by the same RS neurons. If a neuron is activated by a turn in a given plane, its motor effect results in a torque opposing a turn in this plane.

In conclusion, despite different structure of postural networks in the two evolutionary remote species (*Clione* and lamprey), the functioning of their orientation-controlling systems is based on the same principle – interaction between two antagonistic gravitational postural reflexes. Both animals stabilize the body orientation at which the antagonistic reflexes compensate each other. Both animals are able to gradually change the stabilized orientation through the change in the gain in one of the reflex chains. In addition, *Clione* can maintain two distinct orientations due to the reconfiguration of connections between elements of the postural network.

Sympathetic Nervous System

A Dahlström, Göteborg University, Goteborg, Sweden

© 2009 Elsevier Ltd. All rights reserved.

Introduction: Historical Overview

The peripheral autonomic nervous system was classically divided into two systems, sympathetic and parasympathetic, on a physiological basis. In 1904 TR Elliott, experimenting on frogs, suggested that adrenaline (epinephrine; E) was the chemical substance that mediated the effect of nerve impulses to the effector cells from sympathetic nerves. After the concept of chemical neurotransmission was accepted, these nerves were named 'adrenergic' by Sir Henry Dale in 1933, the suffix-ergic meaning 'using as transmitter.' In mammals the peripheral sympathetic nerves use noradrenaline (norepinephrine; NE) for transmitter instead of E, as demonstrated by Ulf von Euler in 1946. It is, however, important to stress that 'sympathetic' is not synonymous with 'adrenergic,' since sympathetic nerves use adenosine 5′-triphosphate (ATP) and neuropeptide Y (NPY) as cotransmitters and some use acetylcholine (ACh) as transmitter. Thus, peripheral adrenergic nerves contain and release NE in mammals (E in amphibians), but in the central nervous system (CNS) NE-containing as well as E-containing neurons exist; the terms 'adrenergic transmission' and 'noradrenergic transmission' therefore have to be used when dealing with the CNS.

The Peripheral Sympathetic System Is Composed of Two Neuron Chains

The sympathetic system in mammals is structured with two neurons connected in series. The first neuron (preganglionic), located in the intermediolateral gray column of the spinal cord, exits from the CNS at spinal cord levels Th1–L3–4 via the anterior roots. The preganglionic axons then deviate from the root via the ramus communicans alba to reach the sympathetic ganglia in the paravertebral chain of ganglia. The axons of this first neuron make synaptic contacts with the cell body of the second neuron in the peripheral sympathetic ganglia, named the postganglionic neuron. The postganglionic axons, which are thin and unmyelinated, return to the main root and accompany the peripheral nerves to the effector sites. The most cranial sympathetic ganglia of this paired chain of ganglia, the superior and middle cervical ganglia, and the stellate ganglia instead send their postganglionic axons directly to the head, neck, and cardiac tissues via thin adrenergic axon bundles. While the preganglionic neuron uses ACh as a classical transmitter in the synapses of sympathetic ganglia, the postganglionic neuron in most cases uses NE, ATP, and NPY as cotransmitters at its very widely ramified nerve terminal varicose plexus.

Structure of the Sympathetic Postganglionic Neuron

Von Euler's studies, published in 1946, demonstrated that tissue homogenates from sympathetic ganglia and sympathetically innervated tissues contained a substance that pharmacologically was identified as NE. However, the exact cellular localization of this catecholamine was not known. Until that time peripheral innervation of tissues was thought to be mediated by a 'syncytium,' since no microscopically identified structures that could be connected to a transmitter function had been observed until then. However, in 1946 Nils-Åke Hillarp was able to present microscopic pictures of a widely ramified network of thin, unmyelinated fibers stained with methylene blue (MB), using a special modification of the then generally practiced MB staining protocol (Figure 1). Also, sympathetic ganglia were found to contain such nets of varicose fibers (Figure 2). Hillarp, in his thesis of 1948, presented strong arguments that this net of varicose fibers was the morphological component that mediated transmitter effects.

The full structure of the sympathetic neuron was clarified in the 1960s, when Hillarp and co-workers succeeded in developing a histochemical fluorescence method that made it possible, for the first time in scientific history, to exactly pinpoint the cellular and intracellular localization of a transmitter. This histochemical fluorescence method used gaseous paraformaldehyde to initiate a ring closure of the side arm of the NE molecule, resulting in a strongly fluorescent isoquinoline. After using this method on an air-dried preparation of rat iris, a brilliantly green fluorescent varicose network of NE-containing sympathetic nerve terminals could be seen in the fluorescence microscope (Figure 3). This method could also be used to demonstrate the other catecholamines (dopamine (DA) and E) with a similar fluorescence spectra, as well as serotonin (5-HT), whose reaction product emitted a strong yellow fluorescence. This method was subsequently used for all kinds of tissues, and was the basis for the first mapping of the brain neuronal pathways that use NE, DA, or 5-HT as a transmitter. These studies were carried out during 1962–69 at the

Figure 1 Net of varicose nerve terminals in spread preparated rat tissue, stained with methylene blue. Small varicosities are seen along terminal branches which intermingle and anastomose in bundles. Large oval structures are Schwann cell nuclei, but the tubular sheaths of Schwann cell cytoplasm, covering the terminal branches, cannot be seen. From Hillarp (1946).

Figure 2 Net of varicose nerve terminal branches penetrating in between ganglion cells, forming baskets around cell bodies. Methylene blue stain. From Hillarp (1946).

Figure 3 Spread preparation of rat iris, exposed to formaldehyde vapor after air drying. Fluorescence micrograph demonstrating the dense net of green fluorescent nerve terminal branches with strongly fluorescent varicosities. V denotes a blood vessel with especially dense innervation of the fluorescent NE-containing nerve terminals. Arrow points to a bundle of preterminal axons with low fluorescence intensity, which have not reached their area of innervation. From Dahlström A (1971) Axoplasmic transport (with particular respect to adrenergic neurons). *Philosophical Transactions of the Royal Society of London B* 261: 325–358.

Figure 4 Section of a sympathetic ganglion demonstrating a postganglionic cell body with many branching dendrites. From Hillarp (1948).

Department of Histology, Karolinska Institute in Stockholm, Sweden.

Using this fluorescence method the full extension of the postganglionic sympathetic neuron was clarified. In the sympathetic ganglia the multipolar nerve cell bodies with many long dendritic neurites (Figure 4)

Figure 5 Fluorescence micrographs from rat sympathetic ganglia. To the left, from a normal rat. Cell bodies contain varying intensities of NE-induced fluorescence, leaving the nucleus nonfluorescent. To the right, a section from a ganglion treated with colchicine, which disrupts microtubules and blocks the export from the cell body of NE storing granules. Markedly increased fluorescence in enlarged cell bodies indicate block in export but continued production. Small arrows indicate swollen postganglionic axons with accumulations of fluorescent NE, due to interrupted axonal transport. From Dahlström (1968).

were found to contain varying levels of the fluorescent NE product, located in the cytoplasm and extending into the neuritic processes (Figure 5). Using the substance reserpine, known earlier to deplete tissues of catecholamines, it was found that the fluorescence was completely abolished, suggesting that the NE in ganglion cells and in nerve terminals was stored in some subcellular compartment which was sensitive to reserpine. Similar depletion of catecholamines was found around 1960 to occur in adrenal glands after reserpine treatment, and this was shown to be due to the blockade of a norepinephrine storage mechanism in subcellular granules, which could be isolated by centrifugation procedures. The storage mechanism for catecholamines in the adrenergic nerves was also reserpine sensitive, and it was thought in the 1960s to be located in the small synaptic vesicles observed by Eccles and others in the electron microscope (EM).

Hökfelt and co-workers, using a modified $KMnO_4$ fixation technique, demonstrated in 1968 that small synaptic vesicles in the ganglion cells and in the nerve terminals were the NE storage organelles for the sympathetic nerves. In normal tissues the vesicles in adrenergic structures contained a small electron-dense core, which was no longer observable after reserpine treatment. With this fixation protocol other nerve terminal structures were found to contain small clear vesicles without a dense core, presumably representing ACh-containing vesicles (Figure 6).

Figure 6 Electron micrograph of adrenergic nerve terminal, fixed in potassium permanganate ($KMnO_4$). A group of granular/vesicular structures can be seen, most of which carry an electron-dense precipitate in the matrix (arrows). From Hökfelt (1968).

The Sympathetic Neuron Has a Widespread Innervation Pattern

With combinations of quantitative biochemical and microscopic methods, the full extension of a sympathetic neuron in rat and cat tissues was investigated (Figure 7). The total NE content of rat irides, as well as a fixed length of rat vas deferens, was measured with the trihydroxyindole (THI) method. Then the total number of fluorescent varicosities in the irides was counted manually in stretch preparations. The lengths of vas deferens were sectioned and the varicosities were counted manually. Since the nonterminal axons contained very weak fluorescence (see arrows in Figure 3) and thus minute amounts of NE, the vast majority of NE would be present in the small, intensely fluorescent varicosities with a diameter of 0.5–1 μm. It was calculated that each varicosity of the sympathetic innervation in the rat iris and vas deferens, and in the cat head structures, contained in the order of 0.005 pg of NE.

The superior cervical ganglia (SCG) give rise to the sympathetic innervation in head and neck structures. In order to measure the NE content in the terminals emanating from this ganglion, all soft tissues of the cat head structures were dissected (in the cold). Five heads were used, and the total NE content in the tissues of each cat's head was found to be about 32 μg of NE. The histochemical formaldehyde fluorescence method demonstrated a linear relationship between NE concentration and fluorescence intensity in model experiments in concentrations well within physiological limits. Since, with the fluorescence microscope, the fluorescence intensity of nerve terminals in the cat was the same as in the rat, we could assume that the content/concentration of the rat and cat tissue varicosities was about the same. The number of nerve cells in a cat's SCG was carefully counted by Billingsley and Ranson in 1918. The majority of the ganglion cells (247 000, as indicated using the microscope) contained 104 ng of NE per pair. The SCG gave rise to a nerve terminal area containing

Figure 7 Schematic drawing illustrating the morphology of a postganglionic sympathetic neuron. From a multipolar cell body, a thin, unmyelinated axon, which can give off collaterals, passes to the area of innervation, where an extensive branching takes place. The peripheral nerve terminal branches carry presynaptic structures, varicosities, which are filled with transmitter organelles. To the left, three varicosities are drawn enlarged to illustrate the packed transmitter organelles in the varicose swelling, while the segments between varicosirites are very thin and devoid of transmitter granules. From Dahlström A (1971) Axoplasmic transport (with particular respect to adrenergic neurons). *Philosophical Transactions of the Royal Society of London B* 261: 325–358.

32 ng of NE. If each varicosity contained 0.005 pg of NE, each ganglion cell, on average, would gave rise to about 30 000 varicosities, corresponding to a total length of the added branches of the nerve terminal tree of about 15 cm. (Later in the 1970s it was reported that a mature SCG of rat contains approximately 30 000 principal ganglion cells.)

This historical work demonstrates the divergence of the sympathetic innervation pattern. At the same time, however, the innervation pattern is converging, since the effector cells (smooth muscle cells, gland cells, cardiac muscle cells, etc.) are usually reached by transmitter release from several neurons. The nerve terminals arrange themselves in a basketlike arrangement near, for instance, salivary gland acini, with a net of intermingling terminals from different neurons, both sympathetic and cholinergic. The ramifications of this intermingled net are coated by thin, fenestrated layers of Schwann cell cytoplasm. This arrangement, observed by Hillarp in his MB preparations, was given the name 'the autonomic ground plexus.'

Also in the ganglia the innervation from the preganglionic neurons is both diverging and converging. As pointed out by Burnstock (see **Figure 8**), each sympathetic ganglion cell receives innervation from many preganglionic axons (convergence), which in turn branch (divergence) to innervate many postganglionic neurons. This organization, together with the fact that the preganglionic axons can ascend or descend to other levels in the sympathetic chain before synapsing in the ganglion, is the reason for the slow, general activation of this emergency system. The physiological effect is one of slowly (some seconds) engaging the whole organism in the reaction. The sympathetic system is normally silent and is called into action during alarming situations. The release of E and NE from the suprarenal medulla is the quickest route by which the organism is alerted, the other parts of the sympathetic system becoming enrolled some seconds later.

NE Storage Organelles Contain Specific Matrix and Vesicle Membrane Components

The matrix of the NE storage organelles contains ATP and NE in a complex similar to that in the adrenal medullary granules. The population of organelles is not uniform in size or composition; both small vesicles (50 nm) and larger (<80 nm) NE-containing organelles ('granules') are observed with the EM. Usually the fraction of large organelles is only about 2–5% of the whole vesicle population in each varicosity, but this varies in different organs. These larger organelles also contain dopamine β-hydroxylase (DBH), which converts DA to NE, and have been proposed to represent the newly arrived, by fast axonal transport, organelles. With each round of exocytotic release, as suggested by Dahlström and Häggendal in 1982, the DBH-containing organelles lose part of the matrix, and the retrieved membrane is used to form the small NE-containing vesicles, which is the fraction that stores most of the NE in the nerve terminals. Studies using reserpine, which causes an irreversible block of NE storage in sympathetic nerves, indicate that the newly formed (after reserpine clearance) NE-storing organelles, recently arrived at the terminals by fast axonal transport, are the main 'NE-releasers,' and that only a few percent of the normal NE content in the nerve terminals is needed for full stimulation-induced effect. It was proposed that this small percentage of NE, sufficient for stimulation response after reserpine, is present in the newly transported granules. Since DBH in the large granules is needed for the NE

Figure 8 Schematic drawing of two postganglionic, sympathetic, ganglion cells which are innervated by two preganglionic axons seen to the left. Both axons branch and form varicose boutons (contacts) on somas and dendrites of both the green and the red ganglion cell, exemplifying 'diverging' innervation. The upper axon contacts both the green and the red neuron. Since the green cell is contacted by both axons and the red cell in innervated by both axons, this represents 'convergence' in innervation. The two blue structures are SIF-cells which are innervated and also lie close to blood vessels, creating a basis for release of chemicals (e.g., DA) into the circulation. From Burnstock G and Costa M (1975) *Adrenergic Neurons*. London: Chapman & Hall.

synthesis in the nerve terminal varicosities, it is obvious that the organelle turnover in sympathetic neurons differs mechanistically from that in cholinergic nerve terminals, where the ACh is synthesized by choline acetyltransferase (ChAT) in the cytosol before being taken up into the synaptic ACh-releasing vesicles by the vesicular ACh transporter (VACT).

The membranes of synaptic vesicles in the sympathetic neuron contain many identified integral proteins – for instance, synaptophysin, synaptic vesicle protein 2 (SV2), synaptotagmin I, synaptobrevin II, and the NE transporter, vesicular monoamine transporter 2 (VMAT2). In addition to the integral membrane proteins, many proteins have been found attached to the surface of the NE-containing vesicles, including synapsin, Rab3a, and clathrin light chain (LC). It is also likely that the enzyme tyrosine hydroxylase (TH), which is present in the soluble fraction when sympathetically innervated tissues are homogenized, attaches to transport organelles when exported from the cell body. This enzyme is transported intra-axonally at fast rates, which would not be the case if it were in the cytoplasmic phase during transport distally.

Peptides and Transmitter Presence Vary in Different Ganglia and in Different Species

In addition to the 'classical transmitter' NE, other small transmitter molecules are present in sympathetic ganglia. Generally, the enzyme TH, which is the rate-limiting step in catecholamine synthesis (a marker for sympathetic structures), is present in the majority of neurons in sympathetic ganglia. Some neurons, however, appear to be cholinergic in nature, since they instead express the enzyme ChAT in adult

animals. In many cases, neurons, which are nonadrenergic (TH-negative) and noncholinergic (VACT- and ChAT-negative), are present. These may contain histamine, but the presence of γ-aminobutyric acid (GABA) ergic neurons has also been reported. These GABA-containing neurons form basketlike nerve terminal connections around other ganglion cells, possibly representing an inhibitory intrinsic system in the ganglia.

Peptides like vasoactive intestinal peptide (VIP), NPY, galanin, enkephalin, somatostatin, and chromogranins may be present together with TH in sympathetic neurons. However, the amine and the peptides are stored in separate subcellular compartments. NPY and other peptides are seen to be stored in larger granules with an electron-dense matrix in regular EM preparations (in contrast to the NE in small synaptic vesicles, which requires fixation in $KMnO_4$ for visibility). NPY has been shown to be expressed in sympathetic neurons that innervate blood vessels, and somatostatin is present in some cells within the prevertebral ganglia, innervating the gut. Interestingly, combined retrograde tracing with triple immunohistochemistry has shown that the target tissue appears to determine which peptide is coexpressed with TH in the ganglion cells. Members of the family of chromogranins are frequently expressed in the sympathetic neurons. Recently the newly identified chromogranin NESP55 was demonstrated to be stored in a subpopulation of ganglion cells, concentrated to the Golgi region. As seen in Figure 9 the NESP55-positive cells were mainly scattered, except for in the thoracic chain ganglia, where groups of NESP55-containing neurons were observed. In only a small percentage, the peptide was colocalized with TH immunoreactivity. Recently it was reported that mouse sympathetic ganglia contain a population of neurons expressing one of the seven identified zinc transporters, ZnT3, co-localized with TH but never with NPY (Figure 10).

Thus, the presence and distribution of peptides vary in different species and in the various ganglia, and the expression is regulated most probably mainly by the target tissue receiving innervation from an individual ganglion cell. Some peptides are not visualized in control ganglia but are upregulated in response to axotomy or denervation. A dense pericellular net of varicose nerve terminals is present in sympathetic ganglia (Figure 2). Most of these fibers represent cholinergic preganglionic terminals storing different peptides – for example, enkephalin. Nerve terminals containing the peptide substance P also originate from sensory dorsal root ganglia. In prevertebral

Figure 9 Rat sympathetic ganglia (label to the left) incubated with anti-TH (red) abd Anti-NESP55 (green). Most ganglion cells contain TH-immunoreactive material while only a small number of cells contain green NESP55-like material. In thoracic ganglia the NESP55-containing cells are often seen in groups, while in other ganglia the green cells are scattered. Some TH-positive cells also contain the NESP55-peptide (yellow cells in the right lane indicating co-localization) while some NESP55 containing cells appear devoid of TH (arrows in lane 2, stellate ganglion). These sympathetic ganglion cells are a heterogenous population as regards transmitter-related substances. From Li and Dahlström (2007).

Figure 10 Sections of mouse sympathetic ganglia incubated with anti-ZnT3 (green) and anti-NPY (red). Many NPY-positive cells and a few ZnT3-containing cells are seen, and there is no indication of co-localization. From Wang et al. (2003).

ganglia, nerve terminals with bombesin-like material are also observed, probably representing a reciprocal innervation from the intramural ganglia in the gut.

The sympathetic neuron in normal adult animals expresses high levels of the growth-associated protein 43 (GAP43), observable with immunohistochemistry in all parts of the neuron. This protein is expressed in other types of neurons mainly as a response to trauma. The high level of GAP43 in sympathetic neurons is likely to reflect the high degree of plasticity of sympathetic neurons.

Intraneuronal Events in the Sympathetic Neuron

In the sympathetic neuron, as in other neurons, all materials necessary for the function of the neuron are produced in the cell body where the nucleus is located. The first observations that demonstrated a fast, distally directed, intraneuronal transport of NE were published in 1965. The rate of accumulation of material proximal to a peripheral nerve crush clearly indicated a rate of 5–10 mm h^{-1} in the sciatic nerve adrenergic axons of rat and cat, respectively. This figure was based on the rate of accumulation proximal to a crush/ligation, but has since been verified in isotope experiments using labeled amino acids incorporated into transported protein.

Later studies by Jia-Yi Li and co-workers, between 1994 and 1997, using immunofluorescence demonstrated a fast anterograde transport of the integral membrane proteins, of matrix peptides, and of surface-associated peptides. It is interesting to note that the amount of retrogradely transported peptides varies between these three classes of organelle components; the integral proteins showed the highest proportion of retrograde transport (about 50–80%, suggesting a recycling of membrane), about 20–30% of matrix peptides were found to recycle, while the surface-adsorbed peptides showed the lowest degree of retrograde transport. These figures probably mirror dynamic events in the nerve terminals; surface-attached proteins detach from vesicles in the nerve endings, matrix peptides are partially released via exocytosis during transmitter release, while integral membrane proteins remain in the membrane and are fully recycled.

Embryology/Development

The autonomic ganglia emanate from the neural crest, like the sensory ganglia and the innervation of the gut. The migration of the neural crest cells is dependent upon chemotaxis, and nerve growth factor (NGF) has been shown to be a prerequisite for the development of sympathetic and sensory innervation. Interestingly, during embryonic development, future sympathetic ganglion cells are initially cholinergic in nature, but alter the phenotype upon maturation. Thus, initially immunoreactive for ChAT, most ganglion cells downregulate the expression of ChAT and instead express TH, the catecholamine-synthesizing enzyme. However, a small proportion of the ganglion cells usually remain cholinergic in the adult animal, as demonstrated by high levels of acetylcholinesterase (AChE) and ChAT, as well as immunopositivity of VACT, the integral membrane protein that transports ACh into the synaptic cholinergic vesicles.

For the development of sympathetic as well as of sensory ganglia the neurotrophin NGF is essential. This peptide couples to two receptors, TrkA and p75; p75 is a common receptor for many neurotrophins, but for the trophic effect of NGF, both the specific TrkA receptor and p75 must be activated. NGF is thought to be supplied by the target area cells, which, thus, attract the outgrowing sympathetic fibers by secreting NGF. The NGF is internalized at the tip of growth cones and transported by retrograde axonal transport to the cell body, where it influences gene transcription and supports outgrowth. By administrating an NGF antiserum to mammals, sympathetic denervation may be carried out, as first demonstrated by Levi-Montalcini and Booker in 1960. Recently it was reported that sympathetic ganglion cells can

synthesize and secrete pro-NGF, indicating the possibility for autocrine stimulation of NGF.

In some lumbar sympathetic ganglia, neurons that innervate the sweat glands of the lower extremities have remained cholinergic, and in addition coexpress the peptide VIP, the vasodilatory peptide, and in some species also the calcitonin gene-related peptide. When stimulated, these sympathetic cholinergic neurons release ACh, which triggers the gland cell receptors to induce secretion, while the coreleased VIP dilates the surrounding blood vessels, thereby ensuring access of the sweat 'precursor,' serum.

Small, Intensely Fluorescent Cells

In addition to the principal ganglion cells, sympathetic ganglia contain so-called small, intensely fluorescent (SIF) cells. These small cells are usually distributed along blood vessels, have short processes, and contain in most cases high concentrations of DA, giving them a strong green fluorescence using the classical paraformaldehyde histochemical method (see previous section). They also may contain serotonin or histamine, usually together with a peptide (e.g., substance P). The catecholamine storage granules and the principal ganglion cells contain the same integral membrane proteins, including VMAT2. The SIF cells originate in the neural crest, but seem to have a somewhat different developmental differentiation scheme compared with principal ganglion cells.

Glia, Satellite Cells

In addition to principal ganglion neurons and SIF cells, a third cell type, called satellite cells, is present, usually located close to the cell body of the multipolar ganglion cells (Figure 11). These cells represent a type of glia cell, but are separate from Schwann cells in the periphery, and from astrocytes and oligodendroglia in the CNS. They do not myelinate, since the sympathetic ganglion cells have unmyelinated thin axons, less than 1 μm in diameter. Satellite cells express S-100 protein but not glial fibrillary acidic protein, and neuropeptides have not been observed to be present in these cells. Satellite cells are probably of importance for the metabolism of the ganglion cells, and *in vitro* studies indicate that they support the outgrowth of dendrites from the perikarya of ganglion cells, possibly by expressing neurotrophic factors. Bone-derived neurotrophic factor immunoreactivity has been reported to occur in SCG of rat, but so far no other trophic factor has been observed. Comparatively little is known at present about the function of satellite cells. Connective tissue and blood vessels are naturally present in sympathetic ganglia; vascular endothelial cells may contribute to the functional complexity of sympathetic ganglia by secreting nitric oxide (NO), for instance.

NO Synthesis in Ganglia

Many studies implicate NO in a multitude of processes in the nervous system. The sympathetic ganglia contain considerable levels of NO synthase (NOS) and NADPH activity. Many studies indicate that most of the NOS appears to be linked to the preganglionic neuron, and, thus, is present mainly in the preganglionic nerve terminals in the ganglia. However, nitrergic nerve cell bodies have been reported in dog SCG, but were not found in rat ganglia. Most likely, the vascular endothelium in sympathetic ganglia also expresses inducible NOS (iNOS), which may be involved in the high degree of plasticity typical for the sympathetic system.

Sex Differences in Sympathetic Ganglia

In the rat, sympathetic ganglia are generally smaller in the female than in the male. This may be explained by the effect of perinatal testosterone in the male, which inhibits the postnatally occurring apoptotic processes, thus reducing the number of ganglionic cells in the female. This sexual dimorphism is not only seen in pelvic ganglia, where a difference may seem obvious, but also in the SCG, where the difference in cell number is found mainly in the population of cells innervating the salivary glands, not in those innervating, for instance, the iris.

The influence of these differences on performance has not been studied in detail, but possibly it may explain a lower physical endurance in females than in males, in line with the higher level of offensive aggression in males, relative to females, in most rat

Figure 11 Routine stained section of sympathetic ganglion of rat, showing large ganglion cells with a few satellite cells clinging to the cell body (arrows). From Hillarp (1949).

strains. Recently it was reported that estrogen alters the expression of TrkA and p75 neurotrophin receptors in sympathetic neurons, probably contributing to sexual differences in functions of the sympathetic system and influencing the survival and function of ganglion cells.

Sympathetic Noradrenergic and Adrenomedullary Hormonal Systems in Stress and Distress

D S Goldstein, National Institutes of Health, Bethesda, MD, USA

© 2009 Elsevier Ltd. All rights reserved.

The body has three peripheral catecholamine systems, corresponding to the three endogenous catecholamines – norepinephrine, epinephrine (synonymous with adrenaline), and dopamine. Each system works differently. Norepinephrine is the main neurotransmitter in sympathetic nervous system regulation of the circulation. In contrast, in the sympathetic cholinergic system, acetylcholine is the neurotransmitter stimulating secretion by sweat glands. In humans, epinephrine is the main hormone of the adrenomedullary hormonal system. Outside the brain, dopamine seems to function as an autocrine–paracrine substance, such as in the kidneys. This article is about the roles of the sympathetic noradrenergic and adrenomedullary hormonal systems in stress and distress. Understanding these roles requires discussion of several concepts – the sympathoadrenal system, stress as a scientific idea, characteristics of distress, allostasis and allostatic load, and scientific integrative medicine. Most of this article is a brief overview of these concepts.

The Sympathoadrenal System

Walter B Cannon proposed that the sympathetic nervous system and the adrenal gland work together as a unit to maintain homeostasis in emergencies – the sympathoadrenal (or sympathoadrenomedullary or sympathico-adrenal) system. This probably was the first suggestion of the existence of an integrated nervous-hormone, or neuroendocrine, system. The notion of a unitary sympathoadrenal system continues in medical thinking, despite evidence for differential changes in sympathetic noradrenergic and adrenomedullary hormonal activities in different forms of stress, as a function of variables such as aging, obesity, and clinical pathophysiologic states.

According to Cannon, in emergencies, rapid activation of the sympathoadrenal system produce compensatory and anticipatory adjustments enhancing the likelihood of survival. Sheltered in a laboratory, with controlled temperature and *ad libitum* water, nutrients, and calories, mammals do not seem to require an intact sympathetic nervous system.

By now it is appreciated that pulse-synchronous bursts of skeletal muscle sympathetic nerve activity and plasma levels of norepinephrine normally are readily detectable even under resting conditions. Norepinephrine continuously enters the venous drainage of most organs. It is also by now clear that continual alterations in sympathetic nervous system outflows attend activities of daily life, such as meal ingestion, changing posture, and locomotion. Each of these activities is associated with a somewhat different set of 'normal' apparent steady states, directed by the brain and determined by coordinated actions of a variety of effector systems. This principle leads directly to the concept of allostasis, discussed below.

Stress and Science

Hans Selye popularized stress as a medical scientific idea. He elaborated a theory based on stress defined as the nonspecific response of the body to any demand, a stereotyped syndrome shared by all organisms in their interaction with the environment. The stress response was nonspecific, meaning that it could be brought on regardless of the stimulus. After specific responses were removed from consideration, the nonspecific syndrome would remain.

Although nonspecific with respect to the inciting agents, the stress response itself was thought to consist of a specific pathological pattern, with three components: enlargement of the adrenal glands, shrinkage of the thymus gland (associated with atrophy of the lymph nodes and inhibition of inflammatory or immune responses), and ulcers or bleeding in the stomach or gastrointestinal tract. The stress response was also thought to have characteristic stages, in a triphasic general adaptation syndrome. The first phase would be a rapid 'alarm' reaction. After an undefined length of time, a longer-lasting stage of resistance would ensue, with increased resistance to the particular stressor but decreased resistance to other stimuli. The stage of resistance would end with depletion of adaptation energy, ushering in the final stage, exhaustion, characterized by resurgence of activity of the adrenal gland, gastrointestinal ulcers, immunological failure, and death. Chrousos and Gold modified the doctrine of nonspecificity by proposing that above a threshold intensity, any stressor elicits the stress syndrome.

More than a half century elapsed before Selye's doctrine of nonspecificity underwent experimental

testing, which failed to confirm it. By now, researchers have largely abandoned both Cannon's and Selye's notions of stereotyped, nonspecific neuroendocrine responses regardless of the stressor. More modern theories view stress as a sensed threat to homeostasis, in which the response has a degree of specificity, depending among other things on the particular challenge to homeostasis and the organism's perception of the stressor and ability to cope with it. Nevertheless, Selye's theory figures prominently in current lay literature on stress.

According to the homeostat theory, stress is not an environmental stimulus or a stereotyped response but a condition, in which expectations, whether genetically programmed, established by prior learning, or deduced from circumstances, do not match current or anticipated perceptions of the internal or external environment, and this discrepancy between what is observed or sensed and what is expected or programmed elicits patterned, compensatory responses.

This sensation requires a comparative process, in which the brain compares available information with set points for responding. Central to the homeostat theory is that the body possesses numerous homeostatic comparators, homeostats. Each homeostat compares information with a set point for responding, determined by a regulator. Homeostatic systems typically use multiple effectors to influence values for the monitored variable. The loop is closed by afferent information about the status of the monitored variables. It is the state of sensed discrepancy that defines stress. The organism responds not to the external or internal perturbation itself but to changes in values of the variable that the afferent information actually delivers to the homeostat, usually located in the central nervous system. According to this definition, even a simple homeostatic reflex, such as the baroreflex, can reflect stress, when a perceived discrepancy between a set point for the monitored variable and information about the level of that variable elicits compensatory responses that decrease the discrepancy.

Homeostatic systems of higher organisms always include regulation by negative feedback. This is the key feature that maintains stable levels of the monitored variable. Increases in values of the monitored variable result in changes in effector activity that oppose and thereby buffer changes in the level of that variable. In homeostatic diagrams, a plus sign denotes a stimulatory and a minus sign an inhibitory relationship. Each minus changes the sign of the next relationship in the loop, whereas each plus does not affect the sign of the next relationship. In a system in which the monitored variable is maintained at a plateau level, the loops involving that variable have an odd number of minus signs.

If a loop has only plus relationships and no minus relationships (a positive feedback loop), the system, if otherwise unchecked, would 'explode'; levels of the monitored variable would increase or decrease exponentially. Positive feedback loops are inherently unstable. If a complex system included both a positive feedback loop and a 'nested' negative feedback loop, then the level of the monitored variable would change but to a stable plateau value.

Homeostatic systems use multiple effectors. This redundancy has several consequences. Disabling an effector compensatorily activates the others, enabling at least partial maintenance of the level of the monitored variable. Multiple effectors improve cost efficiency, measured by the energy used to maintain appropriate levels of the monitored variable. By decreasing wear and tear on effectors, having multiple effectors also prolongs the average useful life of the entire system. Finally, having multiple effectors enables patterning of effector responses. Patterning of hormonal, physiological, and behavioral effectors maximizes the likelihood of responses being appropriate for the particular threat to homeostasis.

The body's responses to different forms of stress occur in relatively specific patterns that help maintain appropriate levels of monitored variables such as temperature, blood pressure, blood glucose, and blood oxygen tension. A general theme of these patterns is that they are automatic, involuntary, and unconscious, but once the organism senses that the compensatory adjustments are not maintaining or will not maintain levels of the monitored variables, then the situation may reach consciousness, with the brain directing the adrenal gland to release epinephrine into the bloodstream and the individual experiencing distress, discussed below.

More than one homeostat can regulate activity of the same effector a phenomenon called effector sharing. Examples of effector sharing abound in physiology. For instance, both increased serum osmolality and decreased filling of the heart increase vasopressin secretion, and both decreased delivery of sodium to the kidneys and decreased blood pressure increase activity of the renin–angiotensin–aldosterone system.

Effectors interact with each other, both indirectly, such as via compensatory activation, and directly. Much of physiology research involves studying effector interactions. Examples are effects of adrenocortical steroids on adrenomedullary function and of angiotensin II on sympathetic nervous system outflows.

Disruption of a negative feedback loop, whether by blockade of afferent information, destruction of

homeostats, or failure of effectors, increases variability of the monitored variable.

Characteristics of Distress

According to the homeostat theory, distress is a form of stress with the additional characteristics of consciousness, aversiveness, observable signs, and adrenal gland activation. Distress is aversive to the organism, as evidenced by motivation for learning to escape or avoid the stressor.

The homeostat theory does not assume that distress causes disease. In contrast, Selye characterized distress as unpleasant or harmful, without separating these two very different characteristics. He never incorporated the relationship between distress and disease explicitly in his theory. Selye's theory emphasizes the nonspecificity of the stress response, whereas according to the homeostat theory, the experience of distress depends on the character, intensity, and meaning of the stressor as perceived by the organism and on the organism's perceived ability to cope with it. Distress responses, as all stress responses, have a 'purpose,' mitigating effects of a stressor in some way. This applies not only to neuroendocrine aspects of those responses but also to psychological aspects. Distress responses evolved and probably continue to be expressed even in higher organisms, including humans who actually are only rarely exposed to true fight-or-flight agonistic encounters, because of the importance of those responses in instinctive communication. Selye's theory does not consider the communication aspect of distress.

Homeostasis versus Allostasis

Claude Bernard propounded the founding concept of scientific integrative medicine, when he theorized that the overall goal of body systems is to maintain a constant internal cellular environment – the *milieu intérieur*. His *Lectures on the Phenomena of Life Common to Animals and Vegetables*, translated in 1974 from the French publication of 1876, contains one of the most famous passages in the history of physiology: "The constancy of the internal environment is the condition for free and independent life.... All the vital mechanisms, however varied they might be, always have one purpose, that of maintaining the integrity of the conditions of life within the internal environment."

Walter B Cannon coined the word homeostasis. By this, he referred to the stability of the internal environment. The concept of homeostasis was a direct extension from Bernard's *milieu intérieur*. According to Cannon, the brain coordinates body systems, with the aim of maintaining a set of goal values for key variables. Internal or external disturbances threatening homeostasis, by causing large enough deviations from the goal values, arouse nervous and hormone systems, induce emotional and motivational states, and generate externally observable behaviors, all of which have the goal of reestablishing homeostasis. The brain would respond to all emergencies in the same way, by evoking increased secretion of epinephrine.

According to the more recent concept of allostasis, no single set of ideal values exists for levels of internal variables. Allostasis comes from two Greek words that together mean 'other sameness.' The term was used by Sterling and Eyer in 1988, referring to levels of activity required for the individual to "maintain stability through change," that is, to adapt. In terms of the homeostat theory, allostasis is the set of apparent steady states maintained by multiple effectors. In the analogy of the home temperature control system, one can keep temperature at constant but different levels by appropriate use of effectors.

Homeostat resetting redefines the conditions required to maintain homeostasis. Regulation around an altered apparent steady state is the essence of allostasis. An example would be the hyperglycemia of exercise. Even in anticipation of the need for metabolic fuel, by activation of 'central command,' the blood glucose level increases. Resetting alters activities of multiple effector systems required to maintain allostasis, at least for short durations. During stress, short-term changes in homeostatic settings generally enhance the long-term well-being and survival of the organism. Responses during exercise provide an obvious example. When superimposed on a substrate of pathology, however, homeostatic resetting can cause harm. For instance, in the setting of ischemic heart disease, global or patterned increases in sympathetic outflows from homeostat resetting increase cardiac work, the resulting imbalance between oxygen supply and demand precipitating angina pectoris, myocardial infarction, or sudden death.

Allostatic Load and Chronic Disease

It is by way of prolonged activation of effectors to maintain allostasis that chronic stress can contribute to the development of chronic degenerative diseases. Allostatic load refers to effects of prolonged continuous or intermittent activation of effectors involved in allostasis. In the analogy of the home temperature control system, allostatic load increases if a window or door is left open. In this situation, one or more effectors are activated frequently or even continuously.

Continued use of the furnace and air conditioner in opposition to one another, an example of an inefficient allostatic state, consumes fuel and contributes to wear and tear on both pieces of equipment. Long-term allostatic load – the wear-and-tear cost of adaptation – provides a conceptual basis for studying long-term health consequences of stress.

Distinct Roles of the Sympathetic Noradrenergic and Adrenomedullary Hormonal Systems

Differences in the extents of activation of the adrenomedullary hormonal and sympathetic noradrenergic systems in different stress responses provide convincing evidence for distinctive neuroendocrine stress response patterns (Table 1). This is ironic, because it was Cannon who was so instrumental in describing and studying these components and yet who advocated the combined and undifferentiated activation of the sympathoadrenal system in response to stress.

After adequately sensitive assay methods for plasma levels of norepinephrine and epinephrine became available, evidence rapidly accumulated for different noradrenergic versus adrenergic responses in different situations. A new concept began to emerge, in which the sympathetic noradrenergic system would help distribute blood flows appropriately, such as during orthostasis, cold exposure, mild blood loss, locomotion, exercise, altered salt intake, and water immersion. The adrenomedullary hormonal system would respond to global or metabolic threats, such as hypoglycemia, hemorrhagic hypotension, exercise beyond an anaerobic threshold, asphyxiation, emotional distress, and shock. Evidence also accumulated for an association between norepinephrine and active escape, avoidance, or attack, and an association in epinephrine and passive, immobile fear. Table 1 provides some examples of different patterns of sympathetic noradrenergic, adrenomedullary hormonal, and hypothalamic–pituitary–adrenocortical responses to different stressors.

Table 1 Hypothalamic–pituitary–adrenocortical (HPA), adrenomedullary hormonal system (AHS), and sympathetic noradrenergic system (SNS) responses to different stressors

Condition	*HPA*	*AHS*	*SNS*
Active escape/avoidance in rats	+	+	++
Cardiac arrest (or bypass)	+++	++++	++
Cold exposure, hypothermia	+	++	++++
Cold exposure, no hypothermia	0	+	+++
Exercise	+	++	+++
Exercise to exhaustion	++	+++	++++
Fainting	++	++++	0
Glucoprivation	+++	++++	+
Handling in rats	++	++	+
Hemorrhagic hypotension	+++	+++	+
Hemorrhage, no hypotension	+	+	++
Immobilization in rats	++++	++++	++++
Laboratory mental challenge	++	++	+
Pain	++	+++	++
Passive/immobile fear	++	+++	+
Public performance	++	+++	+
Social stress in rhesus monkeys	++	++	++
Surgery	+	+	++

Different intensities are indicated from 0 through ++++. There is a generally closer association between AHS and HPA than between AHS and SNS responses.

Thus, in contrast with the doctrine of nonspecificity, according to the homeostat theory of stress, activities of effector systems are coordinated in relatively specific patterns, including neuroendocrine patterns. These patterns serve different needs, and the sympathetic noradrenergic and adrenomedullary hormonal systems play important roles in many of them. For instance, sympathetic noradrenergic system activation predominates in response to orthostasis, moderate exercise, and exposure to cold, whereas adrenomedullary hormonal system activation predominates in response to glucoprivation and emotional distress (Table 1).

In terms of the body's thermostat, studies of humans exposed to cold or with mild core hypothermia have provided support for the notion of primitive specificity of neuroendocrine stress responses. Cold exposure increases plasma norepinephrine levels, with little if any increases in plasma epinephrine levels, consistent with sympathetic neuronal activation and relatively less adrenomedullary hormonal activation. Mild core hypothermia also increases antecubital venous levels of norepinephrine but not epinephrine. Both norepinephrine and epinephrine levels in arterial plasma increase in this setting, but with larger norepinephrine responses. These findings make sense, in that one can maintain body temperature effectively by sympathetically mediated cutaneous vasoconstriction, piloerection, and shivering. When these mechanisms give way, and core temperature falls, then high circulating epinephrine levels increase generation of calories, associated with the experience of distress, which motivates escape and avoidance and augments norepinephrine release from sympathetic nerve terminals for a given amount of nerve traffic.

For each stress, neuroendocrine and physiological changes are coupled with behavioral changes. For instance, the regulation of total body water in humans depends on an interplay between behavior (the search for water and drinking), an internal experience or feeling (thirst), and the elicitation of a neurohumoral response pattern (in this case

dominated by vasopressin, the antidiuretic hormone, and to a lesser extent angiotensin, a potent stimulator of drinking). Evoked changes in homeostat function often produce not only neuroendocrine and physiological effects but also behavioral responses; however, because of traditional boundaries among physiology, endocrinology, and psychology, interactions producing integrated patterns of response remain incompletely understood.

Scientific Integrative Medicine

Scientific integrative medicine is not a discipline, a group of disorders, or a method of treatment, but an approach, a way of thinking. Scientific integrative medicine uses systems concepts to explain disease processes and develop strategies to treat, prevent, or palliate them. It emphasizes disorders of the multiple interacting systems that regulate the body's "inner world." Scientific integrative medicine asks researchers and clinicians to consider more than one system at a time, as assessed by measuring levels of more than one chemical effector at a time. The scientific integrative medicine approach provides a framework for understanding complex and dynamic challenges to our integrity as organisms.

Scientific integrative medicine builds on systems biology, but it is also distinct in several ways. First, scientific integrative medicine recognizes that in higher organisms, including humans, the brain dominates regulation of the inner world. The brain regulates the many internal monitored variables of the body in parallel – analogous to a computer's multitasking. Second, the brain has plasticity, which enables modifications in the step-by-step instructions for cellular, tissue, organ, and systemic processes – the algorithms of life. According to the concept of allostasis, about which you will learn later in this article, set points and other elements of these algorithms vary, depending on recollections, sensations, and anticipations by the brain. Third, scientific integrative medicine is medical; its overall mission is to understand and rationally treat disorders and diseases. The systems that maintain the stability of the inner world eventually degenerate. Their efficiencies decline, and as they decline, the likelihood of deleterious, self-reinforcing positive feedback loops increases, threatening organismic stability and survival. Clinicians rarely cure; they manage. They exploit negative feedback loops and attempt to forestall or counter positive feedback loops. Finally, the medications and treatments clinicians prescribe interact with their patients' internal systems. Multiple, simultaneous degenerations, combined with multiple effects of multiple drugs and remedies and myriad interactions among those processes and the drug used to treat them, have come to the fore.

What renders scientific integrative medicine new, different, and powerful is the focus on disorders of the multiple, interacting, feedback-controlled systems that regulate the monitored variables of the body. Scientific integrative medicine recognizes that the operating characteristics of internal systems change over time, based on numerous life exposures and experiences that range from carrying out genetic instructions (especially in fetal development through adolescence) to aging-related degenerative disorders and interactions between medications and those disorders.

Integrative medicine has gained popularity recently. The word integrative has been used synonymously with holistic, mind–body, complementary, or alternative. The scientific integrative medicine approach, however, actually fits quite well with conventional, mainstream clinical medicine. Effective clinicians apply such an approach all the time. One such approach is to "exploit the lesion," where a treatment's success depends on an abnormality that occurs as part of the disease process itself. An example would be treatment of angina pectoris by nitroglycerine in patients with coronary artery disease. Nitroglycerine relaxes veins, decreasing venous return to the heart and cardiac stroke volume. Normally, decreased cardiac filling 'unloads' baroreceptors, and heart rate increases reflexively. The work of the heart changes little, because while the heart rate increases, the systolic blood pressure falls from the direct effects of the drug. Patients with angina pectoris from coronary artery disease, however, typically have low baroreflex-cardiovagal gain. When they take nitroglycerine, the drug reduces systolic blood pressure, but because of the low baroreflex-cardiovagal gain, the heart rate increases relatively little. The work of the heart therefore decreases, relieving the angina pectoris.

Another adage of scientific integrative medicine is "treat patients, not numbers." For hyperglycemia in gastrointestinal bleeding, or hyponatremia in heart failure, astute clinicians focus on treating the underlying problem. Appropriate treatment eliminates secondary effects of effector sharing, in these cases of the adrenomedullary hormonal system and vasopressin system, whereas attempting to reverse the abnormal laboratory findings directly can make matters worse.

One can also try to prevent compensatory damages, deleterious effects of reflexive effector activation. For instance, patients awakening from general anesthesia typically have postoperative hypothermia. Sympathetic noradrenergic and adrenomedullary hormonal system activation to counter hypothermia increases

myocardial oxygen consumption. This can contribute to the relatively high frequency of morbid events in patients with coronary artery disease during the immediate postoperative period.

The major goal of scientific integrative medicine is to treat effectively or prevent diseases before they become symptomatic. Beyond practices that promote health in general, such as regular exercise, dietary moderation, and refreshing sleep, the rapidly expanding availability of genetic, physiological, and biochemical information enables prevention of allostatic load and timely institution of effective treatments that are specific for the individual.

Induction of a positive feedback loop in a homeostatic system evokes instability. For instance, activation of the renin–angiotensin–aldosterone system in congestive heart failure increases sodium retention and vascular tone, leading to increased cardiac preload and afterload that worsen the congestive heart failure. Therefore, treatment with an angiotensin-converting enzyme inhibitor or angiotensin II receptor blocker can successfully treat congestive heart failure.

The homeostatic theory of stress and the concept of allostasis can help understand chronic as well as acute medical consequences of stress. Chronic activation of allostatic effectors in allostatic states promotes allostatic load. For instance, chronic elevations in adrenomedullary and hypothalamic–pituitary–adrenocortical outflows worsens insulin resistance, and chronic cardiac sympathetic activation accelerates cardiovascular hypertrophy and development of heart failure.

Another application of the homeostatic idea to medical consequences of stress is in terms of the perceived ability to cope. An organism experiences distress upon sensing that the effector responses will not be sufficient to restore or maintain allostasis. In contrast with distress, stress does not imply a conscious experience. Thus, even heavily sedated humans have substantial adrenomedullary stimulation in response to acute glucoprivation. Distress instinctively elicits observable signs and pituitary–adrenocortical and adrenomedullary activation. Via these neuroendocrine changes, distress could worsen pathophysiologic processes. For instance, because of adrenomedullary activation, in a patient with coronary artery stenosis, distress could elicit cardiovascular stimulation and produce an excess of myocardial oxygen consumption over supply, precipitating myocardial infarction or lethal ventricular arrhythmias. Moreover, long-term distress could augment both the risk of a mood disorder and the risk of worsening coronary disease.

Stress is an interdisciplinary topic, and understanding health consequences of stress requires an integrative approach. Research and ideas about stress must move beyond considering only one effector system, such as the pituitary adrenocortical system, and only one monitored variable, such as serum glucose levels, to incorporate multiple effectors that are regulated in parallel by multiple homeostats. They must also move beyond the notion of a single set of ideal values for monitored variables – homeostasis – to incorporate dynamic changes in homeostatic settings – allostasis. Merging of the homeostatic definitions of stress and distress with the concept of allostasis should provide a better understanding of the roles of catecholamine systems in stress, distress, and disease and provide a conceptual basis for the further development of scientific integrative medicine.

Sympathoadrenal System: Neural Arm of the Stress Response

M Palkovits, Semmelweis University, Budapest, Hungary

The sympathetic nervous system, like the other major regulatory mechanisms of the central and peripheral nervous systems, can be divided into afferent and efferent arms. The somatosensory and viscerosensory projections carrying external and internal signals to the spinal and supraspinal compartments of the sympathetic nervous system represent its afferent arm. The efferent arm of the sympathetic nervous system (sympathetic outflow) appears to be organized into two major divisions: sympathoadrenal (SAS) and sympathoneural (SNS) systems. The term sympathoadrenal system is frequently used as a synonym for the sympathetic outflow or for the efferent arm of the sympathetic nervous system in general. It should be emphasized that according to their anatomical organization, neurotransmitter characteristics, and their functional role in the sympathetic outflow, the two systems are different: They may be independently activated, and they independently respond to stressful stimuli.

The activation of these two divisions of the efferent arm of the sympathetic nervous system is organized in a hierarchical manner (Figure 1). First, supraspinal (premotor sympathetic) neurons project to sympathetic preganglionic neurons in the thoracic spinal cord. Second, the sympathetic preganglionic neurons that represent the first compartment in both systems provide anatomical substrate through which selective regulation of sympathetic nervous system targets is accomplished. Fibers of the sympathetic preganglionic neurons innervate the adrenal medulla (SAS) and neurons in the sympathetic ganglia (SNS) (Figure 2). Third, the adrenal medullary chromaffin cells synthesize and release epinephrine (EPI) into the circulation. EPI in the plasma is exclusively of adrenomedullary origin. Neurons in the sympathetic ganglia project to a variety of peripheral targets in which norepinephrine (NE) is stored and released from the postganglionic sympathetic nerve endings, called varicosities. Almost all NE in the plasma originates from these nerve endings.

Activation of the sympathetic nervous system is accompanied by an increase in the outflow of both NE and EPI. Variation in the sensitivity and the number of pre- and postsynaptic receptors in the sympathetic nervous system may account for regional and functional differences in sympathetic activation, especially in response to different stressors.

Sympathetic Preganglionic Neurons

The sympathetic preganglionic neurons provide the anatomical substrate through which selective regulation of sympathetic nervous system targets is accomplished. The adrenal medulla and the sympathetic ganglion cells are directly innervated by sympathetic preganglionic neurons (Figure 3).

The sympathetic preganglionic neurons are cholinergic and form a longitudinal cell line, the intermediolateral cell column (IML), in the lateral portion of the spinal central gray matter, between the first thoracic (T1) and the second lumbar (L2) segments of the spinal cord. Within the IML, the sympathetic preganglionic neurons are topographically organized with respect to their tissue/organ targets. The adrenal medullary sympathetic preganglionic neurons (neurons that selectively project to the adrenal medulla, also called sympathoadrenergic cells) occupy the IML in segments T5–T8, whereas the sympathoneural sympathetic preganglionic neurons occupy, with some overlap, the IML in the other segments. In addition to the IML, scattered sympathetic preganglionic neurons are found in the nucleus intermediomedialis (called the central autonomic area) and in the lateral funiculus, immediately lateral to the IML.

Axons of the sympathetic preganglionic neurons leave the spinal cord through the ventral roots, at the level where their perikarya are located, and initially they run together with somatomotor axons within the spinal nerve. After a short distance, they separate from the spinal nerve and travel in small bundles, called white rami communicantes, to the paravertebral sympathetic chain (Figure 2). The sympathetic chain extends from the base of the skull down to the sacrum, on the two sides of the vertebral column. Some of the sympathetic preganglionic fibers form synaptic contact with ganglion cells within the chain (i.e., in paravertebral sympathetic ganglia). A group of the sympathetic preganglionic fibers establish synaptic contacts with ganglion cells at the same level where they enter the chain, whereas others travel upward or downward in the chain and terminate on paravertebral ganglion cells at more rostral or caudal levels (Figure 2). The vast majority of the ascending presynaptic sympathetic fibers in the sympathetic chain terminate in the cervical paravertebral sympathetic (superior and inferior (stellate)) ganglia.

The other portion of the sympathetic preganglionic fibers pass the chain without establishing synaptic contacts with any of the paravertebral ganglion cells. They enter some of the branches of the sympathetic chain and terminate on ganglion cells in one of the prevertebral

ganglion in the abdomen, such as the celiac/superior mesenteric or inferior mesenteric ganglion (Figure 2). The sympathetic preganglionic neurons with synaptic contacts with either para- or prevertebral ganglion cells constitute the SNS.

A group of the sympathetic preganglionic fibers may pass the sympathetic chain, as well as the para- and prevertebral ganglia, without establishing synaptic contacts with ganglion cells (Figure 2). These presynaptic fibers leave the sympathetic chain for the splanchnic nerves; they enter the adrenal gland and terminate directly on the chromaffin cells in the adrenal medulla. They constitute the SAS.

The Sympathoadrenal System

The SAS is composed of sympathetic preganglionic neurons and the chromaffin cells of the adrenal medulla. Chromaffin cells, like principal sympathetic ganglion cells, are members of the sympathoadrenal lineage derived from the neural crest. They share a common precursor, the sympathoadrenal progenitor cells. The sympathetic preganglionic neurons that innervate chromaffin cells are located in the IML of the thoracic spinal cord, mainly between segments T5 and T9. These neurons are cholinergic; acetylcholine is released from their terminals. Stimulation of the adrenal medulla leads to release of EPI and NE into the blood.

Two populations of adrenal chromaffin cells have been identified: EPI and NE secreting cells. The ratio of EPI- to NE-synthesizing chromaffin cells is approximately 4:1 in humans and slightly different in mammals. Although this ratio varies among species, EPI-synthesizing chromaffin cells predominate in the adrenal medulla. Note that a small number of chromaffin cells are also localized extra-adrenally, inside or around the sympathetic ganglia (paraganglia).

Each chromaffin cell contains approximately 10 000 chromaffin granules, in which EPI or NE are stored. They are secreted via exocytosis, carried by capillaries that drain from the adrenal medulla into the adrenal vein. Then, EPI and NE are transported throughout the body and exert their effects on most of the major regulatory systems. Besides catecholamines, the chromaffin granules contain numerous other transmitters, granins, and neuropeptides, which are co-localized and co-released with catecholamines.

The NE-synthesizing chromaffin cells possess the full repertoire of functions of EPI-synthesizing cells except the capacity to synthesize EPI. The two types of chromaffin cells are innervated by different sympathetic preganglionic fibers. This arrangement provides a basis for distinct sympathetic circuits underlying the differential regulation of EPI and NE secretion from

the adrenal medulla in response to physiological challenges and stressful stimuli.

In addition to chromaffin cells, the adrenal medulla contains a small number of ganglion cells, which synthesize NE. Like chromaffin cells, these ganglion cells are also innervated by sympathetic preganglionic fibers (Figure 2), but they contribute little to NE content in plasma and do not synthesize EPI. Their postganglionic axons distribute in the adrenal and terminate both in the medulla and in the adrenal cortex. Thus, ganglion cells in the adrenal medulla have similar characteristics as ganglion cells in the pre- or paravertebral ganglia, neverthelen they are embedded in the innervated organ, that is, in the adrenal gland. Despite their location, the adrenal medullary ganglion cells functionally belong to the SNS rather than the SAS.

The Sympathoneural System

Neuroanatomically, the SNS is organized in a two-neuron chain. The first neuron (as in the SAS) is referred to as the sympathetic preganglionic neuron, whereas the second neuron is called the ganglionic (or, frequently, postganglionic) neuron, which projects a so-called postganglionic axon. The preganglionic neurons in the IML are cholinergic and innervate the sympathetic ganglion cells by release of acetylcholine as the primary neurotransmitter that acts on nicotinic and, to a lesser extent, muscarinic receptors. Various biologically active neuropeptides, such as substance P, vasoactive intestinal polypeptide, and enkephalins, are co-localized with acetylcholine within the sympathetic preganglionic terminals. They may act as neuromodulators of cholinergic transmission.

The ganglion cells reside in sympathetic paravertebral (superior cervical, stellate ganglia, and ganglion cells in the sympathetic chain) and prevertebral (celiac and superior and inferior mesenteric) ganglia (Figure 2). With terminal branches, a single sympathetic preganglionic axon terminates on several para- or prevertebral ganglion cells. The divergence ratio of the pre- and postsynaptic neurons, depending on the species, is between 20:1 and 5:1. This divergence permits coordinated activity in sympathetic neurons at several different spinal levels. In contrast, ganglion cells establish synaptic contacts with more than one sympathetic preganglionic neuron. Therefore, a substantial convergence of synaptic inputs exists on each ganglion cell.

The sympathetic postganglionic nerve originating from either a pre- or paravertebral ganglion cell establishes a plexus of terminal fibers within a short distance to the target tissue/organ (Figure 2). The length of a terminal fiber may be several millimeters. The postganglionic fibers show a beaded appearance due to local swellings called varicosities. The varicosities are specialized structures involved in the storage and release of NE. They contain a high concentration of large and small granular vesicles that store mainly NE. A single postganglionic fiber may contain more than 20 000 varicosities with more than 1000 granular vesicles in each. Each granule stores approximately 15 000 molecules of NE. The varicosities do not display synaptic junction; NE is released to the extracellular space by exocytosis and diffuses over a large territory of the target area or is drained directly into the blood. Almost all of the NE in the plasma originates from the varicosities of the postganglionic fibers. In certain conditions, the nerve endings may take up and store a significant amount of NE from the extracellular space. The process of synthesis, storage, and release of NE from the varicosities is under the control of the sympathetic preganglionic neurons. In addition to the para- and prevertebral sympathetic ganglia, sympathetic neurons are also found in a small number in ganglia in or near the pelvic organs (pelvic ganglia).

NE is not the sole neurotransmitter in the sympathetic ganglion cells; they express other cotransmitters and neuropeptides, such as neuropeptide Y and galanin. The co-expression and the selective outflow of one or more neurotransmitters or neuropeptides from the sympathetic postganglionic nerve terminals allow the organism to differentiate between sympathetic activities and responses at the level of the target organ.

In addition to ganglion cells, sympathetic ganglia contain small granular cells called intensely fluorescent (SIF) cells. These cells express and store predominantly dopamine, and some of them also express and store EPI. SIF cells, like the sympathetic ganglion cells and the chromaffin cells, are members of the sympathoadrenal lineage derived from the neural crest.

Premotor Sympathetic Neurons

Neurons at multiple levels of the neuraxis, ranging from the lower brain stem to the forebrain, regulate the sympathetic outflow. These neurons, called premotor sympathetic neurons, innervate the sympathetic preganglionic neurons in the IML (Figure 3). Neurotransmitters that regulate the preganglionic neurons include NE, EPI, dopamine, serotonin, and neuropeptides. Thus, sympathetic activities elicited by the activation of sympathetic preganglionic neurons are controlled by distinct neuronal circuits and probably by distinct neurotransmitters. Accordingly, the premotor sympathetic neurons used to be classified as catecholaminergic and noncatecholaminergic (Figure 1).

The hypothalamus is regarded as the principal brain region of central autonomic regulation. Most of the forebrain regions, such as the amygdala, hippocampus, and limbic cortical areas, are involved in the control of the autonomic nervous system outflow. They do not directly innervate the IML; rather, they exert their influence on preganglionic sympathetic neurons by way of the hypothalamus. Hypothalamic neurons projecting to the IML of the thoracic spinal cord reside mainly in the paraventricular nucleus, but some reside in the lateral hypothalamic area and the arcuate nucleus (Figure 3). The hypothalamic premotor sympathetic neurons are peptidergic. Serotoninergic neurons in the rostral ventromedial medulla and the caudal raphe nuclei also project to sympathetic preganglionic neurons. These cells, together with the hypothalamic neurons, represent the noncatecholaminergic premotor sympathetic neurons (Figure 1).

In the lower brain stem, catecholaminergic neurons in the rostral ventrolateral medulla (in the A5 noradrenergic and C1 adrenergic cell groups) constitute the major portion of the catecholaminergic premotor sympathetic neurons that preferentially terminate on the sympathetic preganglionic neurons (Figure 3). In addition, neurons of the A7 noradrenergic cell group in the pons and neurons in the caudal portion of the locus coeruleus belong to this system. The distribution of the descending premotor sympathetic axons in the IML is topographically and functionally organized: The target-specific IML neurons are selectively innervated by different catecholamine premotor neurons. The NE or EPI nerve terminals establish conventional synaptic contacts with sympathetic preganglionic neurons, especially in the segments T5–T9, where the sympathoadrenergic preganglionic cells are located. The IML cell column also receives dopamine innervations, mainly from the A11 dopamine cell group in the posterior diencephalon.

In certain conditions, the two premotor sympathetic systems may act synergistically: Hypothalamic neurons that project to the IML send axon collaterals to catecholaminergic neurons in the lower brain stem (Figure 3).

Sensory Arms of the Sympathetic Nervous System

To maintain homeostasis, the sympathetic nervous system responds to several different types of sensory inputs. Some of these inputs are somatosensory, including nociceptive signals, whereas others – viscerosensory inputs – arise from interoceptors in the internal organs. They may reach spinal and supraspinal receptors by neural or humoral ways. Inputs which influence the activity of the sympathetic preganglionic or premotor sympathetic neurons (Figure 1) are called sympathetic sensory afferents. They represent the sensory (also called ascending or afferent) arm of the sympathetic regulatory circuit.

The sympathetic visceral afferent fibers enter the dorsal horn of the spinal cord through the dorsal roots and innervate the sympathetic preganglionic neurons in the IML via interneurons located in lamina V and lamina VII of the spinal cord (Figure 2). Some sensory fibers that project to the spinal cord also send a branch to sympathetic ganglia forming reflex circuits that may control some visceral autonomic functions.

Viscerosensory signals to supraspinal premotor sympathetic neurons are relayed in the nucleus of the solitary tract (NTS), which represents the primary viscerosensory center in the central nervous system. Viscerosensory fibers travel in cranial nerves (mainly in the trigeminal, glossopharyngeal, and vagal nerves) or in ascending spinal fibers (spino-solitary tract) and terminate in the NTS. The sensory afferents terminate in a topographically and functionally organized manner in the different subdivisions of the nucleus. The ascending fibers from the NTS may reach both the catecholaminergic and the noncatecholaminergic premotor sympathetic neurons in the brain stem and the hypothalamus. Some of them influence the activity of limbic and cortical structures that may respond to these signals through the activation of hypothalamic or brain stem premotor sympathetic neurons.

Sympathetic Nervous System in the Organization of Stress Response

The sympathetic nervous system helps to maintain homeostasis during exposure to stressors. Activation of the sympathetic nervous system leads to the outflow of catecholamines from the adrenal medulla and from the varicosities of the sympathetic postganglionic axons. These two systems constitute the final compartments of the effector loop of the sympathetic nervous system that participate in the organization of stress response.

Under resting conditions, low levels of EPI and NE are released into the blood flow from the adrenal medulla and sympathetic postganglionic nerve terminals, respectively. During stressful situations, large amounts of EPI and NE are released. Depending on the nature, intensity, and duration of stressful stimuli, levels of NE and EPI in the plasma may increase 10- to 100-fold (or even higher) within a very short period of time after the stressful stimuli occur. The tissue levels of NE measured in various organs are reduced in acute stress since approximately 70% or more of the circulating NE is derived from the

varicosities of the postganglionic sympathetic nerve fibers, which provide the sympathetic innervations of the organs. Similarly, levels of NE and EPI are reduced in the adrenal medulla, depending on the intensity and the duration of acute stressors. After long-term or repeated stress exposure, adrenal medullary catecholamine stores are increased in the chromaffin cells. In this situation, the increased catecholamine synthesis, as a consequence of the stress-induced marked elevation of gene expression of catecholamine-synthesizing enzymes (tyrosine hydroxylase, dopamine β-hydroxylase, and phenylethanolamine *N*-methyltransferase (PNMT)) in the adrenal medulla, exceeds the release of NE and EPI.

Based on measurements of plasma levels of EPI, NE, catecholamine precursors, and metabolites in stress, it is generally accepted that SAS and SNS are specifically, and somewhat independently, activated by different stressors. Exposures to cold evoke a selective activation of SNS, as indicated by elevated plasma NE levels, whereas insulin-induced glucoprivation or emotional stressors activate SAS, as indicated by plasma EPI responses. Other stressors, such as restraint or formalin-induced pain, activate both systems. Immobilization represents a severe stress that elicits an extremely large increase in plasma NE and EPI. Results from a variety of studies indicate that not only the peripheral but also the central catecholamine system and the hypothalamic–pituitary–adrenal (HPA) axis respond specifically to different stressful stimuli. An intact HPA axis is essential for the activity of PNMT, the enzyme responsible for EPI synthesis in the adrenal medulla. Thus, depending on the nature and the target sites of various stressors, SAS and SNS may be regulated by different central pathways. For example, a single subcutaneous formalin injection, which strongly increases EPI levels in the plasma in intact animals, may reduce the immobilization-induced high EPI levels whether it was injected before or during immobilization.

Whereas our knowledge of the stress-related activity of SAS is continuously increasing, SNS has been much less studied than the adrenal medulla and relatively little is known about the mechanisms of gene expression of catecholamine biosynthetic enzymes in sympathetic ganglion cells following stressful stimulation.

Sympathomimetic Drugs and Adrenergic Receptor Antagonists

T C Westfall, Saint Louis University School of Medicine, St. Louis, MO, USA

© 2009 Published by Elsevier Ltd.

Sympathomimetics

Sympathomimetic drugs are agents which in general mimic responses due to stimulation of sympathetic nerves. These agents are able to directly activate adrenergic receptors or to indirectly activate them by increasing norepinephrine and epinephrine (mediators of the sympathoadrenal system) levels. Chemically these drugs are catecholamines (Figure 1) or are structurally similar to catecholamines. The parent structure is β-phenylethylamine. When hydroxyls are placed on β-phenylethylamine at the 3 and 4 positions of the aromatic ring (Figure 1), the drugs are called a catecholamine. There are three naturally occurring catecholamines (dopamine, norepinephrine, and epinephrine) as well as various synthetic amines (e.g., isoproterenol and dobutamine).

Adrenergic Receptors

Adrenergic receptors are the specific molecular structures in or on effector cells with which catecholamines or sympathomimetic drugs react in order to elicit the characteristic response(s) of the cells. Adrenergic antagonists also bind to these receptors and prevent the response(s) mediated by endogenous or exogenous agonists. Adrenergic receptors were originally defined by the rank order of potency of a series of agonists, or specificity of antagonists. More recently they are also identified by their molecular structure and cloning of the gene. Currently, there are two general types of adrenergic receptors, α and β, with various subtypes (α_{1A}, α_{1B}, α_{1D}; α_{2A}, α_{2B}, α_{2C}; β_1, β_2, and β_3). All of the adrenergic receptors belong to the family of G-protein-coupled receptors (GPCRs) that link to heterotrimeric G-proteins. Although structurally related, different receptors regulate distinct physiological processes by controlling the synthesis or release of a variety of second messengers or the activity of ion channels. Each major type of receptor shows preference for a particular class of G-protein (e.g., α_1 to G_q; α_2 to G_i). Stimulation of α_1 adrenergic receptors results in the regulation of multiple effector systems. A primary mode of signal transduction involves activation of the G_q/phospholipase Cβ/inositol 1,4,5-trisphosphate/Ca^{2+} and calmodulin-sensitive pathways, such as calmodulin (CaM) kinase. In addition to these pathways, α_1 adrenergic receptor-induced transduction of G_q can lead to elevations of phospholipase D_1, phospholipase A_2, and activation of ligand-gated Ca^{2+} channels. Activation of α_2 adrenergic receptors also couples to a variety of effectors and is transduced through $G_{i1,2,3}$, resulting in a decrease in adenylyl cyclase and cyclic AMP, and through the $\beta\gamma$ subunits of G_i to activate K^+ channels, and through G_o to inhibit L- and N-type Ca^{2+} channels. All three β adrenergic receptors couple to G_s and activate adenylyl cyclase and increase cyclic AMP.

Physiological/Pharmacological Response

The actions of sympathomimetics can be classified into at least seven broad types of responses: (1) excitatory action on smooth muscle (e.g., contraction of vascular smooth muscle), (2) inhibitory action on smooth muscle (e.g., relaxation of bronchiolar smooth muscle), (3) stimulation of the heart, leading to increased heart rate, contraction, and conduction, (4) metabolic actions (e.g., glycogenolysis in liver, resulting in an increase in glucose), (5) endocrine actions (e.g., increasing or decreasing insulin release), (6) actions in the central nervous system, and (7) prejunctional action on nerves, increasing or decreasing transmitter synthesis or release. The response to sympathomimetics often can be predicted on the basis of knowledge of the selectivity of the agent for reacting with a specific α or β receptor and the physiological response governed by these adrenergic receptors in specific cells, tissues, or organs. Table 1 depicts the responses produced following activation of adrenergic receptors or stimulation of sympathetic nerves.

The response of any cell or organ to sympathomimetic drugs is dependent on the density and proportion of α and β adrenergic receptors. An example is bronchiolar smooth muscle, in which the principal adrenergic receptor is β_2. Norepinephrine has little effect on bronchiolar smooth muscle since it has little activity on the β_2 receptor. On the other hand, epinephrine or isoproterenol will relax bronchiolar smooth muscle due to the ability of these compounds to activate β_2 adrenergic receptors. The ultimate response of an effector cell or organ to a sympathomimetic drug is dictated not only by the direct effect of the agents, but also by reflex homeostatic mechanisms. This is illustrated well by α_1 adrenergic agonists. Such drugs will constrict blood vessels, therefore increasing blood pressure. This, in turn, elicits a compensatory decrease in heart rate resulting from the carotid sinus–aortic arch baroreflex system. An increase in blood pressure results

Figure 1 Chemical structure of catechol β-phenylethylamine and naturally occurring catecholeamines.

in a decrease in sympathetic outflow from the central nervous system and an increase in parasympathetic outflow. Decreases in blood pressure result in the opposite: an increase in sympathetic outflow and a decrease in parasympathetic outflow. Although a drug such as phenylephrine has little direct effect on the heart, it can actually decrease heart rate indirectly following its increase in blood pressure (via α_1 activation) and activation of the baroreflex resulting in an increase in parasympathetic outflow.

Classification of Sympathomimetic Amines

Catecholamines and sympathomimetic drugs are classified as directly acting, indirectly acting, or mixed acting (Figure 2). Directly acting drugs may have selectivity for a specific adrenergic receptor subtype (e.g., phenylephrine for α_1, clonidine for α_2) or may act on numerous receptor subtypes (e.g., epinephrine for α_1, α_2 , β_1, β_2, β_3). Indirectly acting sympathomimetic amines increase the amount of norepinephrine available to stimulate adrenergic receptors (e.g., amphetamine, methamphetamine).

Some drugs have the ability to increase the amount of norepinephrine and therefore produce sympathomimetic actions (e.g., cocaine, entacapone) but chemically are not sympathomimetic drugs. In general, drugs can increase the amount of norepinephrine by (1) releasing norepinephrine from sympathetic terminals (amphetamine), (2) blocking the reuptake of norepinephrine into sympathetic neurons (cocaine), or (3) inhibiting the biotransforming enzymes monoamine oxidase (pargyline) or catechol-*O*-methyltransferase (entacapone). Mixed-acting drugs (ephedrine, dopamine) can directly activate adrenergic receptors as well as increase the amount of norepinephrine.

Figure 2 lists some prototypical drugs which act by one or more of these mechanisms. Although the classification of sympathomimetic drugs into directly,

Table 1 Peripheral adrenergic receptors and responses

Organ (site)	*Response*	*Receptor*
Eye		
Dilator or radial smooth muscle of the iris	Contraction (mydriasis)	α_1
Ciliary muscle	Relaxation (accommodation for vision)	β
Heart		
SA node	Increase in rate (positive chronotropic)	β_1 (β_2)
Atria	Increase in contractility (positive inotropic)	β_1 (β_2)
AV node	Increase in conduction velocity (positive dromotropic effects)	β_1 (β_2)
Ventricle	Increase in contraction (positive inotropic)	β_1 (β_2)
Blood vessels		
Arteries (cutaneous, visceral, skeletal, pulmonary)	Contraction	α_1 (α_2)
Some arteries (skeletal and visceral)	Relaxation	β_2
Veins	Contraction	α_1 (α_2)
Veins	Relaxation	β_2
Lung		
Bronchial muscle	Relaxation (bronchodilation)	β_2
Mast cells	Inhibition of mediators	β_2
Mast cells	Stimulation of mediators	α
Gastrointestinal tract		
Motility	Decrease	α_1, α_2, β_1, β_2
Sphincters	Contraction	α_1 (α_2)
Sphincters	Relaxation	β_2
Secretions	Decrease	α_2 (β_2)
Urinary bladder		
Detrusor muscle	Relaxation	β_2
Trigone and sphincter	Contraction	α_1
Uterus	Relaxation	β_2
Uterus	Contraction	α_1
Salivary gland	$\uparrow K^+$ release	α_1
	$\uparrow$ Amylase secretion	β_1
Metabolic or endocrine		
Liver	Increase glycogenolysis	α_1, β_2
Skeletal muscle	Increase glycogenolysis	β_2
Fat cells	Lipolysis (thermogenesis)	α, β_1, β_2, β_3
Pancreatic islets	Inhibition	α_2
Pancreatic islets	Stimulation	β_2
JG cells (kidney)	Increase renin release	β_1
Spleen	Contraction	α_1
Pilomotor muscle	Stimulation	α_1
Nerve terminals	Inhibition of transmitter release	α_2
Autonomic ganglia	Hyperpolarization	α_2

indirectly, or mixed acting is convenient, it is not absolute and there is a continuum from predominantly directly acting, on the one hand, to predominantly indirectly acting, on the other.

Endogenous Catecholamines

Epinephrine; Norepinephrine

Epinephrine is a hormone released from the adrenal medulla as well as a neurotransmitter in the central nervous system (CNS). Norepinephrine is the principal neurotransmitter released from postganglionic sympathetic nerve terminals, a hormone released from the adrenal medulla, and a neurotransmitter in the CNS. The endogenous catecholamines (dopamine, norepinephrine, and epinephrine) are rapidly metabolized by catechol-O-methyltransferase (COMT) and monoamine oxidase (MAO). They are charged molecules at physiological pH and are inactive when given by the oral route. When released from nerve endings they are rapidly and effectively transported by the norepinephrine transporter (NET) or dopamine transporter (DAT) into presynaptic terminals. The uptake may also occur when the three amines are given as drugs. All have short duration of action and do not penetrate into the CNS (across the blood–brain barrier).

As mentioned, epinephrine is nonselective and it can directly activate all adrenergic receptors (α_1, α_2, β_1, β_2, and β_3), whereas norepinephrine activates α_1, α_2, and β_1 receptors but has very little activity on β_2 receptors. This highlights the biggest difference between epinephrine and norepinephrine. The pharmacological actions of the catecholamines can be

Figure 2 Classification of adrenergic receptor agonists (sympathomimetic amines) or drugs that produce sympathomimetic-like effects. For each category, a prototypical drug is shown. (Cocaine, pargyline, and entacapone are not actually sympathetic drugs but do produce sympathomimetic-like effects.) Adapted from Westfall TC and Westfall DP (2006) In: Brunton L, Lazo JS, and Parker KL (eds.) *Goodman and Gilman's The Pharmacological Basis of Therapeutics*, 11th edn., ch. 10. New York: McGraw-Hill.

deduced by examining Table 1. Both norepinephrine and epinephrine have prominent cardiovascular effects, especially after parenteral administration. Since epinephrine is a potent stimulant of both α and β receptors, its effects on target organs are complex. Epinephrine is a potent pressor drug. The mechanism of the rise in blood pressure by epinephrine is due to (1) direct myocardial stimulation which increases ventricular contraction (positive inotropic effect), (2) increased heart rate (positive chronotropic effect), and (3) vasoconstriction in many vascular beds – especially in the precapillary resistance vessels of skin, mucosa, and kidney, along with marked constriction of veins. Depending on the route and dose, epinephrine may also decrease peripheral resistance due to its activation of β_2 receptors in skeletal muscle blood vessels, resulting in vasodilators and an enhancement of blood flow. In this case, mean blood pressure is not greatly elevated and therefore the compensatory baroreflex does not appreciably antagonize the direct cardiac actions. Heart rate, cardiac output, stroke volume, and ventricular work are all increased due to direct cardiac stimulation and increased venous return. The direct effects of epinephrine on the heart are one of a powerful stimulant due to activation of β receptors. All aspects of myocardial function are increased (heart rate, contraction, conduction velocity). Arrhythmias may be seen with high epinephrine concentrations.

The effects on nonvascular smooth muscle depend upon the type of receptor (e.g., relaxation of bronchiolar smooth muscle via activation of β_2 receptors; see Table 1). Epinephrine has been used clinically to treat acute asthma, open-angle glaucoma, and anaphylactic shock, and is used with local anesthetics to prolong their duration of actions. It has also been used occasionally in complete heart block or cardiac arrest.

Norepinephrine is also a potent pressor agent and increases both systolic and diastolic blood pressure and peripheral resistance. Unlike epinephrine, norepinephrine does not activate β_2 receptors in skeletal blood vessels and there is no decrease in diastolic blood pressure. The marked increase in peripheral resistance and mean arterial blood pressure following intravenous administration can result in a compensatory slowing of the heart rate, which overrides the direct effects of norepinephrine on heart rate. Like epinephrine, norepinephrine directly increases all aspects of myocardial function due to activation of β receptors. Norepinephrine is used to treat various forms of hypotension, including shock. Side effects of

epinephrine and norepinephrine include palpitations of the heart, cardiac arrhythmias, cerebral hemorrhage, headache, tremor, and restlessness.

Dopamine

Dopamine is the third naturally occurring catecholamine. It is the immediate precursor of norepinephrine, an important CNS neurotransmitter, an interneuron mediator in some autonomic ganglia, and perhaps a local hormone in the kidney. Dopamine can directly activate α_1 and β receptors and can also evoke the release norepinephrine from sympathetic neurons and is therefore classified as a mixed-acting sympathomimetic. Dopamine is a substrate for both MAO and COMT and is inactive orally. In addition to its effects on α_1 and β receptors it can activate dopamine D_1 receptors located in renal, mesenteric, and coronary blood vessels, leading to dilation. Activation of D_1 receptors on renal tubular cells decreases sodium transport and produces natriuresis. Dopamine is used clinically to treat cardiogenic shock, congestive heart failure, and acute renal failure. A side effect of high doses is vasoconstriction.

Nonselective β Agonists

Isoproterenol

This is a synthetic catecholamine with activity on all β receptors ($\beta_1, \beta_2, \beta_3$). It is readily absorbed when given parenterally or as an aerosol. It is primarily metabolized by COMT, is a poor substrate for MAO, and is poorly taken up by sympathetic neurons. Isoproterenol produces positive inotropic and chronotropic effects, leading to an increase in cardiac output, unchanged or increase in systolic blood pressure, and a decrease in diastolic blood pressure. It will relax nonvascular smooth muscle containing β_2 receptors.

Dobutamine

Although often thought of as the prototypical β_1 selective agonist, its pharmacological effects are complex. It has two enantioimeric forms present in the racemic mixture used clinically. The (−) isomer is a potent α_1 receptor agonist that can cause pressor effects. The (+) isomer is a potent α_1 receptor antagonist which can block the effects of (−) dobutamine. The (+) isomer is a more potent β receptor agonist than is the (−) isomer. Dobutamine is a myocardial stimulant with more prominent inotropic than chronotropic effects. The drug is indicated for the short-term treatment of cardiac decompensation that may occur after cardiac surgery or in patients with congestive heart failure or acute myocardial infarction.

Adrenergic Receptor Agonists

β_2-Selective Adrenergic Receptor Agonists

Metaproterenol, terbutaline, albuterol, isoetharine, pirbuterol, bitolterol, fenoterol, fomoterol, procaterol, salmeterol, and ritodrine comprise a series of drugs which have preferential affinity for β_2 receptors, compared with β_1 receptors. However, this selectivity is not absolute and is lost at high concentrations of these drugs. Chemical modification has resulted in lower rates of biotransformation and enhanced oral bioavailability relative to catecholamines. The selectively for β_2 receptors theoretically allows these drugs to relax airway smooth muscle at doses producing minimal activation of the heart.

Many of these drugs have been found useful in the treatment of asthma, bronchospasm, chronic obstructive pulmonary disease (COPD), and premature labor. Side effects result from excessive activation of β receptors and include tachycardia, arrhythmias, myocardial ischemia, tremor, and increased bronchial hyperreactivity.

α_1-Selective Adrenergic Receptor Agonists

The major effects of phenylephrine, mephenteramine, metaraminol, midodrine, and other α_1-selective adrenergic receptor agonist drugs are to activate α adrenergic receptors in vascular smooth muscle. This results in an increase in peripheral resistance and elevation of blood pressure. These drugs possess some selectivity of α_1 receptors over α_2 or β receptors. Most can be given orally and can be used to treat hypotension, including orthostatic hypotension or shock. They can also be used as nasal decongestants and as mydriatics (dilation of the pupil) (e.g., phenylephrine). Midodrine is an orally effective α_1 agonist and is a prodrug; it is converted to an active metabolite, desglymidodrine, and is used to treat orthostatic hypotension.

α_2-Selective Adrenergic Receptor Agonists

Clonidine, apraclonidine, brimonidine, guanffacine, guanabenz, methyldopa, and tizanidine are α_2-selective adrenergic receptor agonists. Although the principal receptor in vascular smooth muscle is the α_1 type, there are α_2 adrenergic receptors as well, which when activated promote vasoconstriction. Therefore, it is somewhat ironic that many of the α_2-selective adrenergic receptor agonist drugs are used to treat hypertension. The ability to lower blood pressure, however, is the result of activation of α_2 adrenergic receptors in the cardiovascular control centers in the CNS. Activation of α_2 receptors at these sites decreases the outflow of sympathetic nerve activity from the CNS. There is some evidence that clonidine's sympathoinhibitory action is

partly mediated by an action on imidazoline receptors in the brain stem.

A second major use of some of these drugs is to decrease the production of aqueous humor, thus reducing intraocular pressure in the eye in patients with wide-angle glaucoma (praclonidine and brimonidine). These drugs also have the ability to decrease the evoked release of sympathetic transmitters from neurons by acting on the inhibitory α_2 autoreceptors or heteroreceptors on sympathetic or other neurons.

Indirect-Acting or Mixed-Acting Sympathomimetics

Indirect-acting or mixed-acting sympathomimetics (e.g., amphetamine, methamphetamine, methylphenidate, dexmethylphenidate, and ephedrine) have powerful CNS stimulant actions (especially amphetamine and methamphetamine) in addition to peripheral α and β actions. Most can be given orally and have long duration of actions relative to catecholamines. Amphetamines increase both systolic and diastolic blood pressure, directly stimulate the heart, and on occasion may cause a reflex slowing of the heart. CNS effects include wakefulness, alertness, decreased feeling of fatigue, elevation of mood, and increased initiative, self-confidence, and ability to concentrate, in addition to elation, euphoria, and increase in motor and speech activities. Prolonged use may be followed by depression and fatigue.

These drugs are indirectly acting or mixed acting, meaning they release norepinephrine (from sympathetic neurons) and a variety of biogenic amines (from neurons in the CNS), including norepinephrine, dopamine, and serotonin. Side effects are a result of the extension of their pharmacological effects and include increases in blood pressure, anginal pain, and arrhythmias, as well as other cardiovascular effects. CNS effects may include restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and euphoria. More serious effects include confusion, aggressiveness, anxiety delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies. Chronic use can also lead to tolerance and dependence.

Therapeutic uses include attention-deficit/hyperactivity disorder (ADHD) and narcolepsy. Although amphetamine and related drugs can reduce appetite, the use in treating obesity is controversial and considered inappropriate. Many herbal preparations contain ephedrine (ma huang, ephedra) and are used around the world. The safety of many of these products is of concern and therefore the United States Food and Drug Administration has banned the sale of dietary supplements containing ephedra in the United States effectively from April 2004.

Adrenergic Receptor Antagonists

Adrenergic receptor antagonists are drugs that bind to α or β adrenergic receptors and prevent or block the responses produced by catecholamines or sympathomimetic drugs. Almost all of these drugs are competitive antagonists with the exception of phenoxybenzamine. By definition these drugs bind to the receptor site (affinity) but cannot produce a biological response. However, if an endogenous transmitter such as norepinephrine is present, the adrenergic receptor antagonist will result in a physiological response. The pharmacological response to α or β adrenergic receptor antagonists depends upon a composite of (1) degrees of existing sympathetic tone in the cell or tissue at the time of blockade (amount of norepinephrine interacting with the receptor, (2) the type of receptor inhibited (e.g., α_1, β_1), (3) degree and duration of blockade, (4) other drugs present, and (5) actions of the blocker not associated with actions on adrenergic receptors. As with sympathomimetics, antagonists may be selective for one type of receptor (e.g., α_1, β_1) or may be nonselective (β_1 and β_2). Figure 3 classifies numerous adrenergic receptor antagonists as to the receptor or receptor subtype with which they interact.

α Adrenergic Receptor Antagonists

As depicted in Figure 3, α adrenergic receptor antagonists are nonselective (phenoxybenzamine, phentolamine), meaning that they block both α_1 and α_2 adrenergic receptors or that they are α_1 selective (prazosin) or α_2 selective (yohimbine). Some drugs have selectivity for the α_1 or α_2 subtypes (α_{1A}, α_{1B}, α_{2A}, etc.) but such a discussion is beyond the focus of the present article.

A summary of the effects of α adrenergic antagonists is depicted in Table 2. Some of the most important effects of α adrenergic receptor antagonists are on the cardiovascular system. Blockade of α_1 adrenergic receptors inhibits vasoconstriction, and therefore vasodilation in both arteriolar resistance vessels and veins may occur. The fall in blood pressure depends upon the degree of sympathetic tone (higher in erect vs. supine position). For most α blockers the decrease in blood pressure is opposed by baroreceptor reflexes that cause an increase in heart rate and cardiac output.

Blockade of α_2 receptors interferes with prejunctional modulation of norepinephrine release by inhibitory α_2 receptors. The result is enhanced norepinephrine release. As mentioned previously, activation of α_2 receptors in central cardiovascular control sites leads to a decrease in sympathetic outflow and a decrease in blood pressure. Blockade of such receptors will result in an increase in sympathetic

Figure 3 Classification of adrenergic receptor antagonists. The nonselective third-generation β adrenoceptor antagonist drugs carvedilol and labetalol also block α_1 receptors. Adapted from Westfall TC and Westfall DP (2006) In: Brunton L, Lazo JS, and Parker KL (eds.) *Goodman and Gilman's The Pharmacological Basis of Therapeutics*, 11th edn., ch. 10. New York: McGraw-Hill.

outflow and an increase in sympathetically mediated responses (e.g., increased blood pressure).

Phenoxybenzamine is unlike other α adrenergic receptor antagonists in that the tertiary amine cyclizes to an ethylenimonium intermediate. The three-member ring breaks and forms highly reactive carbonium ions that can alkylate various sites. This forms a covalent bond with the α receptors and this produces a nonequilibrium rather than a competitive blockade. Other names given to this type of blockade are 'unsurmountable' or 'competitive irreversible.' Once the blockade has fully developed, it cannot be surmounted by the presence of an α agonist, as takes place with competitive antagonists. The blockade has a long duration of action. Phenoxybenzamine is a very reactive drug and can also block other types of receptors, such as cholinergic, serotonergic, and histaminergic receptors. In addition, it can block norepinephrine uptake into neurons (uptake 1; NET) and extraneuronal sites (uptake 2). The most useful α adrenergic receptor antagonists clinically are the α_1 antagonists that are used to treat essential hypertension. In addition, contractile α_1 receptors are present in the prostate gland and in benign prostatic hyperplasia (BHP) and impede the outflow of urine from the bladder through the urethra. The α_1 adrenergic antagonists are used to relax the prostate in such situations, giving symptomatic relief. In many cases, α_1 adrenergic receptor antagonists are used in combination with 5α-reductase inhibitors.

β Adrenergic Receptor Antagonists

The β adrenergic receptor antagonists are among the most important drugs developed over the past 40–50 years because of their efficacy in treating numerous pathological conditions, including hypertension, ischemic heart disease, heart failure, and certain arrhythmias, to name but a few. Since the development of the first clinically useful beta blocker, propranolol, in the 1960s, there have been numerous additional drugs developed (listed in Figure 3). As with α adrenergic receptor antagonists, drugs are nonselective (blocking β_1 and β_2 receptors) or β_1 selective. In addition to being nonselective or β_1 selective, some beta blockers also have other actions, such as a membrane-stabilizing (local anesthetic) action, or intrinsic sympathomimetic activity. In the latter case such agents are partial agonists, meaning that in the absence of other β agonists they can activate β receptors, but in the presence of other agonists they behave like antagonists. Moreover, the so-called third-generation drugs are also vasodilators and produce this effect by a variety of mechanisms, including β_2 agonism, α_1 receptor antagonism, production of nitric oxide, Ca^{2+} entry blockade, or opening K^+ channels (Table 3).

Pharmacological Actions and Side Effects

As is the case for α adrenergic receptor antagonists, the pharmacological properties of β receptor antagonists can be understood largely from knowledge of the responses elicited by the receptors in various tissues and the activity of the sympathetic nerves that innervate these tissues (Table 1). A summary of β adrenergic antagonists is included in Table 4.

Beta blockers have prominent effects on the heart, including decreasing heart rate, decreasing myocardial contractility, and decreasing cardiac output. The

short-term effect of beta blockers is to increase peripheral resistance; however, long-term use leads to a decrease in or produces no change in total peripheral resistance. These drugs have significant effects on cardiac rhythm and automaticity. Due to activation of β receptors (see Table 1), beta blockers can also antagonize other effects, such as blocking bronchiolar smooth muscle, leading to an increase in airway resistance, reduction of intraocular pressure, inhibition of sympathetic nervous system, stimulation of lipolysis in fat cells and glycogenolysis in the liver, and antagonism of the sympathetic nerve-induced release of renin in the kidney and thus angiotensin formation in the circulation. Many of these effects are considered side effects when beta blockers are being used clinically.

Therapeutic Uses

The β adrenergic receptor antagonists are very useful clinically and have been used to treat a wide variety of conditions, including angina pectoris (ischemic heart disease), essential hypertension, cardiac arrhythmias, idiopathic hypertrophic subaortic stenosis, congestive heart failure, glaucoma, hyperthyroidism, surgical removal of pheochromocytoma, nonparkinsonian tremor, and migraine (prophylaxis), and are used in a wide variety of anxiety situations (e.g., stage fright) and in alcohol and sedative–hypnotic drug withdrawal.

Angina pectoris (ischemic heart disease) Angina pectoris is a syndrome which produces a sensation of strangulation, squeezing, and pressure in the chest region. It is caused by inadequate coronary blood flow that fails to meet oxygen demands of the heart tissue and is associated with acute myocardial ischemia. The most common form is chronic stable angina caused by fixed narrowing or stenosis of the coronary blood vessels. It is often precipitated by exertion, exercise, or stress. Beta blockers are useful in the long-term and prophylactic treatment of angina. These drugs reduce the frequency of angina episodes and improve exercise tolerance. These effects are due to β adrenergic receptor blockade, resulting in a decrease in cardiac work and a reduction in oxygen demand.

Essential hypertension The pathophysiological mechanisms causing essential hypertension are obscure. It is well established that left untreated it can lead to morbid events such as coronary heart disease, renal disease, or stroke. Beta blockers have been proved to be effective in treating essential hypertension and are well tolerated. They reduce both supine and standing blood pressure during long-term treatment, although they are not usually first-choice drugs. They are valuable when used together with diuretics, angiotensin-converting enzyme inhibitor, angiotensin receptor antagonists, and other vasodilators. The precise mechanisms of action of beta blockers in treating essential hypertension are unclear. Suggested mechanisms include reduction in cardiac output, inhibition of renin release and thus angiotensin II production, sympathoinhibition via a CNS mechanism, or blockade of prejunctional excitatory β receptors on sympathetic neurons.

Cardiac arrhythmias The β adrenergic receptor antagonists are effective in treating both supraventricular and ventricular arrhythmias. Indications for use include catecholamine-induced arrhythmias as well as atrial flutter, atrial fibrillation, paroxysmal supraventricular tachycardia, and selected ventricular arrhythmia. These drugs are used to control sinus tachycardia and frequent premature ventricular contractions in patients with catecholamine-secreting tumors and pheochromocytoma, as well as in the surgical management of the tumor.

Glaucoma Beta blockers were found serendipitously to reduce intraocular pressure in glaucoma, and work following either systemic or topical application. They appear to work by reducing

Table 4 Summary of β adrenoceptor antagonists

the production of aqueous humor. They are often first-choice drugs and are devoid of the side effects of blurred vision and have little effect on pupil size or accommodation.

Congestive heart failure Although it is a common observation that acute administration of beta blockers can worsen or even precipitate congestive heart failure in compensated patients, numerous well-designed randomized clinical trials have demonstrated that certain beta blockers are a highly effective treatment for patients with all grades of heart failure secondary to left ventricular systolic dysfunction. The drugs have been shown to improve myocardial function and to improve quality of life and prolong life. Long-term beta blockade has been shown to reduce cardiac volume, myocardial hypertrophy, and filling pressure, and to increase ejection fraction. Large trials have been carried out with carvedilol, bisoprolol, metoprolol, xamoterol, bincindolol, betaxolol, nebivolol, and talinolol.

Other uses Beta blockers have also been shown to be effective in reducing the clinical symptoms of tachycardia, tremors, and anxiety often seen in hyperthyroidism, alcohol and sedative–hypnotic drug withdrawal, and acute situational anxiety (stage fright). They are also useful in the prophylaxis of migraine headache, nonparkinsonian tremor, and urinary incontinence.

Synapse Formation: Competition and the Role of Activity

L Cancedda and M-M Poo, University of California at Berkeley, Berkeley, CA, USA

Introduction

Synaptic competition is a cellular process by which the presence of one synapse affects the stability or survival of other synapses on the same postsynaptic cell. Synapse elimination refers to synapse loss due to either a low 'intrinsic merit' of the synapse for survival or to its failure in winning synaptic competition with other synapses on the same cell. Such competition and elimination can be driven by either neuronal/synaptic activity or other activity-independent processes. The idea that the strength of synaptic connections between neurons may be modified can be traced back to Ramon y Cajal, who proposed that such modification serves as a cellular mechanism for learning and memory. That memory formation involves making and breaking existing synaptic connections has been a popular idea over the past century, but solid experimental evidence in support of this idea has been elusive. Recent morphological studies of synapse stability in the adult rodent brain have revealed rather limited synaptic remodeling under normal conditions. In contrast, initial synaptic connections established early in the developing nervous system undergo substantial remodeling, with some connections stabilized and others eliminated, as a result of experience. This developmental remodeling of connectivity often involves cooperative and competitive interactions between converging synapses on the postsynaptic cell and in many cases depends on the pattern of electrical activity. We here summarize the evidence of activity-dependent synaptic competition and elimination in various brain regions, together with potential underlying cellular mechanisms.

Visual System

Activity-dependent synaptic competition and elimination in the central nervous system was first indicated by work of Hubel and Wiesel on the development of ocular dominance columns (ODCs) in the visual cortex. Cortical neurons preferentially responding to one eye or the other are normally found to be segregated into alternating columns in the primary visual cortex, representing sorting of geniculocortical projections serving two eyes during postnatal development. The sorting process occurs prior to eye opening and is highly sensitive to visual experience. Depriving visual input to one eye of a newborn cat or monkey by suturing the eyelid during a critical period after birth leads to retraction of geniculocortical projections serving that eye. Interestingly, the consequences of visual deprivation during early postnatal period are much more severe in cats subjected to monocular deprivation than binocular deprivation, suggesting that competition driven by activity between two eyes, rather than the reduced activity in one eye, is responsible for sorting geniculocoritical projections. The ODCs develop by a progressive segregation of initially overlapping geniculocortical projections serving two eyes. While the initial alternating pattern of projections is established by mechanisms independent of the retina activity, pruning of extensive overlapping projections is likely to be driven by activity, including spontaneous or visually evoked retinal activity, because blocking the firing of retinal ganglion cells (RGCs) in both eyes prevents complete ODC formation.

Early in development there is also substantial overlap of retinogeniculate projections from the two eyes in the lateral geniculate nucleus (LGN). Segregation of these projections into eye-specific layers occurs before the onset of vision, but at a time when spontaneous activity waves are prominent in the retina. Blocking all activity in both eyes prevents segregation of retinogeniculate projections and can desegregate already existing eye-specific projections later in development, although it is unclear whether the specific pattern of the waves is required for eye-specific segregation. When the activity is altered in one eye, the more active eye acquires more synaptic territory than the less active eye, suggesting activity-mediated competition. Furthermore, even after eye-specific segregation is completed, activity in one eye can further prune retinogeniculate projections by reducing the convergence of RGC inputs onto a single LGN neuron from 12–20 to 1. This within-eye pruning based on activity-dependent competition among RGCs faciliates sharpening of the receptive field of LGN neurons. Such activity-dependent competition may be attributed to the competition in the growth or stability of RGC axonal arbors. In the developing optic tectum of zebra fish, reducing neuronal and synaptic activity in a subset of RGCs leads to suppression of their axon growth and branching and this suppression is relieved by blocking the activity of nearby RGC axons as well.

The successive levels of the mammalian visual system are organized into retinotopic maps that preserve an orderly representation of visual inputs at the retina, through topographically precise retinogeniculate,

retinocollicular, and geniculocoritical projections. Formation of these maps requires specific patterns of spontaneous activity in the retina because disrupting these waves affects map formation at all levels. While the initial projections may establish a crude retinotopic map via axon guidance based on molecular cues, interfering with both axon guidance cues and spontaneous wave activity in the same animal results in a dramatic cumulative effect in disrupting the map in the superior colliculus. Finally, the development of retina circuitry itself also depends on activity. Depriving the retinal activity by blocking spontaneous activity or dark rearing blocks both the normal maturational loss of ON–OFF responsive RGCs and the pruning of dendrites at the stratified ON and OFF layers of the inner plexiform layer, although it is unclear whether dendritic pruning in this layer results from competitive interaction among bipolar inputs.

Somatosensory System

Somatosensory projections in the brain exhibit a somatotopic map, with axons of peripheral receptor sheets projecting in an orderly manner onto central brain structures. The most intensively studied system is the rodent trigeminal pathway where the patterned array of the whisker is replicated in the patchy distribution of afferents and the modular organization of their postsynaptic counterparts along the pathway from the periphery to the primary somatosensory cortex. The whisker-related patterns are first established in the brain stem nuclei, then in the ventroposteromedial nucleus of the thalamus, and finally in the somatosensory cortex ('barrels'), where neurons respond best or exclusively to deflection of the corresponding facial whisker. These somatotopic maps emerge during early development in ascending order along the neuroaxis, with a sequence that includes afferent fibers segregation before rearrangement of their target neurons in discrete zones along the pathway. It is generally believed that the initial crude topographic projection of the afferent fibers is independent of sensory experience, but the presence of segregated afferent fibers and postsynaptic glutamate receptor activities is required for the subsequent parcellation of their postsynaptic targets.

That cortical map formation depends on a competitive process is suggested by the finding that damage of the branch of the trigeminal nerve supplying the whisker pad prior to birth results in a reduction of the cortical representation of the whiskers and a concomitant increase in the representation of other peripheral receptor surfaces. Whether and how such competition occurs through synaptic competition and elimination are unknown. Synapse elimination has been observed in the ventral posteromedial thalamic nucleus of young animals, where multiple afferents on each neuron are reduced to one or two afferents as the animal matures. However, this synapse elimination and remodeling occur even in animals deprived of sensory experience from birth, indicating that the process is independent of sensory experience, although spontaneous neuronal activity may still be required.

Morphological organization of somatosensory cortical neurons into barrels during development depends on signals conveyed by invading thalamic axons and sensory activity. Indeed, primordial visual cortex transplanted into the neonatal somatosensory cortex forms barrels when invaded by axons from somatosensory thalamic nuclei, and genetic manipulations that interfere with the appropriate segregation of these axons disrupt barrel formation. Moreover, that sensory peripheral sensory signals may be instructive in sculpting the somatosensory cortical map is also evidenced by lesion or genetic studies showing that altering the number of functioning whiskers leads to shrinkage, expansion, or addition of barrels. However, such aberrant barrel formation may result from sprouting and retraction of afferents and dendrites due to neuronal degeneration and alteration in the number of afferents, involving competitive synapse formation, rather than activity-dependent synaptic competition. Notably, changes in whisker use drive functional changes in the barrel neurons without affecting anatomical appearance of barrels, suggesting no gross reorganization of synaptic connections. Nevertheless, sensory deprivation results in a specific loss of GABAergic synapses and impairment of secondary dendritic branches in the barrel cortex. Thus, activity may lead to synapse elimination of at least a subset of synapses in the somatosensory cortex, presumably through a competitive process.

Auditory System

Sound entering the ear stimulates cochlear hair cells, which make synaptic connection with spiral ganglion cells that give rise to the primary auditory nerve for carrying auditory information into the brain stem. From there the signals converge in the inferior colliculus that sends projections to the thalamus, which further relays auditory signals to the auditory cortex. In these relay areas, neurons are arranged in a topographic manner according to the sound frequencies to which they are most sensitive. Although the topography of these connections is apparent early in development, the precision of the map is refined later in development through an activity-dependent process.

Developmental pruning of both axonal arbors and dendritic branches has been widely observed in the auditory system. Cochlear nerve axons and their target neurons in nucleus magnocellularis (NM) undergo extensive parallel structural transformations involving pruning of cochlear axonal arbor, massive reduction of dendrites in NM neurons, and elimination of polyneuronal innervation. Since otocyst removal has no effect on the extent, timing, and pattern of dendritic loss, this extensive synapse elimination is independent of the sensory activity. Interestingly, after this early massive remodeling, NM neurons undergo further dendritic growth before maturation in a sensory activity-dependent manner.

In contrast to that in the NM, developmental remodeling of axons and dendrites in the nucleus laminaris and superior olivary nucleus (SON) after the onset of hearing appears to be activity dependent. Cochlea removal or blockade of glycinergic transmission impairs remodeling of axonal and dendritic morphology in SON. Since most of the remodeling occurs after the onset of hearing, acoustically evoked activity is likely to be involved, although spontaneous activity may also contribute. Indeed, correlated spontaneous activity is present in the embryonic brain stem and auditory nerve. The spatiotemporal pattern of spontaneous firing could provide developmental cues for the spatial ordering of auditory projections, as suggested by the presence of a systematic relationship between the rate of rhythmic bursting and the tonotopic location in the chick. Such activity-dependent remodeling of connectivity may contribute to the tonotopic map refinement at many different levels in the auditory system.

After the onset of hearing, the auditory cortex undergoes a transition from a tonotopic map dominated by broadly tuned, high-frequency-selective neurons to the adult tonotopic map consisting of neurons that represent the full spectrum of acoustic inputs. Sensory-evoked activity is responsible for this transition. Early acoustic environment is critical for the maturation of tonotopic maps, because exposing rat pups to pulsed white noise or rearing them in continuous moderate-level noise impairs the emergence of adultlike tonotopic map, whereas exposure to pulsed tones of specific frequencies results in accelerated emergence and expansion of auditory cortex representations of those frequencies. This activity-dependent remodeling of cortical maps is likely to involve synaptic competition and elimination, although whether functional refinement of the map directly reflects structural reorganization of synaptic connectivity remains to be determined.

Olfactory System

The olfactory sensory neurons in mammals express only one of about 1000 odorant receptor genes, and neurons expressing a given receptor are randomly dispersed within one of four broad zones in the olfactory epithelium. The axons of these sensory neurons converge upon spatially conserved glomerulus within the olfactory bulb. The topographic mapping between sensory neurons and specific glomeruli may depend on the expression of specific molecules along their projection pathways or in themselves. There is evidence, however, that activity in these olfactory neurons may also play a role. Although the patterns of axon convergence in the bulb are largely intact in mice lacking functional olfactory cyclic nucleotide-gated channels, hence no odorant-evoked activity occurs in these neurons, noncorrelated spontaneous activity may still be required for the correct mapping process. Indeed, sensory map is not affected when conditional expression of tetanus toxin light chain inhibits synaptic transmission in the majority of olfactory sensory neurons. However, inhibition of synaptic release in a small subpopulation of neurons expressing the P2 receptor results in correct targeting of the sensory axons initially, but the P2 glomerulus is not maintained and P2 neurons ultimately diminish. Preventing excitation of the neuron has a similar effect on the formation of the olfactory map. Thus, spontaneous neuronal activity may play a role in pruning or stabilization of axon terminals of olfactory neurons on their glomerular target cells, but there is little evidence that synaptic competition is involved in olfactory map formation.

Cerebellum

The two main afferent systems in the cerebellar cortex are the climbing fibers (CF) originating from the inferior olivary nucleus and the mossy fibers (MF) from various nuclei in the spinal cord, brain stem, and deep cerebellar nuclei. Each CF directly contacts the proximal dendritic compartment of a single Purkinje cell (PC), whereas the MFs influence PCs indirectly through granule cells, whose axons form the parallel fibers (PFs) that synapse onto the dendrites of many PCs. There is evidence for a complex topographic map of these afferents fibers. For example, cutaneous inputs carried by CFs are topographically organized to form a map of peripheral body, with CF axonal arbors in register with cortical parasagittal bands of chemically heterogeneous PCs. The formation of these precise topographic maps

involves both activity-independent and dependent steps. First, positional information shared between CFs and PCs during embryonic development provides the molecular code for the formation of coarse-grained maps independent of neuronal activity. Activity-dependent mechanisms are later required for the transition to a fine-grained map, by pruning CF terminal arbors on each PC from multiple to single CF innervation. This pruning involves strengthening one CF while weakening all other CFs during the first postnatal week, leading to the elimination of the latter. Moreover, alteration of the temporal pattern of CF activities specifically during development impairs such CF elimination *in vivo,* suggesting an activity pattern-dependent synaptic competition.

In addition to potential competition among homologous CFs, there is also heterologous competition between CFs and PFs that results in their segregation into different dendritic domains of each PC. Weakening of the CF input leads to the reduction of its dendritic territory and concomitant strengthening and expansion of the PF input, and vice versa. Furthermore, elimination of CFs depends on the activity of developing PF–PC synapses, because CF elimination is affected by reducing PF inputs, through granule cell degeneration, impairment of granule cell function, or genetic manipulation of PF–PC synapse formation or efficacy. The similarity in the consequence of reducing CF and PF activities in CF elimination suggests that similar mechanisms may underlie synaptic competition/elimination among homologous versus heterologous inputs.

Autonomic Ganglia

Ganglionic cells in the autonomic nervous system are innervated by preganglionic neurons of the spinal cord or brain stem and send projections to target tissues via spinal nerves to control involuntary functions of the body. In mammals, characteristic patterns of sympathetic and organ responses elicited by the activity of individual spinal axons are due to mapping between specific spinal segments and peripheral targets. This mapping requires a stereotyped and selective innervation of ganglion cells by preganglionic axons, with each ganglion cell innervated by one or few axons from specific contiguous spinal cord segments. During development there is a transition from initially exuberant innervation of each ganglion cell by many preganglionic axons to innervation by only one or a few axons. Since the spinal segment responsible for activating the mature and neonatal ganglion cell is the same, developmental synapse elimination involves reduction of preganglionic axons from the same spinal segment, suggesting competition occurs among axons of nearby spinal neurons. Furthermore, transection of a portion of preganglionic nerve innervating a developing ganglion leads to sprouting of residual preganglionic axons and partial restoration of original multiplicity of innervation. These results are all consistent with the idea that synaptic elimination is not simply due to the intrinsic merit of the input, but involves competition among inputs, presumably for a postsynaptic factor of limited supply, for example, locally secreted trophic factor.

The competitive interaction that determines the final number of preganglionic axons converging upon a single ganglion cell depends on the proximity of competing synapses, with each surviving synaptic terminal claiming a certain territory on the dendritic or somatic surface and neurons with more extensive dendritic arbors receiving more axons. This distance-dependent synapse competition can be explained by a limited amount of available postsynaptic factors. This synapse competition appears to be activity dependent, because among converging inputs to a single ganglion neuron, strong synapses become further strengthened and weak synapses further weakened during synapse elimination. Moreover, the synaptic strength for each synaptic input of a multiply innervated cell is, on average, weaker than that of a singly innervated cell, suggesting that the total synaptic strength of a postsynaptic ganglion cell is conserved, due to a limited amount of a synapse-related factor.

Neuromuscular Junction

Each muscle fiber in the neonatal animal is multiply innervated by axon collaterals of several motor neurons, but becomes singly innervated during early postnatal life. This process depends on synapse elimination involving withdrawal of a subset of nerve terminals of each motor neuron innervating a given muscle (i.e., reduction of the size of motor units) rather than reduction in the number of motor neurons innervating a muscle. Partial denervation of the muscle at birth results in the retention of the large motor unit size without substantial collateral motor axon sprouting. Synapse elimination is competitive rather than a random process of withdrawal, since muscle fiber without a single axon is never observed. The elimination is also activity dependent. Blocking motor neuronal activity prevents elimination, while elevating activity accelerates it. Importantly, when the relative synaptic efficacy of two competing axons at a single neuromuscular junction is impaired by genetic deletion of acetylcholine in one axon, the latter loses the competition, suggesting that the strength of the synapse is predictive of the outcome of the competition.

Mechanisms of Activity-Driven Synapse Competition

The Hebb's Rule for Synapse Competition

Hebb postulated that strengthening of a synapse might be achieved by repetitive presynaptic activation that leads to postsynaptic firing. This postulate was later transformed into a simple rule – coincident pre- and postsynaptic activity leads to synapse strengthening and stabilization. To account for the finding of Hubel and Wiesel on activity-dependent remodeling of connectivity in the developing visual system, Stent further extended the Hebb's rule by assuming that noncoincident pre- and postsynaptic activity leads to synapse weakening and elimination. Modeling studies showed that such correlation-based Hebb's rule could explain activity-dependent refinement of developing visual circuits. In the past decade, a temporally specific form of Hebb's rule has been proposed, based on findings of spike-timing-dependent synaptic plasticity in a variety of systems. The temporal order in the spiking of pre- and postsynaptic neurons was shown to be critical for synaptic modification, in addition to the extent of coincidence in spiking: 'Pre-before-post' results in strengthening, and 'post-before-pre' leads to weakening of the synapse. This spike-timing-dependent plasticity offers an element of causality in the activity-induced synaptic competition: inputs that contribute to (and cause) the postsynaptic spiking are advantageous in synaptic competition over those inputs arriving after postsynaptic spiking has just occurred. Importantly, experimental evidence for the validity of various forms of the Hebb's rule mainly came from studies of activity-induced functional changes of synaptic efficacy, for example, long-term potentiation (LTP) or long-term depression (LTD), rather than changes in the morphological connectivity.

Importance of Temporal Pattern of Activity

The importance of the pattern of activity in synapse competition has been demonstrated mainly in the development of ocular dominance and orientation selectivity of the primary visual cortex. Rearing kittens with induced squint (strabismus), which alters the pattern but not the absolute level of activity, results in striking changes in the binocular property of cortical cells, reflecting altered synapse competition of geniculocortical inputs. Artificially imposing synchronous activity on optic nerves from the two eyes prevents segregation of thalamocortical projections into ODCs, whereas asynchronous activity allows segregation. Similarly, synchronous activation of optic nerves blocks the development of topographic maps in the optic tectum and reduces orientation selectivity in the cortex. Spike-timing-dependent synaptic modification provides a natural basis for such pattern-dependent competition. In the developing *Xenopus* visual system, spike-timing-dependent induction of LTP and LTD has been demonstrated, but whether such persistent changes in functional efficacy of synapse is causally related to structural changes in connectivity remains unknown.

Contribution by GABAergic Inhibition

Activity in the brain depends on a proper balance of excitation and inhibition. It is thus not surprising that GABAergic activity plays a regulatory role in the refinement of developing circuits. In mice lacking one form of the enzyme (GAD65) responsible for GABA synthesis, the ocular dominance plasticity resulting from monocular deprivation is absent, and increasing GABA inhibition in diazepam-treated mutant mice allows the appearance of ocular dominance plasticity. In the developing retinotectal system, a proper level of GABAergic inhibition is required for normal refinement of the retinotopic map in the tectum, both the increase and decrease of inhibition impede map refinement. Interestingly, the role of GABAergic inhibition appears not only to reduce the overall neuronal excitation, but also to sharpen the temporal pattern of the neuronal activity by shortening stimulus-evoked discharges, potentially facilitating spike-timing-dependent refinement of neural circuits. Shunting of specific excitatory inputs may also be achieved by selective distribution of inhibitory synapses on the dendrite. Finally, inhibitory synapses may also undergo competition and refinement as well, because they are integral part of the neural circuit. At present, it is unknown how nascent inhibitory connections, while playing important regulatory roles in refining excitatory connections, can themselves undergo activity-driven refinement and be properly consolidated into the mature circuit.

Causal Link between LTP/LTD and Synapse Competition

At some synapses repetitive coactivation of the pre- and postsynaptic cell leads to not only homosynaptic LTP, but also heterosynaptic LTD of non-coactive converging synapses onto the postsynaptic cell, thus providing a potential competitive mechanism for synaptic elimination. The hypothesis that synapse stabilization and elimination are mechanistically linked to or even result from activity-induced LTP and LTD, respectively, remains to be fully tested. Many lines of correlative evidence support this hypothesis. Blocking NMDA receptor activation, which abolishes many forms of LTP/LTD, impedes refinement of developmental circuits.

Repetitive visual stimuli that modify developing visual circuits can induce NMDA receptor-dependent LTP/LTD of retinotectal synapses. During the postnatal critical period, the composition of NMDA receptors undergoes experience-dependent developmental regulation in the visual system, and there is a correlation between the susceptibility for LTP/LTD induction and for circuit refinement. However, whether LTP/LTD is relevant or a prelude to structural refinement in the visual system remains unknown. Synapse elimination (structurally) will certainly eliminate the synaptic function, but whether LTD will lead to synapse elimination is unclear. Recent studies in hippocampal slices has provided evidence that LTP/LTD induction is followed by a swelling/shrinkage of dendritic spines, supporting the linkage between synaptic efficacy and synaptic structure.

The Trophic Factor Hypothesis

Purves and Lichtman have proposed that synaptic competition involves the competition between co-innervating presynaptic terminals for a limited amount of 'trophic factors' derived from the postsynaptic cell. This hypothesis can be extended to factors in the postsynaptic cytoplasm or plasmalemma, together with a localized retrograde signaling to the presynaptic nerve terminal. Competition for the trophic factor can be regulated by activity. The activity can serve a permissive role for synapse competition by regulating the synthesis and release of trophic factors/retrograde signals, whereas other activity-independent mechanisms determine the competitive advantage of a synapse. For activity to serve an instructive role, the pattern of activity in the co-innervating nerve terminals may determine the outcome of competition by controlling the uptake or the efficacy of the trophic factor at the nerve terminal. The local release of trophic factors may also depend on local synaptic activation, which is in turn driven by the pattern of activity, including the timing of pre- and postsynaptic spiking. The neurotrophin family of proteins, which are known to regulate synaptic function and axon/dendrite morphology, are attractive candidates for the trophic factor in synapse competition. The expression and secretion of neurotrophins, and their potentiating actions on the synapse, are all activity dependent. Neurotrophins are required for the development of ODC and for the induction of activity-induced LTP in several systems. Furthermore, neurotrophin secretion is activity pattern dependent, and the secreted neurotrophins are likely to act locally by its binding to cell surfaces at the synapse, allowing them to serve as local synaptic modulators. Activity-dependent depletion of available neurotrophins in the local environment of the synapse may lead to the functional and structural modification underlying synapse elimination.

Concluding Remarks

Studies of synapse competition and elimination in the near future are likely to be facilitated greatly by the availability of many new technologies for selective neuronal labeling and optical imaging in the living animal. Transgenic animals with selective populations of fluorescence-tagged neurons, together with *in vivo* multiphoton imaging, will allow us to directly monitor changes in the morphology of axons and dendrites during the process of synapse competition and refinement over prolonged period in the intact brain. Fluorescent Ca^{2+} or membrane-voltage sensors will allow us to monitor neuronal activities, and photo-activated probes expressed in selective neuronal populations will allow us to directly manipulate neuronal activity and to examine how activity drives synapse competition and elimination.

Introduction

More than 90% of neurotransmission in the brain occurs at synapses via fast Ca^{2+}-regulated exocytosis of small synaptic vesicles. Synaptic vesicles are relatively stable and do not randomly fuse with the plasma membrane, other organelles, or each other. Instead, they undergo tightly controlled fusion with a specialized area of the plasma membrane called the active zone. After exocytosis, synaptic vesicles are locally reformed via multiple endocytic pathways and reused for subsequent rounds of fusion. Although uniform in size and shape, synaptic vesicles are not functionally equal. At many synapses, they appear to be organized in discrete pools that release neurotransmitters with vastly different probabilities. Thus, rapid recruitment of synaptic vesicles from the reserve pool to the readily releasable pool enables synapses to adapt to a broad range of activities. Molecular mechanisms that govern the size and maintenance of synaptic vesicle pools are not well understood. Extensive studies during the past 30 years suggest that a family of abundant synaptic phosphoproteins called synapsins participates in maintaining stability and pool organization of synaptic vesicles.

Structure of Synapsins

Synapsins are an evolutionary conserved protein family found in most species throughout the animal kingdom, ranging from *Caenorhabditis elegans* to humans. In invertebrates, a single gene for synapsin has been identified. Most vertebrate species contain three synapsin genes, termed I, II, and III. Each synapsin gene appears to include a nested gene for tissue inhibitor of metalloproteinases.

The mRNAs transcribed from synapsin genes are alternatively spliced at the 3′ ends. In mammals, alternative splicing gives rise to two isoforms for each synapsin I and II: the long forms, called synapsins Ia and IIa, and the short forms, called synapsins Ib and IIb. For synapsin III, only the long IIIa isoform has been characterized. However, analysis of gene organization and mRNA transcripts in humans indicates that at least six different synapsin III isoforms may be present.

Sequence comparison reveals that all synapsins consist of an assortment of conserved and variable domains (Figure 1). The first 400 amino acids of all synapsins form three signature domains: a short conserved domain A; a variable domain B that is enriched in prolines, serines, and glycines; and a large highly conserved domain C. The C-terminal parts of synapsins are highly divergent and contain a variety of short domains from D to J (Figure 1). The only domain shared by all three synapsins in this area is domain E, found at the C-termini of synapsins Ia, IIa, and IIIa.

The three-dimensional structure of the largest and most conserved domain in synapsins, domain C, has been determined (Figure 2). Domain C shows remarkable structural similarity to a family of bacterial ligases and synthetases, suggesting that synapsins may be adenosine triphosphate (ATP)-utilizing enzymes.

All synapsins contain several conserved and isoform-specific phosphorylation consensus sites for multiple protein kinases. Domain A in all synapsins carries a phosphorylation site for protein kinase A (PKA) and CaM kinase I/IV. Domain C contains a single conserved site for tyrosine kinase Src. In addition, domains B and D in synapsin I contain multiple sites for MAPK, cdk1, cdk5, and CaMK II kinases.

Expression and Localization of Synapsins

Synapsins are abundant proteins expressed primarily in the brain. Synapsins I and II are expressed at the highest levels and are specifically localized to presynaptic terminals, whereas synapsin III is expressed at very low levels and is also found in cell bodies and growth cones. Synapsins are present at most synapses, with the notable exception of ribbon synapses, and show isoform-specific differential distribution. Synapsin II appears to be relatively enriched in excitatory glutamatergic synapses, whereas synapsin I is more abundant at inhibitory GABAergic synapses. At presynaptic terminals, synapsins dynamically associate with the surface of synaptic vesicles and constitute approximately 9% of total synaptic vesicle protein (~15–20 synapsin molecules per vesicle).

Biochemistry of Synapsins

Synapsins bind to synaptic vesicles with nanomolar affinities. This interaction may occur via binding to lipids, proteins, or a combination of both. *In vitro*, synapsins show saturable binding to synthetic vesicles containing negatively charged phospholipids and are able to stabilize phospholipid bilayers. The N-terminal

Figure 1 Domain organization of the five synapsins. Domains are color coded and labeled on top. Amino acid residue scale is shown below.

Figure 2 Ribbon diagram of the complex of the rat synapsin I domain C complexed with ATP and calcium (PDB entry 1PX2).

domain A appears to be responsible for the electrostatic interaction between synapsins and phospholipids. In addition, the central domain C may mediate hydrophobic protein–lipid interactions.

A plethora of protein interactions for synapsins have been identified *in vitro*. These include components of cytoskeleton (actin and actin filaments, spectrin, microtubules, and neurofilaments), scaffolding proteins (Grb2), lipid-binding proteins (annexins), and protein kinases (c-src and CaM kinase II). Synapsins also bind each other and form stable homo- and heterodimers and tetramers via the domain C. However, the *in vivo* significance of these protein interactions is not clear.

The three-dimensional structure of the domain C resembles that of a family of ATP-utilizing enzymes (Figure 2). Domain C in all synapsins binds ATP with low micromolar affinity (0.15–0.45 μM) and forms a stable complex with ATP and calcium. Surprisingly, ATP binding to synapsins is regulated by calcium in an isoform-specific manner. At low micromolar concentration, calcium facilitates ATP binding to the domain C of synapsin I, has no effect on ATP binding to synapsin II, and inhibits binding of ATP to synapsin III. Synapsins have no detectable ATPase activity *in vitro*. The function of ATP binding to domain C in synapsins is unknown. It has been proposed that synapsins can be ATP-dependent enzymes or ATP sensors at synapses.

Synapsins are phosphorylated *in vivo* and *in vitro* by multiple protein kinases and are major substrates for PKA in brain. Phosphosynapsins show altered biochemical properties and synaptic localization, suggesting that phosphorylation may play an important regulatory role. Phosphorylation by PKA at the conserved site within the lipid-binding domain A appears to cause dissociation of synapsins from synaptic vesicles and accumulation of phosphosynapsins in the cytosol. Interestingly, electrical or chemical stimulation of synapses increases both phosphorylation of synapsins and their dissociation from synaptic vesicles. Thus, the association of synapsins with synaptic vesicles may be dynamically regulated by phosphorylation at the single conserved site. Phosphorylation of synapsins often change their conformation and the apparent affinity of interactions with other proteins. For example, synapsin I that is phosphorylated by CaM kinase II within domain D displays significantly reduced binding to actin.

Functions of Synapsins

Several approaches have been used throughout the years to test functions of synapsins in the regulation of neurotransmitter release. Injection of the whole synapsin I (but not the CaM kinase II phosphorylated synapsin I) into presynaptic terminals inhibits neurotransmitter release. Furthermore, injection of anti-synapsin antibodies or peptides derived from domain E into lamprey reticulospinal axons or giant squid synapses results in depletion of synaptic vesicles away from the plasma membrane but has no effect on the number of docked vesicles. Injected nerve terminals show normal activity under low-frequency stimulation but are rapidly depressed upon high-frequency stimulation. These results combined with several biochemical observations have led to a model proposing that synapsins reversibly cross-link synaptic vesicles to each other and to cytoskeletal elements at synapses, and they regulate their availability for exocytosis. In this model, phosphorylation of synapsins performs a crucial regulatory role by affecting interactions of synapsins with phospholipids and cytoskeletal proteins.

Further evidence for an important role of synapsins in regulating neurotransmitter release is derived from mouse genetic experiments. Mouse lines lacking synapsins I, II, and III individually and double or triple

knockout lines have been described. All knockout mice are viable, fertile, and show no gross morphologic abnormalities. In addition, mice have no apparent change in life span and exhibit a range of normal complex behaviors, suggesting that synapsins are not required for general brain functions such as synaptogenesis or axonal transport. Of all generated lines, synapsin I and II double knockout mice display the strongest abnormalities in synaptic functions. These animals and also single synapsin I and II but not synapsin III knockouts develop frequent epileptoid seizures precipitated by sensory stimuli. The size and density of synapses and active zones in double knockout mice are normal; however, the total number of synaptic vesicles per synapse is reduced by more than half. The remaining synaptic vesicles still form clusters at the release sites. The levels of many intrinsic synaptic vesicle proteins, such as synaptotagmin I, synaptophysin I, and synaptobrevin II, are also reduced in the double knockout line, suggesting that synapsins may be important for the stability of synaptic vesicles. The reduction in synaptic vesicle density appears to be uniform both away from the plasma membrane and in the areas close to the active zone. In electrophysiologic tests, double knockout mice exhibit normal neurotransmitter release under low-frequency stimulation and normal paired pulse facilitation. Thus, synapsins are not required for synaptic exocytosis as such, and they do not significantly modify the release probability of synaptic vesicles at the active zone. However, repetitive high-frequency stimulation of synapses lacking synapsins I and II reveals a severe defect in their ability to sustain high levels of activity. For example, a form of short-term plasticity, posttetanic potentiation, is significantly decreased in these knockouts, and synaptic depression is drastically increased. High-resolution electrophysiological studies of neurotransmitter release at the calyx of Held synapse by direct capacitance measurements did not uncover any defects in spontaneous or single action potential evoked release in the mutants. However, use-dependent synaptic depression induced by high-frequency stimulation was increased in a CaM kinase II-dependent manner. The contribution of synapsin III to these phenotypes is insignificant and the function of synapsin III remains unknown.

Conclusions

Synapsins are a family of abundant evolutionary conserved phosphoproteins found at nearly all synapses in the nervous system. At presynaptic terminals, they reversibly associate with the surface of synaptic vesicles and presumably with cytoskeletal proteins such as actin. These interactions of synapsins are regulated by phosphorylation at multiple sites. A combination of functional and genetic approaches established that synapsins are not essential constituents of the synaptic vesicle cycle. Instead, they appear to regulate the maintenance of the reserve vesicle pool and recruitment of synaptic vesicles from the reserve pool to the readily releasable pool. Synapsins appear to boost the release probability at the synapses under high-frequency stimulation. Thus, synapsins may be especially important for synapses that undergo rapid changes in their levels of activity. The molecular mechanisms by which synapsins exert their action are not fully understood. In particular, it is not clear whether synapsin isoforms generated by alternative splicing have similar or different functions at the synapse. The discovery of the structural homology between synapsins and a family of ATP-utilizing enzymes raises an intriguing possibility that synapsins may have enzymatic functions at the synapse or their function may be regulated by ATP. Future functional studies on synapsins will address these questions.

Neurotransmitter Release Depends on Several Pools of Synaptic Vesicles

Presynaptic terminals rely on a complex cycle of membrane trafficking to release neurotransmitters. After synaptic vesicles (SVs) are synthesized, they undergo repeated cycles of fusion (exocytosis) and subsequent retrieval (endocytosis) within the presynaptic terminal. SVs apparently are not equivalent and can be divided into pools on the basis of the ease with which they undergo exocytosis in response to neuronal activity. One fraction of the SVs is easily mobilized for release, and this fraction is defined as the recycling pool. At most synapses, SVs released from the recycling pool return to this pool after endocytosis, in effect retaining their status. Within the recycling pool, a subgroup of SVs is docked at the plasma membrane at the active zone, poised and ready for fusion with the membrane. Such SVs require no (or minimal) additional molecular adjustments to fuse once an action potential arrives; they constitute the readily releasable pool (RRP) of SVs. Essentially, the RRP is the source of SVs for exocytosis. As its members fuse with the plasma membrane, they are replaced from the recycling pool.

During periods of intense synaptic activity, when demand for transmitter-laden SVs exceeds the supply available in the recycling pool, SVs are mobilized from a reserve pool (RP), where the majority of SVs in the terminal reside. Vesicle mobilization occurs through a poorly defined mechanism that senses synaptic activity. This requirement for activity effectively segregates the RP SVs into a separate pool. Recent results indicate that in many synapse types, the RP and the recycling pool (but not the RRP) are not spatially segregated, suggesting that the division of the SVs into pools is determined by molecular identity rather than by spatial location.

The organization of SVs into pools and their mobilization from the RP to the RRP allows neurons to release neurotransmitters even when the rate of release exceeds the rate at which SVs are recycled. Because the integrative properties of synaptic transmission depend on the dynamics of neurotransmitter release from the presynaptic terminal, it is important to understand the molecular origins of the partitioning of SVs into pools, the spatial manifestation of this division, and the interplay between these vesicle pools. This article concentrates on the role that the synapsins play in controlling SV dynamics.

Synapsins Are a Family of Phosphoproteins Found on SVs

In the 1970s, synapsins were identified by Paul Greengard and colleagues as the most abundant phosphoproteins in the brain. Originally termed 'protein I' and 'protein III,' they were later renamed synapsin I and synapsin II. We now know that there are three mammalian synapsin genes, named synapsin I, II, and III. Each of these genes is subject to alternative splicing, producing at least ten isoforms: synapsins Ia, Ib, IIa, IIb, IIIa, IIIb, IIIc, IIId, and the atypical IIIe and IIIf. The synapsin isoforms arise from the combinatorial arrangement of numerous domains (Figure 1). The N-terminal portion of the synapsins is highly conserved and consists of domains A, B and C, whereas the C-terminal portion is variable because of heterogeneous combinations of domains D–J.

Synapsins are expressed throughout the central and peripheral nervous systems, although their expression varies across synapse types and brain regions. In contrast to synapsins I and II, which are stably expressed in adult presynaptic terminals, synapsin III expression is developmentally controlled and is not confined to synaptic terminals.

Synapsins are associated with SVs and exhibit many intriguing biochemical properties. They are peripheral proteins of SVs that bind to both the membrane phospholipids and the protein constituents of the SV. Synapsins also bind to cytoskeletal elements, such as actin, tubulin, and spectrin, and it is thought that these connections between SVs and the cytoskeleton may be important for the functioning of synapsins. As already mentioned, synapsins are the most abundant phosphoproteins in the brain and serve as substrates for several protein kinases, including protein kinase A (PKA), calcium/calmodulin dependent protein kinase type I (CaMKI), CaMKII, and mitogen-activated protein (MAP) kinase. Phosphorylation by CaMKII and PKA causes synapsins to dissociate from SVs. Synapsins also interact with other cellular signaling elements, such as phosphatidylinositol 3-kinase and regulators of G-protein signaling. Synapsins bind to adenosine triphosphate (ATP) and

Figure 1 Domain structure of the ten known isoforms produced by the three synapsin genes.

have structural similarities to ATP-utilizing enzymes; this suggests that synapsins may possess an as yet unidentified enzymatic function.

Synapsins Regulate SV Trafficking

Several lines of research have investigated the functional role of synapsins in intact synapses. Their role in synaptic transmission has been examined in mice in which some or all synapsins have been deleted, in synapses where synapsin function was disrupted by injection of inhibitory peptides, and in synapses into which purified synapsins were injected. Such treatments produce varied effects on neurotransmitter release, on short-term synaptic plasticity, and/or on the distribution of SVs in terminals. Although the results of these studies present a complex – and at times contradictory – picture of the role played by the synapsins, several consistent themes have emerged. First, synapsins have been shown to control the number and distribution of SVs within presynaptic terminals, in most cases predominantly affecting SVs far from the active zone. This suggests that synapsins maintain SVs in the RP. Second, synapsins have been shown to help sustain synaptic transmission during intense stimulation, also consistent with a role in maintaining the RP. In some synapses, synapsins also appear to regulate fusion of SVs not originating in the RP. Other roles for synapsins have been proposed, including regulation of fusion kinetics, stabilization of SVs, and/or regulation of late steps of endocytosis. Synapsins also have been implicated in neuronal development, synaptogenesis, and maintenance of mature synapses.

Deletion of individual synapsin genes in mice causes varied effects on synaptic transmission. Synaptic depression, a form of plasticity that requires mobilization of SVs from the RP, is not affected by deletion of the synapsin I gene but is accelerated by loss of synapsin II and is slowed by deletion of synapsin III. Since synapsins may have redundant functions, deletion of a single gene does not define its physiological roles because the remaining synapsins may compensate for its loss. In addition, deleting individual genes does not define the importance of the various isoforms produced from each gene by alternative splicing. Thus, deleting all three synapsin genes was a necessary starting point in defining the roles that synapsins play in synaptic function.

Synapsin-Deficient Mice Are Viable

Synapsin triple knockout (TKO) mice were generated by crossing preexisting lines of mice harboring null mutations in single synapsin genes. To serve as a genetically similar control, a line of matching wild-type mice, termed synapsin 'triple wild-type' (TWT) mice, was derived in parallel. The synapsin TKO mice have a normal life span and are fertile, though to a lower degree than the TWT mice. The TKO mice do not express obvious signs of morbidity, except for transient, mild seizures. Thus, synapsins are not 'essential' genes. Gross brain morphology is not affected noticeably by deleting the synapsins, indicating that these proteins do not play a crucial role in the development of the nervous system. However, synapsin TKO mice have various deficiencies in basic neurophysiological performance, such as muscle strength, posture, and reflexes. In addition, the mice show impairments in learning and memory tests, as exemplified by defects in performance in the radial arm maze and the Morris water maze.

Synapsins Regulate the Dynamics of Glutamatergic Synaptic Transmission

To determine the role of synapsins in synaptic function, properties of synaptic transmission have been compared in TKO and TWT neurons, mainly in hippocampal neurons grown in cell culture. The ability of synapsin TKO neurons to form synapses in culture did not differ from that of TWT neurons, which allows any differences in synaptic transmission to be attributed to changes in the properties of release from individual synapses rather than changes in the number of synapses.

The role of synapsins in release of glutamate from pyramidal neurons, the main type of neuron in the hippocampus, has been studied by using stimulation paradigms that report on the properties of the RRP and RP. Spontaneous transmitter release and release

Figure 2 Characteristics of glutamatergic neurotransmission in cultured synapsin triple wild-type (TWT) and synapsin triple knockout (TKO) neurons. (a) Excitatory postsynaptic currents (EPSCs) recorded from cultured glutamatergic autaptic neurons. (b) Mean amplitudes of evoked EPSC of TWT and TKO neurons are not different. (c) Representative traces of spontaneous EPSCs in TWT and TKO neurons. (d) Mean quantal content of EPSCs is not different between TWT and TKO neurons. From Gitler D, Takagishi Y, Feng J, et al. (2004) Different presynaptic roles of synapsins at excitatory and inhibitory synapses. *Journal of Neuroscience* 24: 11368–11380.

evoked by single stimuli draw SVs from the RRP. In contrast, long trains of stimuli elicit synaptic depression, which results from the depletion of SVs from the RRP and the recycling pool, resulting in the mobilization of SVs from the RP.

Properties of synaptic transmission that are related to the size of the RRP – such as the amplitude of evoked excitatory postsynaptic currents (EPSCs; Figures 2(a) and 2(b)), the frequency of spontaneous EPSCs (Figure 2(c)), and the quantal content of evoked EPSCs (Figure 2(d)) – are not different in TKO and TWT neurons. This indicates that loss of synapsins does not affect the RRP of glutamatergic neurons. In addition, stimulation with pairs of stimuli elicits synaptic facilitation that is similar in TKO and TWT neurons, suggesting that synapsins do not affect the probability of release from the RRP.

On the other hand, the rate of synaptic depression is accelerated by the deletion of synapsins (Figures 3(a) and 3(c)). It is important to note that the difference between TWT and TKO neurons is evident only after the neurons have been stimulated 30 or more times (Figure 3(b)), a point at which the synaptic terminal has released most of its RRP. Thus, it appears that the RP of glutamatergic SVs is reduced in the TKO neurons. To quantify the number of exocytotic events evoked during such stimuli, the total amount of synaptic charge produced during the stimulus train can be calculated by integrating

Figure 3 (a) Representative traces showing every 15th excitatory postsynaptic current (EPSC) evoked by a 10-Hz train of stimuli in synapsin triple wild-type (TWT) and synapsin triple knockout (TKO) neurons. (b) Mean EPSC amplitudes during the 500-event trains. Symbols represent EPSC amplitudes normalized to the first response in the train, and every 15th response is plotted. (c) Mean time constants for synaptic depression in TWT and TKO neurons. (d) Cumulative EPSC charge transfer in TWT and TKO neurons. each individual synaptic response (Figure 3(d)). TKO neurons generate much less synaptic charge than TWT neurons do, indicating that loss of synapsins approximately halves the number of SVs mobilized from the RP (Figure 3(e)).

Deleting Synapsins Reduces the Number of SVs

These electrophysiological indications of defects in the RP of TKO neurons can be correlated with other approaches that examine the number and distribution of SVs within presynaptic terminals. For example, the relative quantities of SV proteins (synaptobrevin 2, synaptotagmin I, and synaptophysin I) are reduced in brains from TKO mice, while representative postsynaptic proteins (PSD95 and *N*-methyl-D-aspartate receptor subunits NR1 and NR2B), structural proteins (β-tubulin), and presynaptic plasma membrane proteins (syntaxin I) are not affected. This indicates a specific reduction in the amount of SV proteins in the terminals of TKO mice, consistent with a loss of SVs as a consequence of synapsin deletion.

The density of SVs can also be assessed in live neurons by examining the localization of fluorescently tagged synaptobrevin 2, an integral protein of the SV membrane. Fusing this protein to the green fluorescent protein (GFP) permits visualization of SV clusters in individual presynaptic terminals of cultured neurons. The relative amount of GFP–synaptobrevin 2 in presynaptic terminals is significantly reduced in TKO neurons, again consistent with a reduction in the number of SVs.

Finally, electron microscopy can be used to determine the absolute number and spatial distribution of SVs (Figure 4(a)). Quantitative analysis reveals that TKO terminals have approximately half as many SVs as TWT neurons do (Figure 4(e)). Analysis of the spatial distribution of SVs shows that there is a specific reduction in the number of the SVs located far from the active zone in TKO neurons (Figures 4(b) and 4(c)), although the number of SVs docked at the presynaptic active zone – which presumably includes (and may comprise) the RRP – is unchanged (Figure 4(d)). Thus, several lines of evidence indicate that the absence of synapsins causes the RP to be diminished. This leads to the conclusion that synapsins maintain SVs in the RP, accounting for the observation that TKO neurons cannot maintain glutamatergic transmission during periods of intense synaptic activity.

(2004) Molecular determinants of synapsin targeting to presynaptic terminals. *Journal of Neuroscience* 24: 3711–3720.

Synapsin IIa Maintains the RP of Glutamatergic Vesicles

Although these studies of synapsin TKO mice indicate that synapsins regulate the dynamics of glutamatergic synaptic transmission, it is not clear why so many different isoforms of synapsin exist. Previous experimental approaches using mice in which single synapsin genes are deleted suggest that the three synapsin genes are not equivalent in their ability to support the RP of glutamatergic SVs. However, knocking out entire genes cannot distinguish the roles of the various isoforms generated from each gene. Further, such studies cannot take into account the compensatory influences of remaining synapsin gene products.

TKO mice provide an opportunity to determine the functions of individual synapsin isoforms. On this null background, individual synapsin isoforms can be transfected into cultured TKO neurons, and electrophysiological methods then can be used to examine the effect of the introduced synapsins on synaptic depression. This approach indicates that different synapsin genes are not equivalent in function; indeed even isoforms derived from the same gene differ in their function.

Synapsin IIa slows synaptic depression when expressed in TKO neurons, illustrating that synapsin IIa functions to support the RP of glutamatergic SVs (Figure 5(a)). In contrast, synapsin IIb has no effect on synaptic depression (Figure 5(a)), indicating that isoforms from the same gene are not equivalent in function even though they differ only in their C-terminal tails. In fact, among the several synapsin isoforms that have been examined (synapsins Ia, Ib, IIa, IIb, and IIIa), synapsin IIa is the only one that slows synaptic depression when expressed in TKO neurons. Overexpression of synapsin IIa in TWT neurons also further slows synaptic depression (Figure 5(a)). This result indicates that synapsin IIa can increase the size of the RP. In summary, synapsin IIa apparently is the isoform responsible for the actions of synapsins on the RP of glutamatergic SVs.

Figure 5 Effect of synapsin II isoforms on kinetics of synaptic depression. (a) Normalized excitatory postsynaptic current (EPSC) amplitudes during trains of 500 stimuli delivered at 10 Hz. Shown are mean amplitudes for untransfected synapsin triple wild-type (TWT) and synapsin triple knockout (TKO) neurons, and for TKO neurons transfected with green fluorescent protein (GFP)–synapsins IIa or IIb. Solid lines represent exponential decay curves. (b) As in (a) except data are from control untransfected TWT neurons and from TWT neurons transfected with GFP–synapsin Ib. Syn, synapsin.

Synapsin Ib Serves as a Dominant Negative Isoform

What are the functions of the remaining synapsin isoforms? Hints about the function of synapsin Ib first came from studies of the targeting of synapsins to presynaptic terminals. GFP-tagged versions of any synapsin isoform, including synapsin Ib, properly target presynaptic terminals in TWT neurons. However, in TKO neurons synapsin Ib is not able to target even though other synapsins still target normally (Figures 6(a)–6(c)). This suggests that targeting of synapsin Ib requires the presence of other synapsin isoforms. Previous *in vitro* work shows that synapsin I is capable of dimerizing, either with itself or with synapsin II. Co-transfection of synapsin Ia or synapsin IIa rescues the targeting of synapsin Ib (Figure 6(d)), indicating that targeting of this isoform is mediated by heterodimerization with other synapsin isoforms.

Given that synapsin Ib alone cannot target to presynaptic terminals, it is possible that this isoform could form heterodimers that interfere with the targeting and subsequent presynaptic function of other synapsin isoforms that dimerize with synapsin Ib. This hypothesis has been considered by examining the influence of synapsin Ib on targeting of other synapsins expressed in TKO neurons. Synapsin Ib reduces the targeting of synapsins, particularly targeting of synapsin IIa, the isoform most important for determining synaptic

Figure 6 Synaptic targeting capabilities of synapsins. (a) Green fluorescent protein (GFP)–synapsin Ia and (b) GFP–synapsin IIa localize to presynaptic terminals in cultured synapsin triple knockout (TKO) neurons. (c) GFP–synapsin Ib does not localize to the presynaptic terminals but instead concentrates in the axons of transfected neurons. (d) On co-transfection with yellow fluorescent protein (YFP)–synapsin IIa (red), cyan fluorescent protein (CFP)–synapsin Ib (green) co-localizes (yellow) to presynaptic terminals. Syn, synapsin.

depression kinetics (Figure 7(a)). Likewise, synapsin Ib reduces presynaptic targeting of endogenous synapsins. This was established by immunolabeling TWT neurons with an antibody that recognizes synapsins Ia, IIa, and IIIa yet does not recognize synapsin Ib. Overexpressing synapsin Ib reduces the amount of these endogenous synapsins in the synaptic terminals while causing an uncharacteristic increase in their abundance within axons. Thus, synapsin Ib does interfere with targeting of other synapsin isoforms.

Given that synapsin Ib interferes with the targeting of other synapsins and that reducing the amount of synapsins reduces the size of the RP (in synapsin TKO neurons), it is possible that synapsin Ib reduces the RP. This possibility was examined by evaluating the effect of synapsin Ib on the targeting of GFP–synaptobrevin 2. Synapsin Ib caused a substantial reduction in the targeting of synaptobrevin 2 (Figure 7(b)), indicating that synapsin Ib reduces the size of the RP. To further evaluate this possibility, synapsin Ib has been overexpressed in TWT neurons. In these conditions, synapsin Ib significantly enhances the rate of synaptic depression so that depression kinetics in synapsin Ib-transfected TWT neurons was indistinguishable from that in TKO neurons (Figure 7(c)). Because synapsin Ib has no effect when expressed in TKO neurons, an interaction between synapsin Ib and endogenous synapsins must be responsible for the inhibitory effects of synapsin Ib.

This reduction in the RP seems to be responsible for the acceleration of depression by synapsin Ib because there is a very good correlation between RP size and the rate of depression in neurons expressing synapsin Ib (Figure 7(d)). In summary, synapsin Ib appears to serve as a dominant negative isoform by heterodimerizing with other synapsin isoforms, reducing the targeting of these isoforms and thereby reducing the size of the RP of SVs.

Synapsin Dimerization May Control Synaptic Dynamics

The observations described above suggest that dimerization of synapsins controls the extent of cross-linking of SVs in the presynaptic terminal (Figure 8). This proposal is based on proposed differences in the ability of different synapsin isoforms to cross-link SVs (Figure 8(a)). Synapsin IIa acts as the prototypical synapsin by clustering SVs in the terminals through formation of divalent dimers that can interact with more than one vesicle, either directly with the vesicle or through interactions with cytoskeletal elements. On the other hand, synapsin Ib negates this effect by forming heterodimers with other synapsins that are monovalent for interaction with SVs and thus does not allow cross-linking and vesicle clustering.

This hypothesis predicts that the relative abundance of the synapsin isoforms determines the net behavior of the RP. An increase in the abundance of synapsin IIa will shift the balance toward divalent dimers and thus enlarge the RP and slow synaptic depression (Figure 8(b)). Conversely, a relative increase in synapsin Ib will raise the proportion of

Figure 7 Synapsin Ib interferes with synaptic targeting of other synapsins and decreases the size of the reserve pool. (a) Synaptic localization of yellow fluorescent protein (YFP)–synapsin IIa expressed in synapsin triple knockout (TKO) neurons, in the presence (bottom) or absence (top) of coexpressed cyan fluorescent protein (CFP)–synapsin Ib (not shown in these images). (b) Synaptic localization of green fluorescent protein (GFP)–synaptobrevin 2 when expressed in synapsin triple wild-type (TWT) neurons, in the presence (bottom) or absence (top) of coexpressed CFP–synapsin Ib (not shown in images). (c) Normalized excitatory postsynaptic current (EPSC) amplitudes during trains of 500 stimuli delivered at 10 Hz. Shown are mean amplitudes for untransfected TWT and TKO neurons, and for TWT neurons transfected with GFP–synapsin IIa. Solid lines represent exponential decay curves. (d) Correlation of synaptic depression time constant with synaptic targeting of GFP–synaptobrevin 2 in TKO and TWT neurons. Slow synaptic depression is correlated with a larger vesicle pool in TWT neurons. Expression of synapsin Ib accelerates synaptic depression and reduces the size of the vesicle pool in TWT neurons to the level of the TKO neurons. Syn, synapsin.

ineffective monovalent dimers, thus dispersing the RP and accelerating synaptic depression (Figure 8(c)). Hence, synapsins can bidirectionally fine-tune the characteristics of synaptic depression.

Synapsins Have Different Functions at Other Synapse Types

Many lines of evidence indicate that synapsins regulate the RP of glutamatergic SVs. However, synapsins have other functions at other synapses. At hippocampal γ-aminobutyricacidergic (GABAergic synapses), loss of synapsins also reduces the number of SVs, but this effect is not restricted to the RP. This homogeneous decrease in the number of GABAergic SVs throughout the terminal also reduces the number of docked SVs. As a result, basal evoked release of GABA is diminished, but the kinetics of synaptic depression is unaffected. Thus, loss of synapsins has different structural and physiological effects at glutamatergic and GABAergic neurons. Synapsins appear to play a role also in regulating the RP of striatal and caudate–putamen

Figure 8 Model for synapsin control of vesicle pools in presynaptic terminals. (a) Synapsin IIa forms a divalent dimer that can bind and cross-link synaptic vesicles (SVs), whereas heterodimerization of synapsin IIa with synapsin Ib disrupts this clustering ability. (b) A predominance of synaspsin IIa in the presynaptic terminal favors an increase in the size of the reserve pool, whereas a predominance of synapsin Ib favors a dispersal of this pool (c).

dopaminergic neurons. It will be interesting to determine the molecular mechanisms underlying these differences, as well as to examine the functions of synapsins at synapses that use other neurotransmitters.

Summary and Conclusions

Studies of TKO mice devoid of all three synapsin genes reveal that synapsins have a variety of presynaptic functions which depend on the type of neurotransmitter employed. At hippocampal glutamatergic synapses, synapsins are responsible for maintaining an RP of SVs that are mobilized during synaptic depression, enhancing the duration and frequency range of glutamatergic synaptic transmission. Synapsin IIa seems to be mainly responsible for this action, with synapsin Ib serving as a dominant negative isoform that reduces the RP by heterodimerizing with synapsin IIa and reducing vesicle cross-linking. At GABAergic synapses, synapsins influence both the RRP and the RP of SVs. The synapsin isoforms involved in these functions are not yet clear. At dopaminergic synapses, synapsins also appear to be responsible for maintaining a reserve vesicle pool that is mobilized by cocaine and other psychostimulant drugs. The fact that synapsins appear to play different roles in various synapse types indicates that the molecular mechanisms governing the makeup of functionally defined vesicular populations must differ between these synapses in multiple ways. Elucidation of these mechanisms is one of the targets of intense contemporary research concerning synaptic physiology. The identity of the synapsin isoforms participating in defining the physiology of the synapses is of prime importance in this context, as are the precise molecular pathways by which the synapsins exert their effect.

Gaps and Future Directions

Although the work summarized here provides a coherent picture of the functions of the synapsin protein family, much remains to be understood. First, transmission has been examined at only a very small number of synapses, and it will be important to determine whether the conclusions derived from these initial studies can be generalized to the many thousands of other synapse types found within the brain. Second, synapsins have transmitter-specific functions, and it will be important to find out whether these proteins serve additional functions at synapses employing transmitters other than glutamate, GABA, or dopamine. Third, among the ten known synapsin isoforms, clear-cut roles have been identified for only two, namely synapsins Ib and IIa, which serve opposing functions in regulating the RP of glutamatergic SVs. Future studies certainly will need to identify the function of the eight other isoforms, as well as to consider whether synapsins Ib and IIa have additional roles. Finally, while the synaptic defects in the synapsin TKO mice provide plausible explanations for some of the behavioral phenotypes of these mice, additional work will be required to actually establish cause–effect relationships in these cases.

Synaptic Capture and Tagging

Introduction

Synaptic plasticity, the process whereby neurons alter the strength of their synaptic connections with experience, provides a cellular model for learning and memory in the brain. Since the vertebrate central nervous system consists of approximately 10^{11} neurons and 10^{14} synapses, using the synapse as the unit of plasticity greatly expands the information-processing capacity of the brain. The fact that long-lasting forms of plasticity, like long-lasting forms of memory, require changes in gene expression at the level of transcription, however, raises a cell biological paradox: how can a transcription-dependent process function to alter efficacy at some but not all synapses made by a given neuron? Although it not difficult to envision how short-term changes in synaptic strength, which are dependent on covalent modifications, might occur in a synapse-specific manner, long-lasting synaptic plasticity, which is dependent on transcription within a single, shared nucleus, presents a greater challenge. The synaptic tagging hypothesis provides a resolution to this challenge by proposing that the products of gene expression are delivered throughout the cell but only function to increase synaptic strength at synapses that have been 'tagged' or 'marked' by previous synaptic activity. Studies in a number of systems, including *Aplysia* sensory–motor synapse, crayfish neuromuscular junction, and rodent hippocampal synapses, have described the phenomenon of synaptic tagging and have defined roles for and broad characteristics of the products of transcription ('plasticity factors' or 'plasticity-related proteins') that are 'captured' at synapses tagged by previous synaptic activity. While there is a wealth of evidence showing that synaptic tagging occurs and contributes to synapse-specific, transcription-dependent plasticity, the nature and identity of the synaptic tag remain under investigation. Perhaps not surprisingly, initial studies indicate that a variety of 'tags' exist and can be recruited in distinct cell types by distinct stimuli.

Evidence for Synaptic Tagging

Synaptic Tagging in Rodent Hippocampal Synapses

The first evidence for synaptic tagging during long-term potentiation (LTP) in rodent hippocampus came from a classic series of studies done by Frey and Morris in 1997. In these experiments, the authors showed that when stimuli that produce protein synthesis-dependent, late-phase LTP (L-LTP) were applied to one input (S1) to CA1 neurons in the Schaffer collateral pathway of the hippocampus, and then stimuli that normally would produce only early-phase LTP (E-LTP) were applied to a second input (S2), L-LTP was observed at both S1 and S2, as long as the stimuli to S1 and S2 were delivered within a discrete time window. Specifically, the weaker stimulus to S2 had to be delivered 1–2 h before, or less than 2.5–3 h after, the stronger stimulus was delivered to S1. These results indicated that the weaker stimulus received by S2 created a synaptic tag that could 'capture' the products of gene expression, resulting in persistent synaptic strengthening at S2. They further indicated that the synaptic tag persisted for at least 1–2 h and that the products of transcription, referred to as plasticity-related proteins, persisted for at least 2.5–3 h following stimulation. It is worth noting that similar synaptic tagging experiments performed using *in vivo* electrical recording (i.e., at physiological temperature) have indicated that the tag persists for approximately 30 min.

Kauderer and Kandel, and more recently, Sajikumar and Frey, subsequently demonstrated synaptic tagging during long-term depression (LTD) of hippocampal synapses. In these studies, they found that a strong low-frequency stimulation induced long-lasting, protein synthesis-dependent, input-specific LTD (L-LTD) of hippocampal synapses and that this L-LTD could be captured at a second synaptic pathway receiving a weak low-frequency stimulus that on its own induced only transient, protein synthesis-independent LTD. As was the case with LTP, experiments in which the strong and weak low-frequency stimuli were given with various time delays revealed that the synaptic tag persisted for 1–2 h. Since previous studies had shown a requirement for dopamine during L-LTD, Sajikumar and Frey tested a role for dopamine during synaptic tagging during LTD and found that dopamine application was sufficient to induce synthesis of plasticity-related proteins, which could then be captured by weak low-frequency stimulation to produce L-LTD. They referred to this process as heterosynaptic tagging, reflecting the role of modulatory, heterosynaptic dopaminergic inputs in synaptic tagging of glutamatergic hippocampal synapses. The emerging finding is that modulatory inputs, such as dopamine, can contribute to the synthesis of plasticity-related proteins, but that the synaptic tag is set by the glutamatergic input.

Synaptic Tagging at *Aplysia* Sensory–Motor Synapses

To test the synaptic tag hypothesis at the level of a single cell, Martin and colleagues developed a culture system in which a single *Aplysia* sensory neuron formed synaptic contacts with two spatially separated motor neurons. They found that local application of five pulses of serotonin to the connections made onto one of the motor neurons produced an increase in synaptic strength (measured as an increase in excitatory postsynaptic potential (EPSP) amplitude) that depended on transcription in the sensory neuron. With this culture system of branch-specific long-term facilitation (LTF) of *Aplysia* sensory–motor synapses in hand, they then tested the synaptic tagging hypothesis by asking whether, following induction of long-term, transcription-dependent facilitation at one branch of a bifurcated *Aplysia* sensory neuron, a synaptic tag could be generated at the opposite branch using a subthreshold stimulus. As a subthreshold stimulus, they utilized a single application of serotonin, which on its own produced only a transient increase in synaptic strength. When five pulses of serotonin were applied to the connection made onto one motor neuron, and then a single pulse of serotonin was applied to the opposite connection, that single application of serotonin became capable of producing an increase in EPSP amplitude that persisted for 72 h. This facilitation was referred to as synaptic capture, since the single pulse of serotonin was capable of 'capturing' a transcription-dependent, long-term increase in synaptic strength. LTF could be captured if the single pulse of serotonin was applied 1 h after the five pulses of serotonin were applied to the opposite branch, but could not be captured if the single pulse was applied 4 h after the five applications of serotonin. A converse set of experiments revealed that synaptic capture occurred if the single pulse was given immediately or 1 or 2 h before, but not 4 h before the five pulses of serotonin. These results indicated that the synaptic tag persisted for at least 2 h and that the products of gene expression (plasticity-related factors) persisted for at least 1 h following synaptic stimulation.

Temporal Synaptic Tagging at the Crayfish Neuromuscular Junction

Zucker and colleagues described a form of 'temporal' tagging at the crayfish neuromuscular junction, in which the neuron integrates synaptic stimulation at a single synaptic connection over time. Specifically, they found that presynaptic hyperpolarization-activated cation channels, or I_h channels, become activated during a tetanus and that this activation generates a synaptic tag, which allows the motor neuron to increase transmitter output by subsequently responding to additional stimuli that would otherwise be ineffective. If the activation of the I_h channels occurs concomitant with elevations in presynaptic calcium, tagged synapses can undergo protein-synthesis-dependent, LTF in response to subthreshold stimuli applied at least 1 h after the time the tag was set. While defined as a synaptic tag, there are two important differences between this type of tag and the tag defined for LTF in *Aplysia* and LTP in rodent hippocampus. First, LTF at the crayfish neuromuscular junction does not depend on transcription, but rather on local protein synthesis, and thus this tag does not interact with the cell-wide products of transcription but instead with locally synthesized proteins to produce persistent synaptic strengthening. Second, this tag does not provide spatial specificity (although in another context, it could do so), but rather serves as a 'temporal tag' that provide a history of activity at the synapse, and can combine with subthreshold stimulus over a discrete time window to produce long-lasting changes in synaptic efficacy.

Cross-Tagging

The discovery that both L-LTP and L-LTD can be captured by synaptic tags raised the question of how a single neuron would integrate distinct tags generated by LTP- or LTD-inducing stimuli. Sajikumar and Frey performed a set of experiments to address the functional interactions between LTP and LTD synaptic tagging, which they referred to as cross-tagging. These experiments showed that the products of transcription, plasticity-related proteins, generated following induction of either L-LTP or L-LTD at one pathway could be captured by either LTP- or LTD-induced synaptic tags at a second pathway. These studies indicated that the plasticity-related proteins induced during L-LTP or L-LTD are nonspecific and that the specificity of plasticity is generated by the synaptic tag. This, in turn, focuses attention on the particular nature of the synaptic tag that is produced in response to specific stimuli. A number of studies have begun to identify molecules that function as specific tags during LTD or LTP.

In studying the effects of low-frequency stimulation (LFS) on L-LTP, Young and Nguyen found that LFS applied before a capturing stimulus (a single 100 Hz tetanus) inhibited the capture of L-LTP at that pathway. Further studies indicated that this inhibition occurred at the level of the synaptic tag and indicated that the tag undergoes a period during which it is vulnerable to disruption. Their results, however, were consistent with the rapid generation of a synaptic

tag and the capture of plasticity-related proteins within minutes of synaptic stimulation.

While cross-tagging experiments similar to those performed by Frey and colleagues in hippocampus have not been done at the level of single cells in *Aplysia*, Guan and colleagues undertook a series of experiments to determine how stimuli producing LTF at one branch of an *Aplysia* sensory–motor synapses (five pulses of serotonin) were integrated with stimuli producing LTD (five pulses of the neuropeptide FMRFamide) at another branch. They found that simultaneous application of the facilitatory neurotransmitter serotonin at one branch with the inhibitory neuropeptide FMRFamide at an opposite branch led to inhibition of LTF at the branch receiving serotonin but expression of LTD at the branch receiving FMRFamide. Further investigation indicated that this integration of serotonin- and FMRFamide-induced signals occurred in the nucleus, with FMRFamide inducing a pattern of histone deacetylation that promotes depression and inhibits facilitation. These studies thus indicate that plasticity-related proteins are specific for LTF or LTD in this system.

Synaptic Tagging and Competitive Maintenance

In a further test of the synaptic tagging hypothesis, Fonseca and colleagues reasoned that if long-lasting synaptic plasticity involved both the setting of synaptic tags and the induction of plasticity-related proteins, which they referred to as plasticity factors, then reducing the concentration of plasticity-related proteins would lead to a competition between tagged synapses. They tested this idea using distinct doses of protein synthesis inhibitors to decrease the concentration of plasticity factors and found that under these conditions, capture of LTP at one pathway decreased the magnitude of LTP at the pathway where L-LTP had been induced in a dose-dependent manner, suggesting that the captured synapses were competing with the initially stimulated synapses for a limited pool of plasticity factors. In addition, these investigators found that the greater the distance between inputs, the less the competition for plasticity factors, a finding also consistent with the idea of competitive maintenance. Thus, when L-LTP was induced in apical dendrites and captured in basal dendrites, competition was not observed. These findings not only support the synaptic tagging hypothesis, but also indicate that synapses must compete for plasticity-related factors. They further indicate that such competition may be effectively restricted to larger compartments of neurons, for example, to apical and/or basal dendrites.

Restriction of Synaptic Tagging within Dendritic Compartments

After demonstrating that synaptic tagging and capture could occur in basilar dendritic compartments of CA1 hippocampal neurons in a manner similar to that described in apical dendrites, Alarcon et al. asked whether synaptic capture could occur across apical and basilar dendritic compartments. They found that capture could occur across dendritic compartments only when the intensity of the capturing stimulus was increased, such that capture occurred only when a stimulus that induces intermediate-term potentiation (two 100 Hz tetani with a 30 s intertrain interval) was used and not when a stimulus that would induce early LTP (one 100 Hz tetanus) was used. Together, these results point to a spatial specificity of synaptic capture, in which tags can capture plasticity-related proteins within discrete functional dendritic compartments. This process has been referred to by Tonegawa and colleagues as localized capture associativity.

What Is the Nature of the Synaptic Tag?

While the phenomenon of synaptic tagging and capture has been described by many research groups, identifying the molecules that form the tag, or the plasticity-related proteins that are captured by the tag, has proven more challenging. In part, this difficulty stems from the fact that synaptic tagging and capture occur within spatially restricted compartments and are thus not amenable to biochemical or molecular biological investigation of large populations of neurons. Nonetheless, some progress has been made in identifying molecular components of tagging and capture.

Is Tagging Dependent on Local Translation or Local Protein Degradation at the Synapse?

The activation of local translation meets many of the requirements for a tag that can integrate activity in both temporal and spatial domains. Protein translation at the synapse can alter the composition of the synapse over extended time periods and thereby leave a relatively persistent trace of synaptic activity. In addition, activating translation locally provides a spatial tag for gene expression, because messenger RNAs that are delivered from the cell soma will be preferentially translated at sites at which translation is active. Notably, Ostroff and colleagues have found that the percentage of spines that contain polyribosomes increases markedly in CA1 neurons after LTP induction. Furthermore, after the induction of LTP, the area of the postsynaptic density is significantly larger in polyribosome-containing spines than in spines that lack them.

Despite evidence in hippocampus and in *Aplysia* sensory–motor neurons that local translation plays a role in synapse-specific long-term plasticity, it is also clear that local translation is not required to generate a synaptic tag. Thus, the initial studies demonstrating synaptic tagging in hippocampus by Frey and Morris directly demonstrated that translation could be inhibited during generation of a synaptic tag. Similarly, in the *Aplysia* bifurcated sensory–motor culture system, local translation is not required at the captured branch for 24 h facilitation. It is, however, required for facilitation at 72 h, which is accompanied by the growth of new synaptic connections. These findings indicate that local translation is required not for the initial setting of the synaptic tag, but rather for stabilizing new synaptic growth to create persistent synaptic plasticity. Local translation may thus be found to be required for synaptic tagging at hippocampal synapses when the captured LTP is examined over longer time domains.

Regulated protein degradation provides another means of altering the macromolecular composition of synapses. A role for ubiquitin-mediated protein degradation via the proteasome during plasticity of rodent hippocampal synapses as well as during LTF of *Aplysia* sensory–motor synapses has been described. Zhao and colleagues have shown that serotonin induces increases in polyubiquitination of synaptic proteins in sensory–motor cultures. It is therefore possible that local, ubiquitin-mediated protein degradation of specific molecules in response to synaptic stimulation creates a synaptic tag by altering the composition of the synapse and that this tag combines with the products of transcription to produce a persistent type of synaptic plasticity.

A Role for Specific Kinases in the Generation of Synaptic Tags

Roles for a number of kinases during synaptic tagging have been mathematically modeled by Byrne and colleagues and experimentally demonstrated by a number of groups. Casadio and colleagues found that although 24 h synaptic capture was not dependent on local translation in *Aplysia* sensory–motor synapses, it did depend on activation of protein kinase A (PKA). Studies in hippocampal synapses have also revealed a requirement for PKA during synaptic tagging and capture. Nguyen and colleagues have shown that genetic or pharmacological reduction of PKA activity blocks synaptic capture and that activation of PKA is sufficient to produce a synaptic tag that can capture L-LTP of hippocampal synapses. Abel and colleagues went on to show that the anchoring of PKA to synaptic sites, mediated by interactions with the A-kinase anchoring protein (AKAP), was required for efficient synaptic tagging.

Taking advantage of the finding that synaptic tagging and capture are restricted to discrete dendritic compartments (apical and basilar), and that cross-tagging between LTP and LTD could occur, Frey and colleagues found that calcium/calmodulin-dependent protein kinase II (CaMKII) activity was required for LTP but not LTD tagging, and that p42/44 mitogen-activated protein kinase (MAPK) activity was required for LTD but not LTP tagging in apical dendrites of CA1 hippocampal neurons. In contrast, they found that either PKA or protein kinase Mz, a persistently active PKC isoform, served as LTP-specific tags in basilar dendrites. Together, these findings indicate that distinct molecular tags may be recruited by distinct stimuli and within distinct dendritic compartments.

Conclusions

Synaptic tagging allows the synapse, rather than the nucleus, to be the unit of long-lasting neuronal plasticity. Studies of the phenomenon of synaptic tagging have not only confirmed its existence but also revealed a number of important characteristics, including cross-tagging, competitive maintenance, and localized capture associativity, in which tagged synapses within a dendritic subcompartment compete for a common group of plasticity-related proteins. Together, these findings provide insight into the mechanisms whereby information is stored in the brain. They have given rise to refined models of information storage, including the clustered plasticity model of long-term memory engrams proposed by Govindarajan et al. and the late-associative reinforcement model proposed by Frey and colleagues.

The evidence that synaptic tagging does occur has also kindled deep interest in identifying the molecular nature of the tag, and in understanding the function of synaptic tagging during learning and memory. Progress is being made on both fronts. Specific roles for local translation and for specific kinases have been identified during synaptic tagging and capture, and future years promise to increase the number of identified tags and plasticity-related proteins. Behavioral and *in vivo* electrophysiological recording paradigms are being developed by a number of groups to investigate the existence and function of synaptic tagging in living animals. Together, the results of these investigations promise to shed light on the mechanisms whereby synaptic tagging functions to allow information to be stored at the level of the synapse.

Synaptic Depression

M A Xu-Friedman, University at Buffalo, State University of New York, Buffalo, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Definition

Synapses, the connections between neurons, are highly plastic. Synaptic plasticity arises from a number of mechanisms, with many possible triggers and targets, that can lead to increases or decreases in synaptic efficacy over different timescales. This article focuses on forms of plasticity that cause decreases in synaptic efficacy over short timescales that are triggered by presynaptic activity (Figure 1). These forms of plasticity are collectively known as short-term synaptic depression, and represent a group of mechanisms that can result from a variety of changes both presynaptically and postsynaptically. Other forms of synaptic plasticity (e.g., short-term facilitation, posttetanic potentiation, long-term potentiation, long-term depression, neuromodulation) have different triggers and different targets, and are covered elsewhere in this Encyclopedia.

Short-term depression is widespread throughout the nervous system. Because depression is triggered merely by activity, and takes several seconds to recover, it affects synapses constantly. As a result, depression plays a critical role in the moment-by-moment processing of information that the brain is responsible for during normal behavior. Therefore, in order to understand how the brain processes information, depression and other forms of short-term plasticity must be considered in addition to the longer-term plasticities that may match the more conventional definitions of 'memory.'

Which Synapses Show Depression?

Depression was found in the earliest recordings of synaptic potentials by Feng and by Eccles, Katz, and Kuffler at the neuromuscular junction in the early 1940s. Depression has since been observed at many synapses throughout the nervous system. It is most easily characterized in reduced preparations such as brain slices by stimulating a presynaptic axon with one or more conditioning pulses, waiting some interval, and then stimulating with a test pulse (Figure 1). The postsynaptic response can be quantified using current clamp (to measure the postsynaptic potential) or voltage clamp (to measure the postsynaptic conductance changes).

The amount of depression differs for different synapses, and depends on the recording conditions. Typically, depression is greater at synapses that release neurotransmitter vesicles with high probability. This condition can be mimicked even at synapses that normally show little or no depression, by increasing the external calcium concentration (e.g., from 2 to 4 mM). In a complementary way, depression can be reduced and even eliminated at synapses that normally show depression, by decreasing external calcium (e.g., from 2 to 0.5 mM). These manipulations are thought to change the amount of presynaptic calcium influx, and thus the probability of vesicle release, which affects all the mechanisms that are proposed to underlie depression (described later). These experimental manipulations are relevant to the conditions in the intact brain, as for example neuromodulators may cause presynaptic calcium influx to decrease, which can flip a synapse from depressing to facilitating.

Mechanisms of Depression

Depletion

One of the first mechanisms to be proposed for depression was depletion of neurotransmitter, put forth by Liley and North in 1953 (Figure 2(a)) As more has been learned about synaptic structure, this idea has been further refined. Neurotransmitter is packaged in vesicles, and there is only a limited pool of vesicles (the 'readily releasable pool') that are docked at the presynaptic membrane and ready to release their contents into the synaptic cleft. Action potentials in the presynaptic axon cause vesicles within this pool to release their contents, thereby reducing the size of the pool (Figure 2(a)). The presynaptic terminal recovers from depletion as the pool is restocked through multiple pathways of reuptake or priming of reserve pools of vesicles. Because replenishment takes time, the readily releasable pool remains at least partially depleted for a period usually estimated as being on the scale of a few seconds. If a second action potential arrives during that period of recovery, then fewer vesicles are ready to be released. The reduced pool size causes the amount of neurotransmitter release to be smaller. Thus the characteristics of synapses that are likely to enhance depletion would be a high initial probability of vesicle fusion (such that many of the releasable vesicles are released), and a slow recovery rate (such that there is an opportunity for the smaller pool to have a measurable impact).

Despite the simplicity of the idea, the small scale of synaptic processes makes it difficult to observe directly. The difficulties are compounded by the fact that, as yet, it is not known for even the best-studied synapses how many vesicles are actually ready to be

Figure 1 An example of a depressing synapse. A bushy cell in the anteroventral cochlear nucleus was recorded from in voltage clamp, and a single presynaptic auditory nerve fiber was stimulated at 100 Hz. The sharp negative peaks are inward currents carried by AMPA-type glutamate receptors, which start out very large, but get progressively smaller. Several of the mechanisms discussed in the main text have been proposed at various times to account for this depression. This is an average of four traces recorded in voltage clamp at 34 °C in a brain slice taken from a P21 mouse. Data from Xu-Friedman MA and Regehr WG (2005) Dynamic-clamp analysis of the effects of convergence on spike timing. II: Few synaptic inputs. *Journal of Neurophysiology* 94: 2526–2534, used with permission.

released. Electron micrographs show some vesicles very close to the membrane at active zones, but it is not likely that physical location is the only criterion. In addition, it is not known how many vesicles are released after an action potential invades the presynaptic terminal. There has been some debate over whether only a single vesicle can be released per synapse, or whether multiple vesicles can be released. Part of the reason this is difficult to resolve is that most researchers measure vesicle fusion using the simplest technique, which is to measure the postsynaptic current in voltage clamp. However, this is only an indirect measurement, which is really of the number of activated, open postsynaptic receptors. The relationship between receptor activation and the amount of neurotransmitter released is not well known.

Figure 2 Principle mechanisms of depression. Top, at rest, the presynaptic terminal has a pool of releasable vesicles near the membrane, as well as a reserve pool, and the postsynaptic side has a set of closed ligand-gated receptors. (a) Depletion. The first action potential triggers the fusion of a large fraction of the releasable pool with the presynaptic membrane, and the activation of postsynaptic receptors (in green). If the second action potential arrives before the releasable pool has been replenished, fewer vesicles will be released. (b) Desensitization. Neurotransmitter released during the first action potential first activates (green), then desensitizes (red) the postsynaptic receptors. If a second action potential arrives before the receptors return to the resting state, then fewer will be able to conduct current, and the PSC will be depressed. (c) Saturation. Neurotransmitter released during the first action potential binds to the receptors for a prolonged period (green). If a second action potential arrives before ligand unbinds, only initially unbound receptors will be available to provide additional current.

To get around these difficulties, different techniques have been applied. Some of the best evidence for depletion comes from recordings made in a very reduced preparation from the retina by Gary Matthews and colleagues. The retinal cells they studied (retinal bipolar cells) have large presynaptic terminals, which can be directly studied with electrophysiology techniques. These terminals also have a characteristic ultrastructure, called the synaptic ribbon, which makes it easier to identify vesicles that are likely to be in the releasable pool. Matthews and colleagues quantified the amount of vesicle fusion using the capacitance of the cell, which increases as a result of the small neurotransmitter vesicles fusing with the membrane, thereby adding their capacitance to it. By depolarizing the retinal cell for different periods of time and measuring transient increases in capacitance, they estimated the number of vesicles that fuse with the membrane. They could cause fusion of larger number of vesicles using longer depolarizations, but only up to a certain limit, suggesting that the releasable pool size was limited. In addition, Matthews and colleagues counted the number of vesicles positioned along the ribbon. The correlation between the size of pool measured anatomically and physiologically was remarkably strong. These results suggested that different pools of vesicles do exist, have a physical basis, and can be depleted through activity.

One question is whether the findings in the rather specialized retinal bipolar cells apply to other cells in the nervous system. Retinal bipolar cells are unusual in that they release neurotransmitter in a graded fashion, rather than in response to action potentials. In addition, most cells lack the bipolar cell's synaptic ribbon. Some attempt has been made to examine cells in the rest of the brain. Capacitance techniques have been successfully applied to the calyx of Held synapse in the auditory pathway. However, the morphological correlate of the releasable pool has been more difficult to distinguish than in the retinal synapse studied by Matthews and colleagues. Another direct method to look for depletion is to drive a synapse to release its complement of vesicles, and then examine the synapse using electron microscopy to look for changes in the spatial locations or numbers of vesicles. Unfortunately, it is not possible to get 'before' and 'after' pictures of a synapse, because the fixation required for electron microscopy destroys the tissue. In addition, even comparisons between synapses are complicated by the presence of recovery mechanisms that operate on the timescale of seconds, and it may be difficult to deplete a synapse to a measurable extent. One method has been to eliminate recovery mechanisms entirely by using temperature-sensitive mutants of the recovery machinery. A temperature-sensitive mutation of the dynamin protein has been described in *Drosophila* (called *shibire*). When these organisms are warmed, vesicles cannot be taken back up, and electron micrographs reveal a lack of vesicles, which matches a drop in the size of synaptic potentials. While this shows that vesicles are consumed by activity, it has not been shown yet how this relates to a readily releasable pool.

For some synapses, an indirect approach can also be used to examine the loss of vesicles, called 'variance-mean analysis.' This method makes certain assumptions about the statistics of vesicle release, and uses the mean and variance of synaptic currents or potentials to estimate the total number of vesicles. This approach has been used by Wade Regehr and colleagues at the climbing fiber synapse in the cerebellum to show that the number of vesicles available for release is lower after bouts of activity. However, the preconditions that allow this statistical analysis to be used are difficult to meet experimentally, and it has provided mixed results at other synapses.

Desensitization

A second form of depression relies on a postsynaptic mechanism – receptor desensitization. This occurs when a ligand-gated receptor is exposed to its ligand for an extended period, whereby it transitions through the open state to a fully bound, but nonconducting state, referred to as 'desensitized.' Acetylcholine receptors at the neuromuscular junction were among the first to be shown to exhibit desensitization, and, subsequently, all ionotropic neurotransmitter receptors were also found to desensitize. Receptor desensitization can be examined in great detail using the outside-out patch technique. These experiments have demonstrated that α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-type glutamate receptors desensitize particularly rapidly compared to other ligand-gated ion channels, and among the AMPA receptors, some subunit types desensitize more rapidly than others.

It is possible that postsynaptic receptor desensitization could play a role in depression. Neurotransmitter released during the first action potential initially activates receptors, which causes synaptic currents and potentials (**Figure 2(b)**). Then, the receptors may enter a desensitized state, provided ligand does not unbind before the channel changes conformation and enters the nonconducting state. If a second action potential were to arrive during this period, then postsynaptic receptors may not be ready to respond to the fresh elevations in ligand concentration. Thus,

synapses would tend to be most subject to desensitization provided receptor channels enter desensitized states rapidly, and persist in them for a long time. In addition, desensitization is more likely to be found at synapses where neurotransmitter lingers in the synaptic cleft. Recovery would depend on the rate of neurotransmitter removal from the cleft, as well as the rate of ligand unbinding.

The first evidence that desensitization could actually play a role in depression came from the work of Laurence Trussell and colleagues. They examined a synapse in the chick auditory brain stem that had both characteristics mentioned above. First, the synapse expresses AMPA receptors that desensitize particularly rapidly ($GluR4_{flop}$). Second, the synapse is calyceal in structure, with many active zones clustered together. These active zones do not appear to express glutamate transporters, so the clearance of glutamate probably takes place through simple diffusion. A number of experimental approaches lent support to the idea that desensitization contributes to depression there, including (1) that depression increases with the amount of neurotransmitter released, (2) that depression recovers relatively rapidly (50–100 ms), (3) that miniature postsynaptic currents (mPSCs) that occur right after a large synchronous PSC are reduced in size, and (4) that pharmacological compounds that prevent desensitization also reduce depression. These drugs include cyclothiazide and aniracetam, which appear to interfere with various kinetic properties of the AMPA receptor, including the conformational changes that lead to desensitization.

Since then, desensitization has been found to contribute to depression at a number of additional synapses, in the thalamus, cortex, and cerebellum, as well as in invertebrates. These synapses have been investigated in less detail than the chick calyx, but do appear to share some characteristics. Further investigation of these as well as comparison with nondesensitizing synapses will help reveal the critical conditions. In addition it remains to be seen whether desensitization contributes to depression at synapses expressing different receptor types, such as γ-aminobutyric acid (GABA), glycine, and *N*-methyl-D-aspartate (NMDA)-type glutamate receptors. Pharmacological tools that interfere with desensitization of these receptor types would be particularly helpful.

Saturation

A third mechanism that affects depression is postsynaptic receptor saturation. This occurs when an action potential leads to neurotransmitter release, and the binding and activation of a pool of receptors. If a second action potential arrives while these receptors are still bound, then they provide no additional synaptic current because they are already occupied (**Figure 2(c)**). This state is referred to as saturation. In the extreme case, all the receptors are occupied, but saturation would also have an impact even if only a subset of receptors in the active zone are claimed by the first action potential.

Saturation is most likely to be important at synapses with certain properties. First, synapses are more likely to be saturated if they express receptor types that remain bound to ligand or are exposed to ligand for an extended period. In addition, saturation should depend on the spatial distribution of postsynaptic receptors and their physical distance from the site of neurotransmitter release. For example, a small synapse would likely undergo significant saturation even if only one vesicle were to be released. By contrast, a large synapse may not experience saturation unless vesicles are consistently released in a limited area, or if many vesicles are released at once. As yet, there is little experimental evidence to support the relationship between saturation and synapse size, as the ultrastructure has been well measured for only a few synapses, and the amount of saturation has proven difficult, or at least controversial, to estimate.

The most likely example of saturation causing depression is with NMDA-type glutamate receptors. NMDA receptors typically have very slow kinetics, and the synaptic currents passed by NMDA receptors last for several hundred milliseconds. If a second action potential arrives during that period, it typically has a smaller amplitude. It must be pointed out that the second synaptic current rides on top of the first, so the net effect may be a summed synaptic current of similar amplitude to the first. Thus, saturation, while technically resulting in depression, does not really suppress synaptic strength in the same spirit as do depletion and desensitization. Rather, saturation effectively results in a prolongation of synaptic currents.

There is still considerable disagreement whether NMDA receptors actually are saturated. Low-affinity antagonists have been used to reduce saturation, and the evidence appears fairly clear that NMDA receptors are saturated at some synapses, such as the retinal ganglion cell synapse in the lateral geniculate nucleus. GABA and glycine receptors are usually somewhat faster than NMDA, but can show a similar phenotype (i.e., a relatively smaller second peak that rises to the same absolute height). Further study with low-affinity antagonists may help shed light on this issue.

Under special conditions, saturation can actually play a role in reducing depression. This happens

because saturation reduces the amount of receptor activation for a given amount of neurotransmitter released. It is most easily understood with a very artificial example. Suppose a synapse is completely saturated by the total neurotransmitter contained in two vesicles. Then there is no difference in postsynaptic response whether the presynaptic terminal releases eight vesicles (say from a fully stocked releasable pool) or just two. That means that a depleted synapse will show no obvious depression, provided it can still squeeze out two vesicles. The principles of this example would hold under less extreme conditions, as long as there is saturation and multivesicular release at individual release sites. Evidence for this phenomenon was found by Wade Regehr and colleagues at the climbing fiber synapse in the cerebellum. The overall effect of saturation is to reduce the effects of depletion, and accelerate the synapse's recovery.

Other Mechanisms

The mechanisms described above have received the strongest experimental support at a number of synapses. There are additional mechanisms that have been proposed to underlie depression in more special conditions, or have not been described as widely – depletion of extracellular calcium, calcium channel inactivation, and incomplete vesicle refilling.

Depletion of extracellular calcium Synapses are usually present in a dense neuropil, where the amount of extracellular space is quite small. Thus, the activity of neurons could, in principle, affect the ionic concentrations in extracellular space. Some researchers have proposed that calcium flux through voltage-gated calcium channels or calcium-permeable receptors can deplete the calcium in the extracellular compartment, which could reduce calcium influx and neurotransmitter release. Borst and Sakmann suggested that strong bouts of activity could deplete calcium around the calyx of Held synapse, though it is not yet clear that this would take place under physiological conditions, or whether other forms of depression would dominate with such intensive activity. It has proven difficult to measure extracellular calcium depletion experimentally, in part because the domains where it might take place form such a small percentage of the total extracellular space.

Calcium channel inactivation Voltage-gated calcium channels can be inactivated by high levels of internal calcium. Since neurotransmitter release is highly sensitive to the calcium concentration, even a slight reduction in available calcium channels could contribute significantly to depression. Ling-Gang Wu and colleague provided convincing evidence that this can cause depression at the calyx of Held synapse, by measuring presynaptic calcium currents and postsynaptic currents. The form of depression they studied had a very slow onset, taking ~100 ms to reach a peak, which is consistent with the slow onset of inactivation. However, the calyx is normally active at very high rates, in which case depletion and desensitization appear to have somewhat greater influence over depression. Additional study at other synapses will be necessary to determine if it can play a significant role at more slowly firing synapses.

Incomplete vesicle refilling After a vesicle fuses with the membrane and releases its contents, many steps are required before the vesicle can again become readily releasable. In addition to the physical reuptake of the vesicle membrane proteins and translocation to the active zone, it is necessary that the vesicle be reloaded with neurotransmitter. Current estimates suggest that reloading takes several seconds. If vesicles enter the releasable pool prematurely, then they could be incompletely filled. If these vesicles were to release their contents, then fewer postsynaptic receptors would be activated resulting in smaller postsynaptic currents. While this seems a reasonable possibility, there is little evidence for it contributing to depression. In fact, it is unknown whether variability in vesicle content might not be common even with resting synapses, as the variability in size of spontaneous mPSCs is notoriously unaccounted for.

Functional Role of Depression

A natural question that arises is, does depression play a role in the everyday function of the nervous system? It is hard to imagine that it does not, especially as depression can be profound at some highly active synapses. But does depression actually contribute useful computational properties to synapses? Or is it just an undesirable side effect of synaptic transmission? These questions are difficult to answer. Ideally depression could be prevented, and the ensuing changes in nervous system function studied in its absence. But because depression currently appears to be an inevitable consequence of vesicle fusion and neurotransmitter release, blocking it is impossible.

Instead, several workers have used modeling approaches to try to understand the effects of depression. This has led to a number of insights into potential roles of synaptic plasticity. One theme that runs through the proposed functions of depression is that it keeps a highly active presynaptic input from

swamping the postsynaptic cell and dominating its output. This allows smaller signals to emerge, and helps to keep neurons responsive over a wider range of stimuli. These effects have been examined in cortical neurons by Laurence Abbott and colleagues, in auditory neurons responsible for sound localization by William Spain and colleagues, and in *Aplysia* motor neurons by John Byrne and colleagues. In addition, Harunori Ohmori and colleagues have suggested that depression could enhance the specificity of coincidence detection by keeping the postsynaptic potentials small, so only precise coincidences can trigger a postsynaptic response.

These explorations of function represent only the beginning, and many issues remain to be resolved. For example, desensitizing synapses recover much more rapidly than depleted synapses. Does this have functional consequences? Do selection pressures underlie the differences between synapses? Is desensitization selected for because it has different computational properties from depletion, or are these forms of plasticity side effects of other functions? Also, some synapses show profound depression with a single conditioning pulse, whereas others do not, and may even facilitate. What are the mechanisms that determine the level of depression at different synapses, and what are the functional consequences? These are only a few of the many functional issues surrounding short-term plasticity.

Synaptic Mechanisms of Learning

Introduction

Most adult behavior involves the performance of skilled movement, and we spend much of our lives expanding our repertoire of motor skills. Motor skills are characterized by the fact that they develop slowly through repetition (practice) and are highly resistant to decay over time. This suggests that skills are progressively encoded as enduring neurophysiological changes within motor areas of the central nervous system. Although numerous areas of brain and spinal cord are certainly involved in skill learning, primary motor cortex (M1) is arguably the key brain structure performing skilled limb movement. The axons of the corticospinal neurons along the bank of the precentral gyrus can be considered the final common path for motor output. Other motor structures, such as basal ganglia and cerebellum, modulate movement indirectly by adjusting the activity of neurons within motor cortex. Further, there are progressive changes in motor cortex activity during motor learning that parallel the development of skilled action patterns. Motor learning also causes enduring changes in cortical organization that can be observed outside the training experience. There are profound changes in the topography of movement representations ('motor maps') within motor cortex such that areas of cortex controlling trained movements become larger and more overlapping. All this suggests that skill learning drives changes in cortical circuitry. To this end, there is now a large body of evidence showing that (1) synaptic plasticity can be induced within motor cortex circuits in response to electrical stimulation, (2) similar synaptic changes occur in association with motor learning, and (3) synaptic plasticity is the mechanism underlying learning-dependent reorganization of cortical movement representations.

Evidence for Synaptic Plasticity in Motor Cortex

Long-Term Potentiation and Long-Term Depression of Cortical Synapses

Much of the evidence for synaptic plasticity within motor cortex has come from studies of long-term potentiation (LTP) and long-term depression (LTD) of various extra- and intracortical pathways. Experiments in animal preparations have shown that synapses within layer II/III can be potentiated via tetanic (high-frequency) stimulation of thalamic and somatosensory afferents. It is interesting that thalamocortical inputs can be potentiated only when activity is paired with stimulation of cortico–cortico afferents. Synapses onto neurons in layer V can be potentiated in response to white matter stimulation, presumably because the stimulated fibers contain both thalamocortical and cortico–cortico afferents. This associative LTP is thought to represent a neural mechanism by which sensory inputs act to facilitate skill learning.

In vitro studies of cortical slice preparations have shown that intracortical synapses can also be modified through stimulation. Tetanic stimulation of horizontal fibers within layer II/III and V induces potentiation of synapses along these fibers up to several millimeters away. Further, stimulation of vertical afferents from layer II/III can enhance synaptic responses in layer V. Thus, local circuits can be modified by coordinating activity of both horizontal and vertical pathways. These forms of synaptic plasticity are also believed to represent the mechanism by which movement representations reorganize during skill learning (see the section titled 'How does synaptic plasticity in motor cortex support motor skill learning?').

The neurochemical and intracellular signals required for LTP in motor cortex have also been investigated using motor cortex slice preparations in which specific pharmacological manipulations can be made. This approach has demonstrated that stimulation-induced LTP in layer II/III requires the presence of γ-aminobutyric acid ($GABA_A$) receptor antagonists. This suggests that a minimal amount of neuronal depolarization is required for LTP to occur. Application of potassium channel blockers or increasing extracellular calcium levels can also facilitate the induction of LTP. Both glutamate and acetylcholine are critical neurotransmitters as both *N*-methyl-D-aspartate and acetylcholinergic receptor antagonists block LTP of horizontal afferents. These same systems may also be engaged during skill learning as similar manipulations also impair skill learning. LTP is also dependent on the activation of specific intracellular signaling pathways, including extracellular signal-regulated kinase and protein kinase A. Blockade of either pathway prevents synaptic potentiation in response to stimulation. These same signaling pathways have been shown to be involved in orchestrating synaptic plasticity in several

brain areas and likely act to coordinate the expression of various genes required for long-term changes in synapse number or morphology.

Although much of what is known about LTP in motor cortex has come from *in vitro* preparations, LTP can also be induced in awake, freely behaving rats. However, unlike the slice preparation, LTP in the whole animal cannot be induced in a single session. Daily stimulation must be given for several days before significant changes in synaptic responses are observed. Further, synaptic potentiation continues to increase each day and does not reach asymptote for 10–14 days. This observation is consistent with the fact that motor skill learning also requires several days of training before significant motor improvements are observed. In addition, the learning-dependent changes in motor maps, believed to be mediated by synaptic plasticity in motor cortex, also require several days to appear (see the section titled 'Learning-dependent synaptic plasticity in motor cortex').

If skill learning occurs only through the strengthening of synapses within motor cortex, then with continued skill learning, all synapses would eventually become saturated. Therefore, synapses within motor cortex must be capable of not only potentiation but also depression. In support of this idea, LTD of synaptic efficacy can also be induced within motor cortex. Low-frequency stimulation of horizontal afferents reduces synaptic responses within layer II/III. The depression can also be reversed through high-frequency stimulation of the same pathways. Thus, cortical circuitry can be altered through bidirectional changes in synaptic strength.

Synaptic Plasticity in Human Motor Cortex

Demonstrating synaptic plasticity in human motor cortex is somewhat more difficult than in animal preparations. However, such plasticity can be inferred by measuring motor-evoked potentials (MEPs) in response to transcranial magnetic stimulation (TMS). TMS involves sending an electrical charge carried on a magnetic pulse through the skull and into the cortex to activate corticospinal neurons. It is a noninvasive method for stimulating cortex that can be done repeatedly in unanesthetized participants. Corticospinal output is then assessed by measuring small changes in MEPs in target muscles. Because TMS drives corticospinal neurons transsynaptically, the changes in MEP amplitude are thought to be due to changes in the strength of synapses onto corticospinal neurons. MEP facilitation and inhibition can be elicited in response to different TMS protocols. Paired pulse stimulation has been used to show that MEP amplitude can be increased or decreased by varying interstimulus interval. Intracortical facilitation is observed with longer (25 ms) interstimulus intervals, whereas intracortical inhibition occurs with shorter (2 ms) interstimulus intervals. Repetitive TMS (rTMS) is a stimulation protocol in which repeated pulses are presented over a short time. This is reminiscent of the tetanic stimulation given in animal models of synaptic plasticity. Low-frequency stimulation reduces MEPs, whereas high-frequency stimulation enhances them. An associative form of synaptic facilitation can also be demonstrated by pairing TMS pulses with peripheral nerve stimulation that activates somatosensory inputs into motor cortex. The pairing of direct TMS stimulation with sensory nerve stimulation increases the amplitude of TMS-evoked MEPs. This phenomenon is reminiscent of the associative LTP observed in animal preparations in which potentiation of layer V and layer II/III synapses can be induced via conjoint stimulation with somatosensory cortex afferents. Finally, the level of cortical excitability prior to stimulation can also influence the capacity and direction of stimulation-induced synaptic plasticity. Preconditioning with transcranial direct current stimulation prior to rTMS can increase or decreases cortical excitability depending on the stimulation parameters used. If the cortex is previously facilitated, rTMS decreases excitability, whereas if the cortex is previously inhibited, rTMS increases excitability. This is further evidence that synaptic strength within motor cortex can be increased or decreased.

Learning-Dependent Synaptic Plasticity in Motor Cortex

If synaptic plasticity such as that observed in the above studies of human and animal motor cortex stimulation does underlie learning, then similar plasticity should be observed in response to motor skill training. There is now convincing evidence from animal and human experiments to support this idea. Training on a skilled reaching task induces an increase in synaptic strength of horizontal afferents in slices of rat motor cortex contralateral to the trained paw but not in slices from ipsilateral cortex. It is interesting that the amount of LTP that can be induced after training is reduced in the trained hemisphere whereas the amount of LTD is enhanced. This is consistent with the notion that skill learning alters cortical connectivity by changing the range of efficacy within which individual synapses can operate and allows for a greater degree of specificity for synaptic changes within cortical circuits.

Chronic studies in awake behaving animals have revealed similar results. Training on a skilled reaching task induces a transient increase in synaptic potential

within layer V of motor cortex in response to white matter stimulation that coincides with an increase in task proficiency during later stages of training. Further, compared with the ipsilateral side, less potentiation but more depression can be induced on the side contralateral to the reaching forelimb. Enhanced synaptic responses of intracortical afferents also appear at approximately the time when animals reach behavioral asymptote, and the potentiation is maintained with continued training. Thus, different pathways within cortical circuitry may undergo changes in synaptic strength at different stages of training.

Motor skill training can also induce synaptic potentiation in human motor cortex. Skill training increases MEP amplitudes in trained muscles of naïve participants, and MEP amplitudes are consistently larger in professional athletes and musicians. For example, volleyball players have larger MEPs in shoulder muscles and racquet ball players have larger MEPs in wrist muscles. Motor learning also occludes stimulation-induced enhancement and augments depression of MEPs. These changes are specific to motor learning and are not observed in participants who experience a similar type of muscular activity without learning. These findings are strikingly similar to the changes in capacity for synaptic potentiation observed in animal experiments of skill learning and provide further evidence for the role of adaptations in the range of synaptic strength as a mechanism of learning in motor cortex.

In addition to physiological measures of synaptic plasticity, changes in synapse number also occur with skill training. Layer V and layer II/III neurons of rats trained to perform a skilled reaching task have more-extensive dendritic arborizations in the motor cortex contralateral to the trained forelimb. The increased dendritic arbor likely reflects an increase in synapse number as there are more synapses per neuron in motor cortex of reach-trained animals than in untrained and activity controls. Further, the synaptogenesis paralleling the acquisition of skill is detectable only after significant improvements in performance. This is consistent with studies of synaptic physiology showing potentiation of synaptic responses only after several days of training. Thus, it is not simply the acquisition of skilled movement that drives synaptogenesis but the continued repetition of the novel movement sequences once acquired.

How Does Synaptic Plasticity in Motor Cortex Support Motor Skill Learning?

Skill Learning Alters Motor Map Organization

Motor learning induces changes in synaptic strength within motor cortical circuits. But how does such plasticity contribute to the encoding of skilled movement? Some insight can be gained from examining how movement is organized within motor cortex and how motor learning alters this organization. First, movement dexterity is reflected in the topography of movement representations within motor cortex (the 'motor map'). Body parts such as the hands, that have a high degree of dexterity, are represented across larger regions of cortex than body parts with low dexterity, such as the leg. Furthermore, motor map organization is not fixed and is capable of reorganization in response to a variety of manipulations, including motor skill training. Studies in rats, monkeys, and humans have all shown that skill training leads to an increase in the proportion of motor cortex containing representations of trained movements. Skilled reach training in rats, for example, causes an increase in the area of cortex from which distal forepaw movements can be elicited. Training on a skilled digit movement task in monkeys causes an increase in the area of digit representations. In addition to causing changes in the representation area, training causes the maps to become more fractured (intermixing of representations) and the number of sites where stimulation evokes multiple movements to increase. Professional athletes and musicians have larger representations of trained muscles that are more overlapping than those of amateurs. Therefore, movement representations become more overlapped and interdigitated with skill training. This is thought to represent the enhanced capacity for producing skilled movement sequences.

Synaptic Plasticity Supports Motor Map Reorganization

It is hypothesized that changes in synaptic strength within intracortical afferents are the mechanism by which movement representations in motor cortex reorganize. Neurons within motor cortex are aggregated such that small groups of cells appear to encode elementary movement representations. Further, these pools of neurons are interconnected by dense horizontal connections that can extend several millimeters. Both intracortical microstimulation and TMS evoke muscle contraction via transsynaptic activation of corticospinal neurons. Thus, any change in motor map topography must therefore involve changes in the pattern of intracortical connectivity.

The development of skilled movement sequences involves strengthening the spatiotemporal relationship between specific muscle synergies. This process may occur through changing the connectivity between specific sets of corticospinal neurons through changes in synaptic efficacy. Movements that are repeatedly produced as part of an acquired sequence would then

become more connected within motor cortex. This would result in a biasing of cortical circuitry such that trained movements are more likely than untrained movements to be evoked in response to cortical stimulation. In support of this hypothesis, learning-dependent synaptogenesis is colocalized with regions of motor cortex that exhibit map reorganization. During skill learning, synaptic potentiation appears at approximately the same time as changes in motor map topography appear. Inducing LTP through tetanic stimulation also induces synaptogenesis and map expansion, whereas LTD causes synapse loss and map shrinkage. Finally, pharmacological manipulations that impair induction of synaptic potentiation also impair map reorganization and motor skill learning.

The key factor in driving learning-dependent synaptic plasticity within cortical circuits is therefore timing. Hebb postulated that synaptic efficacy between two neurons is enhanced when the first repeatedly contributes to the firing of the second. Further, if the second neuron is coincidently active when the synaptic inputs from the first arrive, the connectivity is further strengthened. This form of associative LTP has been demonstrated clearly in motor cortex. Stable reorganization of motor output can be induced by creating an artificial connection between two sites in motor cortex of freely behaving monkeys. That is, the output produced by stimulation of a cortical site can shift toward that of a neighboring site when the two sites are coincidently activated. During skill training, this kind of coincident activity is observed as a progressive increase in the synchrony of neural activity within motor cortex. The coactivation of circuits during practice would lead to plasticity of intracortical synapses resulting in a strengthening of connections between neurons. Cortical representations of trained movements would therefore become larger and more overlapping. Thus, synaptic plasticity provides a neurophysiological mechanism for enhancing dexterity and creating the muscle synergies required for performing skilled movement.

Synaptic Plasticity and Place Cell Formation

Introduction

In the mid-1950s, an epileptic patient with the initials HM underwent a neurosurgical operation to remove his hippocampus and surrounding parts of his medial temporal lobe in order to excise the source of his life-threatening seizures. As an unexpected consequence of this procedure, HM lost the ability to form new, declarative (conscious) memories. His general intellect and personality were unaffected, and his memories of his past were generally intact. However, from that day onward, HM has not been able to create any new, long-lasting memories about the events that happen to him. He can retain information for brief periods, but as soon as he is distracted or a few minutes go by, he loses all memory of what just occurred. To this day, he has little, if any, memory of his life history after the operation. This type of amnesia has since been studied in numerous patients that have suffered hippocampal and medial temporal lobe damage as the result of stroke, infection, brain trauma, or neurodegenerative disease (e.g., Alzheimer's disease).

From the initial case report of HM's condition by William Scoville and Brenda Milner, the hippocampus has become the premier site to investigate the mechanisms of learning and memory in the mammalian brain. The decade after Scoville and Milner's report witnessed a number of laboratories engaged in attempts to discover physiological correlates of learning and memory in the hippocampus. The early 1970s produced two seminal discoveries about hippocampal physiology that still dominate this research three decades later. In 1971, John O'Keefe and Jonathan Dostrovsky reported that, in freely moving rats, hippocampal pyramidal neurons fire selectively in specific locations in an environment (Figure 1). Subsequent research on these cells and a thorough review of the experimental literature on hippocampal lesions led O'Keefe and Lynn Nadel in 1978 to propose a theory that these hippocampal 'place cells' were the building blocks of an internal, cognitive map of the environment. This map was necessary not only for flexible, spatial navigation, but also as a framework to organize the items and events of an organism's experience into a long-term memory store.

In 1973, another landmark paper by Timothy Bliss and Terje Lømo presented compelling evidence that strong, electrical stimulation of hippocampal input fibers can cause a long-lasting potentiation of the synaptic efficacy of these presynaptic fibers onto their hippocampal targets. This phenomenon, called long-term potentiation (LTP), has become the predominant model for how neural activity can cause changes in the strength of synapses between neurons, thus serving as a cellular mechanism for information storage (i.e., learning and memory). The initial discovery of this phenomenon in the hippocampus was thought to perhaps reflect the special role of the hippocampus in learning and memory. It is now known that there are multiple forms of learning in different brain systems, and that LTP (and its counterpart, long-term depression, or LTD) can be elicited in many different brain structures (including the neocortex and cerebellum). LTP and LTD are fundamental physiological mechanisms that fine-tune the synaptic connectivity of the brain as it wires itself during development and as it adapts to the constantly changing circumstances that an organism experiences throughout its lifetime.

In the first couple of decades after the appearance of these two papers, surprisingly little published research directly investigated the relationship between LTP and place cells. Place cell research focused on the questions of what external and internally generated cues generated the spatial specificity of these neurons and whether hippocampal neurons were sensitive to nonspatial variables as well as spatial location. LTP research focused on establishing a direct link between LTP and learning in behavioral studies and on investigating the cellular and molecular mechanisms of LTP induction and maintenance. In recent years, a number of investigations have begun to focus explicitly on the role of synaptic plasticity in place field formation and function.

Experience-Dependent Properties of Place Cells

Given the strong link between the hippocampus and LTP, it is perhaps surprising that much of the spatially selective firing of place cells does not appear to be learned. Rather, place cells can demonstrate their spatially selective place fields from the very first time an animal enters the place field. These fields are not static, however, which suggests that some form of plasticity occurs in these networks. One demonstration of this plasticity comes from the application of multielectrode recordings of dozens of CA1 place cells, which allows the offline reconstruction of the animal's trajectories through an environment by

Figure 1 Examples of place fields from the rat hippocampus. Each figure is a spatial firing rate map for a CA1 place cell, in which red indicates a location in which the cell fired at a high rate and blue indicates a region where the cell was silent. The example from the left is from a rat foraging for food on a square platform. The cell fires selectively in the middle of the southeast quadrant of the platform. The example on the right is from a rat running clockwise on a circular track. The cell fires selectively at the northwest section of the track.

analyzing the population activity of the recorded cells (i.e., by knowing the subset of active place cells at a given moment, one can accurately determine the location of the animal at that moment). In a novel environment, the accuracy of this reconstruction increases over the first 10 min of exploration. Thus, some fine-tuning of the place fields must occur, such as an increase in the specificity or reliability of individual firing fields. Although the place field 'map' is evident immediately in a novel environment, the first few minutes of exploration cause changes to the cells that improve the spatial signal at the population level.

The place fields appear to become bound to external sensory landmarks through a learning process. In a familiar, stable environment, the firing locations of place cells can be controlled by external landmarks, such as visual cues at the periphery of an environment, in that rotation of these salient landmarks can cause an equal rotation of the place cell map. However, if an animal is disoriented each time it enters an environment, such that it perceives that the landmarks in that environment are unstable relative to its own, internal direction sense, the ability of the landmarks to control the location of the place fields becomes weakened. Similarly, if the landmarks are moved around in the presence of the animal, they can lose the ability to control the place fields. Individual place cells maintain their firing locations relative to each other, however. Under these conditions, and under conditions of darkness or other external sensory deprivation, the cells appear to be under the dominant control of path integration mechanisms, presumably provided by the input from the medial entorhinal cortex. This input is probably always at work as a major drive onto place cells, and it endows the cells with their immediate spatial specificity in a novel environment. As the animal explores the new environment, the place cells are thought to form associations with other inputs that represent the landmarks in that environment through an LTP-dependent mechanism. This learned association eventually allows the landmarks to control the place fields, and can be disrupted when the animal perceives that the landmarks are unstable directional cues. Furthermore, these associations allow the hippocampus to activate the proper subset of place cells when the animal reenters that environment in the future.

Changes to the environment can trigger complex alterations in the ensemble activity of place cells. Cells that were previously silent can form new place fields when new objects are placed in the environment or when expected rewards are omitted. In many cases, changes in the environment can produce wholesale changes in the populations of active place cells. This phenomenon, called 'remapping' by Robert Muller and John Kubie, can occur immediately when the change is first made; can occur abruptly some time after the change is made; or can develop slowly and continuously over many experiences in the altered environment. The phenomenon of place cell remapping is not entirely understood, and it certainly encompasses a variety of different neural mechanisms. As such, it is a prime candidate to address the relationship between place cell function and synaptic plasticity.

Place field plasticity has also been correlated with the temporal dynamics of LTP induction. As first demonstrated by William Levy and Oswald Steward, LTP is temporally asymmetric. That is, presynaptic cells must fire before postsynaptic cells in order to produce LTP. If the postsynaptic cell fires first, then LTD is produced. This spike-timing relationship preserves the causal relationship of firing. If the presynaptic cell fires shortly before the firing of the postsynaptic cell, then presumably the presynaptic cell had an impact on causing the postsynaptic cell to fire and, according to Hebb's rule, should increase its strength of connection. If the timing is reversed, however, then the firing of the presynaptic cell could not have caused the firing of the postsynaptic cell, and therefore the connection strength should be decreased. Evidence that such timing rules might be useful for encoding spatiotemporal sequences of activity was found in place cells. When rats run stereotyped routes, the place fields expand backward (i.e, in the direction opposite to the direction of travel of the rat) with experience, as predicted by computational models that applied spike-timing-dependent plasticity rules toward place cells. As illustrated in Figure 2, as

Figure 2 Backward expansion of place fields. Originally discovered by Mehta and colleagues, this NMDA receptor dependent phenomenon suggests a relationship between temporally asymmetric induction of LTP and the possible encoding of spatial sequences in the hippocampus. (a) The first time a rat runs on a linear track, the linear place fields are symmetric and are presumably driven by external spatial inputs (landmarks, self-motion cues, etc.), indicated by thick arrows. The place cells are also interconnected weakly (thin, curved arrows). The rat is in the middle of the track, where the red place cell is active, and the green and blue place cells are about to be activated as the rat moves to the right. (b) After a number of laps where the rat runs from left to right, LTP has strengthened the connections between pairs of cells that fired in temporal order (e.g., the connection of the green place cell onto the blue cell was strengthened, because the green cell always fired before the blue cell, but its connection onto the red cell was not strengthened, because it always fired after the red cell). As a result, each cell now gets strong external input as well as strong input from its preceding neighbor. This added input causes the cell to fire earlier in the sequence than it did in (a).

the rat runs from left to right, the red place cells always fire before the green place cells, which fire before the blue place cells. As a result, the red place cell over time increases its connection strength onto the green place cell, causing the green place cell to fire earlier than before (i.e., the green place field expands backward). The same expansion happens for all of the place fields on the track. After experiencing these stereotyped sequences of locations, the earliest spikes of each place field may serve as a prediction of where the animal will be if it continues on its learned path, rather than a representation of the animal's current location. That is, in Figure 2(b), the late spikes from the red cell indicate the current location of the animal, whereas the early spikes from the green cell indicate that the animal will arrive at the green location next, which will then predict the blue location, and so on. This backward expansion is apparent in both CA1 and CA3 place fields. CA3 appears to be the location where the sequences are initially learned (in as little as one trial) and stored for the long term. In CA1, the sequences are stored only for a few hours, suggesting a role for CA1 in the online encoding of sequences and comparison with the long-term stored sequences in CA3.

Place Cells in Aged Rats

Some of the earliest evidence linking LTP to place cells came from studies of aged rats. Old rats have well-documented deficits in LTP and in spatial learning. However, the specificity of individual place fields is only modestly affected in aged rats, which is consistent with the immediate presence of place fields in a new environment and implies that place fields themselves do not always require synaptic plasticity to form. A number of secondary properties of place fields that are thought to depend on synaptic plasticity are disrupted in aged rats. Aged rats appear to have deficits in activating the proper subset of place cells when entering a familiar environment. In parallel, they have deficits in changing stable representations when faced with environmental alterations. In other words, place cells of aged rats or more likely than young rats to inappropriately remap a stable environment, even though no salient changes have been made to the environment. Whereas young rats will display the same place fields in a familiar environment day after day, aged rats are more likely to display different place fields on different visits to the same environment. The binding of place fields to individual landmarks allows the young rat to recognize a familiar environment and activate the proper set of place cells. This binding is a learning process that appears to be impaired in aged rats.

Conversely, place cells of aged rats are less adaptable to environmental changes or to behavioral task changes than are place cells of young rats. As mentioned before, place cells of young rats can remap an environment in response to salient changes, as the hippocampus creates new, context-specific representations of different environments or even the same environment under different circumstances. The place cells of aged rats are more rigid and inflexible, however, as they are less likely to remap under these conditions. This rigidity may be a reflection of deficits in synaptic plasticity mechanisms.

Place cells of aged rats also fail to show the backward expansion/shift effect when the rats run a stereotyped route. Taken together, these results are consistent with the notion that deficits in LTP in aged rats impair the ability of place cells to encode relevant information about changes to the environment and also impair the rats' ability to retrieve the proper hippocampal representations for familiar environments. If this retrieval failure subsequently prevents retrieval of the nonspatial information that has become associated with the

hippocampal map, this result may explain many of the learning impairments that are seen in senescent animals (including humans).

Place Cells and LTP

The work on place cells and aged rats provides striking evidence of a relationship between synaptic plasticity and high-order cognitive representations. A major advantage of this work is that it capitalizes on a natural experimental manipulation. That is, the well-characterized deficits in LTP that occur naturally in the aging process can be correlated with changes in place cell properties without the need for experimental manipulations. A disadvantage, however, is that the results are by nature correlational and indirect, and one would also like to study the question under conditions that are more explicitly under experimental control. These experiments can be performed with the use of pharmacological agents that block LTP and genetic techniques that can alter specific molecular aspects of the LTP induction, expression, and maintenance pathways.

LTP blockers have been used to study the remapping phenomenon. Rats injected with pharmacological blockers of LTP can remap an altered environment similar to controls. That is, when the environment is altered, new place fields emerge and old place fields become silent or scramble. This result demonstrates once again that the expression of place cell spatial selectivity does not depend on LTP mechanisms. However, in contrast to control rats, rats with LTP blockers are not able to maintain a stable representation of the altered environment when they are reintroduced into it a day later. It appears that LTP is necessary for the sensory landmarks that allow the rat to recognize the new environment to become associated with the new place field map and reactivate it when the rat is placed back into the environment. Without this binding in the initial visit to the environment, the hippocampus treats the second visit to the environment as if it were a completely novel environment and activates a subset of place cells that is different from the subset active in the first exposure (Figure 3). This result demonstrates explicitly that LTP is necessary for the binding of a particular subset of place cells to represent a particular environment, and supports the argument that LTP deficits in aged rats cause the improper 'remapping' of familiar environments due to a deficit in this binding.

LTP blockers have also been shown to block the backward expansion of place fields, providing direct evidence that this phenomenon is dependent on the proper functioning of *N*-methyl-D-aspartate (NMDA) receptors (the type of glutamate receptor that is essential for LTP induction). This result lends credence to Hebb's ideas that synaptic plasticity can generate phase sequences: cell assemblies that are serially linked together in a learned temporal order. Such phase sequences endow the brain with two important properties: predictability and temporal recall. That is, if synaptic strengthening causes one cell assembly (e.g., a cell assembly representing location A) to activate the cell assembly that tends to follow it (e.g., a cell assembly representing the next location on a familiar route), which activates the next assemblies in order, this sequential activation becomes a prediction of what events are likely to follow given the current state of the animal. This predictability can then be used to alter behavior adaptively (i.e., if the end of the phase sequence predicts a negative consequence, alter one's behavior; if the end predicts a positive consequence, maintain the behavior). Second, storing these sequences allows the cell assemblies to be reactivated in order, thus allowing the recall of the temporal sequence of events, which is a hallmark of episodic memory that is thought to rely critically on hippocampal processing. Evidence for these sequences arises from studies of rats during sleep, in which the temporal order of place cell firing that occurs during the behavior of the animal is preserved when these cells

Figure 3 NMDA receptor antagonists prevent the binding of place fields to the cues that define a particular environment. This figure illustrates schematically the demonstration by Kentros and colleagues that, under normal conditions, a place cell will show different place fields in a familiar environment (the square) and a novel environment (the circle). When reintroduced into the novel chamber the next day, the place cell 'remembers' where it should fire in the new environment, presumably due to an associative binding between the neural representations of landmarks in that environment and the place cell. When NMDA receptors are blocked, however, this binding does not take place. The initial formation of a new place field is unaffected in the novel chamber on the first day. However, the next day, the place field fires in yet another location. Apparently, the blockage of LTP the day before prevented the landmarks in the novel chamber from activating the cell in the proper location a day later. The cell has a place field, but the population representation is substantially different from the first exposure.

fire during subsequent sleep periods. This temporal reactivation has been proposed to reflect an offline process by which the hippocampus 'replays' to the neocortex the activation patterns it experienced in the recent hours, thus allowing the slower plasticity mechanisms of the neocortex to gracefully integrate the hippocampus-mediated new learning into the long-term memory stores of the neocortex.

The emergence of site-specific, inducible genetic knockouts and transgenic animals has opened a new avenue of investigation of the relationship between synaptic plasticity and place cells. Different knockout lines have targeted NMDA receptor subunits in the CA1 and other forebrain regions and in the CA3 region. Other genetically altered mouse lines have eliminated or mutated other molecules that are necessary for normal LTP, such as calmodulin (CaM) kinase II and cAMP response element binding (CREB). In general, the mutant mice tend to have place fields that are unstable or less specific than wild type, although they show clear spatial specificity. These results support the findings that place cells do not require LTP to show spatial selectivity, but that the selectivity is fine-tuned by synaptic plasticity. Particularly interesting is the CA3 NMDA receptor knockout, which inhibits one-trial learning in a match-to-place version of the Morris water maze and reduces the selectivity of downstream place fields in CA1 during first exposure to a novel environment. In subsequent exposures, the animals are able to perform the task and the CA1 place fields are normal. These results suggest that CA3 plays a critical role for rapid, one-trial learning, and that CA1 is able to support learning only at a slower time course, consistent with other pharmacological investigations of site-specific NMDA receptor blockade on the relative contributions of CA3 and CA1 plasticity in learning and with differences between CA3 and CA1 place fields in spatial sequence encoding when the animal experiences an altered environment.

Associative Memory: Theory and Experiment

An autoassociative network is one in which the output patterns of activity can be associated with themselves through feedback pathways. The recurrent collateral pathway of CA3 has for a long time suggested to theoreticians that CA3 may form an autoassociative network for memory storage. An important property of such a network is called 'pattern completion,' whereby a degraded or incomplete input pattern can reactivate the entire, originally stored input pattern via the recurrent collaterals. Such an organization can also be used to generalize input patterns, as similar input patterns can cause the same output pattern to be activated in the network. In some cases, however, if similar input patterns represent distinct states that must be kept segregated, a memory storage system should be capable of 'pattern separation,' whereby similar input patterns are made more dissimilar before being stored in the synaptic weights of the network. Pattern separation allows the network to store more memories before they begin to interfere with each other.

Place cell recordings have shown evidence for both pattern separation and pattern completion in the CA3 region. In agreement with computational models that suggest a sigmoidal relationship between input pattern similarity and output pattern similarity, when changes are made to local cues in a familiar environment, the CA3 region outputs a representation that is similar to the original representation. In contrast, the CA1 region outputs a representation that is less similar to the original representation than CA3. When the animal is brought into an entirely different environment, the CA3 region outputs a completely new representation. In contrast, the CA1 region outputs a representation that maintains a degree of similarity with the representation of the first environment. Thus, CA3 appears to reflect a pattern completion process when inputs are modified to a limited degree, whereas it reflects a pattern separation process when the inputs are altered more extensively.

Further evidence for the role of CA3 in pattern completion comes from genetic studies. CA3 mice with NMDA receptor knockout show deficits in pattern completion. Place cells recorded from CA1 in these mice had larger place fields compared to wild-type mice when a number of the salient spatial cues in an environment were removed, suggesting that the mutant mice had a reduction in the ability to pattern complete the partial input. These mice also showed deficits in LTP in CA3 and in spatial learning under the partial cue conditions.

Summary

Place cells of the hippocampus are a prime example of a robust, high-order, cognitive representation. Because of the well-documented role of the hippocampus in learning and memory and the extensive knowledge of LTP in the hippocampus, place cells are becoming an important model system for neural plasticity as well. These studies rely heavily on the use of multi-electrode recording technologies, which can provide critical data on the changes that occur in many neurons in a small period of time. Because the hippocampus is thought by many to be particularly important for one-trial, episodic memory, these ensemble recordings will become increasingly essential toward understanding the role of synaptic

plasticity in hippocampal function, and the role of hippocampal function in the neuropsychology of memory.

Introduction

In neural networks activity-dependent synaptic plasticity can be long lasting and bidirectional. Synapses can be potentiated (long-term potentiation (LTP)) or depressed (long-term depression (LTD)), enabling the storage (and erasure) of information at selected sets of synapses. LTP and LTD provide the most convincing cellular candidate mechanisms for learning and memory ('synaptic memory'), which explains the high level of attention that these synaptic alteration processes have received during the past three decades. In the cerebellum, LTD at parallel fiber (PF) to Purkinje cell synapses is believed to provide a cellular basis for forms of cerebellar motor learning, such as associative eyeblink conditioning or gain adaptation of the vestibulo-ocular reflex. More recently described forms of LTP might, in turn, provide reversal mechanisms. This article describes cerebellar LTD and LTP from a cellular/molecular perspective and points out similarities and differences to their counterparts at hippocampal synapses.

LTD at Parallel Fiber–Purkinje Cell Synapses

Purkinje cells form inhibitory synapses with their target cells in the deep cerebellar nuclei (or the vestibular nuclei). Therefore, theories of cerebellar function have described PF-LTD, rather than PF-LTP, as a central component of motor learning because LTD at excitatory synaptic inputs to Purkinje cells was expected to cause a disinhibition of the target neurons in the cerebellar or vestibular nuclei.

PF-LTD can be monitored as a downregulation of PF-evoked excitatory postsynaptic currents (EPSCs). In the example shown in Figure 1(a), LTD was measured using somatic whole-cell patch-clamp recordings from Purkinje cells in rat (postnatal days 18–28) cerebellar slices. Typically, in these experiments spontaneous spike firing is prevented by the injection of small hyperpolarizing currents and fast inhibitory transmission is blocked by bath application of $GABA_A$ receptor antagonists. Both measures allow us to characterize excitatory synaptic events in isolation.

Next to the synapses provided by PFs, Purkinje cells receive a second type of excitatory synaptic input, provided by a single climbing fiber (CF), which originates from the inferior olive. PF-LTD induction depends on paired PF and CF activation (Figure 1(a)). LTD is optimally induced when PF activity slightly precedes the activation of the CF input (by 50–200 ms), which corresponds well to the timing requirements for the application of conditioned and unconditioned stimuli in associative eyeblink conditioning.

CF activity results in an all-or-none complex spike in Purkinje cells, which is associated with a widespread calcium transient in Purkinje cell dendrites. This heterosynaptically evoked calcium transient is required for PF-LTD induction, reflecting the involvement of a threshold level of postsynaptic $[Ca^{2+}]_i$. At the PF synapses, both α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) receptors and type 1 metabotropic glutamate (mGluR1) receptors need to be activated for LTD induction. Glutamate binding to mGluR1 receptors results in the activation of phospholipase C and subsequently in the production of inositol-1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol (DAG). IP_3 signaling might contribute to the total calcium transient by releasing calcium from internal stores. The participation of this signaling pathway, however, has been controversial. In contrast, the second product of phospholipase C activity, DAG, could be unequivocally linked to LTD induction. DAG and calcium (provided by voltage-gated calcium channels opened by AMPA receptor-mediated depolarization) synergistically activate protein kinase C (PKC). The critical involvement of PKC in LTD induction has been demonstrated using pharmacological approaches as well as transgenic mice (L7-PKCI), in which a PKC inhibitory peptide is specifically expressed in Purkinje cells. It has also been shown that LTD is impaired in cerebellar slices obtained from *αCaMKII−/−* mice, suggesting that not only PKC but also αCaMKII is involved in LTD induction. Finally, it has been suggested that the gaseous second messenger nitric oxide (NO) is involved in LTD induction by triggering an NO/cGMP/PKG cascade.

How does activation of various kinases mediate LTD at PF synapses? The chain of events leading from PKC activation to LTD has been characterized in detail. In Purkinje cells, the majority of AMPA receptors are constituted by GluR2–GluR3 heteromeres. PF-LTD results from a clathrin-mediated endocytosis of GluR2, which requires PKCα-dependent phosphorylation of GluR2 at serine 880. The internalization of GluR2 involves unbinding from glutamate receptor-interacting protein (GRIP) and binding to protein interacting with C-kinase 1 (PICK1). In contrast, the role of αCaMKII in GluR2 endocytosis

Figure 1 Three forms of long-term plasticity at cerebellar parallel fiber synapses. (a) Postsynaptic LTD is induced by paired parallel fiber (PF) + climbing fiber (CF) activation at 1 Hz for 5 min ($n = 15$). The traces show EPSC pairs (50 ms delay) before and after LTD induction. PF-LTD is not associated with changes in the PPF ratio. (b) Postsynaptic LTP is induced by isolated PF stimulation at 1 Hz for 5 min ($n = 8$). Traces show EPSC pairs (50 ms delay) before and after LTP induction. This form of LTP is not associated with changes in the PPF ratio. (c) Presynaptic LTP is induced by isolated PF activation at 8 Hz for 15 s ($n = 12$). Traces show EPSC pairs (100 ms delay) before and after LTP induction. The PPF ratio is reduced after tetanization. (d) Diagram showing the electrode arrangement used for LTP and LTD experiments *in vitro*. Whole-cell patch-clamp recording is used to monitor electrical responses to PF and/or CF stimulation. For extracellular stimulation, glass pipettes are used (Stim) that are filled with ACSF.

and LTD remains to be examined. PKG likely has an indirect role. It seems possible that phosphorylation of G substrate by PKG can cause an inhibition of protein phosphatases that might dephosphorylate the same substrates that are phosphorylated by PKC or αCaMKII.

PF-LTD is mediated by an endocytosis of AMPA receptor subunits and, consequently, in a reduction of the postsynaptic AMPA receptor density. The postsynaptic expression side is confirmed by an absence of changes in the paired-pulse facilitation (PPF) ratio.

LTP at Parallel Fiber–Purkinje Cell Synapses

If PF-LTD is a correlate of forms of cerebellar motor learning, it can be predicted that at least one type of LTP exists to enable reversibility. In fact, both pre- and postsynaptically expressed forms of PF-LTP have been described. Postsynaptic LTP can be induced by the same low-frequency PF activation protocol used for LTD induction (1 Hz, 5 min), when the CF input is not coactivated (Figure 1(b)). LTP requires a dendritic calcium transient for induction, but the calcium threshold for LTP induction is lower than that for LTD induction (hence, CF activity is needed for LTD induction). This type of LTP is postsynaptically expressed, as indicated by the absence of changes in the PPF ratio. Moreover, the low-affinity competitive AMPA receptor antagonist γ-D-glutamylglycine, which can be used as a reporter for changes in glutamate release, reduces EPSC amplitudes to the same level after LTP induction as it does before, suggesting that transmitter release does not change after tetanization.

Unlike LTP at most other types of synapses, postsynaptic LTP at PF synapses does not require kinase activation. PF-LTP is insensitive to bath application

of the PKC inhibitor chelerythrine or the general kinase inhibitor H-7. Moreover, LTP is intact in slices prepared from *αCaMKII*−/− mice. In contrast, LTP depends on the activation of protein phosphatases 1, 2A, and 2B, as suggested by the blockade of LTP in the presence of the phosphatase inhibitors okadaic acid (PP1/2A), microcystin LR (PP1/2A), inhibitor-2 (PP1), fostriecin (PP2A), and cyclosporin A (PP2B).

The phosphatase involvement in synaptic potentiation suggests that LTP and the kinase-dependent LTD can indeed reverse each other. Electrophysiological saturation experiments confirm this hypothesis. When LTP is saturated first by application of two subsequent LTP protocols, application of the LTD protocol leads to a depotentiation. This synaptic depression is truly a 'depotentiation' (rather than just a masking effect) because the subsequent application of a third LTP protocol allows for a potentiation of the previously depressed EPSC amplitudes. Such a re-potentiation would not be possible when the LTP mechanism would still be saturated. As discussed previously, LTD is mediated by GluR2 endocytosis. LTD reversal might thus involve a mechanism enabling GluR2 membrane insertion. Indeed, it has been shown that PF-LTP is associated with GluR2 insertion following NO-mediated *N*-ethylmaleimide-sensitive factor binding to GluR2.

PF stimulation alone can also elicit a presynaptic form of LTP. For induction, PF stimuli are applied at higher frequencies and for shorter durations (e.g., 8 Hz, 15 s) compared to the protocols used for induction of postsynaptically expressed LTP. The presynaptic expression side of this second form of LTP is evident from a reduction in the PPF ratio (Figure 1(c)). Moreover, injection of the calcium chelator BAPTA at a concentration high enough to block all postsynaptic forms of plasticity (30 mM) does not affect LTP resulting from 8 Hz, 15 s PF stimulation. The latter finding suggests the involvement of a presynaptic induction cascade. Indeed, presynaptic LTP depends on the activation of calcium/calmodulin-sensitive adenylyl cyclase I and the subsequent activation of protein kinase A (PKA). A PKA substrate involved in LTP induction is the active zone protein RIM1α, whose phosphorylation by PKA promotes a long-lasting increase in transmitter release.

LTD and LTP at Parallel Fiber Synapses under Heterosynaptic Climbing Fiber Control

Adult Purkinje cells receive synaptic input from only one CF, which is the result of an activity-dependent elimination process that is completed at approximately postnatal day 18. CF activation evokes in Purkinje cells an all-or-none response, the so-called 'complex spike,' which is associated with a widespread calcium transient in Purkinje cell dendrites. This heterosynaptically evoked calcium surge is crucial for PF synaptic plasticity. Studies have revealed that the CF input, through complex spike-associated calcium transients, in fact controls all forms of long-term plasticity at PF synapses that have been characterized so far. Three ways of interference have been observed:

1. Prolonged PF tetanization at low frequencies can induce either LTD or LTP (postsynaptically), depending on whether or not the CF was coactivated. Paired PF and CF activation results in LTD induction, whereas LTP can be observed after PF stimulation alone. The CF controls the direction of synaptic gain change through the calcium signal that it adds on top of the calcium transient locally elicited at the PF input sites. Indeed, a higher calcium threshold level needs to be reached for LTD induction than for LTP induction (Figure 2).
2. Synaptic plasticity is not only a feature of PF synapses but also a feature of the CF input. Brief isolated CF tetanization at slightly elevated frequencies (5 Hz, 30 s) results in CF-LTD, which actually is a multicomponent phenomenon: a depression can be seen at the level of CF-EPSCs (voltage-clamp mode), the complex spikes (current-clamp mode), complex spike-associated calcium transients, as well as the afterhyperpolarization following complex spikes. The long-term reduction in calcium transients that accompanies CF-LTD has consequences for PF plasticity. When the PF-LTD protocol is applied after previous CF-LTD induction, PF-LTP is induced instead. The most likely explanation is that the overall reduction in the calcium transient shifted the relative probabilities for PF-LTD and PF-LTP induction. Thus, this phenomenon describes a new form of heterosynaptic metaplasticity.
3. CF activity, while postsynaptically promoting PF-LTD, blocks presynaptic LTP induction, thus providing a 'safety-lock' mechanism that prevents a postsynaptic downregulation of AMPA receptor function (postsynaptic LTD) is counterbalanced by an upregulation of transmitter release (presynaptic LTP). The CF blocks presynaptic LTP by promoting the release of endocannabinoids from Purkinje cell dendrites. The endocannabinoids act as retrograde messengers and bind to presynaptic CB1 receptors, whose activation blocks adenylyl cyclase activity. Because LTP is triggered by a signaling cascade involving adenylyl cyclase 1 activation, the production of cAMP, and subsequent PKA activation, CB1 receptors can efficiently control this presynaptic form of plasticity.

Figure 2 LTP and LTD induction cascades at hippocampal (left) and cerebellar synapses (right). LTD induction cascades are shown in blue, and LTP induction cascades are shown in green. The dashed line separating the 'pyramidal cell' from the 'Purkinje cell' does not continue all the way to the top because PICK1-controlled GluR2 endocytosis (right) occurs in both types of neurons. *N*-methyl-D-aspartate receptor (NMDAR) TARP, transmembrane AMPA receptor regulatory protein. Cerebellar LTD and LTP: Mirror Image of Hippocampal Plasticity

The signaling cascades involved in LTP and LTD induction at excitatory synapses onto hippocampal and neocortical pyramidal cells have been particularly well studied. In fact, the synapses between Schaffer collaterals and CA1 pyramidal cells are considered as reference synapses for LTP and LTD studies in general.

At these types of synapses, both LTP and LTD can be triggered by dendritic calcium transients. In 1982, Bienenstock, Cooper, and Munro suggested that synaptic modification is controlled by an activity-related two-threshold mechanism. In an updated version, in which the general term 'activity' was more specifically replaced by amplitudes of postsynaptic calcium signaling, the 'BCM rule' suggests that a higher calcium threshold amplitude has to be reached for LTP than for LTD induction. In contrast, LTP and LTD at cerebellar PF synapses are governed by an 'inverse' calcium threshold mechanism: a higher calcium threshold amplitude has to be reached for LTD than for LTP induction (Figure 2).

Can this mirror-image-like arrangement of induction cascades also be found downstream of the calcium transients? AMPA receptors are heteromeric complexes of the four homologous subunits GluR1–GluR4. In hippocampal pyramidal cells, the majority of AMPA receptors consists of GluR1–GluR2 and GluR2–GluR3 heteromeric complexes. Hippocampal plasticity is assumed to primarily rest on modifications of GluR1 subunits, resulting in single channel conductance changes and/or altered GluR1 subunit trafficking. LTP induction is promoted by large calcium transients that activate αCaMKII, PKC, and PKA, whereas LTD induction is promoted by direct or indirect activation of protein phosphatases 1 and 2B by prolonged, low-amplitude calcium transients. Although these findings suggest that LTP and LTD, respectively, are determined by the phosphorylation level of only one GluR1 phosphorylation site, it currently seems that at least three different phosphorylation sites on GluR1 are involved as well as several scaffolding/anchoring proteins.

In cerebellar Purkinje cells, GluR1 subunits are only weakly expressed and the majority of AMPA receptors consist of GluR2–GluR3 heteromeric complexes. At the level of kinase/phosphatase requirements, bidirectional cerebellar plasticity provides an almost perfect mirror image of its hippocampal counterpart. PF-LTD induction is dependent on the activation of PKC and αCaMKII, whereas PP1, PP2A,

and PP2B are involved in LTP induction (Figure 2). In the case of PKC, the subsequent steps of the signaling cascade have been described in detail: PKCα phosphorylates GluR2 at serine 880, which initiates GluR2 endocytosis. Evidence suggests that a similar PKC-triggered cascade leading to GluR2 endocytosis is also involved in hippocampal LTD induction.

Conclusion

It seems that LTP and LTD at PF synapses in the cerebellum are governed by induction cascades that, at the level of calcium and kinase/phosphatase dependencies, operate 'inverse' in comparison to their hippocampal counterparts. At the level of AMPA receptor trafficking, the 'mirror image' does not describe perfectly well the difference between pyramidal cells and Purkinje cells but, rather, that between GluR1–GluR2 heteromeres and GluR2–GluR3 heteromeres.

Synaptic Plasticity: Diacylglycerol Signalling role

W S Sossin and C A Farah, McGill University, Montreal, QC, Canada

Diacylglycerol and Synaptic Plasticity

Diacylglycerol (DAG) is one of the most important second messengers produced by neurotransmitters. In this article, we highlight the mechanisms for production and removal of DAG by neurotransmitters, the targets of DAG, and the role that these targets play in neuronal plasticity.

Phospholipase Cs are the Major Source of DAG Production

DAG is a glycerol derivative that has two hydroxyl groups esterified by fatty acids (groups R1 and R2 in Figure 1). While DAG is a normal metabolite produced during the synthesis of many membrane lipids, steady-state levels of DAG are low and its production is stimulated upon activation of different cellular cascades. The critical enzyme that generates DAG after extracellular signals is the phosphatidylinositol-4,5-biphosphate (PIP_2)–specific phospholipase C (PLC) which produces DAG and inositol-1,4,5-triphosphate (IP_3) from PIP_2 (Figure 1). Another way for signals to produce DAG is from phosphatidylcholine (PC) by two reactions involving PC-specific phospholipase D (PLD) isozymes and phosphatidic acid (PA) phosphohydrolase (PAP) (Figure 1). This second pathway has been proposed to be important for more persistent increases in DAG but has not yet been established in any plasticity paradigms. It should be noted that the DAG produced from PC differs from that produced by PIP_2 in the saturation of positions R1 and R2. It is not yet known if different DAGs can differentially activate distinct targets.

Phospholipase C

There are four classes of PLCs: β, γ, δ, and ε (Figure 2). PLCs β, γ, and δ have in common a PH domain, connected through an EF hand motif to the catalytic region (Figure 2). C-terminal extensions and inserts in the catalytic domain are isoform and class specific. Distinct processes regulate different classes of PLC: PLCβ isoforms are activated downstream of G protein-coupled receptors (GPCRs); PLCγ is activated downstream of receptor tyrosine kinases (RTKs); PLCδ is activated by calcium ions; and PLCε is activated by small GTPases including Ras and Rho. Below is a brief description of the regulation of each class of PLC and its relevance for synaptic plasticity.

PLCβ PLCβ isoforms are activated both by $G\alpha_q$ and $\beta\gamma$ subunits; however, different isoforms show relative preferences for activation by either $G\alpha_q$ or $\beta\gamma$ with PLCβ1, β3 and β4 best activated by $G\alpha_q$ and PLCβ2 and β3 being best activated by $\beta\gamma$. The two effectors bind to distinct regions of PLCs, with $G\alpha_q$ binding to the C-terminal extension and $\beta\gamma$ binding to a loop in the catalytic domain. Thus the two pathways can be additive. PLCβ is also an effective GTPase for $G\alpha_q$, stimulating GTP hydrolysis and inactivation of the effector. This is one reason why PLC signaling and DAG production downstream of GPCRs is usually transient.

In the brain, most PIP_2 turnover is mediated through $G\alpha_q$ due to the abundance of PLC isoforms β1 and β4, and neurotransmitters that signal through $G\alpha_q$-coupled receptors, particularly 5-HT 2 receptors, type I metabotropic glutamate receptors (mGLURs) 1 and 5, and muscarinic receptors (m1 and m3), all activate PLCβ isoforms in the brain. Interestingly, mGLURs are more coupled to PLCβ4 while muscarinic receptors are more coupled to PLCβ1. Thus, PLCβ4 knockout animals have major deficits in mGLUR-mediated PIP_2 turnover, and several forms of neuronal plasticity are mediated by mGLURs, such as developmental pruning of climbing fibers in the cerebellum, cerebellar long-term depression (LTD), forms of neuropathic pain and circadian rhythmicity. In contrast, PLCβ1 knockout animals have major developmental disorders and seizures through loss of developmental plasticity in the cortex and a major deficit in muscarinic-mediated PIP_2 turnover, with no change in mGLUR PIP_2 turnover.

In *Drosophila* photoreception, a specific isoform of PLC is part of a signaling complex held together through protein–protein interactions with both upstream and downstream effectors, and these types of signaling complexes may also be important in the mammalian brain to provide for additional specificity such as described above for differential regulation of PLC isoforms.

PLCγ PLCγ isoforms contain SH2 domains that directly bind to phosphorylated tyrosines of activated RTKs. This binding both localizes PLCγ to membranes where its substrate PIP_2 exists and leads to phosphorylation of PLCγ on tyrosines, which

Figure 1 *Sn*-1,2-Diacylglycerol (DAG) can be generated from two different pathways. The first one involves hydrolysis of PIP_2 into DAG and IP_3 by phospholipase C. IP_3 acts on IP_3 receptors to trigger calcium release from endoplasmic reticulum stores. The second pathway, which generates DAG from PC, comprises a two-step reaction involving PLD and PAP, respectively. PA generated by the action of PLD or DAG kinase can be converted back to PIP_2 by the action of type I phosphatidylinositol-4-phosphate-5-kinase. DAG kinases terminate DAG signal by phosphorylating DAG to generate PA. Groups R1 and R2 are fatty acids.

increases its activity. Interestingly, activation of PLCγ downstream of tropomyosin receptor kinase (Trk) activation is particularly important for Trk signaling in synaptic plasticity such as long-term potentiation (LTP).

PLCδ PLCδ is particularly sensitive to regulation by calcium ions. While all PLCs can be regulated by calcium binding to the EF hand motif, PLCδ is the only isoform regulated by physiological levels of calcium. PLCδ is responsible for DAG production that is observed downstream of *N*-methyl-D-aspartate (NMDA) receptor activation and activation of voltage-gated calcium channels independently of GPCR activation.

PLCε PLCε has two unique regions responsible for activation by small GTPases. Ras activates PLCε through a C-terminal Ras-association domain, while Rho activates PLCε through an insertion in the catalytic domain. Modulators that act through $G\alpha_{12,13}$ such as thrombin and lyosphosphatidic acid (LPA) activate DAG production through Rho and PLCε.

DAG Kinases Are the Key Enzymes Responsible for Termination of the DAG Signal

As a second messenger, DAG can regulate the function of many signaling proteins by recruiting them and

Figure 2 Schematic representation of the PLC and DGK isozymes. PH, pleckstrin homology domain; SH2 and SH3, Src homology domains 2 and 3; X and Y, split catalytic domain of PLC; RA, Ras association domain; RasGEF, Ras guanine nucleotide exchange factor-like domain; SAM, sterile alpha motif; MARCKS, myristoylated alanine-rich C-kinase substrate like-domain. The shaded C1 domains of DGKβ and DGKγ are typical C1 domains, which bind to phorbol-esters, while the other DGK isoforms contain atypical C1 domains, PDZ (postsynaptic density protein 95/discs large/zonula occludens protein 1 domain).

activating them. As for all second messengers, mechanisms exist for removing the second messenger and this pathway is highly regulated. This is best illustrated by the tumor-promoting agents phorbol esters, which are DAG analogs that are only slowly metabolized and lead to the promotion of tumor formation by persistently activating DAG targets. DAG is metabolized in three ways: addition of cytidine diphosphate–choline (CDP–choline) or –ethanolamine to form PC or phosphatidylethanolamine, hydrolysis of a fatty acyl chain by DAG lipase to produce a monacylglycerol and a free fatty acid, and phosphorylation of the free hydroxyl group by DAG kinase (DGK) to generate PA. DGK is considered to be the major pathway for removal of the second messenger pool of DAG.

DAG Kinase

There are nine known mammalian DGK isoforms (Figure 2). Most, if not all of them, are expressed abundantly in the brain. Based on the structure of their regulatory domain, the DGKs are grouped into five subtypes. DGKs need to be translocated to DAG-rich membranes to be effective, and isoforms differ in their mechanisms for membrane translocation. For example, type II DGKs are translocated through their PH and SAM domains, while type IV DGKs have PDZ (postsynaptic density protein 95/discs large/zonula occludens protein 1 domain) and ankyrin binding domains. All DGKs also have C1 domains that bind phorbol esters/DAG in other

proteins (see below). However, in most DGKs, C1 domains do not bind phorbol esters (with the exception of DGKβ and DGKγ), and probably do not bind DAG, but allow regulation by other lipids. Genetic evidence suggests that DGKε participates in the regulation of synaptic transmission. Mice lacking DGKε were shown to have reduced LTP in the perforant path and are resistant to electroconvulsive shock. However, these results are probably not due to acute affects of signal prolongation, but to long-term changes in levels of various lipids that are altered due to feedback mechanisms that occur when DAG levels are unregulated.

DAG Targets Have C1 Domains

For DAG to act as a second messenger, it needs to bind to downstream effector modules. Other than the possible exception of Trp channels (see below), all DAG targets contain a high-affinity module known as a C1 domain based on its initial identification as PKC-conserved domain 1. C1 domains are also the targets of the DAG analogs, phorbol esters. The C1 domain is a zinc-finger-like motif of 50–51 amino acids that is rich in cysteine residues and possesses the pattern $HX_{12}CX_2CX_{13/14}CX_2CX_4HX_2CX_7C$ (H is histidine, C is cysteine, and X is any other amino acid). The two histidines and five of the cysteines are responsible for coordinating two Zn^{2+} ions. The zinc-finger motif forms a single ligand-binding site for DAG or phorbol-ester. Some proteins possess two copies of the C1 domain named C1A and C1B, but each C1 domain can bind DAG independently. The structure of the C1B domain of PKCδ in complex with the high-affinity DAG analog, phorbol-ester, has been elucidated. The domain consists of two small β-sheets and a C-terminal α-helix. Phorbol-ester binding to the C1 domains of PKC does not induce conformational changes. It rather alters the nature of the protein surface and stabilizes the membrane-inserted state. Phorbol ester inserts lengthwise into a groove between the two pulled-apart β-strands at one tip of the domain forming a contiguous hydrophobic surface that mediates membrane targeting. Figure 3(a) shows the molecular surface properties of the C1 domain, and a model for the membrane-inserted form of the C1-phorbol ester complex is shown in Figure 3(b). Thus, the C1 domain allows protein to target themselves to DAG-rich membranes when DAG is produced as a second messenger. A fairly similar structure is seen in the C1 domain of Munc13-1, another important target of DAG (Figures 3(c) and 3(d)). The major difference is in the orientation of a tryptophan residue that partially occludes the DAG and phorbol ester-binding site. This may lead to lower affinity for these targets, or to more substantial conformational changes after DAG binding.

Not all C1 domains bind DAG, as noted above for DGKs. These include Raf-1 and PKCζ, whose C1 domains lack essential properties for DAG/phorbol ester recognition and are thus called atypical C1 domains. Atypical C1 domains often bind related lipids such as PA.

DAG Targets

Below we list the known DAG targets and summarize how DAG binding affects their activity. In some cases, such as for PKC, the major role for DAG is to translocate the protein to the membrane, while for others, such as myotonic dystrophy kinase-related cdc42-binding kinase (MRCK), DAG directly stimulates enzyme activity. In many cases, the target is a substrate for PKC, and thus localized pools of DAG may act to co-localize the kinase and substrate leading to efficient substrate phosphorylation.

Protein Kinase C's

The PKC isozymes are the most well known targets of DAG. PKCs are grouped into three subclasses: the classical PKCs or cPKCs, the novel PKCs or nPKCs, and the atypical PKCs or aPKCs (Figure 4). aPKCs have a single C1 domain that does not bind DAG, and thus is not a direct target of DAG. All PKCs consist of a regulatory domain, containing an autoinhibitory pseudosubstrate sequence and a catalytic domain. Lipid binding to the regulatory domain (phosphatidylserine (PS) for most PKCs) causes a conformational change, removing inhibition from the pseudosubstrate and allowing the catalytic domain to phosphorylate downstream targets. However, the affinity of the resting enzyme for PS is low and activation of the enzyme requires targeting to PS-containing membranes, mainly through binding of the C1 domain to DAG. There are four cPKCs in vertebrates: PKCα, $\beta1$, $\beta2$, and γ, where $\beta1$ and $\beta2$ are spliced isoforms that differ in their C-terminal domain. cPKCs also contain a C2 domain following the C1 domains that allows for calcium-dependent phospholipid binding and synergistic activation by the two messengers. The nPKCs comprise PKCδ, ε, η, and θ. These isoforms also contain a C2 domain; however it differs from the C2 domain of cPKCs in its position (at the N-terminal of the enzyme) and its inability to bind to calcium ions. The C2 domain plays several roles in regulating PKCs: it inhibits binding of DAG to the C1 domain; acts to localize PKC through protein–protein interactions, and, particularly in the cPKCs, it contributes to

Figure 3 (a) The molecular surface properties of the C1B domain of PKCδ in complex with phorbol-ester (carbons colored yellow and oxygens colored red) binding in the deep groove at the top of the structure. On the protein surface of the C1B domain, hydrophobic residues are green, positively charged residues are blue, negatively charged residues are red, and neutral polar residues are white. (b) represents a model for the membrane-inserted form of the cys2–phorbol-ester complex based on the molecular surface of the protein–phorbol complex and the crystal structure of dimyristoyl phosphorylcholine. The molecular surface of the protein–phorbol complex is colored as in (a), except that phorbol-ester is also colored green. The membrane model is intended only to represent the estimated depth of penetration of the protein into the bilayer. Lipids in front and in back of the domain have been removed for clarity. (c) and (d) represent the occlusion of the ligand binding-site on the Munc13-1 C1 domain by the W588 side chain. (c) is a space filling model and (d) is the accessible surface of the Munc13-1 C1 domain, viewed from the top of the domain, illustrating how the W588 side chain packs against the rest of the domain. Backbone atoms of loops 1 and 2 are colored yellow and violet, respectively, and side chain atoms from these loops are colored red and orange, respectively, except for those of the W588 side chain, which are colored green (for carbon atoms) and blue (for nitrogen atoms). The positions of some of the side chains are labeled. (a, b) Reproduced from Zhang G, Kazanietz MG, Blumberg PM, and Hurley JH (1995) Crystal structure of the cys2 activator-binding domain of protein kinase Cδ in complex with phorbol ester. *Cell* 81: 917–924, with permission from Elsevier. (c, d) Reprinted with permission from Shen N, Guryev O, and Rizo J (2005) Intramolecular occlusion of the diacylglycerol-binding site in the C1 domain of Munc13-1. *Biochemistry* 44(4): 1089–1096, Copyright (2005) American Chemical Society.

membrane binding and specificity. PKCs are also regulated by phosphorylation. Three ordered phosphorylations are required for the enzyme to gain catalytic competence. The first phosphorylation occurs on a loop near the beginning of the catalytic site called the activation loop by phosphoinositide-dependent kinase (PDK1). This phosphorylation correctly positions residues for catalysis and unmasks the entrance to the substrate-binding site. Phosphorylation at the activation loop rapidly triggers the autophosphorylation at the turn motif in a proline-rich region. Activity is regulated by phosphorylation at the final site known

as the hydrophobic motif. This site may be autophosphorylated or phosphorylated by the kinase, target of rapamycin (TOR). However, unlike many TOR substrates, phosphorylation of PKC is rapamycin insensitive and is a product of the TOR-Rictor complex.

Finally, PKC is regulated through protein–protein interactions. Some PKCs bind directly to actin, which is important for PKC regulation of the cytoskeleton. Scaffolding proteins like receptors for activated C kinase (RACKs), A kinase anchoring proteins (AKAPs), and PDZ domain-containing proteins organize PKC into signaling complexes, localizing them close to particular substrates.

Munc13s

Munc13 proteins consist of four mammalian homologs (Munc13-1, -2 and -3, and -4) of the *Caenorhabditis elegans* Unc13 protein that was isolated in a screen for uncoordinated worms. Munc13-2 is expressed as a brain specific (b) and ubiquitous (ub) splice variant, whereas Munc13-1 and -3 are only found in the brain and Munc13-4 is expressed mainly outside the brain. Munc13s contain a central C1–C2 tandem domain, a large Mun domain, and a C-terminal C2 domain (Figure 4). Munc13–1 also contains an additional N-terminal C2 domain (Figure 4). Munc13 isoforms are specifically localized to presynaptic active zones, the neurotransmitter secreting compartment, and are critical for synaptic vesicle priming. In the absence of Munc13, there is no transmitter release. The Mun domain is sufficient to reconstitute transmitter release in Munc13-negative cells, while the other domains act to regulate the level of Munc13 activity. At the molecular level, Munc13s are thought to act by unfolding and

activating the SNARE protein syntaxin through regulating its interactions with another priming factor Munc18. All Munc13s bind to DAG/phorbol-esters through their C1 domains, and this leads to translocation to the plasma membrane in response to DAG binding. Translocation to the membrane and possible conformational changes that occur upon binding to DAG enhance priming. As evidence for this, phorbol-ester-mediated increases in transmitter release in hippocampal CA1 neurons are lost when Munc13-1 is replaced by a version that does not bind to DAG/phorbol ester. Moreover, mice containing this version of Munc13-1 do not thrive, suggesting a critical role for regulation of Munc13 by DAG for ongoing synaptic transmission.

Chimaerins

Chimaerins were the first family of non-PKC phorbol-ester receptors to be discovered. These proteins resemble a 'chimaera' between the typical C1 domain of PKC isozymes and the GTPase-activating protein (GAP) domain of the breakpoint cluster region protein (BCR), involved in chronic myelogenous leukemia (Figure 4). The GAP domain has activity for Rac and was shown to promote the hydrolysis of GTP to GDP from this small GTP-binding protein. *n*-Chimaerin (later named α1-chimaerin) was first isolated from the brain. Three other isoforms were discovered later: α2-, β1-, and β2-chimaerins produced from alternative splicing of the α- and β-chimaerin genes. The C1 domains of α- and β-chimaerins are almost identical. The main difference between the spliced variants is an SH2 domain located at the N-terminal of α2- and β2-chimaerins (Figure 4). Phorbol-ester treatment was shown to induce translocation of β2-chimaerin from the cytosolic compartment to the Golgi and the plasma membrane. However, phorbol-esters do not affect the GTPase-activating function of chimaerins, suggesting that the function of DAG binding is primarily to translocate chimaerins to membranes, thus spatially restricting their Rac-GTPase-activating effects and to place them near active PKC, since phosphorylation of chimaerin by PKC is required for chimaerin activity.

Ras Guanyl Nucleotide-Releasing Proteins (RasGRPs)

The RasGRP family is composed of four isoforms, RasGRP1–4. All but RasGRP4 are highly expressed in the brain. RasGRPs contain a guanine nucleotide exchange factor domain for Ras-like GTPases (RasGEFN/RasGEF) at their N-terminal. They also contain two EF hand motifs and a C-terminal C1 domain (Figure 4). RasGRPs promote GDP/GTP exchange and activation of Ras and related small GTPases through their RasGEFN/RasGEF domains. This leads to the stimulation of the Raf-MEK-ERK cascade and to the regulation of other signaling pathways. All the RasGRPs contain C1 domains that bind DAG/phorbol-esters. RasGRP1, -3, and -4 were shown to translocate to membrane compartments in response to phorbol-esters and, similar to other Ras guanine nucleotide exchange factors, this may be sufficient to activate the enzyme. In addition, translocation to DAG rich membranes may be important to facilitate phosphorylation of RasGRPs by PKCs that activates some, but not all isoforms of RasGRP. RasGRPs are essential for DAG-mediated increases in ERK phosphorylation in immune cells, but the contribution of RasGRPs to ERK activation downstream of DAG production in neurons is not known.

Protein Kinase D

The protein kinase D (PKD) family consists of PKD1, PKD2, and PKD3. All PKDs contain two C1 domains, a negatively charged central domain, a PH domain, and a serine/threonine protein kinase catalytic domain (Figure 4). PKD1 contains an additional N-terminal apolar domain. Similar to RasGRPs and chimaerins, the C1 domains of PKD1 are not only important for translocation, but also to localize them near PKCs; since phosphorylation of PKD by PKC is required for enzyme activity. Interestingly, the majority of PKD translocation is to the Golgi apparatus and translocation to the Golgi apparatus is also seen in some isoforms of PKC, such as PKCε and η. PKDs are important for vesicle budding from the Golgi and Golgi structure. It is not clear whether DAG production in the Golgi compartment is regulated by extracellular messenger or may be more important in intracellular homeostatic pathways.

Myotonic Dystrophy Kinase-Related cdc42-Binding Kinase

MRCKα and β, are kinases related to Rho kinase (Figure 4) and are implicated in regulation of neurite outgrowth and other cytoskeletal rearrangements through phosphorylation of the myosin light chain phosphatase. While MRCKs bind to cdc42, this does not increase enzyme activity; instead, MRCKs are activated by phorbol-esters binding to their C1 domain.

Trp Channels and the Visual Response in *Drosophila*

Trp channels are cation channels involved in many types of neuronal processes including sensory

transduction such as mechano- and heat sensation. Some forms of Trp channels appear to be regulated by DAG even in the absence of a C1 domain. It is not yet clear if Trp channels have a unique DAG binding domain, or whether activation by DAG is indirect. The most powerful example of this regulation is seen in visual transduction in *Drosophila*, where Trp channel opening is the end result of the phototransduction cascade. In *Drosophila* photoreceptors, the Trp channel, PKC, and PLC are all organized into a signaling complex by a scaffolding PDZ protein. The Trp channel is either directly activated by DAG or by a further metabolite of DAG, while PKC activation is required for signal termination and adaptation. The importance of DGK is also illustrated by this example since in the absence of DGK, the light response is constitutively on leading to retinal degeneration.

Synaptic Plasticity and Behavior

Many transmitters act through GPCRs or RTKs to produce DAG. In the following sections, we review several of the important forms of plasticity regulated through this pathway and, when appropriate, discuss behaviors that are regulated by this plasticity.

Increases in the Probability of Transmitter Release

Many neurotransmitters increase transmitter release through DAG production. There are two major targets of DAG in the presynaptic terminal, PKC and Munc13, and their importance for DAG actions can vary widely in different neurons. Activation of Munc13 by DAG increases synaptic vesicle priming, as noted above, and increased priming will lead to an increased probability of transmitter release. PKCs regulate transmitter release in several ways. PKC phosphorylation of calcium channels relieves inhibition by $\beta\gamma$ subunits, although this regulation is only important for the reversal of previous inhibitory transmitter action. In *Aplysia* neurons, PKC also regulates transmitter release in a state-dependent manner; activation of PKC by DAG does not increase transmitter release at synapses that had not recently fired, but can reverse synaptic depression at synapses that have recently been active. This is thought to mediate behavioral dishabituation. PKC phosphorylates the SNARE protein SNAP-25, and this can increase the size of the readily releasable pool. PKC regulation of the cytoskeleton may also regulate transmitter release. Activation of PKCε increases glutamate release from synaptosomes, and this requires a specific actin-binding site located between the two C1 domains.

Ion Channels

Slow neurotransmission is the process by which neurotransmitters alter membrane properties through activation of second messengers, such as DAG. Most slow neurotransmission downstream of DAG is due to the direct phosphorylation of ion channels by PKC. There are numerous ion channels regulated by PKC phosphorylation including voltage-gated channels (potassium, sodium), cation channels, calcium-dependent potassium channels, and ligand-gated channels such as AMPA and NMDA receptors. PKC regulates many aspects of channel functions including efficacy, inactivation rates, and cycling between the plasma membrane and internal stores. While there are many forms of synaptic plasticity that utilize this mechanism, two examples are described below where there is a clear link between synaptic plasticity and behavior.

Pain sensitization One particularly important example is the regulation of primary nociceptor channels, such as vanilloid receptors by PKCε. Acute sensitization of these receptors is mediated by peptides that act through PLC such as epinephrine and bradykinin, and increased levels of PKCε may mediate the prolonged sensitization of these receptors observed in persistent pain models. Thus, in animals lacking PKCε, there is a decrease in the ability to sensitize nociceptors through a number of different stimuli.

Cerebellar LTD One attraction of the dual role of calcium and DAG in activation of cPKCs is that PKC can be an associative molecule. This is exemplified in Purkinje neurons where PKC is activated by the conjunction of granule cell and climbing fiber activity. The activation of PKC requires DAG produced by activation of mGLUR1 after granule cell activity and calcium produced by depolarization and opening of voltage-gated calcium channels after climbing fiber activity. PKC then phosphorylates the ionotropic glutamate receptor GluR2 at a residue near the C-terminal that causes endocytosis of the receptors through regulating the binding partners of this C-terminal sequence. This endocytosis leads to a LTD of the synaptic response from the granule cells. Interestingly, this plasticity is mediated by the cPKC, PKCα, and requires the PDZ binding C-terminal of PKCα. Thus generation of a signaling complex is critical for this plasticity. This type of cerebellar LTD is thought to underlie several forms of behavioral plasticity that require Purkinje cells such as the VOR reflex and eyeblink conditioning. Indeed, mice that constitutively express a PKC inhibitor only in Purkinje cells have major problems in learning the timing needed for proper eyeblink conditioning.

Protein Synthesis and Gene Expression

Many neurotransmitters activate gene expression through activation of a cascade including ERK, and this leads to long-term changes in neuronal properties and gene-expression-dependent long-term memories. DAG pathways activate ERK through both PKC phosphorylation of upstream kinases such as β-Raf and through RasGRPs. Regulation of local protein synthesis is also an important mechanism for certain types of synaptic plasticity. Activation of mGLUR1 or -5 in hipppocampal neurons causes a LTD that requires local synaptic translation, and regulation of the translational process is mediated through PKC.

Morphological Plasticity

DAG signaling is important for various types of morphological plasticity, and this is mediated by a number of DAG targets that regulate the cytoskeleton. For example, stimulation of PLCβ-coupled cell surface receptors recruits β1-chimaerin to the plasma membrane resulting in the pruning of dendritic spines and branches. This pruning activity required both the DAG-binding and Rac GAP activity of β1-chimaerin. PKC phosphorylates many cytoskeletal regulators such as growth-associated protein-43 (GAP43), MARCKS, and adducin. Neurite outgrowth is also regulated through other C1 domain proteins including MRCK and RasGRPs, suggesting many overlapping pathways between DAG and the cytoskeleton in order to orchestrate complex morphological changes during neuronal development and perhaps during learning and memory as well.

Persistent Activation of PKCs

Several persistent types of plasticity and behavior are caused by persistent activation of PKC. A form of intermediate sensitization in *Aplysia*, associative learning in *Hermissenda*, and hippocampal LTP can all be blocked in the maintenance phase by PKC inhibitors. However, there is no evidence in these paradigms for persistent increases in DAG levels. Rather, other mechanisms of PKC activation, such as formation of PKMs (PKCs that lack the regulatory domain), or alteration in phosphorylation of PKC are required for the persistent activation of kinase activity. In particular, a form of PKC known as PKMζ (Figure 4) is expressed in the nervous system from an alternative promoter. Specific inhibitors of PKMζ can block LTP even 5 h after induction, suggesting that this form of plasticity requires persistent phosphorylation of target proteins. Thus, at least during the initial phases of memory formation, persistent activation of PKCs can act as a memory trace.

© 2009 Published by Elsevier Ltd.

LTP/LTD and Learning and Memory

Since the first publication reporting the existence of long-term potentiation (LTP) by Bliss and Lomo, there has been a plethora of papers, books, symposia, and meetings devoted to the discussion of the relationship between this molecular/cellular form of synaptic plasticity and some behavioral forms of learning and memory. Although the issue may occasionally still be debated, there is little doubt that LTP indeed represents one of the cellular mechanisms that is used in a number of neuronal networks for the storage of new information. This has been particularly evidenced in the hippocampal formation, to which a wealth of pharmacological and genetic manipulations have been applied to attempt to demonstrate that LTP induction and maintenance are causally related to memory formation and duration. According to this body of work, LTP in hippocampus would be ideally suited for the formation of episodic or declarative memory. LTP has been observed in a large variety of mammalian species, including humans, clearly indicating the universality of this phenomenon.

On the other hand, the relationship between long-term depression (LTD) and learning and memory has not been as clearly established until now. The best case for such an association has been made in cerebellar learning, in which LTD of synaptic transmission at the parallel fibers to Purkinje cell synapses is likely to participate in certain forms of motor learning. In other brain structures, the potential link between LTD and learning of specific types of information is much more tenuous, and further work is needed to establish convincingly that LTD is necessary and sufficient for any particular form of learning. Note that another form of synaptic plasticity referred to as depotentiation has also been discussed as a potential mechanism for memory erasure. Whereas LTP is generally elicited by trains of high-frequency stimulation, depotentiation is generally elicited by trains of low-frequency stimulation delivered to pathways previously potentiated. Whether this form of plasticity is related to 'forgetting' is still a matter of speculation.

This article focuses on age-related alterations in LTP/LTD, on the one hand, and on learning and memory, on the other hand, and we argue that age-related cellular modifications leading to changes in LTP/LTD properties are also responsible for age-related changes in properties of some forms of memory. We first summarize the main findings regarding age-related changes in learning and memory. Changes in LTP/LTD properties are then reviewed. Finally, we discuss the potential cellular origins of age-related modifications in LTP/LTD and illustrate how these changes reflect basic age-related changes in cellular function.

Learning and Memory and Aging

It has long been recognized that aging is associated with a loss of learning and memory; this has led to the definition of age-associated memory impairment and has been a strong stimulus for the development of new drugs that could remedy this impairment first in the extreme case of this condition – that is, Alzheimer's disease – but also in its milder version, known as mild cognitive impairment (MCI). However, it is only recently that this view has been modified with the appreciation that the decline in learning and memory is in fact taking place throughout the life span and is initiated very soon after the peak in learning and memory at the beginning of adulthood. It has been argued that mechanisms of learning and memory are critical during the developmental period when the organism needs to adapt to the environment, whereas the focus of adulthood is on the transmission of genes to the next generation. The extreme form of this argument is that evolution of memory was associated with that of the aging process. Such a view is similar to the idea that plasticity and age-related deterioration of neuronal function involve the opposite requirements for neurons to be stable to resist injuries and insults and to be plastic to continue the adaptation of the organism to a continuously changing environment. According to this view, the existence of mismatch between resources and requirements to satisfy these two sets of constraints results in the progressive impairment of synaptic plasticity during aging.

A wealth of experiments have documented age-related impairments in learning and memory in a wide variety of tasks in experimental animals as well as in humans. Barnes and colleagues in the late 1970s used learning to escape a circular platform to show age-related impairment in spatial learning in rats. Using the Morris water maze to study behavioral learning, numerous laboratories have since reported

that cohorts of aged rats can be subdivided into learning-impaired and learning-nonimpaired animals. Reasons for this dichotomy are not clear, although it is intimately related to a similar dichotomy in plasticity properties at the cellular level. Age-related learning deficits have also been reported in mice both in spatial tasks and in fear conditioning. Trace eyeblink conditioning also requires hippocampal function, and impairment of this form of learning has been found in aged mice, rats, rabbits, and humans. Much less has been done regarding progressive memory decline in experimental animals during the life span, although results indicate that environmental events in early life can produce learning impairment in middle-aged rats.

Age-related impairment in delay eyeblink conditioning, a cerebellar-dependent form of learning, has also been found and, interestingly, is already present in middle-aged mice. It is also present in humans and, in fact, it might even be more dramatic than impairment in a verbal task, which would be considered more declarative and therefore more hippocampus dependent.

Age-Related Changes in LTP/LTD

Although it was initially thought that cognitive decline with aging was due to massive neuronal loss and alterations in neuronal morphology, particularly dendritic branching, reexamination of this issue has led to the conclusion that aging is not associated with a general loss of neurons, dendritic alterations, or loss of synaptic contacts. Likewise, aging is not associated with gross alterations in biophysical properties of neurons in hippocampus. The most significant change in membrane biophysics associated with aging is an increased conductance for calcium, possibly due to an increased number of L-type voltage-dependent calcium channels. As discussed later, this change in calcium conductance may have a critical role in age-related changes in synaptic plasticity and learning and memory.

Although the intimate details of the mechanisms involved in LTP and LTD are not completely known, there is a growing consensus for the major events responsible for the induction and expression of the long-term increase (LTP) or decrease (LTD) in synaptic transmission elicited by the specific patterns of electrical stimulation required to produce them (Figure 1). In the case of LTP, brief bursts of electrical stimulation result in sufficient postsynaptic depolarization to relieve NMDA receptors from the voltage-dependent magnesium blockade of their associated channels. In turn, activation of NMDA receptors results in calcium influx in postsynaptic spines and the stimulation of a host of calcium-dependent processes, including calcium-dependent protein kinases (in particular, calcium/calmodulin protein kinase (CamKII)), calcium-dependent proteases, and calcium-dependent phospholipases. The combined action of these processes results in changes in spine cytoskeleton, the insertion of AMPA receptors in postsynaptic density, and the modification of cell adhesion proteins involved in pre/postsynaptic interactions. It has thus been proposed that dendritic spines modify their structures providing for increased insertion of AMPA receptors or, conversely, that a regulated process of receptor insertion imposes increased surface area for the postsynaptic density. Moreover, integrin activation has been proposed to represent a form of consolidation because interfering with this class of adhesion proteins within a short time after tetanus is capable of preventing LTP maintenance. It has also been proposed that protein synthesis as well as gene transcription participate in the late phase of activity-dependent changes in synaptic structure and function, although the exact nature of the genes activated and the proteins translated remains unknown. Numerous studies point to a critical role for brain-derived nerve growth factor (BDNF) in the translation of brief bursts of electrical activity into long-lasting changes in synaptic efficacy. BDNF would be released as a result of NMDA receptor activation and activate its membrane-associated receptor, trkB, in an autocrine-type manner. Stimulation of trkB would trigger a number of signaling pathways and, in particular, by regulating protein synthesis localized in dendrites, BDNF appears to be a regulator of synaptic consolidation. It is also noteworthy to mention the existence of non-NMDA receptor-dependent LTP that requires activation of the voltage-dependent calcium channels for its induction.

Although the detailed mechanisms underlying LTD are not as clearly established as those for LTP, several of the same processes participating in LTP have also been shown to be activated in LTD. Two major forms of LTD have been particularly well studied – an NMDA receptor-dependent form and a metabotropic glutamate receptor (mGluR)-dependent one. In both cases, internalization of AMPA receptors appears to be responsible for the maintenance of decreased synaptic efficacy.

Several studies have indicated alterations in both LTP and LTD properties in old animals, although there are differences in the details of these age-related modifications depending on the anatomical regions evaluated and the protocols used to elicit LTP or LTD. The first studies performed approximately 30 years ago indicated that following a strong stimulus to elicit LTP at the synapses of the perforant path to dentate gyrus or to CA3 pathways, LTP induction was similar

Figure 1 Schematic representation of a glutamatergic synapse and the events involved in induction and expression of synaptic plasticity and potential mechanisms accounting for age-related impairment in synaptic plasticity. (Top left) Dendritic spine with AMPA and NMDA receptors as well as mGluRs and voltage-dependent calcium channels (VDCC). Also represented are calmodulin kinase (CaK), calcineurin (PP2B), and calpain. In addition, an intracellular pool of AMPA receptors is shown. BDNF and the trkB receptors are also present postsynaptically, as are mitochondria and endoplasmic reticulum (ER). Finally, ribosomes with mRNAs are represented in the base of the spine. (Top right) LTP/LTD induction. An influx of calcium is the major trigger for induction of synaptic plasticity. Depending on the amplitude and duration of the calcium signal, LTP or LTD will be elicited due to changes in the balance between protein kinase and protein phosphatase activity and calpain activation. Stimulation of BDNF release and activation of trkB also participate in the regulation of the changes in synaptic structure and function. Note that VDCC, ER, and mitochondria will participate in the regulation of the calcium signal generated by the stimulation protocol. (Bottom left) LTP expression. Increase in synaptic efficacy is due to an increase in the available number of AMPA receptors produced by the insertion of AMPA receptors in the postsynaptic membrane. This effect might be associated with a change in the morphology of the dendritic spine (note the enlarged spine head). Local translation of mRNAs might provide for newly synthesized proteins that could stabilize the modifications produced by proteolytic activation. (Bottom right) Potential mechanisms responsible for age-related impairment in synaptic plasticity. 1, Changes in NMDA receptor function or signaling; 2, changes in calcium regulation (VDCC, ER, and mitochondria); 3, changes in BDNF signaling; 4, changes in calcineurin activity; 5, changes in free radical production or elimination; 6, changes in protein synthesis.

in aged and young rats but decayed faster in the former than in the latter. On the other hand, altered LTP induction was observed at the Schaffer collateral to CA1 pathway. More recent studies have used induction protocols more closely related to natural stimulation frequencies, such as the so-called theta burst stimulation (TBS), in which brief bursts of high-frequency stimulation (generally 100 Hz) are delivered at the frequency of the theta rhythm (5–7 Hz). Under these conditions, LTP induction was impaired at the Schaffer collateral to CA1 synapses. Interestingly, using a 5-Hz stimulation protocol to induce LTP revealed the same dichotomy between subgroups of rats previously mentioned, with rats exhibiting learning impairment in the Morris water maze also exhibiting decreased amplitude of potentiation at these synapses. In addition, another form of NMDA receptor-dependent LTP elicited by prolonged paired-pulse stimulation delivered at 1 Hz appears in aged animals. Finally, one study indicated that, similar to the gradually occurring learning deficits over the life span, deficits in LTP can also be found in middle-aged rats; thus, although LTP induction was not modified in the basal dendrites of

CA1 pyramidal neurons of 7- to 10-month-old rats, it failed to stabilize and excitatory postsynaptic potentials returned to baseline levels within 30 min after TBS.

Age-related changes in LTD are almost the mirror images of those found for LTP. Thus, whereas LTD is difficult to elicit in hippocampal slices prepared from adult and middle-aged rats using prolonged trains of low-frequency stimulation (generally 1 Hz for 15 min), it is readily produced in hippocampal slices from aged rats. Again, an interesting dichotomy was reported regarding LTD properties in hippocampus of learning-impaired versus learning-unimpaired aged rats: learning-unimpaired rats 'switched' from NMDA receptor-dependent LTD to non-NMDA receptor-dependent LTD. No data are available regarding potential age-related changes in LTD in cerebellum.

Potential Cellular Mechanisms Underlying Age-Related Changes in LTP/LTD

Changes in NMDA Receptors

In view of the critical role of NMDA receptors in the induction of LTP and LTD, numerous studies have evaluated potential changes in NMDA receptor properties with age. Although several developmental changes in NMDA receptor properties have been described, it does not appear that changes in NMDA receptors account for age-related changes in LTP/LTD. However, because the NMDA receptor is part of a large complex of more than 200 proteins, it is plausible that changes in the organization/function of this complex take place during aging and modify some intracellular signaling cascades associated with activation of the NMDA receptors.

Changes in Calcium Regulation

As mentioned previously, one of the most conspicuous age-related changes in neuron biophysical properties consists of a change in calcium regulation and, in particular, in an increased number of L-type voltage-dependent calcium channels. Although the increase in calcium channels does not affect basal intracellular calcium concentration, it produces a significantly higher calcium concentration as a result of synaptic activity in neurons from aged rats compared to that in young rats. In turn, this results in increased afterhyperpolarization (AHP) resulting from the activation of calcium-dependent potassium channels. Interestingly, the amplitude of the AHP is a good predictor of learning ability in rabbits, and learning results in decreased amplitude of the AHP. AHP decreases excitability and may thus be responsible for the age-related decrease in LTP because increased AHP would decrease the ability of trains of stimulation to depolarize the postsynaptic membrane sufficiently to activate the NMDA receptors. Results indicate that calcium-induced calcium release from intracellular stores is actually responsible for the increased AHP observed in aged animals, further incriminating calcium dysregulation as the primary cause for age-related impairment in synaptic plasticity. Interestingly, pharmacological or genetic manipulations directed at calcium-activated potassium channels eliminate age-related impairment in LTP and in cognitive function.

Changes in BDNF Signaling

As discussed previously, BDNF has been implicated as a critical regulator of synaptic efficacy in hippocampus and some age-related alterations in synaptic plasticity could be due to age-related changes in BDNF levels or signaling. Conflicting reports regarding changes in expression and levels of BDNF have been published, but the overall view is that there are no significant changes in the levels of BDNF in hippocampus between 2 and 24 months of age. On the other hand, there appears to be a consensus regarding age-related decrease in trkB, the major receptor for BDNF, in hippocampus. Accordingly, BDNF-mediated effects should be significantly reduced in old animals. Understanding the precise role that this decreased signaling plays in age-related decrease in LTP/LTD requires further investigation. Interestingly, whereas increased physical activity does not seem to reverse age-related decrease in BDNF signaling, enriched environment does seem to do so.

Changes in Calcineurin

Calcineurin is a calcium-dependent phosphatase that also plays a critical role in synaptic plasticity because the balance between protein kinase and protein phosphatase activity is a major determinant of the direction and amplitude of activity-dependent changes in synaptic efficacy. It is clear that calcineurin activity is increased with aging, and this has major consequences for the regulation of the state of phosphorylation of several targets of this phosphatase at synapses. Previous results have shown that calcineurin inhibition results in LTP that occludes tetanus-induced potentiation. Moreover, in aged rats, inhibition of calcium release from intracellular stores results in LTP, an effect that is blocked by calcineurin inhibition. It has thus been proposed that calcineurin indirectly regulates the phosphorylation of voltage-dependent calcium channels, thereby contributing to the regulation of cell excitability and LTP induction.

Role of Oxygen Radicals

One of the key contributors to age-related changes in cellular function is oxidative stress, and it has been repeatedly shown that aging is associated with increased protein oxidation and lipid peroxidation as a result of increased formation of reactive oxygen species in the absence of increased levels of detoxifying enzymes (superoxide dismutase, catalase, and peroxidases) and scavengers of free radicals. In recent years, it has been proposed that free radicals exhibit opposite effects on synaptic plasticity, LTP in particular, in adult and aged rats. In the adult, low levels of reactive oxygen species, specifically H_2O_2, would be required for the normal induction of LTP, whereas high concentrations would be detrimental. Moreover, the effects of low concentrations of H_2O_2 on LTP would be mediated through the stimulation of calcineurin and the regulation of voltage-dependent calcium channels. On the other hand, reactive oxygen species would be mostly detrimental to LTP induction in the aged animals. In this case, high concentrations of H_2O_2 are presumed to stimulate calcium release from internal stores, resulting in activation of calcineurin and thus interfering with LTP induction. Furthermore, reactive oxygen species have been shown to interfere with proteolytic mechanisms such as the proteosome and the lysosomes. Studies have shown a critical role for the proteosome/ubiquitin proteolytic pathway in synaptic plasticity.

Changes in Protein Synthesis

Whereas aging does not appear to be associated with major changes in LTP-induced gene expression, the transcription of c-fos appears to be decreased in CA1 pyramidal neurons from old rats. As discussed previously, BDNF enhances translation rate in dendrites, and the decrease in BDNF responsiveness with aging is likely to affect protein synthesis, thereby further contributing to age-related impairment in synaptic plasticity.

Conclusions

It is clear that the data strengthen the argument that LTP and, to some extent, LTD represent cellular correlates of learning and memory. In fact, in several instances, the parallel is striking, as in the studies demonstrating the dichotomy in subgroups of rats between learning-impaired and learning-unimpaired with the similar dichotomy with impaired LTP or normal LTP. The data also provide better evidence for a role of LTD in learning and memory; in particular, in young rats, there is a significant correlation between the amplitude of NMDA receptor-dependent LTD and an index of performance in the learning task. Interestingly, in aged rats, successful learners switch from NMDA receptor-dependent LTD to non-NMDA receptor-dependent LTD. As more information has become available regarding the cellular and molecular mechanisms underlying LTP/LTD, it has become easier to assess which components of the complex machinery linking selective pattern of electrical activity to long-lasting changes in synaptic structure and function are exhibiting age-related alterations. Thus, it has become clear that since LTP/LTD use a number of basic mechanisms of cell biology involved in cell motility, cell signaling, and cell communication, age-related changes in basic cell function have significant impact on the features of LTP/LTD in aged organisms.

Synaptic Plasticity: Neuronal Sprouting

J Nilsen, University of Southern California, Los Angeles, CA, USA

Introduction

In neuroscience the term 'sprouting' refers to any phenomena invoking neurite growth; sprouting occurs through the life span in the mammalian central nervous system (CNS) and in nonmammalian brains and the peripheral nervous system (PNS). These changes in neurite growth are usually represented by modifications to synapses, evidenced as either alterations in synapse number or junctional area. Such alterations can occur in response to normal and pathological stimuli as part of the overall plasticity of nervous system circuitry, believed to underlie changes in behavioral activity. The structural synaptic changes are referred to as 'synaptic plasticity,' as a reference to the term 'behavioral plasticity.' The latter term was first defined by William James in 1890 as any meaningful change in behavior of an organism.

Synaptic plasticity was first recognized during observations of reactive synaptogenesis and sprouting that occurred in response to extension lesions. It was demonstrated that in response to neuritic loss the nervous system was able to form new synapses, and undamaged neurons were able to form new branches (sprouts) with the capability of making new synaptic connections. This led directly to the examination of synaptic plasticity in neurodegenerative diseases and injury. Although the field started with the examination of plastic responses to neuronal injury, it is clear that plasticity occurs throughout life as a normal response and it is recognized that synaptic plasticity is more pervasive than just a compensatory mechanism. It is a subtle, ongoing process in the normal organism, responding to the environment and endogenous rhythms.

Normal Adult Plasticity

The nervous system is very dynamic, even down to the level of its synaptic connections. Proper mental function is based upon a dynamic organization of synaptic structure. The lability of these neuronal networks is highest in the phylogenetically young brain structures involved in realization of perception and self-awareness, which rely upon continual readjustment and refinement. This lifelong self-optimization process underlying neuronal complexity is remodeled to meet environmental demands. Experience-dependent learning combines both additive and subtractive processes. In response to an organism's attempt to control aspects of a new, complex environment there is the creation of new synaptic connections. Then, through the process of pruning, the brain selects the strongest neural circuits, fine-tuning the connections in a subtractive process. Thus experience-dependent learning couples sprouting with selective pruning, with a net gain of synapses. This constant, dynamic synaptic turnover makes it possible to adapt to complex, changing environments. Thus these synaptic connections are in a constant state of flux, responding to hormonal and environmental alterations with adaptive changes in neural circuitry and resulting behavioral alterations. However, the selective dynamic stabilization and destabilization of synaptic connections are accompanied by increasing inherent potential of failure and neuronal vulnerability during the aging process.

Neuronal plasticity mediated by sprouting can involve alteration in dendritic spine number and/or size or alterations in neuritic complexity (length and branching). Dendritic spines are micrometer-sized protrusions of the dendritic membrane that serve as the postsynaptic component for the vast majority of central nervous system excitatory synapses. Spine synapses, in contrast to shaft synapses, act to create spatially isolated compartments, confining biochemical signals and membrane trafficking to localized regions, allowing for fine-tuning of individual synaptic responses. Spine turnover and morphological changes in existing spines are important for the modulation of neuronal circuits during development and plasticity. Dendritic spines are highly dynamic in size, shape, and number, with highest density occurring during late development and decreasing to a relatively stable level throughout adulthood. Changes in spine number and shape are observed in response to high-frequency synaptic activity, behavioral stimuli, or endogenous hormonal cycles.

Further refinement of the neuronal circuitry can be imposed by the function of neighboring glial cells. Soluble glia-derived factors are also important in synaptogenesis, synapse maturation, and plasticity. Neuronal sprouting is dependent upon astrocyte-derived apolipoprotein E (apoE) and cholesterol, which complex into apoE-containing lipoproteins involved in membrane remodeling, repair, and lipid redistribution. Further, neuritic sprouting is impaired by activated glial cells and can be enhanced by reduction in the expression of glial fibrillary acidic protein (GFAP). Increased astrocyte contact with neurons and coverage

of neuronal surface area can modify synaptic activity by controlling local neurotransmitter concentrations and by spatially restricting neuron–neuron contact.

The structural plasticity described by synaptic plasticity is beginning to be linked to functional plasticity. Such functional plasticity can be seen as alterations of synaptic transmission that are strengthened or weakened in response to previous activity. These alterations in synaptic transmission can be of short duration, as in paired-pulse depression and posttetanic potentiation, or long-lasting, as in long-term depression and long-term potentiation (LTP). LTP, generated in the hippocampus, is thought to be a synaptic component of learning and memory, one form of behavioral plasticity. LTP is expressed as an increase in synaptic strength in response to a stimulus train, with increased amplitude being observed after 10–20 s and for many hours, or even up to days or weeks. Accompanying the change in synaptic transmission there is an expansion of the area of the synaptic junction. Although the number of synapses and the shape of dendritic spines do not change after the induction of LTP, stimuli that alter spine number or shape have been shown to also regulate LTP generation. Thus, the functional plasticity represented by LTP is tightly linked to structural changes associated with synaptic plasticity.

Synapse turnover is a constant process of loss and replacement of synapses, with total synapse number determined by the relative rates of synaptogenesis and synaptic regression. One set of stimuli may result in a net increase in synapse number by increasing synaptogenesis. Likewise, competing stimuli may induce synaptic regression, resulting in a net decline in synapse number. The subtle balance between stimuli may represent a mechanism underlying the synaptic plasticity observed as part of the normal life cycle, dependent upon developmental stage, experience, and age.

Neurons have the capacity to respond to perturbations to maintain their function within normal physiological range, such that the neuron can regulate the function of each impinging synaptic terminal, decreasing or increasing the strength of each synapse, resulting in a normal sum total excitation despite inappropriate innervation. Such homeostatic regulation of neuronal activity would maintain the robust function of the nervous system during the restructuring and refinement of neural circuits during the postembryonic developmental period. Such homeostatic regulation would establish limits beyond which activity-dependant changes in synaptic number would not reasonably alter cellular activity. This allows for maintenance of cellular physiological responses during the tumultuous periods of synaptic pruning required for establishment of synaptic structure and function. As the dendrites of the central nervous system, preexisting synaptic connections grow physically and chemically more removed from the cell soma, and more surface area is exposed for the inclusion of new synaptic contacts, leading to new functionality imposed by the changing response properties of the neuron.

The continual turnover of synapses, coupling sprouting with selective pruning underlying experience-dependent learning, allows for efficient memory storage in the brain, balancing the energy and metabolic demands of synapse maintenance with the extra energy cost of synaptic overgrowth required to obtain selective removal. Such a scheme allows for the judicious refinement of neural circuits required for proper memory storage within a highly adaptable context that is modifiable by endogenous and extrinsic environmental cues. However, the reliance of this system on exquisite balance between continual synaptogenesis and synaptic regression is vulnerable to maladaptive alterations in either side of the equation, leading to declines in cognitive function. The importance of correct pruning of the neural circuitry is observed in seizure patients. In the dentate gyrus, aberrant development of recurrent collaterals branching from granule cell axons (the mossy fibers) may contribute the scrambling of neural circuitry and to the epileptogenic activity in patients with temporal lobe epilepsy.

Puberty, Reproduction, and Sex Steroids in Synaptic Sprouting

Synaptic density peaks in the early postnatal period; this is followed by an extended time period of continuous synaptic turnover balanced toward synaptic removal or pruning, leading to a gradual decline to adult levels of synapses by puberty. Puberty is the point of transition, marking the metamorphosis of the child into the adult, with accompanying changes in reproductive maturity and alterations in body growth and composition, as well as profound changes in brain function. Not only does puberty mark the end of the extensive period of synaptic pruning that occurs during development, but it is also represented by the initiation of adult patterns of synaptic plasticity and sprouting. Neuronal connectivity is not fixed once development is complete but instead continues to change throughout life. However, there is a reduction in synaptic elimination, shifting the balance of the continuous synaptic turnover from a state of pruning to a state of maintenance.

Most dramatic are the alterations in synaptic connectivity in the hypothalamic centers governing sexual physiology and behavior. Here, steroid hormones both remodel and activate neuronal circuits during

adolescent brain development, establishing recurrent interactions between steroid hormones and the central nervous system. The release of gonadotropin-releasing hormone (GnRH) from GnRH neurons, a process that couples brain activity and gonadal function, is accomplished by these recurrent interactions, establishing a controlled cyclic gametogenesis and gonadal hormone production. In females, the midovulatory gonadotropin surge that stimulates ovulation is preceded by an estrogen-inducible retraction of axosomatic synapses in the arcuate nucleus. Following ovulation there is a recovery to baseline levels of synaptic connections, representing defined cyclical synaptic plasticity under control of sex hormones governing reproductive physiology. Due to the lack of alterations in spine or neurite morphology, these events are not sprouting *per se*; however, they remain reminiscent of the sex hormone-induced sprouting involved in the development of these same neural circuits.

Although the ovarian cycle-related synaptic changes in the hypothalamus do not involve neuritic outgrowth, in the hippocampus and prefrontal cortex there is an accompanying alteration in dendritic spine density. Specifically, there is significantly lower spine density during estrus than during proestrus. In addition, removal of circulating gonadal steroids via ovariectomy results in a significant decrease in spine density of the hippocampus in adult female rats, and spine density increases upon replacement of estrogen. This effect is reminiscent of the estrogen-induced sprouting during development of hypothalamic circuits underlying reproductive physiology and behavior.

Further supporting a role of sex hormones as environmental regulators of synaptic sprouting in the adult animal, gonadal steroids have been shown to be involved in regulating lesion-induced axonal sprouting. Although lesion-induced sprouting is more akin to pathological alterations in neuronal function, it is a useful paradigm to study the interaction of aging and environmental factors on normal aging-related synaptic plasticity and sprouting. These effects are often too subtle to isolate the mechanisms underlying normal synaptic turnover that are revealed by magnifying the effect via reactive regenerative processes. Sprouting is increased in the presence of sex hormones and in response to environmental enrichment or exercise *in vivo* following perforant path lesions of the hippocampus, and *in vitro* in the wounding-in-a dish model. The role of glial cells in the sprouting response is supported by the inverse relationship between astrocytic glial fibrillary acidic protein expression and neuritic sprouting. However, the influence of sex steroids on synaptic sprouting invites another point of vulnerability to the proper maintenance of the synaptic circuitry with the decline in hormonal control in aged animals, emphasized by the loss of sex hormone production in reproductive senescence, as discussed later.

In addition to the intrinsic regulation of synaptic density by gonadal hormones, extrinsic environmental cues can support sprouting as well. Environmental enrichment and exercise have been well established as one means of promoting neuritic sprouting and the incorporation of newly generated neurons into existing neuronal circuits. Exposing rodents to an enriched environment, consisting of large cages with toys ladders, mazes, and social interactions, results in increased performance on spatial learning tasks, compared with rodents housed in impoverished conditions. Similar results are obtained with increased physical exercise. These behavioral modifications are complemented by physical brain changes consisting of increased synaptic density and increased complexity of dendritic branching. While these adaptive responses are most pronounced in the young brain, environmental stimulation produces effects in the aging brain as well.

Neuronal Sprouting and Aging

Aging is associated with a decline in cognitive function that can be explained in part by alterations in cellular response directly affecting plasticity, in which the ability to learn new tasks decreases with age. On the cellular level, synaptic contacts, synaptic strength, and plasticity are reduced with age. These changes are much more subtle than are the dramatic alterations in neuronal morphology and survival that occur in age-associated neural disorders such as Alzheimer's disease and Parkinson's disease. In contrast to these pathological states, neuron loss does not appear to be an important contribution to age-related functional decline. Rather, subtle shifts in dendritic branching and spine density occur in region-specific patterns.

Although there is little evidence of significant neuronal loss during normal aging, alterations in dendritic extension of the neuronal soma occur in a large number of cells during aging. Many neurons show progressive restriction and atrophy of their more peripheral dendrite branches and, especially in cortical pyramidal cells, among the basilar shafts. The remaining dendritic branches often demonstrate beaded swellings, in correlation with the irregular dendritic spine loss. However, during these aging-related losses to dendritic systems, the potential for neuronal growth is not lost. Possibly as a compensatory response to increase available synaptic area, other neurons grow further dendritic extensions.

Even though there are these dendritic alterations in many neurons, they do not represent a gross regression of dendrites and remain region specific. There is

a reduction in dendritic branching with age in the prefrontal cortex in humans and rodents. In contrast, the hippocampus of humans and rodents does not experience significant changes in dendritic length with age, with net stabilization of dendritic extent in CA1, CA2, CA3, and the subiculum. In fact, in many brain regions, including the parahippocampal gyrus and the dentate gyrus, the aging brain is associated with increased dendritic branching, until very old age, when there is a consistent regression of the dendritic tree back to that of mature young adults. The region specificity of the dendritic losses indicates that the declines in neuronal plasticity are not merely consequences of wear and tear or global aging. This variability in aging that occurs within subpopulations of neurons reflects the different demands throughout the life span.

The observed region-specific increases in dendritic plasticity may be a compensatory response to partial cell loss that occurs during normal aging. New connections would be formed by healthy neurons within the population, assuming parallel functions. Such an extension of existing inputs would maintain circuit function, but would limit the amount of redundancy in the system, making it more vulnerable to further alterations in synaptic connectivity. Alternatively, the new connections could be formed by fibers from converging pathways that can act to boost weakened signals and maintain functional stability. This response may be a recapitulation of the developmental environment in which many neurons are programmed to form a certain number of terminals or to synapse, and if they cannot do so in one region, they will tend to increase terminal growth elsewhere. The increase in available synaptic area in response to the progressive regression of neighboring dendritic systems works to maintain the total postsynaptic surface per neuron. This leads to a concept of two neuronal responses to aging, one involving dendritic retraction and one involving reactive dendritic expansion. This two-stage response of dendritic spines (loss of total number but enhanced sprouting of remaining spines) represents a neuronal response to the decreased allostatic load, defined as a decrease in the capacity of neurons to oppose the damaging effects of strong, excessive stressors, compatible with full function at normal levels of load. The decreased allostatic load, or homeostatic reserve, is a characteristic of normal aging, resulting from continual or repeated stress.

Even though the structural and behavioral plasticities associated with sprouting are present in the normally aged brain, functional decline and its associated synapse loss are still observed. The aged rodent brain has a remarkable capacity for sprouting and synaptogenesis. However, aged synapses respond to plasticity-inducing stimuli differently than do young synapses, and the degree of sprouting is often blunted with respect to young animals. Further, even though in many brain regions the absolute number of spines is often not altered, there are significant changes in the shape and distribution of synaptic contacts. With increasing age there is a shift from L-type (lollipop shape) to N-type (nubby-like shape) synapses. The spine head becoming smaller, the spine shaft thickening, and a decrease in spine length characterize this shift. Cognitive-sparing diet alterations have been demonstrated to prevent the loss in L-type synapses. The aging-related shift in spine makeup and response is demonstrated by the interaction between vulnerability to aging and sex steroids in female rats. The estrogen-induced spine increase seen in CA1 of young rats does not occur in response to estrogen in aged rats. However, in the aged rat, estrogen increases the number of *N*-methyl-D-aspartate (NMDA) receptor per synapse, restoring the more youthful receptor profile that is lost in normal aging. Thus estrogen may help preserve hippocampal function in the context of a decreased synaptic density. This is another case in which the aged response to environmental stimuli maintains the circuit function, but with a decrease in the system's redundancy. This alteration in estrogen responsiveness is species specific. In contrast to the rodent, the CA1 region of the aged monkey hippocampus is still as responsive to estrogen-induced spine density and synapse number increases as is the young monkey.

Many of the other age-related changes in neuronal plasticity are generally subtle and may only be observationally manifested under conditions of perturbation. This was first observed in 1978 by Scheff and colleagues, who demonstrated that there is a clear reduction in collateral sprouting and regeneration in the aged nervous system. This limited response of reactive sprouting in aged animals has been well characterized by many groups since. Following entorhinal lesion, both young and aged rats can replace synapses lost in the dentate molecular layer of the hippocampus. However, this reinnervation, which begins very rapidly in young animals, is delayed in aged animals, with impairment in the initial phases of synaptic sprouting. Thus the rate of reactive sprouting is decreased as a function of age.

The age-related alterations in neuronal plasticity are emphasized again with the interplay between sex steroids and reactive sprouting. As discussed earlier, estrogen greatly enhances neurite outgrowth in various models of sprouting. However, in the aged female rat the induction of neuronal sprouting is impaired and, unlike in young adults, the sprouting is not sensitive to estradiol. This effect may be due to the increased glial activation associated with aging,

as evidenced by an increase in the activation marker GFAP. GFAP expression is usually regarded as secondary to neurodegenerative processes. However, glia become activated early in aging without concurrent clinical manifestations of pathology. Since neuritic sprouting is inversely related to GFAP expression, normal aging-related glial activation may have a profound impact on synaptic functions. Increased glial activation and GFAP expression may shift the balance of sprouting and retraction unfavorably during the ongoing synaptic turnover, leading to age-related declines in cognitive function.

Age-related alterations in synaptic plasticity may be due to changes in the properties of individual neurons or due to changes in the nervous system itself, as the individual neurons exist within a highly organized system. The decrements in neuronal plasticity could be due to inherent changes in the neuron's ability to extend neurites or form new spines. Alternatively, the decrement could be due to alterations in the complex system of extrinsic signals that trigger the requisite outgrowth. However, there has not been a consistent observation of age-related changes in neurotrophic factors to support the latter scenario. Another alternative to intrinsic changes to the aged neuron diminishing its capacity for growth involves alterations in the target neural circuitry in a way that lessens the accommodation or stimulation of sprouting. This is a model supported by the fact that the aged hippocampus supports less neuron ingrowth than does young hippocampus, whereas aged transplants show robust innervation in young host hippocampal tissue. This is an effect that does not appear to be due to reductions in baseline substrate properties that promote neurite outgrowth. Further support is provided by the observation that sprouting in the wound-in-a-dish model is diminished when neurons are co-cultured with astrocytes from aged animals, as compared to astrocytes from young animals. Thus, in the target region preventing efficient sprouting, there are likely changes that are marked by increased glial activation. This increased glial activation could result from the increase in allostatic load imposed by the results of cumulative reactive oxygen species (ROS) production or excessive stress. Both increased oxidative load and stress (or its hormonal effector, glucocorticoid) have been shown to reduce neuronal plasticity, LTP, and behavioral learning. Further implicating oxidative load in aging-associated cognitive decline, spine losses can be attenuated by superoxide dismutase overexpression (antioxidant defense).

In addition to reduced oxidative load and hormonal modification, synaptic sprouting can be altered favorably by other means. Calorically restricted diets can retard synapse loss, mostly through maintenance of L-type synapses, rather than preventing a decrease in total spine number. The processes of synaptic plasticity appear to be strengthened by increased neuronal activity, driven by enriched environment or behaviors such as exercise. Such age-associated dendritic morphologies are also reflected in the region-specific alterations in spine density. This continued structural plasticity of the aged brain is reflected behaviorally, in that age-related loss in speed of mental processing can be offset by continual environmental enrichment and challenge so as to promote synaptic plasticity. The fact that aging-vulnerable circuits are still responsive to environmental stimuli indicates that the aged synapse remains plastic. This is in contrast to cognitive deficits due to neuronal loss, in which case little can be done to restore circuit function. If the cognitive deficit of normal aging is due to the frailty of the synapse, the mechanisms of synaptic plasticity might be harnessed to for therapeutic intervention.

Synaptic Plasticity: Neuronogenesis and Stem Cells in Normal Brain Aging

G M Bernal and D A Peterson, Chicago Medical School at Rosalind Franklin University of Medicine and Science, North Chicago, IL, USA

Introduction

Although the postnatal brain had long been thought to lack the capacity to generate new neurons, the past decade's research has radically changed this assumption with ample evidence that new neurons are generated in some regions of the adult brain. This process is referred to as neuronogenesis for the specific production of neurons and more broadly as neurogenesis when all neural cell types may be generated. In many cases the terms neuronogenesis and neurogenesis are used interchangeably, as they will in this article. Neural stem cells and neurogenesis are restricted to specific areas in the adult brain: the subventricular zone/rostral migratory stream/olfactory bulb system and the dentate gyrus of the hippocampus. This spatial restriction means that most of the brain does not support neurogenesis under normal conditions and is thus referred to as nonneurogenic. Understanding the capacity of different regions to support survival and integration of neural stem cells will be of importance for the potential use of stem cells for brain repair, as it is this wider, nonneurogenic portion of the brain that will most frequently need to be the target of repair strategies.

Within the young adult brain, neurogenesis routinely contributes large numbers of new neurons to the olfactory bulb and small numbers of new neurons to the dentate gyrus. Many studies have shown that the rate of neurogenesis in the young adult brain is not fixed, but subject to stimulation by experimental manipulation. Neuropathological studies of the aging central nervous system (CNS) frequently utilize young adult, rather than aged, animals in experimental models or transgenic mutations of senescence-associated diseases, such as Parkinson's, Alzheimer's, or Huntington's diseases. Less is known about the underlying changes leading to the decline in normal (nonpathological) brain aging, yet this characterization will be necessary to interpret the contribution of specific disease pathology to impaired brain function. Here we look at the effects of normal aging on neurogenesis in the adult mammalian brain, the process in which resident neural stem cells give rise to new functional neurons that are incorporated into the circuitry. We discuss how age-induced changes may modulate neural stem cell activity resulting in a significant decline in neurogenesis and the implications of this for the aging brain.

Characterization of Neural Stem Cells

Many postnatal mammalian tissue systems contain cells that possess the features consistent with the definition of a stem cell, that is, the capacity for unlimited self-renewal and the ability of their progeny to differentiate into different cellular types. Stem cells present during embryonic development have considerable flexibility in sculpting tissues; however, this capacity may be restricted in postnatal tissue. In fact, it is a matter of debate as to whether stem cells found in certain adult tissues, such as the CNS, are truly stem cells or would be better termed progenitor cells, reflecting their more restricted proliferate capacity and differentiation potential to the same tissue in which they reside.

At present, there is no single definitive marker by which neural stem cells in tissue can be identified. Identification of stem/progenitor cells in adult tissue is usually accomplished through labeling the proliferating cells and assessing their subsequent lineage outcome. Most *in vivo* studies of neurogenesis have used administration of the thymidine analog bromodeoxyuridine (BrdU) to identify new cells. The duration of BrdU delivery and the interval between administration and examination are both of critical importance in interpreting the cell type under study. For example, sustained delivery of BrdU over several days labels a population of proliferating cells, but obscures the ability to distinguish whether those proliferating cells are slowly dividing or rapidly dividing, or whether the labeled cohort contains a heterogeneous population of both cell types. Therefore, many studies with longer BrdU administration do not provide information discriminating between slowly cycling stem cells and rapidly cycling progenitor cells. The ability to ascertain the frequency of reentry into cell cycle is of importance for understanding the contribution of this parameter to age-related changes in neurogenesis.

Another important parameter to establish when assessing neurogenesis is to extend beyond the quantification of changes in BrdU-positive cell number by also assessing their fate to determine the frequency at which they turn into neurons. As no single definitive marker exists for neural stem cells, identification of progression through lineage commitment is accomplished by combinatorial expression of various

markers. There has been considerable progress in defining the sequential expression of lineage markers in the young adult CNS, but our knowledge of whether the same sequence of markers and duration of their expression are invariably expressed in the aging brain is less than complete. In addition, parameters of neurogenesis differ between mice and rats, suggesting that species differences should be kept in mind when extrapolating results from animal studies.

Neurogenesis Is Decreased with Aging

Neurogenesis does persist in the aged brain, including that of elderly humans. Quantitative studies evaluating age-related changes have consistently reported lower levels of neurogenesis in both the subventricular zone and the dentate gyrus that become statistically significant by mid-age. In aged dentate gyrus of various rat or mouse strains, neurogenesis has been reported to be at the level of 10–20% of young adult animals. Olfactory bulb neurogenesis is significantly reduced to approximately 30% of neuronal production in the young brain and is accompanied by decreased proliferation in both the subventricular zone and the rostral migratory stream to approximately 20–40% of levels in the young brain. The decline of hippocampal neurogenesis is accompanied by a decrease in cell proliferation in addition to a decline in the number of cells expressing doublecortin, a marker associated with early neuronal lineage commitment. However, despite the age-related reduction in neurogenesis, the capacity of newly generated cells in the aged brain to migrate, survive, and differentiate into mature neurons is maintained. Furthermore, early work demonstrated that the age-related decline in dentate neurogenesis could be partially reversed in some conditions, such as environmental enrichment or alteration of glucocorticoid levels. Those reports suggest that neurogenesis in the aged brain is not absolutely diminished, but there remains a capacity to elevate neurogenesis, at least in the hippocampus.

Despite the reduced proliferation of new cells in the aged hippocampus, the proportion of those newly generated cells that differentiate into neurons is comparable to the young hippocampus. One interpretation of these data was that there are fewer neural stem cells in the aged brain generating the basal level of cell production. Studies using BrdU labeling of cell proliferation could not address this possibility, as they fail to discriminate between slowly dividing stem cells and rapidly dividing progenitor cells. However, recent work assessing expression of a stem cell marker, Sox2, in combination with other lineage markers indicates that the subpopulation of Sox2-positive cells that correspond most closely to the likely neural stem cell population is not reduced in the aging brain. These results suggest that the age-related reduction in neurogenesis is not due to there being fewer neural stem cells, but rather that these cells may be more quiescent in the aged CNS. In addition to quiescent stem cells producing fewer new cells in the aged brain, the maturation of newly generated neurons appears delayed and the extent of their dendritic arborization is less in the aged hippocampus.

Modulation of Neurogenesis in the Aged Brain

The observed age-related decrease in neurogenesis may result from a combination of environmental changes and cell-intrinsic limitations with increasing age. The quiescence of neural stem cells in the aged hippocampus may be a cell-autonomous property, but proliferation in aged hippocampus can be stimulated under certain conditions. Thus, there is substantial evidence that environmental factors play an important role in the age-related reduction in neurogenesis.

Overexpression of trophic factors has been shown to enhance neurogenesis in the young brain. Protein levels for some of the key trophic factors (such as brain-derived neurotrophic factor (BDNF), fibroblast growth factor-2 (FGF-2), insulin-like growth factor 1 (IGF-1), and vascular endothelial growth factor (VEGF)) promoting neural stem cell proliferation, differentiation, and survival show a decline as early as mid-age, correlating with the observed decrease in the proliferation of stem cells and neurogenesis in the aged brain. These changes may be accounted for by alterations in gene expression and/or posttranslational modification. Enhanced availability of trophic factors has been explored as an attractive target for therapeutic manipulation to promote neurogenesis in the young brain. Increased neurogenesis in the young brain has been reported following delivery of BDNF, FGF-2, IGF-1, VEGF, and epidermal growth factor (EGF). The aged brain, likewise, can be stimulated to increase cell proliferation and possibly neurogenesis following delivery of FGF-2, BDNF, IGF-1, and heparin-binding EGF (HB-EGF). However, in neurogenic regions, any enhancement of neurogenesis appears to be modest and does not restore neurogenesis to the level seen in the young brain. These results suggest that the decline of trophic factor support alone may not be responsible for age-related changes.

Trophic support of cell proliferation and differentiation may be regulated by the availability of both ligand and the receptors to bind to those ligands. Changes in the expression of trophic factor receptors, either on the neural stem cells themselves or on other cells in the neurogenic niche, may contribute to reduced neurogenesis in the aged brain. Relatively little is known, at present, about possible changes in

receptor expression on neural stem cells themselves, but there are indications that alteration of receptor expression occurs in other types of cells residing in the neurogenic niche, suggesting possible secondary effects on neural stem cell proliferation. Age-related changes in receptor expression would support possible cell-autonomous mechanisms for modulating neurogenesis through downstream alteration of the local environment. For example, there is reduced expression of FGFR-2 on astrocytes of the aged neurogenic niche, which may reflect an impairment of these cells to respond to FGF-2 signaling and/or in their autocrine regulation to produce FGF-2. This may, in turn, reduce the paracrine effect of FGF-2 on neural stem cells in the aged neurogenic niche.

Structural plasticity of dendrites and spines in the aging hippocampus can be significantly modified by alteration of hormone levels. Neurogenesis may also be modulated by other factors such as hormones and inflammatory molecules that show age-related changes. Despite the strong evidence for age-related hormone-induced plasticity in the hippocampus, relatively few studies have directly examined modulation of neurogenesis in this context (Table 1). Changes in glucocorticoid regulation do appear to influence neurogenesis in the aging brain. Stress has a potent effect on neurogenesis in both the young and aged brain, although the precise linkage with glucocorticoid as the proximal mechanism of that change is a matter of debate. Unfortunately, few studies on the important estrogen-related changes in the aging brain have investigated neurogenesis. There is evidence that neurosteroids, such as allopregnanolone, can promote neurogenesis in an Alzheimer's disease (AD) mouse model, although these mice were still relatively young. The role of hormonal modulation is an active area of investigation with important clinical implications, and assessment of neurogenesis is likely to be incorporated into future reports.

Implications of Decreased Neurogenesis in the Aging Brain

While numerous studies have demonstrated that neurogenesis can be enhanced, the advancement of our understanding about the biology regulating neurogenesis has been hampered by an inability to experimentally block neurogenesis. In this regard, studying age-related neurogenesis provides a natural model of reduction that may reveal the key regulatory elements for sustaining the generation of new neurons.

Table 1 Reported effects of hormonal alteration on neural stem cell proliferation and neurogenesis in the hippocampal dentate gyrus

Hormone	*Natural age-related change*	*Experimental manipulation of hormonal levels*	*Outcomes*
Corticosterone	Increased	*Rodents*	
		Intact young (exogenous corticosterone)	Decreased neurogenesis
		Intact young (following various stressors)	Decreased cell proliferation and/or neurogenesis
		Intact aged	Decreased neurogenesis
		Intact aged (following psychosocial stress)	Additional decrease in neurogenesis
		Adrenalectomy (decreased corticosterone)	
		Early postnatal; tested young and aged	No effect on neurogenesis at either age
		Young	Increased neurogenesis
		Mid-aged- tested when aged	Increased neurogenesis
		Aged	Increased neurogenesis (reversed by corticosterone)
		Primates	
		Young adult (following psychosocial stress)	Decreased cell proliferation
Gonadal hormones (estrogen)	Decreased in females	*Young female rodents*	
		Ovariectomy (OVX; results in decreased estrogen):	
		OVX	Decreased cell proliferation
		OVX + single estradiol administration	At 1 week, increased cell proliferation At 4 weeks, no effect on cell proliferation
		OVX + single estradiol and progesterone administration	No effect on cell proliferation
		OVX + chronic or cyclic estradiol administration	No effect on cell proliferation
		Aged female rodents	
		OVX ± chronic or cyclic estradiol administration	No effect on neurogenesis reported
		Aged female primates	
		OVX ± chronic or cyclic estradiol administration	No effect on neurogenesis reported

While individual new neurons are generated in the adult brain that assume functional characteristics of mature neurons, the extent to which their integration in a larger neuronal network directly contributes to a functional outcome remains unclear. Numerous studies have sought to establish a link between the generation and addition of new neurons in the olfactory bulb and hippocampus and functional output from those systems. With its natural reduction in neurogenesis, the study of aging animals may provide one approach to addressing the question of function. Unfortunately, studies attempting to correlate the level of impairment in hippocampal-dependent learning tasks and the extent of age-related reduction in neurogenesis have yielded mixed results. Some results have suggested that the aged animals most impaired in behavioral performance had fewer new hippocampal neurons, and other studies have indicated that animals in this group had the highest levels of neurogenesis. However, stimulation of hippocampal neurogenesis in aged animals, such as enriched environment or running, has been reported to correlate with improved performance in hippocampal-dependent tasks. It remains to be demonstrated if this correlation of stimulated neurogenesis and improved performance is causal (i.e., due to increased neurogenesis) or if it is a secondary effect to other biological changes, such as improved blood flow, elevation of circulating cytokines, etc. Although models of hippocampal-dependent learning are relevant to assessing function of hippocampal neurogenesis, there is no evidence to date suggesting that neurogenesis plays a role in age-related mild cognitive impairment in humans.

The incidence of anosmia (decreased or absent sense of smell) is increased in elderly patients with attendant risks for malnutrition and food poisoning. Newly generated olfactory bulb neurons in young animals have been shown to integrate and possibly participate in processing of olfactory input, and it had been postulated that the age-related reduction of olfactory bulb neurogenesis may contribute to the development of anosmia. However, it has been reported recently that humans lack a defined rostral migratory stream, making the extent to which stem cells in the subventricular zone contribute to olfactory bulb neurogenesis in humans unclear. This report also creates uncertainty as to the extent to which age-reduced neurogenesis may contribute to anosmia in elderly humans.

The aging brain is vulnerable to a variety of insults and neurodegenerative disease. With our understanding that neurogenesis persists in the adult and aging brain, there has been enthusiasm for utilizing neural stem cells for structural brain repair, where dysfunctional or dead neurons are replaced by grafted neural stem cells. Much of the work in grafting of neural stem cells has been performed in young animal models. It will be important to assess the physiological changes in the aged brain that may constrain the ability of grafted neural stem cells to survive, differentiate, and integrate into the aged brain. In particular, more information is needed about the ability of nonneurogenic regions of the aged brain to support neural stem cell survival and differentiation, as it is primarily the nonneurogenic regions that will be the target of stem cell therapy. Establishment of these parameters will be critical for discriminating between nonpathological aging and the contribution of pathology in animal models of neurodegenerative disease. Further study of the regulation of neurogenesis in the aged brain should provide useful insights into the development of therapeutic strategies for repairing the aged brain.

Synaptic Plasticity: Short-Term Mechanisms

Introduction

One of the fascinating features of chemical synapses is their capacity to alter their output based on past history. This temporal plasticity is thought to contribute to the brain's faculty for computation, learning, and memory. Short-term synaptic plasticity (STSP) occurs over a range of milliseconds to minutes and involves temporary enhancement or depression of synaptic strength. The molecular mechanisms that underlie STSP involve regulation of neurotransmitter release (presynaptic) and changes in sensitivity to neurotransmitter (postsynaptic). This article focuses on the mechanisms and molecules that underlie presynaptic STSP.

After an action potential (or series of action potentials) invades a presynaptic terminal and triggers calcium-dependent fusion of one or more synaptic vesicles (SVs), the likelihood of releasing neurotransmitter in response to subsequent action potentials may either increase or decrease. These increases and decreases in likelihood are referred to as short-term enhancement (STE) and short-term depression (STD), respectively. Historically, STE has been divided into several distinct processes, such as paired-pulse facilitation (PPF), augmentation, and posttetanic potentiation (PTP), based on kinetics and pharmacology. These forms of plasticity are in large part driven by the residual intracellular calcium that accumulates in presynaptic terminals following depolarization. Presynaptic STD may simply reflect a transient depletion of available SVs, although there is evidence for a refractory period during which SVs cannot fuse. Recovery from STD is regulated by residual calcium and therefore represents another type of STSP.

The molecular processes that account for presynaptic STSP are only just beginning to be revealed as experimental synaptic preparations are becoming more amenable to genetic perturbations and imaging techniques. Hundreds of proteins play a role in coordinating neurotransmitter release, and mutations in some of these proteins can result in changes in both basal synaptic transmission and STSP. It is difficult to ascribe specific contributions of these proteins solely to STSP because any change in synaptic transmission can indirectly affect STSP as well. For instance, many perturbations that raise the probability of transmitter release will concomitantly decrease the amount of PPF or PTP simply because there is less room for further increase in release probability. These changes may incorrectly be interpreted as playing a crucial role in STE when in fact they may be entirely independent of facilitation. However, most of the proteins that coordinate SV docking and priming with calcium-triggered fusion have multiple interactions with other proteins and lipids, and removal of any one of these will likely affect numerous processes involved in both basal synaptic transmission and presynaptic STSP. Thus, the selective removal of a particular form of plasticity without altering basal transmission may be the exception to the rule when analyzing synaptic mutations. Despite these limitations, several molecules have been implicated in STSP and regulation of the SV cycle.

Activity-Dependent Regulation of Neurotransmitter Release

The centerpiece of presynaptic function is the SV cycle, which is composed of vesicle biogenesis and trafficking to the plasma membrane, docking and priming steps which determine the SVs that are competent for fusion, calcium-dependent fusion of the SV, retrieval of SV membrane and proteins, and, finally, refilling with neurotransmitter and reentry into the SV cycle. A synaptic varicosity typically contains hundreds of SVs, but only a small number are competent to fuse with the plasma membrane at any particular time. This subset of SVs is called the readily releasable pool (RRP), and the size of the RRP may be a key determinant of synaptic strength. Processes that modulate the RRP are therefore wellsuited to account for various forms of presynaptic STSP.

Active Zone Proteins

SVs fuse at a specialized site within the synapse known as the active zone (AZ) which is composed of a variety of protein families, including RIMs, Munc13s, ELKS proteins, Liprin-αs, Piccolo, and Bassoon. Munc13-1 and -2 are large multidomain cytoplasmic proteins that play an important role in the priming of SVs in part by facilitating the formation of the ternary SNARE complex (synaptobrevin on SVs, and syntaxin and SNAP-25 on the plasma membrane) which brings SVs in close apposition with the plasma membrane. In addition, Munc13s appear to serve other functions in supporting SV fusion. They interact

with RIMs, syntaxin, spectrin, the ARF-GEF Msec7-1, diacyl glycerol (DAG), and calmodulin.

The relative abundance of Munc13-1 versus Munc13-2 may determine whether a synapse expresses STE or STD when challenged with a high-frequency stimulus. Residual calcium bound to calmodulin has been shown to interact with a conserved region near the N-terminus of Munc13s. This interaction appears to increase STE (Munc13-2) and recovery from STD (Munc13-1). In both of these cases, the underlying mechanism of Munc13-dependent enhancement of release is thought to be increased SV priming. The details of this process are not fully understood but may involve interactions with the plasma membrane SNARE protein, syntaxin 1. Syntaxin 1 can exist in a 'closed' conformation which cannot participate in forming complexes with the vesicle SNARE, synaptobrevin. Munc13 interactions may convert syntaxin 1 into an 'open' or permissive conformation thereby facilitating a complete SNARE complex formation required for maturation of the SV to a release-ready state. There is also evidence that Munc13s facilitate vesicle fusion at an additional step downstream from open syntaxin. Phorbol esters are known to enhance transmitter release in large part through their interaction with C1 domain-containing proteins such as protein kinase C (PKC) and Munc13s. This protein–lipid interaction is thought to be a pharmacological mimetic of DAG–C1 interactions occurring *in vivo* to recruit C1 domains during signaling. Thus, local DAG production near AZs may recruit and activate Munc13s, which in turn increase SV priming and release probability.

NCS-1/Frequenin

Another molecule implicated in facilitation of neurotransmitter release is NCS-1 (also known as frequenin). NCS-1 is a small cytoplasmic protein possessing an EF-hand domain that binds calcium. This protein localizes to presynaptic terminals and enhances transmitter release when overexpressed. In hippocampal cultures, overexpression of NCS-1 converts the form of STSP from depression to facilitation without altering basal release probability, perhaps by mobilizing additional SVs or activating silent release sites. This observation implies that at least in some cases, a form of STSP can be separated from the core process of synaptic transmission. Interactions with phophatidylinositol 4-kinase and extracellular signal-related kinase (ERK1/2) appear to be important for the function of NCS-1. These interactions may connect residual calcium with lipid signaling, IP3-gated intracellular calcium stores, small GTPases such as Ras, and the MAP kinase pathway, which have been implicated in STSP in *Aplysia* and mice. There is also evidence that NCS-1 can affect P/Q-type voltage-dependent calcium channels, which in turn provide the calcium that drives SV fusion. Thus, NCS-1 appears to have a central role in coordinating calcium increases with a variety of intracellular signaling pathways that modulate transmitter release.

SNARE Regulation

Interactions between vesicular and plasma membrane SNAREs play a critical role in determining both where an SV can fuse and how likely it is to fuse. Furthermore, after fusion, plasma membrane ternary SNARE complexes must be separated and sorted in order to provide free synaptobrevin upon endocytosis. Several molecules have been suggested to inhibit synaptic transmission via inhibition of SNARE complexes and thus provide a means of modulating synaptic transmission. The transmembrane vesicular protein synaptotagmin IV (SytIV) can act to inhibit SV fusion by direct interaction with SNAREs, perhaps by competing with synaptotagmin I (SytI). SytI and SytIV are members of a family of transmembrane proteins containing tandem C2 domains (C2 domains are Ca^{2+}-dependent membrane-targeting protein modules). SytI is required for normal calcium-triggered SV fusion and believed to be the primary 'sensor' of the calcium that triggers synchronous release by acting on the SNARE complex. Presynaptic expression of SytIV can be rapidly induced in particular brain regions of rodents, and increased SytIV decreases basal synaptic transmission and leads to enhanced PPF and PTP. This inhibition is hypothesized to result from SytIV competing with SytI for SNARE binding. Thus, SytIV can modulate synaptic transmission by inhibiting normal SNARE function.

Another molecule which is proposed to inhibit SNARE function is the syntaxin-interacting protein tomosyn. Tomosyn is a large cytoplasmic protein that contains a SNARE motif at its C-terminus. By binding to syntaxin and SNAP-25 in place of synaptobrevin, tomosyn prevents assembly of the ternary SNARE complex. Regulation of tomosyn function would therefore be predicted to modulate the priming of SVs. Overexpression of tomosyn in chromaffin cells and pancreatic β cells inhibits fusion of large dense-core vesicles. In *Caenorhabditis elegans*, removal of tomosyn increases the size of the RRP and prolongs the decay time of evoked EPSCs. Protein kinase A (PKA) has been shown to phosphorylate tomosyn,

decreasing its affinity for syntaxin. These observations suggest that tomosyn is a critical regulator of SNARE complex formation and may be an important target of PKA-mediated enhancement of synaptic transmission.

SNAP-25 has been studied as a regulator of facilitation. In mammals, there are two splice variants of SNAP-25 (SNAP-25a and -b), and their expression changes during development such that there is a shift from SNAP-25a to SNAP-25b. Artificial sustainment of high levels of SNAP-25a results in an enhancement of PPF without altering basal transmission. SNAP-25 has also been shown to be a target of PKC, and blockade of this phosphorylation appears to inhibit SNARE assembly. The isoform and phosphorylation state of one of the SNAREs therefore contributes to STSP in addition to its role as a core component of SV fusion.

Finally, recycling of SNAREs may also be an important site of SV regulation. SNAP-29 is a small cytoplasmic protein that binds to plasma membrane ternary SNARE complexes and prevents disassembly by competing with α-SNAP. Inhibition of disassembly ultimately may slow the rate of recovery from STD. Indeed, decreased SNAP-29 levels have been found to correlate with increased recovery from STD, whereas increased SNAP-29 slowed recovery from STD, and this slowing could be reversed by overexpression of α-SNAP.

Kinase Pathways

Signaling complexes associated with receptor tyrosine kinases (RTKs) have been proposed to regulate synaptic strength and STSP. In particular, the brain-derived neurotropic factor receptor TrkB is complexed with an actin-based motor protein myosin VI (Myo6) and a Myo6-interacting protein GIPC1. Loss of either Myo6 or GIPC1 results in decreased basal synaptic transmission and increased PPF, whereas PTP is decreased. The Abl family nonreceptor tyrosine kinases Abl and Arg have also been implicated in STSP. *abl*−/− and *arg*−/− mice show normal basal synaptic transmission and PTP, whereas PPF is selectively reduced. Since RTKs and non-RTKs such as Abl and Arg will be unlikely to phosphorylate their targets on the rapid timescale of facilitation, it is more likely that loss of these kinases alters the function of many synaptic proteins that require constitutive phosphorylation for optimal function. Other kinases, such as CaMKII, PKA, and PKC, may also contribute to STSP, and it will be important to identify the phosphorylation states of the molecules that regulate synaptic transmission so that the pleiotropic effects of disrupting kinases and phosphatases can be interpreted in terms of their net effects on critical downstream targets.

G-Protein-Mediated Regulation of Neurotransmitter Release

Short-term plasticity of neurotransmitter release is not only triggered by activity-dependent changes within the terminal itself but also can be induced by activation of presynaptic G-protein-coupled receptors (GPCRs). GPCRs represent a large family of seven transmembrane domain receptor proteins that, when activated by a ligand, function as guanine nucleotide exchange factors (GEFs) for heterotrimeric G-proteins. This GEF activity leads to the replacement of bound GDP by GTP on Gα subunits, resulting in the dissociation of the α and β/γ subunits and their subsequent interaction with effector molecules. G-protein signaling is terminated by the hydrolysis of α-bound GTP to GDP and the reassociation of α and β/γ subunits. Although more than 300 different types of GPCRs have been described, they can be generally classified by their interactions with different types of G-proteins.

$G_{i/o}$-Coupled Receptors

Presynaptic modulation of neurotransmitter release is best characterized for $G_{i/o}$-coupled receptors, which include group II and III metabotropic glutamate receptors (mGluRs), $GABA_B$ receptors, adenosine A1 receptors, cannabinoid CB1 receptors, opioid receptors, and muscarinic M2 and M4 receptors. These GPCRs are widely expressed and are often found presynaptically adjacent to active zones. They can be activated through the spillover of neurotransmitter from the active zone or through the actions of modulators released from other neurons, including the postsynaptic cell. Although presynaptic activation of $G_{i/o}$-coupled receptors almost invariably leads to inhibition of neurotransmitter release, this may be in large part due to their localization near the release machinery, which would permit certain target interactions, primarily via β/γ signaling mechanisms. Signaling through α subunits is also likely to play an important role through modulation of cAMP levels and kinase activity. Additional functions of Gα subunits may include determining the specificity of β/γ subunit interactions, as well as the termination of G-protein signaling through reassociation with β/γ subunits following GTP hydrolysis.

$G_{q/11}$-Coupled Receptors

$G_{q/11}$-coupled receptors, such as group I mGluRs and muscarinic M1 and M3 receptors, are also critical for short-term presynaptic modulation, although the best-described example comes from their postsynaptic role in the production of endocannabinoids. In numerous brain regions, including the cortex, striatum, hippocampus, and cerebellum, group I mGluR-mediated activation of $G_{q/11}$ signaling leads to the postsynaptic biosynthesis of endocannabinoids, at least in part due to the activation of phospholipase C beta (PLCβ) and DAG production. A similar effect of M1/M3 receptor activation has been observed in the striatum and hippocampus, indicating that activation of PLCβ represents a common target for enhancing endocannabinoid release through different $G_{q/11}$-coupled receptors. After synthesis and release from postsynaptic neurons, endocannabinoids can bind to presynaptic $G_{i/o}$-coupled receptors and inhibit neurotransmitter release for tens of seconds.

Direct presynaptic actions of $G_{q/11}$-coupled receptors have been more difficult to establish, particularly given the need to rule out endocannabinoid signaling in cases of apparent direct presynaptic inhibition. Because no firm evidence exists for presynaptic G_q-coupled receptor modulation, it is difficult to predict the effects of such signaling. Although it is possible that G_q-coupled receptors could have inhibitory actions via β/γ subunit signaling, $G_{q/11}$-mediated DAG production via PLCβ as well as subsequent PKC activation are predicted to have powerful excitatory presynaptic effects, given the actions of phorbol esters and PKC-mediated phosphorylation on proteins involved in vesicle priming and exocytosis. If presynaptic G_q signaling does occur, its precise nature may depend on the localization of the receptors relative to their possible signaling targets.

G_s-Coupled Receptors

Presynaptic G_s-coupled receptors are far less characterized in the central nervous system, but evidence suggests that these receptors can enhance neurotransmitter release, presumably through cAMP-dependent mechanisms. Paradoxically, some of the reported presynaptic actions of G_s-coupled receptors, such as dopamine D1 receptors, are actually inhibitory. For example, presynaptic G_s-coupled dopamine D1 receptors in the nucleus accumbens and cortex have been reported to reduce glutamate release. One explanation for these findings is that β/γ subunits released following activation of G_s-coupled receptors can inhibit release through mechanisms described later, although this has never been demonstrated in neurons.

Another peculiar finding is that some metabotropic receptors seem to be able to switch their G-protein coupling in response to different conditions. For example, $G_{i/o}$-coupled cannabinoid CB1 receptors may switch to G_s signaling when activated with low agonist concentrations or when associated with dopamine D2 receptors. In the cortex, $G_{q/11}$-coupled 5-HT2A receptors appear to also signal through $G_{i/o}$ when activated by class 5-HT2A agonists that have hallucinogenic properties in humans. Thus, metabotropic receptors may be capable of multiple conformational states that can modulate their coupling to G-protein signaling cascades.

Effectors and Targets of Presynaptic G-Protein Signaling

Many of the signaling targets of presynaptic modulation are the same proteins involved in activity-dependent short-term plasticity described in previous sections. Indeed, some signaling pathways may require both presynaptic activity and G-protein signaling. Thus, Gα signaling can lead to increases or decreases in important second messengers that control the phosphorylation state and function of presynaptic proteins involved in the docking, priming, and exocytosis of vesicles at the active zone. On more rapid timescales, Gβ/γ signaling can cause rapid and transient modulation of voltage-gated conductances as well as the protein complexes involved in SV priming and fusion.

Presynaptic Gα Signaling

Among the first signal transduction pathways described was the stimulation (by G_s) and the inhibition (by G_i) of adenylyl cyclase (AC) and cAMP. A striking feature of G_s activation and other similar signaling cascades is the capacity for robust signal amplification. In the case of G_s, only one or two GPCRs is required to stimulate GDP turnover on tens of G_s subunits, and each G_s-activated AC can in turn produce thousands of cAMP molecules. Another important aspect of signaling cascades is the divergence of signaling targets. In the case of the cAMP cascade, signaling can proceed in parallel through different mechanisms, including activation of PKA as well as activation of cAMP-GEFs (Epacs), both of which have been shown to mediate enhancement of neurotransmitter release at central nervous system synapses. PKA can phosphorylate numerous proteins, such as synapsin, snapin, α-SNAP, syntaphilin, tomosyn, CSP, SNAP-25, and RIM. All of these proteins are involved in the SV cycle, and their phosphorylation may alter

docking, SNARE complex formation, and release of SVs. In addition to these actions, Epac activation of monomeric G-proteins such as Rap and Ras can lead to additional signaling through MAP kinases and other signaling pathways, although the precise presynaptic actions of Epac have yet to be determined.

A second major signal transduction cascade in the presynaptic terminal is mediated by $G_{q/11}$ activation of PLCβ. The same principle of amplification applies for PLC-mediated synthesis of DAG and IP3, although membrane availability of the DAG precursor PIP2 can play a limiting role in this reaction, and PIP2 may be under dynamic control. DAG can activate PKC, which, like PKA, has numerous synaptic protein targets. For example, the syntaxin-binding protein Munc18, which binds to and stabilizes the closed form of syntaxin, is phosphorylated by PKC, leading to a decrease in its affinity for syntaxin and an increase in the probability of SNARE formation. PKC also phosphorylates other key synaptic proteins, including calcium channels and SNAP-25. DAG may also be important for presynaptic signaling independent of PKC via its interactions with Munc13, which were discussed previously.

Presynaptic Gβ/γ Signaling

Given the critical role of calcium channels in the triggering of neurotransmitter release, it is perhaps not surprising that modulation of calcium channels represents a major target for G-protein signaling. However, what initially surprised investigators was that this inhibition was not mediated by Gα subunits but instead by direct binding of G-protein β/γ subunits to calcium channels. In contrast to Gα signaling, no amplification occurs with β/γ signaling, suggesting that such signaling is likely to be more local and also have faster kinetics. Interestingly, Gα subunits may play an important role not only in the localization, specification, and timing of Gβ/γ signaling but also through downstream kinase signaling. For example, β/γ binding to calcium channels can be blocked by phosphorylation of the channel by PKC, suggesting the possibility of metaplastic control by $G_{q/11}$ signaling.

G-protein β/γ subunits can also directly bind and activate a class of potassium channels known as G-protein-activated inward rectifying K-channels (GIRKs). Although in theory, such a mechanism could reduce calcium influx by speeding action potential repolarization, little evidence for a presynaptic role of GIRKs has been found. It has also been recognized that β/γ subunits can exert an inhibitory influence on AC activity, particularly calcium- and calmodulin-dependent AC1 and AC8, suggesting that metabotropic receptor signaling can override activity-dependent changes in cAMP. Perhaps the most intriguing target of Gβ/γ is SNAP-25, a critical component of the SNARE complex that binds synaptotagmin and mediates vesicle fusion. Gβ/γ subunits can directly bind to SNAP-25 and inhibit release, possibly by disrupting the association of SNARE complexes with synaptotagmin 1, providing a direct mechanism for G-protein-mediated modulation of the release machinery independently of calcium influx.

Regulation of G-Protein Signaling

Initially, it was thought that G-protein signaling was activated solely by metabotropic receptors and terminated by the intrinsic GTPase activity of Gα subunits, but the discovery of activators of G-protein signaling (AGS) and regulators of G-protein signaling (RGS) proteins suggests that these concepts need revision. AGS proteins represent a family of receptor-independent G-protein activators that function through either GEF activity or by sequestering Gα or Gβ/γ subunits. A number of different AGS family members are expressed in neurons, where they could modulate receptor-mediated signaling in unexpected ways, such as uncoupling metabotropic receptors from $G_{i/o}$ or G_s pathways or enhancing basal inhibition by Gβ/γ through sequestration of Gα-GDP. However, their specific roles in presynaptic neuromodulation have yet to be characterized.

On the other hand, RGS and related family proteins have already been shown to play important roles in neuronal modulation and presynaptic plasticity, both through their GTPase-accelerating protein (GAP) activity and through other domain–domain interactions. For example, RGS6, -7, -9, and -11 have a G-protein γ-subunit-like domain that can bind to Gβ5 subunits. Gβ5 acts with RGS as an obligate heterodimer to drive GAP activity rather than as a classical β subunit in the β/γ complex. RGS12 and -14 contain Ras binding domains (RBDs) as well as $G\alpha_i$ binding domains. Interestingly, the RGS14 RBD binds Rap, suggesting a possible interaction between Epac and RGS signaling. Functionally, RGS proteins have been shown to modulate both basal synaptic properties and presynaptic modulation. In cultured hippocampal neurons, RGS2 overexpression gives rise to enhanced release probability and paired-pulse depression, whereas RGS2 knockout mice exhibit decreased release probability and enhanced paired-pulse facilitation, without any alterations in vesicle cycling, indicating that RGS2 is likely modulating basal G-protein inhibition of calcium channels. In the striatum, RGS9-2 has been reported to reduce modulation by dopamine

D2 receptors in both cholinergic and medium spiny neurons, and RGS4 reduces the efficacy of muscarinic M4 autoreceptor inhibition from cholinergic interneurons. Thus, the RGS family likely provides a widespread mechanism for the regulation of G-protein signaling in the central nervous system.

Conclusion

Short-term plasticity can arise from numerous sources, including presynaptic calcium-dependent signaling pathways, changes in the distributions and associations of presynaptic proteins following vesicle fusion, as well as transient cell surface signaling through G-protein-coupled receptors. However, all of these signaling mechanisms appear to converge onto common targets representing the proteins mediating SV trafficking, docking, priming, fusion, and recovery. In order to fully understand the mechanisms of neurotransmitter release and STSP, a comprehensive list of presynaptic proteins involved in neurotransmitter will have to be determined. Furthermore, three-dimensional models will have to be developed that incorporate the massive web of intermolecular associations among these proteins, as well as their regulation by calcium and phosphorylation, in both space and time. Although such a description is many years away, some of the most important proteins and their interactions are beginning to be characterized, giving us a glimpse into the vast complexity underlying regulated neurotransmitter release.

Filopodia as Synaptic Precursors

The vertebrate central nervous system (CNS) contains billions of neurons connected by an even greater number of synapses. Despite this complexity, the CNS develops reliably and precisely. The goal of developmental neurobiologists is to understand the mechanisms that control the accurate formation of synaptic connections in the developing brain. This article will review evidence that axonal and dendritic filopodia are fundamental players in the assembly of functional neural circuits. As will become apparent during the course of this article, the highly motile nature of filopodia and the relationship of filopodia to synaptogenesis are central to their role in generating a precisely ordered nervous system. This article is structured, therefore, around the participation of filopodia in synapse formation, the regulation of filopodial motility, and the way such regulation is fundamental to the genesis of appropriate and ordered synaptic connections. In part one we concentrate on a phenomenological discussion of the role of filopodia in synaptogenesis and growth and branching of axonal and dendritic arbors. This is followed by a discussion of intrinsic and extrinsic factors that may regulate the formation of synaptic contacts by altering filopodial motility in developing neurons.

Dendritic Filopodia as Spine Precursors

Dendritic spines were discovered in 1888 by Ramon y Cajal, who noticed that Purkinje cells' dendrites were decorated with small thorns ('espinas'). He later proposed that these small, submicrometer protrusions from the parent dendrite were the site of axodendritic contact. Cajal's hypothesis was proved correct 60 years later, when the electron microscope was employed to show that spines were indeed sites of synaptic contact between axons and dendrites. In fact, more recent estimates suggest that more than 90% of excitatory axodendritic synapses in the mature CNS occur on dendritic spines. Spines must therefore be key elements in neuronal circuitry, and their structure suggests that one fundamental function of spines may be to bridge physical gaps between densely packed dendrites and axons. Hence, the mechanisms governing spine morphogenesis likely play a fundamental role in the selection of synaptic partners and establishment of functional connectivity.

A clue to the developmental origins of spines comes from the observations that prior to the overt presence of spines, many elongated filopodia extend from dendritic shafts. These filopodia are long (2–20 μm), thin (<0.3 μm) structures and lack the bulbous head that is characteristic of spines. The elongated morphology of dendritic filopodia hints at an exploratory role, and further evidence for this has come from time-lapse imaging studies showing that filopodia are highly motile structures. For example, in early postnatal hippocampal slice cultures, filopodia extend and retract rapidly from dendritic shafts and have a mean lifetime of only 10 min or so. At later developmental times, there are progressively fewer filopodia, a trend accompanied by a steady increase in the number of more-stable spinelike structures. The scarcity of filopodia on mature dendrites suggests a mainly developmental role, and the structural similarities and sequential appearance of filopodia and spines suggests that filopodia might be spine precursors. Consistent with this hypothesis, in dissociated hippocampal neurons maintained *in vitro*, the appearance of spines coincides with an increase in the number of functional synapses and a reduction in the number of motile filopodia. Furthermore, the total number of filopodia formed is more than sufficient to account for the entire spine population. Formation of a contact between a dendritic filopodium and a nearby axon has also been observed directly in hippocampal neurons *in vitro*. This contact event resulted in the stabilization of the filopodium and the formation of presynaptic bouton at the contact site. These *in vitro* studies have been complemented by several electron microscopy studies of developing tissues that demonstrate the presence of synapses on filopodia, clearly demonstrating that filopodia also form synapses *in vivo*. These findings have been incorporated into a filopodial model of synaptogenesis and spine formation: (1) dendritic filopodia on immature dendrites are highly dynamic, facilitating short-range exploration and contact initiation; (2) contact between a filopodium and a neighboring axon may result in the formation of a nascent synapse; and (3) maintenance of the nascent synapse stabilizes the filopodium on which it is located, transforming it into a dendritic spine. In contrast, filopodia that fail to contact an axon, or contact an axon but fail to form a stable synapse would then be rapidly eliminated.

Caveats and Alternative Models of Spine Formation

Presented with the evidence above, one could be forgiven for thinking that spinogenesis is essentially a

process of trial and error. Highly labile filopodia extend randomly from the dendritic shaft, and those that establish a stable synaptic contact with a presynaptic axon are transformed into a more stable spine. While this may be the case for some neurons, it does not appear to be true for all neuronal cell types. A number of lines of evidence suggest that spine formation can occur independently of a presynaptic cell. For example, in 'weaver' mutant mice, granule cells – the presynaptic partners of the vast majority of Purkinje cells – are absent. In these animals, the main Purkinje cell dendrites are abnormal but are nevertheless decorated with spines. Even in the normal cerebellum, the distal dendritic branches of Purkinje neurons develop spines before synaptic contact with parallel fibers' axons. Thus, the normal developmental sequence of events suggests that Purkinje cell spines can exist in the absence of presynaptic axons. Such uninnervated spines have also been observed in the barrel cortex of adult mice. Time-lapse imaging *in vivo* has demonstrated the emergence of new spines from layer 5 pyramidal neuron dendrites. Reconstruction of new spines using serial electron microscopy has shown that at least some of them lacked a presynaptic partner. These data suggest a model in which spine formation is an intrinsic property of some neurons and so can occur without interaction with a presynaptic cell. However, given the importance of reciprocal pre- and postsynaptic interactions during nervous system development, it is unlikely that uninnervated spines are completely normal.

Filopodia and Formation of Dendritic Branches

The data described previously suggest that filopodia are important for establishing synaptic contact with nearby axons and that successful filopodia are stabilized as spine precursors. However, synapses are also present on dendritic shafts, and shaft synapses are particularly prevalent at early developmental stages. How are shaft synapses formed? Also, filopodia occur in neurons that do not form spines. What is the function of filopodia in nonspiny neurons? One intriguing idea that could answer both of these questions is that filopodia are important not only for establishing spines and spine synapses but also for development of dendritic branches and the shaft synapses on them. Support for this idea has come from time-lapse imaging studies of nonspiny tectal cell dendrites as they arborized in the tectum of live zebra fish larvae. Engineering zebra fish tectal neurons to express a fluorescent postsynaptic marker has enabled time-lapse imaging to be used to study the relationship between dendritic filopodia, synaptogenesis, and growth of dendritic arbors *in vivo*. Growth of tectal dendrites is highly dynamic, involving prolific extension and retraction of filopodia, and the use of a fluorescent synaptic marker has revealed that virtually all tectal synapses form on newly extended filopodia. It is surprising that the majority of these nascent synapses and the filopodia that bore them were transient, lasting only tens of minutes or so, indicating a high turnover rate for both synapses and filopodia. The crucial finding, though, was that the fraction of synapses that were maintained in turn stabilized the filopodia on which they were located, and these stabilized filopodia matured into dendritic branches (see **Figure 1**). Successive iterations of filopodial extension and stabilization by synapses resulted in growth and branching of the entire dendritic arbor. Thus, in nonspiny tectal dendrites, filopodia are important for establishing synaptic contacts (as they do in spiny neurons), but in these cells, stabilized filopodia go on to form dendritic branches. Thus, the dendrite essentially grows out to meet axons via filopodial stabilization at the point of synaptic contact. It is not yet known whether shaft synapses and dendritic branches form this way in dendrites that go on to form spines.

Filopodia and Synaptotropic Growth of Dendrites

The data obtained from zebra fish tectal neurons are interesting for several reasons: first, the high turnover of nascent synapses implies that an important function of filopodial dynamics is to establish many trial synapses with nearby axons. Those synapses which are maintained, and presumably 'correct,' in turn stabilize growth of the dendrite in regions of appropriate synaptic partners. Conversely, filopodia which do not form stable synapses are rapidly retracted, and further growth in these regions is prevented. Second, because growth is stabilized only in correct target regions, filopodia that extend from a previously stabilized one are more likely to make contact with correct targets. Thus, once a correct synapse forms, a positive feedback is established that guides growth of the arbor into appropriate target regions (see **Figure 1**). Synaptogenesis in this context is effectively a growth guidance mechanism that provides a means to match the extent of a dendrite to the set of connections it forms, that is, there are no branches without synapses. This mechanism relies on randomly distributed filopodial extension and a local stochastic process of synapse stabilization. Modeling studies have shown that such a process can generate precise patterns of connectivity independently of innate dendrite branching programs or expression of dendritic guidance molecules. This is potentially very important as it is unlikely that the genome can encode

Figure 1 (a) Growth of zebra fish tectal cell dendrites *in vivo*. Growth occurs by an interactive sequence of selective filopodial stabilization and synapse formation. Still images from time-lapse series, accompanied by a schematic rendering for clarity. Green represents accumulations of the postsynaptic marker PSD-95: green fluorescent protein (GFP), and red areas are newly formed (often transient) branches. Brown in the schematic represents persistent branches. (b) Model of synaptotropic guidance of dendrite arbor growth. A number of filopodia (solid red) extend from a dendritic branch. Those that encounter correct partners and form synaptic connections (green dots) are stabilized as new branches (brown), whereas those that establish inappropriate contacts (blue dots) are retracted (dashed red). Successive rounds of selective stabilization result in arborization within a field of appropriate synaptic connections (dashed green region).

explicit instructions to form every synapse in the nervous system. The 'synaptotropic hypothesis' of dendrite growth described above was first proposed based on electron microscopy studies of developing rat spinal cord. The presence of synapses on filopodia and the fact that dendrites did not extend until presynaptic partners had arrived are both consistent with the idea that formation of a synapse could stabilize nascent dendritic branches and bias further growth in that direction. A very similar pattern of dendritic growth has been observed in real time in the zebra fish retina. Similar to tectal cell dendrites, retinal ganglion cell (RGC) dendrites were highly dynamic at early developmental stages and demonstrated little net growth indicative of unguided exploration. However, as the laminar organization of amacrine cell processes (the presynaptic partners of RGC dendrites) began to develop, RGC dendrites became progressively more stable and ramified sequentially in amacrine plexuses. Thus, growth and targeting of prepatterned afferents by RGC dendrites appear to occur by a process of selective stabilization of nascent branches, perhaps by a synaptotropic mechanism.

However, there is ample evidence indicating that many dendrites do not rely on a synaptotropic mechanism. For example, hippocampal neurons form complex dendrites *in vitro* in the absence of presynaptic partners, and in the drosophila olfactory system, second order projection neurons elaborate dendrites in a highly stereotyped manner prior to the arrival of the olfactory sensory neurons. Therefore, during development, multiple strategies are employed to generate appropriate dendritic arbor morphology. Further studies should allow the relative contribution of each strategy to be tested and the contexts in which a particular strategy predominates to be elucidated.

Axonal Filopodia, Synaptogenesis, and Growth of Axonal Arbors

So far this article has focused on the role of dendritic filopodia. However, filopodia also extend from shafts of axonal branches. These filopodia are therefore distinct from the filopodia that emanate from the leading edge of axonal growth cones. While growth cone filopodia mediate axonal navigation, the filopodia that emerge from axonal branches appear to play a

role similar to that of dendritic filopodia, that is, in synaptogenesis and the formation of axon branches. Since the role of axonal filopodia has been investigated less extensively, the data that support this idea will be summarized only briefly. Time-lapse imaging has shown that axonal filopodia are highly motile *in vitro* and *in vivo*, consistent with an exploratory role. Most axonal filopodia are transient, lasting only a few minutes or so. Second, motility of axonal filopodia is downregulated as development and synaptogenesis proceed. Third, a number of different techniques have been employed to show that axonal filopodia are able to establish synaptogenic contact *in vitro* and *in vivo*. These studies have also indicated that formation of a stable synapse stabilizes the axonal filopodium on which it is located. As is the case with zebra fish tectal cell dendrites, axonal filopodia of retinal axons (the presynaptic partners of tectal cells) that are stabilized by synapses go on to form new axon branches from which further growth can occur. Selective stabilization of axonal branches by synapses has also been observed in the *Xenopus* retinotectal projection. These data suggest that as is the case with tectal cell dendrites, there is also a synaptotropic component to growth of retinal axonal arbors. Thus, stabilization of filopodia by synapses is important for guiding the formation of retinotectal connectivity from both the pre- and postsynaptic sides.

Despite the obvious similarities between axonal and dendritic filopodia, there is one notable difference. Axonal filopodia contain clusters of vesicles that are capable of exo-endocytic recycling, whereas dendritic filopodia do not. Thus axonal filopodia may be sources of neurotransmitter release prior to the formation of obvious synapses. Local release of neurotransmitters (and neurotrophic factors) may have an important role in regulating synapse formation by locally modulating filopodial dynamics.

Regulation of Filopodial Motility

Filopodia serve an exploratory function during synaptogenesis, actively probing the extracellular environment for instructive cues located in the extracellular environment and on the surface of other cells. Filopodial motility increases the probability of synaptic contact between pre- and postsynaptic cells simply by increasing the area sampled in search of an appropriate synaptic partner. Filopodial motility also provides a mechanism that allows neurons to form many trial synapses with multiple potential synaptic partners. Because of the complexity of nervous system connectivity, this element of trial and error is indispensable as it allows for the formation of precise circuitry without the need to explicitly encode every synaptic connection within the genome. In contrast to the trial-and-error nature of synaptogenesis, filopodial motility is highly regulated by both intrinsic and extrinsic signals. While intrinsic signals may function to promote filopodial motility throughout the entire neuron, extrinsic signals may function to guide synapse formation and arbor growth through local regulation of filopodial motility. In the following section we describe well-characterized intrinsic and extrinsic factors that regulate filopodial motility and discuss the potential role of these factors during the process of synaptogenesis.

Intrinsic Regulation of Filopodial Motility

One potential explanation for the early prevalence of filopodia in developing neurons is that filopodium formation during this developmental period is increased as a result of an intrinsic genetic program. This idea is supported by evidence that cytoskeletal proteins associated with neurite growth are expressed at high levels during periods of neurite growth and synapse formation and are subsequently downregulated in the mature nervous system. Filopodial protrusions consist primarily of parallel-bundled actin filaments oriented with the growing 'plus' end toward the filopodial tip. Filopodial initiation and extension occur through regulated actin monomer addition at the plus ends of preexisting actin filaments. Neuronal actin consists of two distinct isoforms, γ- and β-actin, of which β-actin is strongly enriched at sites of dynamic cytoskeletal remodeling, such as filopodia and spines. High expression levels of neuronal β-actin during periods of neurite growth and synaptogenesis are consistent with actin-dependent filopodial dynamics' being controlled by an intrinsic genetic program. In addition to regulation by protein expression, actin dynamics in developing axons and dendrites could be elevated through upregulation of cytoskeletal regulatory proteins. Several types of signaling proteins have been shown to regulate actin dynamics and neuronal architecture, including actin-binding proteins, Rho family guanosine triphosphatases (GTPases), tyrosine and serine-threonine kinases, and motor proteins. In axonal growth cones, several cytoskeletal regulators have been localized to a filopodial tip complex located at the interface between the distal, growing ends of filopodial actin filaments and the plasma membrane. Recent studies also suggest that local intracellular signals generated within this specialized tip complex, function to direct local actin polymerization and drive filopodial extension. Proteins localized to the tip complex in developing

neurons include members of the Ena/VASP family of actin-binding proteins, Src-family tyrosine kinases, the Rho family GTPase Cdc42, and the Cdc42 effector protein p21-activated kinase (PAK). Although these mechanisms have been best characterized in axonal filopodia, Cdc42 activation has also been shown to correlate with increased motility of dendritic filopodia. This indicates that, in addition to obvious structural similarities, the motility of axonal and dendritic filopodia is regulated by common signaling pathways. Intrinsic regulation of growth-associated mechanisms may contribute to cellwide filopodial motility in neurons during development. However, a synaptotropic model of synapse formation suggests that filopodial dynamics be locally regulated, implying the involvement of extrinsic regulators of filopodial dynamics.

Regulation of Filopodial Dynamics by Brain-Derived Neurotrophic Factor

Activity-dependent secretion of neurotrophins may guide synaptotropic arbor growth by promoting filopodial motility at synapse-rich regions of developing neuronal arbors. Brain-derived neurotrophic factor (BDNF), signaling through its receptors TrkB and p75, may serve this function within the CNS. It is secreted in an activity-dependent manner and has been shown to alter neuronal morphology and synapse density. Furthermore, BDNF application has also been shown to promote filopodial motility in axons and dendrites of several types of neurons *in vitro*. BDNF stimulation has been shown to modulate filopodial dynamics by stimulating the GTPase activity of Cdc42, which likely acts through downstream targets such as PAKs, which regulate filopodial motility in growth cones and synaptogenesis and spinogenesis in hippocampal neurons. Recent findings have also demonstrated that clusters of TrkB receptors are transported into both axonal and dendritic filopodia, consistent with the idea that filopodia can sense extracellular BDNF. In *Xenopus laevis* tadpoles, local BDNF administration in the optic tectum has been shown to increase the density of synapses on retinal axons and tectal neuron dendrites. This increased synapse formation correlates with an increase in retinal arbor complexity. Together these studies suggest that activity-dependent secretion of BDNF may promote filopodial motility locally and in so doing promote synaptogenic contact between axons and dendrites.

Regulation of Filopodial Motility by Neurotransmitters and Neuronal Activity

It is well established that neuronal activity plays an important role in the accurate formation and refinement of neuronal connections during development. Given the central role of filopodia during synaptogenesis, an attractive model is one in which neuronal activity promotes filopodial exploration and stability. Globally, action potential firing may operate in conjunction with intrinsic genetic programs to promote filopodial motility in immature neurons during development. In addition, synaptic transmission and local depolarization of specific dendritic regions may promote synaptotropic growth by promoting filopodial extension in the vicinity of functional synapses. Evidence for this model was first provided by reports that application of the excitatory neurotransmitter glutamate stimulates rapid filopodial growth from hippocampal neuron dendrites (see Figure 2). These findings suggested that neurotransmitter secretion could promote synaptogenic contact by triggering local filopodial growth from potential postsynaptic partners. However, it should be noted that glutamate has been shown to either increase or decrease the motility of axonal and dendritic filopodia, suggesting that its effects are highly context dependent. Synaptically evoked action potential firing has also been shown to promote the formation of motile dendritic filopodia. This suggests a mechanism that promotes dendritic filopodial exploration and subsequent synaptogenesis and arbor growth in neurons receiving strong synaptic inputs. Such a mechanism could locally promote further synaptogenic contact between appropriately matched axonal and dendritic arbors. In support of this model, *in vivo* imaging has provided evidence that sensory experience promotes the protrusion of dendritic filopodia from pyramidal neurons in the developing rat barrel cortex and *Xenopus* tectal neurons. In the barrel cortex, reduced filopodial motility induced by whisker trimming correlates with the formation of less refined receptive fields, suggesting that activity-dependent filopodial exploration is necessary for accurate formation of sensory maps during development. Neuronal activity may promote filopodial motility by direct activation of second-messenger signaling cascades or by heightening sensitivity to locally secreted cues such as BDNF.

Role of Calcium Signaling in Filopodial Motility

The regulation of filopodial motility by action potential firing and glutamate application suggests that intracellular calcium elevations may mediate observed changes in neuronal structure and motility. This possibility is supported by several reports of neuronal growth and morphology being regulated by calcium-sensitive proteins such as calmodulin, calmodulin-dependent protein kinase II (CaMKII), the intracellular protease calpain, and the phosphatase calcineurin. The β isoform of CaMKII has been shown to specifically regulate the motility of dendritic filopodia and the formation of

Figure 2 Rapid modulation of filopodial motility by glutamate and brain-derived neurotrophic factor (BDNF). (a, b) High-magnification view of a hippocampal neuron dendrite at indicated times after local pulatile application of glutamate. Note rapid increase in filopodial number and length. Arrow indicates a newly sprouted filopodium. (c) Measurement of filopodial length as a function of time in response to glutamate application for the filopodium indicated by arrow in (b); time in seconds. (d–g) Time-lapse differential interference contrast (DIC) and fluorescence images of a *Xenopus* spinal neuron expressing green fluorescent protein (GFP)-dSH2, a fluorescent indicator of tyrosine phosphorylation (PY), at indicated times after bath application of BDNF. Note that many filopodia lack enriched GFP-dSH2 at their tip before BDNF application but accumulate GFP-dSH2 after BDNF stimulation. (j), (k) Time-lapse DIC and GFP-dSH2 fluorescence images of boxed regions indicated in (d)and (f)at indicated times after BDNF application. Time between images is 10 s. Arrows point to one preexisting filopodium that acquires tip PY at 80 s after BDNF stimulation and three newly extended, PY-containing filopodia. (h, i) Kinetics of increased filopodium formation and increased GFP-dSH2 accumulation at filopodial tips in response to BDNF. Scale bar = 5 μm (d).

excitatory synapses by hippocampal neurons *in vitro*. The beta isoform of CaMKII, which is the predominant isoform expressed during early development, has also been specifically shown to bind to F-actin in hippocampal dendrites and to localize to dendritic regions undergoing dynamic structural rearrangements. Although the specific mechanism by which CaMKIIβ functions to promote filopodial motility is unknown, one possibility is that actin binding functions to localize CaMKIIβ to a multimolecular signaling complex. Within such a complex, CaMKIIβ activation by intracellular calcium elevation and calmodulin binding may lead to spatially precise activation of downstream signaling proteins that regulate the actin cytoskeleton. Another mechanism by which calcium signaling may regulate local motility of filopodia is through the generation of local calcium transients restricted to small regions of a dendritic or axonal arbor. The function of dendritic spines as discrete calcium signaling compartments has been demonstrated by monitoring intracellular calcium levels in response to synaptic transmission. However, similar observations have been made in axonal and dendritic filopodia, suggesting that calcium signaling may regulate filopodial motility and thereby influence synaptogenesis. Consistent with this possibility, calcium imaging in RGCs has revealed that newly formed dendritic branches also exhibit local neurotransmitter-evoked calcium elevations, and these signals may function to stabilize nascent synaptic contacts. This model for calcium-dependent stabilization of dendritic branches is consistent with calcium imaging studies examining the function of local calcium transients in filopodia of hippocampal neuron dendrites and *Xenopus* spinal neuron growth cones. In both systems, increased frequencies of local calcium transients correlated with the stabilization of active filopodia, suggesting that extracellular signals that promote the stabilization of synaptic contacts may do so through modulation of intracellular calcium levels. Although calcium-sensitive signaling cascades can control neuronal motility, the way in which calcium signals regulate distinct aspects of filopodial motility such as growth and stabilization remains unclear.

Filopodial Stabilization by Adhesion Molecules

During synaptogenesis, filopodial exploration and recognition of a putative synaptic partner lead to filopodial stabilization through an adhesive interaction with the target cell. Initial contact is mediated by the binding of transmembrane adhesion receptors such as members of the cadherin, protocadherin, and SynCAM protein families as well as neuroligin and β-neurexin. Of these adhesion molecules, N-cadherin has been localized to early contacts between dendritic filopodia and axons, where it functions to stabilize synapses and promote the formation of mature spine synapses. Following transmembrane engagement, structural stabilization of this contact site arises through direct interaction between n-cadherin and α-catenin, an actin-binding protein that forms a functional linkage between the transmembrane adhesion protein and the actin cytoskeleton. Disruption of either n-cadherin or α-catenin function results in altered spine morphologies characterized by the appearance of filopodia-like motile protrusions extending from the spine head. This suggests that in a system in which filopodia function as spine precursors, synapse stabilization by cadherins and catenins normally inhibits filopodial exploration. In addition to serving a structural function in maintaining physical contact between pre- and postsynaptic cells, transmembrane adhesion proteins can serve a signaling role in directing the assembly of synaptic specializations at the original site of adhesion. The homophilic adhesion molecule SynCAM has been shown to be necessary for the formation of glutamatergic synapses by directing the formation of presynaptic specializations. Similarly, presynaptic neuroligin binding to postsynaptic β-neurexin stimulates the local recruitment of both pre- and postsynaptic components. Although the dynamic localization of SynCAM and β-neurexin–neuroligin during synaptogenesis has not yet been determined, the fact that filopodia are known to make synaptic contacts suggests that these synaptogenic molecules may well be expressed on them. Expression of synaptic cell adhesion molecules on the surface of filopodia may function to halt filopodial exploration on formation of a synaptic contact, thereby allowing differentiation of these early contacts into mature, stable synapses.

Synaptic Transmission: Models

Introduction

Chemical signaling at a synapse occurs when a synaptic vesicle fuses with the presynaptic membrane in response to calcium influx through voltage-gated calcium channels. Vesicle fusion results in the formation of a fusion pore through which neurotransmitter packaged in the vesicle can escape into the synaptic cleft. The released neurotransmitter then diffuses through the synaptic cleft and binds to ligand-gated receptors on the postsynaptic membrane, which then lead to current flow across the postsynaptic membrane. To understand synaptic transmission, it is necessary to determine the spatiotemporal pattern of channel opening. However, physical limitations preclude direct observation of the dynamics of neurotransmitter release and receptor activation at single synapses. With the vast amount of biophysical and structural data that are now available, it is possible to make constrained models with sufficient biological realism that can be used to answer the following questions about the generation of synaptic responses:

1. How does the structure of the synapse shape the response?
2. How does the biophysics of receptor activation contribute to the response?
3. What is the influence of the kinetics of release of neurotransmitter and its reuptake or degradation?

We first discuss modeling methods that can be used for the study of synapses and then discuss the application of these methods to the study of excitatory transmission at the frog neuromuscular junction and at central glutamatergic synapses.

Modeling Approaches

The physical processes involved in chemical synaptic transmission are neurotransmitter diffusion and binding to receptors followed by conformational transitions of receptors, neurotransmitter binding to transporters for re-uptake (at central synapses), and neurotransmitter hydrolysis (in case of the neuromuscular junction).

The average time evolution of the neurotransmitter concentration in the cleft subject to these processes can be succinctly written as

$$\frac{\partial C(\mathbf{r},t)}{\partial t} = \left.\frac{\partial C(\mathbf{r},t)}{\partial t}\right|_{\text{diffusion}} + \left.\frac{\partial C(\mathbf{r},t)}{\partial t}\right|_{\text{reaction}} + \left.\frac{\partial C(\mathbf{r},t)}{\partial t}\right|_{\text{uptake}} \quad [1]$$

where $C(\mathbf{r}, t)$ is the concentration of the neurotransmitter at the spatial location $\mathbf{r}$ and time t. The diffusion of neurotransmitter is given by

$$\left.\frac{\partial C(\mathbf{r},t)}{\partial t}\right|_{\text{diffusion}} = D^2 C(\mathbf{r},t) \quad [2]$$

where ∇^2 is the diffusion operator, and D is the diffusion constant (measured in $\text{mm}^2\,\text{s}^{-1}$).

These processes can be simulated on computers using two fundamentally different mathematical approaches. In the first, the molecular nature of the neurotransmitter and receptors is ignored. The neurotransmitter concentration and the probability of receptor activation are treated as continuous quantities that vary smoothly in space and time. The time evolution of these quantities is then modeled using analytic approximations or partial differential equations. A second approach respects the discrete, probabilistic nature of neurotransmitter diffusion and receptor interaction. The ligand and receptor molecules are represented individually and undergo random motions (corresponding to Brownian diffusion) and stochastic interactions and transitions (corresponding to the reactions).

Continuum Methods

The main advantage of these continuum methods is their rapid implementation and the precise prediction of average quantities such as the time course of neurotransmitter clearance or receptor activation. Whereas early work using continuum models used simplified geometries, newer methods have allowed the incorporation of complex geometries, such as that of the neuromuscular junction.

In continuum models, the equations for neurotransmitter diffusion, uptake, and binding are supplemented by equations for the concentrations of receptors in different states. This system of differential equations is subject to the appropriate initial conditions, specifying the concentration of the neurotransmitter and the receptor states at time $t = 0$ at different spatial locations. The information on the synapse geometry is contained in the boundary conditions that govern the behavior of the neurotransmitter at reaction

boundaries as well as the inert surfaces. The latter represent physical barriers that the diffusing neurotransmitter cannot cross. These are mathematically known as zero flux boundaries, where the spatial gradient of the concentration $\partial C/\partial x = 0$. Uptake mechanisms or receptors located on the boundaries of the reaction space are instead modeled as absorbing boundaries where the concentration vanishes-that is, $C(r, t) = f(C)|_{\text{surface}}$.

In the absence of reaction and degradation/uptake terms in eqn [1], closed-form solutions of the diffusion equation are only possible for idealized geometries, which have a high degree of symmetry. Some example geometries include a cube, a cylinder, and a sphere. For example, a thin circular disk, with one face representing the presynaptic terminal and the other the postsynaptic membrane, is a good approximation of small central synapses. The solution of the diffusion equation in cylindrical coordinates is given in the form of Bessel functions, which can then, in principle, be used to study the dynamics of receptor opening. However, simple analytic models do not capture the complexity of the diffusion and reaction processes, and one must resort to numerical techniques for the solution of the full equation, including reaction terms and neurotransmitter uptake/degradation. A number of techniques have been developed for the solution of these equations under various approximations. Those relevant for synaptic transmission are discussed next.

Finite difference methods Finite difference (FD) methods are a powerful set of techniques to solve nonlinear reaction-diffusion equations (e.g., eqn [1]). These methods represent the concentration $C(\mathbf{x})$ by its values at discrete points in the reaction volume and approximate the derivatives (in space and time) as differences between adjacent points. This discretization results in a set of algebraic equations for the concentration of the diffusing neurotransmitter that can be solved using standard methods of linear algebra which have been implemented in software packages such as MATLAB. This approach is particularly useful for studying the synaptic current due to receptors with complex multistate kinetics as well as the effects of antagonists and modulators of receptors. Due to the long history of FD methods and their wide application, many optimization techniques are available for the simultaneous solution of the neurotransmitter diffusion, uptake, and receptor binding and even complex receptor kinetics. However, these methods are best suited for simplified geometries, but even here, the amount of discretization places severe restrictions on the accuracy of the method as well as its implementation on readily available personal computers.

Finite element methods Finite element (FE) methods are widely used in engineering applications to study how material structures behave under applied loads. These methods have been extended to a wide variety of partial-differential equations, including nonlinear reaction-diffusion equations (e.g., eqn [1]). In a strict mathematical sense, FE methods find a piecewise approximation to the solution of eqn [1]. This is done by subdividing the arbitrarily complex reaction space into small (finite) elements and decomposing the solution as a linear weighted sum of functions that are defined only over the finite elements. This decomposition then results in a nonlinear matrix equation that must be solved in order to determine the coefficients. In three-dimensional space, these elements are usually trapezoidal (other more complex shapes are possible). The accuracy of the method, as for the FD method, depends on the discretization (with finer subdivisions yielding better accuracy.) Similar to FD methods, the discretization can be adaptive, with high spatial resolution where the concentration of neurotransmitter varies rapidly.

The diffusion of acetylcholine (ACh) in complex geometries can be implemented using publicly available FE packages to gain insight into the structure-function relationship at neuromuscular junctions (NMJs). Similarly, the effect of vesicular release and acetylcholinesterase (AChE) distribution on miniature excitatory postsynaptic current (mEPSC) kinetics has also been studied using such models. The key advantage of the FE method is that the computational cost is proportional to the number of finite elements. Thus, a full endplate current (representing the release of approximately 200–300 quanta in a geometrically complex NMJ) can be simulated. However, the implementation of the reaction terms in FE models is nontrivial. The esterase and the receptors must be represented as spatially delimited sinks resulting in the boundary condition

$$\hat{n}(\mathrm{x})D\Delta C(\mathbf{x}, t) = -kC(\mathbf{x}, t) \qquad [3]$$

where $\hat{n}(\mathbf{x})$ is the surface normal, and k is a constant that is related to the steady-state constant of ACh to the esterase or receptor. The kinetics of the ACh receptor are relatively simple (the only isomerization step involves the opening of the channel), which makes its implementation possible within the FE formalism. More complex reaction schemes (e.g., glutamate receptors) are much more difficult to represent using this method. This method has been used in a few cases to study the effect of differences in fold geometry on the kinetics of the mEPSC. Ultrastructural observations show that fast-twitch and slow-twitch muscles have different structures. Muscular

dystrophy is also known to distort NMJ structure, leading to differences in mEPSC kinetics.

Monte Carlo Approaches

Continuum methods such as FD and FE outlined previously predict the average properties of chemical reactions. Such models are accurate (within the limits imposed by stability and accuracy considerations) as long as the number of reactions modeled is large. However, the chemical reactions that underlie neurotransmission at a single central synapse present a challenge to such models. Experiments show that the synaptic current at small central synapses is due to the opening of tens of receptors. This implies that each vesicle only contains a few thousand molecules of neurotransmitter, of which several tens participate in receptor activation. Finally, the amplitude of the individual synaptic response is often variable from trial to trial. These considerations imply that the stochastic or 'noisy' nature of chemical reactions must be accounted for in modeling synaptic transmission. The main source of this noise is the ubiquitous 'thermal noise' that characterizes the diffusive (Brownian) motion of molecules and conformational transitions of receptor proteins. The Monte Carlo method assumes that the physical processes in synaptic transmission are inherently probabilistic. The dynamics of the individual reactions are then followed by rolling a dice at each time step (hence the name Monte Carlo) to decide how much a given ligand molecule will move and whether a particular reaction will occur or not. Thus, variability is an inherent part of the simulation procedure. The average behavior of the system is obtained by averaging the results of the simulations across multiple trial runs. One strength of the Monte Carlo method is the high level of spatial and temporal detail that can be achieved.

The heart of the Monte Carlo method is its approach to modeling the diffusion of neurotransmitter in complex reaction spaces. In general, a diffusing molecule at a point P at time $t=0$ has some thermal velocity and undergoes collisions with water molecules on the sub-picosecond timescale at room temperature. After many collisions (over a nanosecond timescale), the molecule may have moved to a new location in a random direction. The distribution of displacements from the original location can be calculated from the diffusion equation (eqn [1]). For diffusion in free space, the solution of this equation is given by

$$C(r,\Delta t) = \frac{C_0}{(4\pi D\Delta t)^{3/2}}\,\mathrm{e}^{-r^2/4D\Delta t} \qquad [4]$$

Thus, the fraction of molecules in a spherical shell (of volume $4\pi r^2 dr$) is

$$f_r = \frac{1}{(4\pi D\Delta t)^{3/2}}\,\mathrm{e}^{-r^2/4D\Delta t}(4\pi r^2 dr) \qquad [5]$$

which is the same as the probability of a radial displacement of a single molecule. Thus, diffusion of a single neurotransmitter molecule is simulated by choosing a random number with the previous probability distribution. A second random number specifies the direction of this displacement in three dimensions. When the diffusing molecule encounters an impenetrable barrier, it is reflected back into the reaction volume by an elastic collision. In this way, the zero flux boundary conditions specified previously are naturally handled. Note that collisions need not occur with nonreactive boundaries but also with reactive boundaries (representing a surface receptor). In this case, the reflection occurs with a probability that is related to the macroscopic on-rate constant of the ligand with its receptor. This probability is given by

$$p_{\mathrm{b}} = k_{\mathrm{on}}\frac{1}{2N_{\mathrm{av}}A_{\mathrm{tile}}}\left(\frac{\pi\Delta t}{D}\right)^{1/2} \qquad [6]$$

where k_{on} is the macroscopic on-rate constant for the ligand to bind to the receptor, N_{av} is Avogadro's number, and A_{tile} is the area of the surface element occupied by the receptor. Unimolecular reactions, such as conformational changes of receptors, also occur in a probabilistic manner, with the probability of any given transition at a time step given as

$$p_{\mathrm{u}} = 1 - \exp\left[-\left(\sum_i k_i\right)\Delta t\right] \qquad [7]$$

where k_i is the macroscopic rate constants of the ith possible reaction for a receptor at any given state (e.g., a ligand can unbind from a receptor or the receptor might isomerize to a new state). The choice of the time step is dictated by the fact that the reaction probabilities must be $<<1$. The power of the method comes from the realization that fixing the time step automatically fixes the spatial resolution of the method. The size of the reactive and nonreactive surfaces, on the other hand, can be specified to a much higher precision (a small multiple of the area of a receptor, ~10–20 nm). The Monte Carlo technique is thus a powerful approach to simulating ligand–receptor interactions in arbitrarily complex geometries as well as receptors (and ligands) with complex kinetic properties. However, this power comes at a high computational cost. The advent of modern computers and the powerful program MCell, which includes many optimizations that speed up the calculations necessary to track diffusion and ligand–receptor interactions, makes the use of this approach entirely feasible.

Measurement of synaptic response: Quantal analysis The postsynaptic response to stimulating a single input axon may be quite complex; several synapses may be involved and multiple vesicles may contribute to the response, even at a single synapse. The factors that determine the dispersion of vesicle-release times are complex, and it is desirable to simplify the issue by studying the response generated by a single vesicle. Miniature synaptic currents (mEPSCs) occur spontaneously and are thought to result from the release of a single vesicle. Computational modeling of the synaptic response has thus focused on whether the properties of mEPSCs can be accounted for. These include the rise time, fall time, and variance. The rise time of the mEPSC at the NMJ is approximately 100 ms. It initially appeared that the rise time of the mEPSC at glutamatergic synapses of the hippocampus was considerably longer, but with the development of dendritic recording methods that eliminated distortions due to inadequate voltage clamp, rise times similar to those at the NMJ were found. The decay times are also similar (5–10 ms), but the amplitudes differ enormously: 4 nA in the frog compared to 15pA at hippocampal synapses. Interestingly, the geometries of the two synapses, although having obvious differences, are similar in size. Each presynaptic active zone at the NMJ is organized in a linear array approximately 1 μm long; the largest hippocampal synapses have similar dimensions (the smallest are ~0.2 μm in diameter).

Information needed for modeling A full consideration of the various numerical values that must be known to model synaptic function is beyond the scope of this article. Here, we list the various constants that must be estimated:

1. The transmitter content of the vesicles is estimated to be approximately 2000–4000 for glutamate and approximately 10 000 for ACh.
2. This transmitter exits the vesicle into the cleft through a fusion pore. There is considerable research on the size of the fusion pore; it may be much smaller during kiss-and-run release than during full fusion. Importantly, several methods are available that can provide at least a rough estimate of the size of the fusion pore.
3. The geometry of the cleft can be determined from electron micrographs.
4. The diffusion constant of transmitter in the cleft has been estimated and shown to be close to the diffusion limit; apparently, occlusion of the cleft by transsynaptic structures is not a major impediment.
5. Transmitter may bind to proteins other than the transmitter channels (e.g., transport proteins). The concentration of these sites is probably sufficiently low that their influence on the rising edge of the response is negligible.
6. The density of transmitter-activated channels has been measured directly. Interestingly, the density of ACh receptors (the channel at the NMJ) is approximately 10^4 mm^{-2}, which is approximately 10 times higher than that of AMPA channels (the major type of glutamate channels).
7. A kinetic model of the transmitter-activated channel is required. This will specify the on-rate constant for binding, the rate constant for opening and desensitization, and so on. Generally, the development of such models is based on data from systems in which transmitter can be applied rapidly and under controlled conditions.

Modeling Cholinergic Transmission at the Neuromuscular Junction

The vertebrate NMJ is one of the best-studied model synapses because of its large size, which makes it easy to obtain electrical recordings. The basic rules of synaptic transmission were worked out in this system, and a large amount of physiological and morphological data are available. The NMJ is composed of three distinct compartments: (1)the presynaptic nerve terminal, which contains a large number of vesicles containing the neurotransmitter ACh-a subgroup of the these vesicles is located directly adjacent to the active zones; (2) an extensively folded postsynaptic membrane; and (3) the intervening 50 nm-wide synaptic cleft. The junctional folds (JFs) have variable depth (0.5–1 μm) and are contiguous with the cleft. The acetylcholine receptor (AChR) is a pentamer (subunit composition) and is distributed on the crests of the JFs with a density of approximately 7000–12 000 mm^{-2}, declining by 30–50% at the bottom of the folds. In addition to the receptors, the enzyme AChE, which degrades ACh, is present on the postsynaptic membrane at densities of 2000–3000 mm^{-2} on the primary cleft and the JFs in clusters of 12 (three tetramers).

Insights from Modeling

The key challenge in modeling synaptic response due to the release of ACh at the NMJ is to incorporate the intricate geometry of the cleft. The physical properties of the NMJ place strong constraints on the time course and magnitude of the mEPSC. Simulations incorporating the synaptic geometry, receptor properties, and speed of vesicle release led to the concept of a saturated disk-a region on the postsynaptic membrane where nearly all the ACh contained in a single vesicle can be bound to receptors. An important

implication of this finding is that the synapse has evolved for a near perfect postsynaptic detection of each molecule of ACh release (this is not the case for glutamatergic synapse). The area of this saturated disk, $a_{\text{disk}} \propto N/\sigma$, where σ is the density of AChRs and N is the number of ACh molecules in the vesicle. For typical values of σ of approximately 10 000 mm^{-2}, the area of the saturated disk is approximately 0.5 mm^2. Simulations of the mEPSC in a comblike approximation of the NMJ or a detailed reconstruction demonstrated the existence of this saturated disk. The idea of a saturated disk can be used to estimate the contribution of diffusion, binding, and receptor kinetics to the rise time of the mEPSC. Assuming that the entire content of the vesicle is released instantaneously into the cleft, the time required for this ACh to diffuse over the saturated disk is

$$t_{\text{diff}} \propto \frac{N}{\sigma D} \qquad [8]$$

where D is the diffusion constant of ACh in the cleft, N is the number of ACh molecules, and the numerical factor C arises due to the cleft geometry. For typical values in the NMJ, this corresponds to approximately 50 μs. Similarly, the contribution of binding to the rise time is given by the time taken for a given concentration of ACh in the cleft to bind to the receptor:

$$t_{\text{bind}} \propto \frac{h}{\sigma k_+} \qquad [9]$$

where h is the height of the cleft, σ is the concentration of AChR in the cleft, and k_+ is the binding constant of ACh to the receptor ($\sim 4 \times 10^7\,\text{M}\,\text{s}^{-1}$). This value ($\sim 40$ μs) is comparable to the diffusion time t_{diff}. Since ACh does not leave the cleft over the rise time, binding can keep pace with diffusion and all the ACh can be optimally bound to receptors in a small area, ensuring saturation. The third contribution to the rise time is due to the finite time taken for the receptor to change conformation from the doubly bound state to the conducting state. The relevant time constant for this conformational change is approximately 50 μs. These considerations give a rather straightforward account of the 100 μs rise time of the mEPSC.

One assumption in the models is that the concentration of ACh builds up rapidly (nearly instantaneously) in the cleft. Ultrastructural studies on the NMJ have led to a model of neurotransmission in which rapid fusion of a vesicle with the presynaptic membrane releases neurotransmitter into the synaptic cleft. Following fusion, a membrane pore approximately 10–15 nm long forms, connecting the vesicle interior to the cleft. The neurotransmitter then flows down the concentration gradient (~200–500 mM in the vesicle and ~0 mM in the cleft). The diameter of the pore has not been directly measured. However, AC capacitance measurements have been used to measure the conductance of fusion pores formed by small synaptic vesicles. These typically estimate the pore conductance to be >500 ps. Given this geometry, one can use computational models of diffusion through the fusion pore and within the cleft to determine the time course of ACh within the cleft. One can then determine whether this time course, together with the properties of the ACh channel, can account for the measured 100 μs rise time of the mEPSC. Monte Carlo simulations of the NMJ with realistic geometries have shown that the fast rise time is accounted for by passive diffusion provided that the pore expands in diameter at a rate greater than 25 nm ms^{-1} (i.e., the pore would expand by 2.5 nm over the rise time of the mEPSC), which is well within the working stroke of many molecular motors.

The power of the Monte Carlo method is best illustrated when studying the factors governing the variability of the quantal response. The stochastic opening and closing of the channels as well as randomness in the release location lead to a CV of 0.02–0.03, which is much smaller than observed (~0.2). What are the additional factors? One factor is the variation in the amount of ACh in a single vesicle. However, experimental measurements suggest that the mEPSC amplitude is uncorrelated with its rise time, whereas the simple considerations discussed previously suggest that large mEPSC (corresponding to larger amounts of ACh in a vesicle) would have a longer rise time. However, simulations using detailed spatial reconstruction of the NMJ have been used to show that variations in the cleft height and branching of the JFs contribute a significant amount of the variability.

Hippocampal Synapses

Morphological Constraints

There is generally a single synapse on spines of CA1 pyramidal cells. This synapse has a single presynaptic active zone and a single postsynaptic density. There is a large variation in the size of these synapses. The average nonperforated synapse on mushroom or stubby spines on P15 CA1 pyramidal cells is 0.1 mm^2; perforated synapses are larger, whereas synapses on thin spines are considerably smaller (0.05–0.07 mm^2 area). Immunogold labeling suggests that glutamate receptors of α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) type are fairly uniformly distributed within the synapse, with a density of approximately 1000 mm^{-2}. Thus, large mushroom or stubby

spines can contain approximately 100 receptors, whereas thin spines have fewer than 20. On the other hand, *N*-methyl-D-aspartate type glutamate receptors are found on almost all synapses and their number is weakly correlated with the area of the synapse. The presynaptic bouton typically contains a single active zone whose size is matched to the postsynaptic density. The intervening synaptic cleft is typically 15–20 nm in width.

Central synapses lack enzymatic processes analogous to AChE to degrade and thus dilute the neurotransmitter released in the cleft. At central synapses, diffusion is the major mechanism for the clearance of neurotransmitter from the synaptic cleft. Thus, a good estimate of the diffusion constant of glutamate is essential for modeling the efficacy of receptor activation at synapses. Most neurotransmitters are small molecules whose diffusion coefficient in free solution is approximately $1\,\mathrm{mm}^2/\mathrm{ms}$. However, in the brain, their diffusion is likely to be slower for two reasons: The extracellular space resembles a porous medium (much like a sponge) and diffusion is restricted to small (nanomolar-sized) channels, and the synaptic cleft and the extrasynaptic space are packed with both charged and neutral macromolecules which further impede diffusion by volume exclusion. The hindrance of diffusion due to the porous nature of extracellular space as well as macromolecular crowding can be accounted for by estimating an effective diffusion coefficient, $D_{\mathrm{eff}} = D/\lambda^2$, where $\lambda > 1$ is the tortuosity of the medium, a measure of the hindrance (geometric or otherwise) experienced by the diffusing molecules. Measurements suggest that glutamate diffusion in the cleft is similar to its value in solution (decreased by approximately a factor of 2).

In the hippocampus, electron microscopy studies show that most functional synapses seem to have glial processes at the perimeter of the axon-spine interface. At most CA1 synapses, the astrocytic processes only partially surround the synapse, allowing glutamate to freely escape into the extracellular space. The astrocytes make up nearly 10% of the total membrane in CA1 and are lined with glutamate transporters (proteins that move glutamate from the extracellular space into the glial cell) at a density of approximately $10\,000\,\mathrm{mm}^{-2}$. These transporters also bind glutamate with high affinity (10–20 μM) and serve to either buffer or remove synaptically released glutamate. From a modeling standpoint, it is not correct to incorporate the effect of transporters by slowing the diffusion of glutamate in the extracellular space. This is because the buffering action of the transporters means that glutamate actually binds to them, resulting in a loss of glutamate from the extracellular space. Instead, the effects of transporters should be included by explicit modeling of the binding and unbinding of glutamate rather than a reduction of its diffusion constant.

Kinetic Constraints

AMPA receptors act on a rapid timescale and display weak affinity to glutamate (the dissociation constant, $K_D \sim 400\,\mu\mathrm{M}$). In recent years, these channels have been cloned and expressed in heterologous systems in order to study their electrophysiological properties under controlled conditions, leading to a deep understanding of the structure and kinetic properties of AMPA channels. These channels are tetramers composed of several stoichiometric combinations of glutamate receptor subunits (GluR) 1–4. Thus, channels may be homomers composed of identical subunits ($\mathrm{GluR1}_4$) or heteromers composed of distinct subunits in a strict stoichiometric manner ($\mathrm{GluR1}_2$–$\mathrm{GluR2}_2$, $\mathrm{GluR2}_2$–$\mathrm{GluR3}_2$, etc.). Depending on the subunit composition, AMPA channels may have distinct kinetic properties that shape channel kinetics and even permeability to different cations ($\mathrm{GluR1}_4$ are calcium permeable). Each subunit has a binding domain which can bind glutamate independent of whether glutamate is bound to any of the other subunits (i.e., there appears to be no cooperativity in glutamate binding). Structural studies indicate that agonist binding causes a closure of the binding domain and initiates conformational changes that serve to activate the channel. It appears that at least two subunits need to have glutamate bound in order for the channel to conduct ions. Importantly, additional binding greatly speeds channel opening and enhances the single channel conductance (typical values of conductance are 5–8, 7–10, and 12–15 ps, depending on subunit occupancy). However, it is not entirely clear whether these conductance steps occur for channels natively expressed in synapses. Furthermore, it appears that glutamate binding and unbinding can occur from both closed and open states, but binding and unbinding from the open states is slow.

A hallmark of glutamate channels is their ability to rapidly desensitize–that is, switch to a nonconducting conformation upon binding glutamate. The exact conformational changes that lead to desensitization are a subject of active research, but it is widely accepted that glutamate binding to the subunit can set in motion conformational changes leading to either activation or desensitization. Additionally, desensitization as well as recovery from desensitization show a concentration dependence that can be best explained by considering that each subunit is capable of desensitization upon binding glutamate (i.e., desensitization is not a cooperative phenomenon). These

considerations lead to models of AMPA receptor gating that may typically have 40–50 distinct states. Once the state diagram for the receptors is chosen, the transition rates between these states can be determined by fitting the data on channel activation and desensitization produced by the controlled application of glutamate to patches excised from neurons. Many of these rate constants are fixed to be multiples of each other due to the assumption of subunit independence. Further reduction is possible due to the presence of loops in the state diagram (different paths through a loop should be equivalent according to the principle of microscopic reversibility). The model that best fits data from controlled glutamate application to AMPA channels from CA1 pyramidal cells suggests that at low concentrations, desensitization competes effectively with channel opening, whereas at higher concentrations the cooperative process of channel opening makes the opening rate much higher than the desensitization rate.

Insights from Modeling

This model of receptor kinetics was used in a geometrically constrained model of a synapse to determine the influence of various parameters on synaptic transmission.

Time course and amplitude of the mEPSC At large mushroom spines in CA1, the number of neurotransmitter molecules vastly exceeds the number of receptors, and neurotransmitter diffusion and clearance is rapid. Thus, the loss of neurotransmitter due to receptor binding can be largely neglected. Moreover, the uptake mechanisms at central synapses are located outside the cleft. With these simplifications, eqn [1] can be solved analytically for a cylindrical cleft where glutamate is released at the center of the top face of the disk with absorbing boundary conditions at the cleft edges. Modeling the escape of neurotransmitter from the vesicle through a narrow fusion pore leads to a brief 'concentration spike' during which a large amount of neurotransmitter is confined to a small volume of the cleft near the release site. This spike extends approximately 100 nm from the release site and is dissipated within 100 μs (i.e., the concentration declines by $1/e$ of its peak value). During this spike, the glutamate concentration builds up to nearly 3 mM near the fusion pore. The rapid diffusion of glutamate dilutes this spike. The efficacy of the spike in producing receptor occupancy is made clear by a calculation analogous to the neuromuscular junction. If we take the area of the spine to be the upper limit in the expression for t_{diff} ($\sim$0.1 μm^2 for larger spines), we obtain a diffusion time of approximately 10 μs, which is much shorter than that in the NMJ. Assuming typical values of forward binding rate of 2×10^7 $M\,s^{-1}$, t_{bind} is 80 μs. This implies that the rise time at central synapses would almost entirely be determined by the binding of glutamate to the receptors as well as the receptor kinetics.

Solving the equations for receptor activation using the concentration of glutamate calculated previously results in a simulated mEPSC with an amplitude of approximately 10–15 pA and a 20–80% rise time of $<$100 μs, which matches experimental observations. Most of the current (nearly 80%) at the peak of the mEPSC is carried by a small number of channels in a 250-nm hot spot around the release site ($\sim$25). The multiple glutamate binding sites on the channel and the concentration dependence of desensitization play an important role in determining the size of this hot spot. Near the site of release, the concentration is in the millimolar range, which is required to effectively load the multiple glutamate binding sites on AMPA channels; the channel then opens efficiently because channel opening is greatly favored over desensitization. Outside the hot spot, opening is inefficient because site occupancy is low and the opening rate is therefore slower than the desensitization rate. If desensitization is blocked with cyclothiazide (a drug that inhibits desensitization of AMPA receptors), channels outside the hot spot can open, albeit slowly, and enhance the tail of the mEPSC.

Unlike the NMJ, the majority of the glutamate content of a vesicle at hippocampal synapses leaves the cleft without activating receptor channels. Moreover, a single vesicle is only able to activate a fraction of channels at a medium to large synapse. This nonsaturation has been observed experimentally. The implication of this nonsaturation is that hippocampal synapses, despite their low receptor density, can respond in a graded manner, which has consequences for the dynamic range of hippocampal synapses.

Origins of quantal variability A critical issue regarding the characteristics of transmission at central synapses is the variability of the mEPSC amplitude. At the NMJ, the distribution of the peak mEPSC is roughly Gaussian, with a CV of approximately 0.2. At CNS neurons (specifically at hippocampal CA1 synapses), early work showed that the mEPSC amplitude distribution exhibited a broad tail. This broad distribution could be due to the variation in the amount of glutamate contained in vesicles. Modeling and experimental studies that have varied the vesicular glutamate content do not show the distinct rise time–amplitude correlation that is observed experimentally.

On the other hand, histograms of responses evoked by minimal stimulation (stimulation of a single axon synapsing onto a target cell) often show peaks that are narrow, indicative of low quantal variation,

whereas the overall distribution is broad and skewed. Simulations using Monte Carlo models show that amplitude histograms with multiple narrow peaks could arise from single synapses releasing multiple vesicles. These simulations show that effective quantal summation can occur at single synapses and that fluctuations in release time and position are not sufficient to strongly smear the peaks. Although summation is nearly linear, there are interactions of the glutamate released by multiple quanta that produce some nonlinearity. These may explain why the spacing between quantal peaks may not be exactly even. Furthermore, the CV of high peaks is not higher than that of small peaks as would be expected if quantal responses were independent, and it may decrease and can even be less than that of small peaks. There is extensive experimental evidence of multivesicular release at hippocampal synapses. These considerations suggest that the broad distribution of mEPSCs could also arise from the spontaneous release of multiple vesicles at single synapses.

One implication of these results is that the quantal size can be relatively insensitive to the number of channels at the synapse (except at the smallest synapses, which have the dimension of the hot spot). The main postsynaptic determinant of quantal size is the local density of AMPA channels in the region of the synapse where a vesicle has been released. It is necessary to use the word 'local' because of the possibility that density may not be uniform within a synapse, as has been found at GABAergic synapses. The unimportance of total AMPA channel number in determining quantal size is illustrated by mossy fiber inputs to CA3 pyramidal cells. This connection occurs on a single giant spine that contains many synapses. These have a nearly identical AMPA channel density but highly variable size and AMPA receptor content. Consistent with importance of density rather than size, quantal size at these synapses is restricted to a narrow range.

Glutamate diffusion in extracellular space Synapses in the CNS are packed very tightly. Ultrastructural studies suggest that a cubic micrometer of cortex contains approximately one or two synapses. Unlike the NMJ, a typical hippocampal synapse contains a small number of receptors (1–200). Given a maximum of four binding sites per receptor, the number of glutamate molecules in small vesicles is far in excess of the number of receptors. If a large number of vesicles are released at different synapses, this excess glutamate will build up, leading to a nonnegligible amount of ambient glutamate available that can affect synaptic transmission. Since neurotransmitter released at central synapses is not degraded enzymatically, it can escape from the cleft by diffusion and activate receptors at nearby synapses. This heterosynaptic activation would appear as a slowly decaying tail in the AMPA receptor responses. Direct manipulations of glutamate diffusivity by large-molecular-weight polymers dramatically alter the tail of the AMPA response while minimally affecting the peak of the response. The process of glutamate diffusion and receptor activation in a geometrically complex space has been modeled in simplified geometries to show that extrasynaptic spillover plays an important role in excitatory transmission in the neocortex, hippocampus, and the cerebellum.

Further Directions in Modeling of Synaptic Transmission

Synaptic transmission involves a large array of molecules that show complex regulation and intricate localization properties. It is becoming increasingly apparent that realistic models of synaptic transmission hold great promise in making quantitative predictions. However, these models are only as good as the input parameters, such as accurately reconstructed diffusion volumes, measurements of receptor densities and kinetics, as well as dynamics of the release process. Many of these technologies are under rapid development. For instance, electron tomography in conjunction with improved sample preparation techniques can generate highly detailed (~3–8 nm resolution) three-dimensional structures of synapses. Highly sensitive freeze–fracture replica labeling has been used to determine the density of AMPA receptors in synaptic sites. Finally, new recording techniques allow for the detection of sub-millisecond vesicle fusion events. Numerical algorithms that can integrate this level of structural detail in computer models are also a subject of active research. However, these tend to be scattered across many disciplines (e.g., computational geometry and parallel computing). The main challenge is to combine these disparate approaches into a unified model of synaptic transmission including both presynaptic and postsynaptic aspects to obtain a deep quantitative understanding of synaptic physiology.

Synaptic Vesicle Protein-2 (SV2)

R Janz, University of Texas Medical School, Houston, TX, USA

© 2009 Elsevier Ltd. All rights reserved.

Synaptic vesicle protein-2 (SV2) was originally identified with a monoclonal antibody generated against synaptic vesicles purified from the electric organ of the ray *Discopyge ommata*. SV2 was characterized as a glycoprotein that was associated with synaptic vesicles from neurons as well as with secretory vesicles in neuroendocrine cells. The SV2 antibody reacts with all types of vertebrate synapses, from fish to mammals, and is used widely as a synaptic marker in immunohistology.

There are three homologous isoforms of SV2 in mammals: SV2A, SV2B, and SV2C. Each isoform is encoded by a different gene, and all three isoforms react with the SV2 monoclonal antibody. All three SV2 proteins are integral membrane proteins with predicted 12 transmembrane domains and N- and C-termini facing the cytoplasm. An alignment of the protein sequences of the three SV2 isoforms is depicted in Figure 1. The three proteins share a high degree of homology, with approximately 60% identical sequences. SV2 proteins share significant homology with proteins of the major facilitator superfamily (MFS) of transporters, which has lead to the hypothesis that SV2 proteins are also transporters.

Structure of the Proteins

The cytoplasmatic N-terminus is the most divergent domain among the three SV2 isoforms. This domain is relatively similar between SV2A and SV2C, with homologous stretches of amino acids interrupted by nonconserved blocks of amino acids. In contrast to SV2A and SV2C, the N-terminal domain of SV2B is much shorter and shares less homology with the other isoforms. The N-terminal domain of all SV2s contains a short stretch of amino acids that is conserved among all SV2 proteins. This sequence is probably the epitope for the monoclonal SV2 antibody. Most loops connecting the 12 transmembrane domains are relatively short. Exceptions are the cytoplasmic loop connecting transmembrane domains 6 and 7 and the intravesicular loop connecting transmembrane domains 7 and 8. SV2 proteins have five conserved cysteine residues in intravesicular loops that are potentially involved in disulfide bonds. However, the actual location of the disulfide bonds is not currently known. All SV2 isoforms are highly glycosylated. Three predicted N-glycosylation sites are located in the large intravesicular loop between transmembrane domains 7 and 8. An interesting feature in the SV2 protein sequence is the presence of two conserved negatively charged amino acids (D179 and E182 in SV2A) located in the first transmembrane domain.

SV2 proteins share significant homology with the large gene family MFS. This gene family codes for a large group of proteins that catalyze the transport of specific substrates across biological membranes. Most MFS proteins have 12 transmembrane domains with the same topological orientation as SV2 proteins. Recently, high-resolution structures of two members of the MFS family, the glycerol-3-phosphate antiporter and lactose permease, have been solved. The orientation of the transmembrane domains is remarkably similar in these two bacterial proteins, indicating a conserved structure for this gene family. These high-resolution structures reveal that the 12 transmembrane domains form two 6-helical bundles. These two helical bundles comprise transmembrane domains 1–6 and transmembrane domains 7–12. A hydrophilic cavity is formed at the interface between the two helical bundles that is open to the cytoplasmic side. This cavity most likely forms the binding site for the substrate to be transported.

Based on the orientation of the transmembrane domains of the MFS proteins, a corresponding model for the structure of SV2 was generated, depicted in Figure 2. In this model, the two negatively charged amino acid residues in transmembrane domain 1 are facing the hydrophilic cavity. These residues could potentially mediate the binding of a positively charged substrate. It should be pointed out that this structural model is purely based on the homology of the SV2 proteins to the MFS and has not been tested experimentally.

Distribution of SV2 Proteins

The expression of the SV2 isoforms has been well characterized in the rat brain. SV2A is widely expressed and found in all synaptic layers of the brain. SV2B is also widely distributed in the brain. However, some areas of the brain do not express SV2B. SV2B is not expressed at mossy fiber synapses of the hippocampus, which are projections from pyramidal cells of the dentate gyrus to the CA3 region. In addition, SV2B is not expressed in synapses from projections of Purkinje cells to the deep cerebellar nuclei.

In contrast to the widespread distribution of SV2A and SV2B, SV2C has more restricted expression. SV2C is detectable at very low levels in the neocortex and the hippocampus and at high levels in synapses of

Figure 1 Structure of SV2 proteins. The protein sequences of rat SV2A, SV2B, and SV2C are aligned for optimal homology. The sequences are identified on the left and numbered on the right. Residues that are conserved between at least two of the isoforms are highlighted in white on a black background. At the N-terminus, the predicted epitope sequence for the SV2 monoclonal antibody is marked in green. The 12 predicted transmembrane regions are numbered and marked with lines above the sequences. The conserved negatively charged residues in the first transmembrane domain are marked in blue on a gray background. The three N-glycosylation consensus sequences located in the intravesicular loop between transmembrane domains 7 and 8 are marked by triangles above the sequences. Conserved cysteine residues in intravesicular loops that are potentially involved in disulfide bonds are labeled in yellow on red background. The binding domain for botulinum toxin A is labeled in red.

the basal ganglia and brain stem. In addition, SV2C protein is found in projections from Purkinje cells to deep cerebellar nuclei.

Outside the central nervous system, all SV2 isoforms are found at the neuromuscular junction. SV2A is also located in adrenal chromaffin cells and the pheochromocytoma cell line PC12. SV2B is not detectable in these two cell types. SV2C is expressed in adrenal chromaffin cells but not detected in PC12 cells.

Role of SV2 in Ribbon Synapses of the Retina

The analysis of the distribution of SV2 proteins in the mouse retina revealed that SV2A is found in all conventional synapses, but is absent in the specialized ribbon synapses of the rod photoreceptors and the bipolar cells. Ribbon synapses are characterized by a specialized presynaptic structure, the synaptic ribbon. These synapses release synaptic vesicles at an extremely high rate compared to conventional synapses.

Ribbon synapses from rod photoreceptors and bipolar cells express only SV2B. Interestingly, SV2B is absent from conventional synapses of the retina. This distribution indicates that SV2B might have a specialized role in ribbon synapses. Interestingly, rod photoreceptor synapses from SV2B-knockout mice show a reduction of the levels of the SV2-interacting protein synaptotagmin 1.

Cone photoreceptor synapses are a special exception to the typical retinal ribbon synapses because they also express SV2A. In contrast to the other SV2 isoforms, SV2C is detectable only in a small subset of retinal synapses formed by amacrine cell projections.

Figure 2 Model of the structure of SV2. proteins in the synaptic vesicle membrane, generated by adapting the arrangement of the transmembrane domains from the known structures of two bacterial MFS proteins. The predicted transmembrane helices are numbered and two potential disulfide bonds between conserved cysteine residues in the intravesicular loops are depicted. The binding domain for botulinum toxin A and the three predicted glycosylation sites in the intravesicular loop between transmembrane helices 7 and 8 are marked. The positions of the two negatively charged amino acid residues in transmembrane domain 1 are labeled. MFS, major facilitator superfamily.

Interacting Proteins

The exocytosis of synaptic vesicles is thought to be catalyzed and regulated by a controlled set of protein–protein interactions between synaptic vesicle proteins and plasma membrane molecules. One possible molecular mechanism for the role of SV2 in the regulation of synaptic vesicle exocytosis is through interaction with other synaptic proteins. Studies using native and recombinant proteins have established an interaction between SV2 proteins and the Ca^{2+} sensor for fast, Ca^{2+}-triggered exocytosis, synaptotagmin 1. However, the physiological role of this interaction is still unclear.

Analysis of synaptic vesicle exocytosis in hippocampal neurons from SV2A/B double knockout mice do not indicate a change in the Ca^{2+} dependence of synaptic vesicle exocytosis, indicating that the Ca^{2+}-sensing function of synaptotagmin 1 is unaffected by the removal of SV2. However, as previously mentioned, the removal of SV2B from photoreceptor synapses is correlated with a strong reduction in synaptotagmin 1 protein levels. These results indicate that SV2B may stabilize synaptotagomin 1 in this special set of synapses.

Functional Studies

The analysis of SV2A- and SV2B-knockout mice has demonstrated a role for SV2 proteins in the regulation of synaptic vesicle exocytosis. SV2A-knockout mice develop severe seizures after 1 postnatal week. The onset of these seizures is followed by weight loss and death of the mutant pups within 2–3 postnatal weeks.

Studies of synaptic transmission in cultured SV2A/B double knockout hippocampal neurons show reduced

synaptic depression after repetitive stimulation compared to wild-type mice. This phenotype was reversed by buffering residual synaptic Ca^{2+} using the Ca^{2+} chelator ethylene glycol tetraacetic acid (EGTA). These results suggest that SV2 proteins may regulate presynaptic Ca^{2+} levels. Because homology suggests SV2s may be transporters, they may regulate Ca^{2+} levels by transporting Ca^{2+} into synaptic vesicles.

Further studies from cultured SV2A/B double knockout hippocampal neurons show the removal of SV2 results in reduced synaptic vesicle exocytosis with low-frequency stimulation and reduced size of the readily releasable pool of synaptic vesicles. Recovery of the knockout phenotype to wild-type levels with high-frequency stimulation suggests that SV2 may regulate synaptic transmission in quiescent neurons.

Role of SV2 Proteins in Epilepsy

A first indication that SV2s might be involved in epilepsy came from the observation that SV2A-knockout mice develop severe seizures. In addition, SV2A was recently identified as the binding site for the antiepileptic drug levetiracetam (Keppra™, USB Pharmaceuticals). Levetiracetam is an FDA-approved drug that successfully treats drug-resistant, chronic epilepsy. The mechanism of action is currently not known. Because knockout of SV2A leads to seizures in mice, it is unlikely that levetiracetam works as an inhibitor of SV2A function. A more likely mechanism of action is that levetiracetam binding to SV2A activates or stabilizes the protein.

SV2 Proteins as Receptors for Botulinum Toxin A

Botulinum toxin A (botox A) is one of the highly effective neurotoxins produced by the bacterium *Clostridium botulinum*. Botox A consists of a heavy chain that mediates entry of the toxin into the presynaptic terminal and a light chain that cleaves synaptosomal-associated protein of 25 kDa (SNAP-25), thereby blocking synaptic vesicle exocytosis. The uptake of botox A into synapses is dependent on SV2 proteins. Botox A binds the loop between the transmembrane domains 7 and 8 of SV2 (see Figures 1 and 2) when that loop is exposed to the synaptic cleft after synaptic vesicle exocytosis. SV2-bound botox A is then endocytosed when SV2 is recycled into a synaptic vesicle. After endocytosis, the regulatory domain of botox A facilitates the translocation of its catalytic domain from the synaptic vesicle lumen into the cytoplasm of the presynaptic terminal. Once translocated, botox A wreaks havoc on a synaptic terminal through the cleavage of SNAP-25, completely shutting down neurotransmission. All SV2 isoforms are capable of mediating entry of botox A into synapses.

Synaptic Vesicles

S Takamori, Tokyo Medical and Dental University, Tokyo, Japan

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Communication between neurons or from neurons to their target tissues takes place at a specialized structure called the 'synapse' (Greek meaning 'to clasp'). Synapses consist of two functionally and morphologically distinct components: the presynapse, from which neurotransmitter molecules are released, and the postsynapse, where specific receptors for the respective neurotransmitters are localized on the surface and the complex signaling cascades proceed. As such, one neuron can activate or inactivate connected neurons or target tissues, depending on the transmitter molecule they utilize for their signal transmission. Based on electrophysiological experiments pioneered by Katz and colleagues in the 1960s, it has been postulated that neurotransmitters are released from presynaptic terminals in discrete packets termed 'quanta.' Electron microscopy revealed that at presynaptic terminals, hundreds of small and round membranous vesicles – synaptic vesicles (SVs) – are clustered, which can be reasonably linked to the quanta (Figure 1(a)). Furthermore, biochemical experiments using isolated vesicles from mammalian brains have proven that SVs exhibit a variety of transport activities for major chemical transmitters. Based on these findings, it is generally believed that SVs store neurotransmitters and the fusion of SV membrane to the plasma membrane elicits the quantal release of neurotransmitters. Because of their important roles in basic neural functions, much effort has been focused on understanding the molecular machinery of SVs. This article focuses on general features of SVs in terms of morphology, biogenesis, and recycling and their overall molecular composition.

General Features of Synaptic Vesicles as an Organelle

Clustered at the nerve endings, SVs are one of the most striking morphological hallmarks of presynaptic terminals in electron micrographs. They appear to be roughly homogeneous in size and shape, but it has been determined that some heterogeneity exists among them. Under certain experimental conditions, their shape appeared to be of two types – almost spherical and oval or flat. This difference may be an experimental artifact presumably from the fixation process. Interestingly, this difference in shape may be associated with their transmitter content. It was found that most excitatory, asymmetric glutamatergic synapses contain spherical vesicles, and inhibitory, symmetric, GABAergic synapses contain the latter. Regardless of the functional significance, this observation has provided a possible morphological characteristic to distinguish glutamatergic SVs and GABAergic SVs.

Due to their uniformity in size and abundance in the brain, it is feasible to isolate SVs with high purity and in large amounts – a prerequisite for biochemical and biophysical experiments (Figure 1(b)). Electron microscopic observations of isolated SVs from rat brains have revealed that the surface is uneven. They are decorated with one or more prominent globular structures and several spiky or amorphous substructures are observable under electron microscope. After proteolytic digestion these structures are removed and the rims of the lipid bilayer become clearly visible, demonstrating that the vesicles are coated with proteins on the surface (Figures 1(c) and 1(d)). As measured by electron microscopy, their size varies substantially: The diameter of the outer bilayer ranges from 35 to 50 nm, with an average peak at 42 nm. The total dry mass of an average SV was deduced from a combination of protein quantitation, lipid quantitation, and SV particle counting, resulting in approximately 30 attograms (ag) per vesicle, which consists of 17 ag of proteins and 12 ag of lipids. Assuming the thickness of a lipid bilayer is 4 nm, the average inner volume can be estimated as approximately 20×10^{-21} l, which provides enough space for approximately 1800 transmitter molecules at a concentration of 150 mM. Within these physical and molecular constraints, SVs are effectively equipped with a unique set of proteins and lipids necessary for executing the fundamental tasks in neurotransmitter release.

Biogenesis of Synaptic Vesicles

Like other proteins of the secretory pathway, most SV proteins are synthesized at the endoplasmic reticulum and processed through the Golgi apparatus for maturation in the cell body of neurons (Figure 2(a)). Conceptually, subdomains which selectively collect the SV proteins bud off from the Golgi apparatus and then travel along the axon to the presynaptic terminals. However, since no vesicles are as small as mature SVs, and some larger nonuniform tubulovesicular structures are seen in the axons, SV constituents are thought to travel along the processes on heterogeneous membranes termed SV precursors.

Figure 1 Morphology of synapse and synaptic vesicles. (a) A transmission electron micrograph of synapse. The presynaptic terminal (T) contains numerous synaptic vesicles (SVs) and mitochondria (Mit). A small portion of SVs is attached to electron dense structures at the presynaptic plasma membrane termed the active zone (AZ), where exocytosis of SVs takes place. Opposite the AZ, there are electron dense structures beneath the postsynaptic membrane termed postsynaptic density (PSD), where neurotransmitter receptors form signaling complexes. D, dendrite; SC, synaptic cleft. (b) An electron micrograph of synaptic vesicle fraction. SVs were purified from mouse whole brains, negatively stained, and imaged by transmission electron microscopy. Inset shows immunogold labeling of the vesicles with an antibody against an SV marker protein, synaptophysin. Approximately 95% of the membranous structures are labeled. (c, d) SVs before (c) and after (d) proteolysis imaged by cryo-electron microscopy. Scale bar = 1 μm (a), 100 nm (b, inset), 20 nm (c). (a) Adapted from the George E. Palade EM Slide Collection at Yale University School of Medicine. (c, d) Reproduced from Takamori S, Holt M, Stenius K, et al. (2006) Molecular anatomy of a trafficking organelle. *Cell* 127: 831–846, with permission from Elsevier.

Once formed, the SV precursor needs a pathway to reach its destination. Microtubules are known to serve as the roads for transporting cargo. Motor proteins of the kinesin superfamily (KIFs) bind to both the microtubules and the cargo, and they control the directional transport of intracellular transporting cargo. Among the KIFs, KIF1A and KIF1Bβ are known to participate in axonal transport of SV precursors. Gene disruption of either KIF1A or KIF1Bβ results in reduction of SV density at the presynaptic terminals and therefore impaired neurotransmission.

The KIF1A- and KIF1Bβ-carrying SV precursors contain the major SV marker proteins, such as synaptophysin, synaptobrevin, synaptotagmin, and rab3A, but not presynaptic plasma membrane proteins, such as syntaxin 1 and SNAP-25. In addition, proteins that form the cytomatrix at the active zone, such as piccolo and bassoon, are transported to the axon on distinct cargo, suggesting that segregation of the presynaptic proteins is initiated before they arrive at the terminals. The mechanism by which the SV constituents are selectively recruited into the SV precursor is unknown. It is possible that SV proteins have a specific signal sequence that is assembled and forms microdomains at the exit of the *trans*-Golgi network, but no such common signal sequence has been found. Furthermore, the molecular mechanism regarding how the constituents of the SV precursors can be recognized by KIF1A/1Bβ proteins is poorly understood.

When SV precursors arrive at the presynaptic terminal, they fuse with the plasma membrane where the main route for SV biogenesis is initiated. This route, the AP-2-dependent pathway, is mediated by several essential proteins for vesicle endocytosis, namely clathrin, dynamin, and AP-2. An alternative route by

Figure 2 Biosynthesis and recycling of SVs. (a) Biosynthesis of SVs. SV proteins are synthesized in the cell body of neurons and the SV precursors bud off from the *trans*-Golgi network. The SV precursors are transported along the axon, guided by the microtubules and kinesin motor proteins (KIF1A and KIF1Bβ). (b) SV cycle at presynaptic terminal. (1) SVs are filled with neurotransmitter. (2) The SVs are then transported to the active zone and docked to the presynaptic plasma membrane (docking) (3). The docked SVs become fusion competent by molecular events called priming (4). When an action potential arrives at the terminal, calcium influx through voltage-dependent calcium channels triggers fusion of SV membrane with the plasma membrane (exocytosis), causing discharge of SV content (5). Exocytosed SVs are regenerated either by clathrin-independent fast endocytosis (6) or by clathrin-dependent slow endocytosis (6′). The newly regenerated SVs are immediately refilled with neurotransmitters (7) or, in some case, they undergo fusion steps with early endosomes (7′).

which SVs are generated from early endosomal membranes at the presynaptic terminal is dependent on AP-3. The latter pathway does not seem to account for the majority of SVs since there are no remarkable alterations in SV morphology and numbers in the *mocha* mouse, which lacks functional AP-3. How, then, can SV proteins, but not plasma membrane residents, be recruited into newly generated SVs? Several amino acid sequence motifs or molecular determinants for each SV protein have been proposed to

explain this mechanism. First, a dileucine motif located in the cytoplasmic tails of vesicular transporters (VMAT2, VAChT, and VGLUT1) is important for precise sorting and fast recruitment of those SV proteins. A VAChT mutant which lacks the dileucine motif was trapped at the plasma membrane of the cell body of the differentiated cholinergic SN56 cell lines, and the targeting of the mutant protein to neurites and varicosities (which resemble axon terminals) was dramatically reduced, indicating that the SV precursor cargo carrying VAChT is not directly transported through the axon but is delivered to the plasma membrane of the cell body before being transported along the axon. Second, the intravesicular N-glycosylation of synaptotagmin 1 is essential for its vesicular targeting. Interestingly, synaptotagmin 7, one of the synaptotagmin family members which resides preferentially on the plasma membrane, is targeted to vesicles when the intravesicular portion is replaced with a portion containing the N-glycosylation site of synaptotagmin 1. The mechanistic basis and involvement of other factors is not clear, but the interaction of glycoresidues of synaptotagmin 1 with other proteins at the cell surface may govern the targeting of synaptotagmin 1 to vesicles.

It is likely that multiple factors, including protein–protein interactions and glycoresidue–protein interactions, modulate the sorting of SV proteins. The general principle of the segregation of SV proteins from plasma membrane proteins during SV biosynthesis has not been clarified.

The Synaptic Vesicle Cycle

At the presynaptic terminals, SVs are not of 'single use.' They are regenerated at the terminals independent from protein synthesis in the cell body. The SV cycle can be outlined, with the uptake of neurotransmitter into SVs as a first step (**Figure 2(b)**, step 1). Neurotransmitters in the central nervous system (CNS) are synthesized locally in the cytoplasm of the presynaptic terminals and are actively transported into SVs. Away from the plasma membrane, the majority of neurotransmitter-filled SVs are either diffusively floating in the cytoplasm or tethered with cytoskeleton components such as actin and spectrin (step 2). For exocytosis, SVs must come into physical contact with the plasma membrane (docking; step 3). SVs do not evenly dock to the whole area of the presynaptic plasma membrane but, rather, to a restricted area called the active zone. There, large cytomatrix proteins, such as bassoon, piccolo, and munc13, form huge protein complexes that appear as electron-dense structures on electron micrographs. Docked SVs are then transformed into fusion-competent SVs via a process called priming (step 4). As soon as an electrical stimulus arrives at the terminal, voltage-dependent calcium channels at the active zone open, resulting in a rapid and local increase in Ca^{2+} concentration. Ca^{2+} ions trigger the fusion of the SV membrane with the plasma membrane in less than 100 μs. Since other exocytotic reactions (i.e., hormone secretion from endocrine cells) take much longer (seconds to minutes), there must be unique factors present only in neurons to perform such a rapid membrane fusion reaction.

After exocytosis, SV components that are incorporated into the plasma membrane are retrieved to form a new SV by endocytosis. There are at least two kinetically distinct modes of endocytosis. The time constants of the fast and slow phase are approximately 1 and 10 s, respectively. Whereas the molecular machinery for the fast phase is not well understood, the slow phase is mediated by the formation of clathrin-coated pits. In both modes, GTP hydrolysis by the GTPase protein dynamin is indispensable for the fission of the invaginated membranes of newly formed SVs. Although various endocytosis-related proteins, such as AP-2, endophilin, amphiphysin, and synaptojanin, have been identified and implicated in controlling endocytosis, their precise roles are a matter of intense research.

The reformed SVs then either recycle back and are refilled with neurotransmitters (step 1) or pass through the early endosomal intermediates before recycling back to step 1. An alternative pathway has been proposed that is similar to the exocytosis of secretory granules; that is, SVs do not fully collapse with the plasma membrane upon fusion but instead form a narrow and transient fusion pore which does not allow a complete discharge of neurotransmitter content. As soon as the pore closes, the half-empty SV can either be immediately engaged in another round of exocytosis or go back to step 1. The existence of such a rapid recycling mode in the CNS, termed the 'kiss-and-run' mechanism, is under debate.

The SVs clustering at the presynaptic terminals can be divided into two functional pools. The first pool contains a small fraction of SVs (5–10% of the total SVs at the presynaptic terminals) that can be released rapidly by a brief high-frequency train of action potentials or by stimulation with hypertonic solution. This pool is thought to be release-ready and is therefore referred as to the readily releasable pool (RRP). The second pool, the reserve pool (RP), represents a vesicle fraction that does not immediate participate in exocytosis. Instead of participating in exocytosis, the RP vesicles replenish the RRP pool after the RRP vesicles undergo exocytosis. Both the amount of the RRP and the rate of replenishment of RRP with RP are critical parameters to determine the availability of vesicles for exocytosis, thereby affecting the

characteristics of short- and long-term plasticity of a given neuron. Classically, the RRP was related to a fraction of morphologically docked vesicles at the plasma membrane and the RP was thought to be spatially distant from the plasma membrane. However, one study suggested that the RRP vesicles do not necessarily correlate with the morphologically docked vesicles but are randomly distributed in the SV cluster at the terminal, indicating that there are no correlations between the anatomical locations of SVs and their functional fusion competence. Mechanisms underlying how the mobility and the fate of an individual SV can be molecularly defined are uncertain.

Molecular Composition of Synaptic Vesicles

With respect to SV functions as described previously, SVs should be equipped with two classes of essential protein components: transport proteins involved in neurotransmitter uptake into SVs and membrane trafficking proteins involved in the regulation of vesicle cycle and exo-endocytosis. A large body of work has focused on identifying protein components on SVs, leading to an almost complete identification of SV proteins. The stoichiometry of SV proteins may be flexible because many cytoplasmic proteins are temporarily attached to and detached from SVs depending on the status of a specific SV during recycling. On the other hand, a basic set of essential proteins must be present on all SVs for vesicle functions, and the numbers of individual proteins and the proportions within an SV might proteins within an SV to be maintained (Figure 3(a)). Furthermore, immunohistochemical studies on SV proteins have demonstrated that most of the major SV proteins consist of multiple isoforms whose expressions in the CNS are partially overlapping or mutually segregated, the combinations of which would create heterogeneity in protein composition in each SV. In contrast to the identification of SV proteins which became relatively handy with advancements in mass spectroscopy, understanding the mechanistic function(s) of each protein has been not so trivial, mainly because of technical limitations with regard to manipulating and measuring the intracellular events with high temporal and spatial resolution. The following sections introduce some of the essential and abundant SV proteins, which are stoichiometric components with at least one copy per SV.

Proteins for Neurotransmitter Uptake

The accumulation of neurotransmitters in SVs is driven by a proton electrochemical gradient which is generated by a vacuolar-type proton ATPase. The proton pump consists of at least 13 subunits and is the largest functional protein complex in the SV membrane. It contains two functional units – a larger peripheral protein complex (V_1) which catalyzes ATP hydrolysis and an integral membrane protein complex (V_o) which builds up a ring structure in the membrane and mediates proton translocation. The molecular weight of the entire complex is approximately 800 kDa; therefore, a single complex accounts for approximately 10% of the total SV protein. An SV contains a single copy of the proton pump complex, which may be sufficient to energize neurotransmitter uptake into the SVs.

With the aid of a proton electrochemical gradient, vesicular transporters specific for neurotransmitter-type mediate neurotransmitter uptake into the vesicles. There are four distinct uptake systems for neurotransmitters in the CNS. Three isoforms of vesicular glutamate transporters (VGLUT1–3) transport glutamate into SVs. GABA and glycine share the same transporter, the vesicular inhibitory amino acid transporter (VIAAT; initially called vesicular GABA transporter (VGAT)). Two monoamine transporters (VMAT1 and VMAT2) transport all biogenic amines, with VMAT2 preferentially expressed in the brain. The uptake of acetylcholine is mediated by the vesicular acetylcholine transporter VAChT. All four transporter families belong to the solute carrier protein family, but there are no sequence homologies among the transporters for different neurotransmitter types. There are differences in energetics of the transport; some of them preferentially utilize the membrane potential (VGLUTs) and others use the pH gradient (VMATs and VAChT) as the main driving force. The expression of a particular transporter in the SV membrane is the ultimate determinant for the type of neurotransmitter which is released from a given neuron. Moreover, there are indications that the expression level of the transporter per SV modulates the amount of neurotransmitters accumulated in an SV, thereby regulating quantal size.

In addition to the neurotransmitter transporters discussed previously, SVs contain a chloride channel to facilitate the acidification of SVs. The voltage-dependent chloride channel ClC-3 was proposed to confer this activity on SVs. Although several channel activities, such as a cation selective channel, have been demonstrated by electrophysiological methods on reconstituted systems, the molecular identities of the activities have been elusive. The SV2 protein family and tetraspan vesicle membrane proteins (synaptophysin, synaptogyrin, and SCAMPs) have been identified as SV-specific proteins, and their predicted protein structures suggest their role as a transporter or a channel.

Figure 3 Molecular composition of SV. (a) Protein composition of SVs visualized by 16-BAC/SDS two-dimensional gel electrophoresis. A total of 500 μg of SV proteins was applied. The spots containing the major SV proteins are circled. (b) Structural model of an average SV. Based on quantitative measurements, a three-dimensional model of an average SV was constructed. An average SV contains 70 copies of synaptobrevin, 30 copies of synaptophysin, 10 copies of neurotransmitter transporter (VGLUT), 8 copies of synapsin, 15 copies of synaptotagmin, 25 copies of Rab GTPase, and 1 or 2 copies of SV2, synaptogyrin, SCAMP, and V-ATPase. The numbers of phospholipids and cholesterol are estimated to be approximately 7000 and 6000, respectively.

However, no clear transport activities associated with these proteins have been demonstrated. It should be noted that although not related to an intrinsic function of SV2s, they have been shown to function as a protein receptor for botulinum neurotoxin A.

Proteins for Membrane Trafficking

Neural exocytosis is a tightly regulated process elicited by a rapid increase in Ca^{2+} concentration. Since Ca^{2+} ions induce neurotransmitter release within 100 μs, a series of complex enzymatic reactions could not be expected for exocytosis within the short time frame. Thus, SVs that undergo exocytosis not only should be docked but also primed for membrane fusion, waiting for the final stimulus for exocytosis. Two abundant integral membrane proteins on SVs, synaptobrevin (also referred as to VAMP2) and synaptotagmin 1, have been established as the most important players in Ca^{2+}-triggered exocytosis. Furthermore, SVs contain two abundant peripheral protein families, rab-GTPases and synapsins, which are implicated in the modulation of vesicle pools.

Synaptobrevin is a small integral membrane protein that contains a SNARE motif and is thus called a v-SNARE (vesicular SNARE, also referred to as R-SNARE because of a conserved arginine in the middle of the SNARE motif). Synaptobrevin forms a tight four-helix bundle, the SNARE complex, with two other SNARE proteins at the plasma membrane – syntaxin 1 and SNAP-25 (t-SNAREs named after target-SNAREs; also referred as to Q-SNARE, which has a conserved glutamine in the middle of the SNARE motif). The SNARE hypothesis regarding membrane fusion in general proposes that the assembly and tight complex formation of appropriate pairs of SNARE proteins pulls the two membranes close together so that the two membranes become competent for fusion. Analogously, SVs become 'primed' when synaptobrevin forms the SNARE complex with syntaxin 1 and SNAP-25. The importance of SNARE proteins in neuronal exocytosis is emphasized by the fact that the clostridial neurotoxins, a family of metalloproteases which specifically cleave the neuronal SNARE proteins, abolish Ca^{2+}-dependent neurotransmitter release while the docked vesicles remain unchanged by the toxin treatment. The formation of the SNARE complex is affected by other binding factors of the SNARE proteins. For instance, it has been proposed that Munc18 protein binds to syntaxin, keeping the syntaxin molecule in a close conformation and thereby preventing syntaxin from forming the SNARE complex. Biochemical experiments using the SNARE-reconstituted proteoliposomes suggest that the SNARE complex indeed mediates membrane fusion. However, the liposome fusion with SNAREs alone is slow and spontaneously occurs without any regulation, indicating that other factors might play a role in synchronizing the fusion reaction.

Synaptotagmin 1 is known as a vesicular Ca^{2+} sensor for exocytosis that accomplishes rapid membrane fusion in response to Ca^{2+} ions. It has an N-terminal highly glycosylated intravesicular domain and two cytoplasmic C_2 domains that interact with Ca^{2+} ions. Ca^{2+}-triggered exocytosis in synaptotagmin 1-deficient neurons is severely impaired, indicating its role as the Ca^{2+} sensor for exocytosis. The affinity of C_2 domains of synaptotagmin 1 for Ca^{2+} ions is very low, but it increases dramatically (up to 0.5–5.0 μM) when the C_2 domains bind to phospholipids. Its apparent affinity to Ca^{2+} meets the requirement that it should have a Ca^{2+} concentration sufficient for triggering exocytosis *in vivo* (in the calyx of Held or in chromaffin cells). However, investigations of synaptotagmin 1-deficient neurons and chromaffin cells have suggested that synaptotagmin 1 is a Ca^{2+} sensor only for the fast, synchronous exocytosis and not for the slow, asynchronous component. It is not clear if other synaptotagmin isoforms (at least 15 members in mammals which differ in affinity to Ca^{2+} and subcellular localizations) function as a Ca^{2+} sensor for the latter.

Rab proteins are known to be involved in a variety of intracellular membrane trafficking events. Among the Rabs, Rab3A, Rab5, and Rab11 are abundant isoforms on SVs. They associate with SVs in the GTP-bound forms, whereas they dissociate from SVs in the GDP-bound state. The association and dissociation cycle of Rab3A occurs in parallel with SV exocytosis, although Rab proteins are not directly involved in exocytosis or membrane fusion. In Rab3A-deficient neurons, some forms of synaptic plasticity, such as long-term potentiation in hippocampal mossy fibers, are affected, indicating that Rab3A modulates the efficacy of neurotransmission, probably by changing the vesicle pools available for exocytosis.

In addition to Rab proteins, the synapsin family represents abundant peripheral membrane proteins which may interact with SVs in an activity-dependent manner. The synapsin family consists of five isoforms (I/IIA, IIB, IIIA, and IIIB) and they form homo- or heterodimer on the surface of SVs. Originally, it was discovered as a neuron-specific abundant protein substrate for the cyclic AMP-dependent protein kinase (protein kinase A) at presynaptic terminals. Their function in synaptic transmission remains unclear. It has been proposed that synapsins function as an anchoring protein to cytoskeleton components to make a portion of vesicles immobile because they exhibit a binding property to actin, tubulin, and spectrin. Such a view is partially supported by the fact that although

Ca^{2+}-triggered exocytosis is intact, short-term synaptic plasticity is impaired in the absence of synapsin 1 and 2. Therefore, synapsins might play a modulating role in controlling the vesicle pools at the terminals.

Conclusion

Although significant progress has been made in understanding molecular mechanisms of neurotransmitter release, a mechanistic understanding of SVs is yet to be achieved. Until recently, even elementary quantitative information about SV components was lacking. Quantitative analyses of SV proteins and lipids have allowed, for the first time, the proposal of a structural model of an average SV shown in Figure 3(b). The model demonstrates that SVs are highly decorated with proteins. Numerous copies of the essential proteins for exocytosis, such as synaptobrevin and synaptotagmin, are present on a vesicle indicating that the surface densities of these proteins are not rate limiting for fusion. Furthermore, SVs contain large numbers of the neurotransmitter transporter, supporting a high-speed refilling of the vesicles upon strong repetitive stimulations. One exception among the essential proteins is the V-ATPase, which is estimated to have one or two copies per vesicle, further indicating that the retrieval of SV constituents by endocytosis has to be guaranteed by precise processes. More studies are needed to explore the structure–function relationships of each SV constituent to understand the function of this intriguing organelle.

Introduction

Optimal neurotransmission relies on the proper trafficking of synaptic vesicles in nerve terminals. At the beginning of the cycle, synaptic vesicles dock at the active zone of nerve terminals where they undergo a priming step that makes them competent for Ca^{2+}-dependent fusion. When action potentials reach nerve terminals, the entry of Ca^{2+} triggers the fusion of synaptic vesicles with the plasma membrane, resulting in the release of neurotransmitters into the synaptic cleft, which in turn stimulate postsynaptic receptors. Following exocytosis, the synaptic vesicle membrane is rapidly retrieved from the cell surface and recycled to generate new synaptic vesicles. This process is crucial to prevent plasma membrane expansion and synaptic vesicle depletion, both of which would impair neurotransmission. A major recycling pathway is clathrin-mediated endocytosis, although faster recycling parallel pathways (e.g., 'kiss-and-run') have been described. After pinching off from the plasma membrane, clathrin-coated vesicles rapidly shed their coat and are directed back to the synaptic vesicle cluster, where they are refilled and can participate in new rounds of release. The recycling machinery includes coat components as well as a variety of accessory proteins, such as membrane deforming factors, scaffolding molecules, and signaling components. In addition, a variety of enzymes modifying the lipid content of membranes have been implicated in the recycling process. The best-characterized family of lipid enzymes involved in membrane trafficking at the synapse is that of synaptojanins, the focus of this article. These proteins largely function as phosphatases that dephosphorylate phosphoinositides (i.e., phosphorylated derivatives of phosphatidylinositol). These phospholipids are major membrane-bound signaling molecules that regulate intracellular organelle transport, cytoskeletal dynamics, the function of ion channels and transporters, as well as signal transduction mechanisms.

Structure of Synaptojanins

Synaptojanins constitute a protein family that is conserved from yeast to humans. Whereas yeast expresses three synaptojanin-like genes (*Sjlp1, -2,* and *-3* or *INP51, -52,* and *-53*), the worm and fly genomes contain only one synaptojanin gene. The mammalian genome contains two genes, *Synj1* and *Synj2* (Figure 1). All synaptojanins consist of a central inositol 5-phosphatase domain, which is flanked by an NH_2-terminal Sac1 domain and a COOH-terminal proline-rich region (Figure 1). Both inositol 5-phosphatase and Sac1 domains are highly conserved within the family and possess polyphosphoinositide phosphatase activity, whereas the variable proline-rich tail serves as a targeting domain. The term 'synaptojanin' was derived from the two-headed Roman god Janus to reflect the unique properties of synaptojanins (among the family of inositol 5-phosphatases), namely the presence of two domains involved in inositol phosphate metabolism.

Based on genetic studies in independent organisms, a fundamental function of synaptojanins is to catalyze the dephosphorylation of phosphatidylinositol-4,5-bisphosphate [PtdIns(4,5)P2]. Thus, the inositol 5-phosphatase domain is likely the business part of the molecule, though the Sac1 domain has also been shown to play a role in some of synaptojanin's functions. Currently, structural information on synaptojanins is only available for this catalytic domain. Although the primary sequence of the 5-phosphatase catalytic domain shares no resemblance to any other classes of enzymes, the catalytic residues are highly conserved with those of nucleases, particularly the alkaline phosphatase (AP) endonucleases, and thus the structures of the catalytic domains were predicted to be similar. The inositol 5-phosphatase catalytic domain from the *Schizosaccharomyces pombe* synaptojanin ortholog, SPsynaptojanin, was crystallized in both the apo- and product-bound states, revealing that not only is the positioning of the critical catalytic residues of the 5-phosphatases and AP endonucleases similar but also the overall structure is similar. The SPsynaptojanin catalytic domain structure reveals a center composed of two β sheets, positioned like the slices of bread in a sandwich, flanked on either side by several α helices (Figure 2). The active site is formed by the funnel-shaped depression located at one end of the β sheet sandwich. Mutagenesis targets suggested by the structure revealed that the surface composed of loops from β sheet II that surrounds the active site is involved in specificity toward lipid and/or soluble inositol phosphates and that the α_7–β_9 loop determines dephosphorylation site selectivity (Figure 2).

Expression, Localization, and Interacting Partners of Synaptojanins

Of the two genes encoding mammalian synaptojanins, *Synj1* is the best characterized. *Synj1* occurs as

Figure 1 Domain structure of synaptojanins. The domain structure of the synaptojanin proteins is conserved from yeast to humans. The NH_2-terminus contains a Sac1 domain, followed by a central inositol 5-phosphatase domain and a COOH-terminal proline-rich region (PRD). Human Synj1 has two major isoforms, Synj1-145 and Synj1-170. The Synj1 gene is transcribed into a cDNA containing two open reading frames (ORFs) separated by an in-frame stop codon; the first ORF is translated into the 145-kDa product, Synj1-145, whereas Synj1-170 is an alternative splice product from both ORFs that splices out the in-frame stop codon. An additional alternatively spliced product of rat Synj1 yields Synj1-145 variant with an additional exon of 16 amino acids (not shown). The human Synj2 gene encodes two alternative splice forms – Synj2A, which is localized to mitochondria, and Synj2B, which more closely resembles Synj1 proteins. Synj2B is further alternatively spliced into Synj2B1 and Synj2B2. Both flies and worms possess only one synaptojanin gene. Protein sequences were obtained from the Swiss-Prot database.

two main isoforms – a 145-kDa protein (Synj1-145) and a 170-kDa protein (Synj1-170). These two isoforms are expressed in various tissues; Synj1-145 is heavily enriched in the adult brain, whereas Synj1-170 is predominantly found in the developing brain as well as in nonneuronal cells. Synj1 was originally isolated as a major Grb2-binding protein via the interaction of its PRD domain with the Grb2–SH3 domain. In addition, the Synj1 PRD domain has been shown to interact with other SH3-containing proteins involved in endocytic processes, such as endophilin and amphiphysin. The two main Synj1 isoforms arise from alternative splicing of its mRNA that contains two open reading frames (ORFs) separated by an in-frame stop codon. Synj1-145 is the protein product of the first ORF, whereas Synj1-170 is the product when the stop codon is spliced out and both ORFs are translated. Thus, in addition to the Synj1-145 sequence, Synj1-170 possesses a COOH-terminal extension with unique properties. Importantly, it contains NPF repeats, a motif involved in binding to the EH domains of endocytic protein Eps15. This same COOH-terminal extension of Synj1-170 has also been shown to bind to clathrin and to have three distinct AP-2 α-subunit binding motifs – DPF, FXDXF, and WXXF – that help coordinate the precise temporal recruitment of this and other endocytic accessory proteins to clathrin coats. Although the subcellular localization of endogenous Synj1-170 has not been clearly determined, transfection studies suggest that the protein is localized to endocytic pits, consistent with its ability to bind to the clathrin coat. In contrast, the localization of adult brain-enriched isoform Synj1-145 is well characterized and has been shown to coincide with mature nerve terminals in various regions, such as the hippocampus (Figure 3(a)), the granule cell layer of the cerebellum, and the brain stem. Based on immunogold electron microscopic analysis of broken nerve terminals, Synj1-145 appears to be concentrated at clathrin- and dynamin-coated endocytic intermediates, consistent with a role in endocytosis (Figure 3(b)).

Similar to Synj1-170, the various isoforms of Synj2 exhibit a wide tissue distribution. Subcellular fractionation shows that Synj2 is predominantly in the particulate fraction. The *Synj2* gene has three alternatively spliced isoforms – Synj2A, Synj2B1, and Synj2B2 – and their localization is dependent on the activity of

Figure 2 Crystal structure of SPSynj1. A ribbon diagram of the SPsynaptojanin inositol 5-phosphatase catalytic domain with bound Ca^{2+} and Ins(1,4)P_2 molecules. The structure reveals a center composed of two β sheets, positioned like two slices of bread in a sandwich, flanked on either side by several α helices. The active site is formed by the funnel-shaped depression located at one end of the β sheet sandwich. The active site was determined by soaking the apo crystals in a solution containing the substrate Ins(1,4,5)P_3 and 1 mM $CaCl_2$. The electron density showed that the reaction product, Ins(1,4)P_2, was bound to the molecule instead of Ins(1,4,5)P_3, and structures obtained with a shortened substrate incubation yielded a complex electron density map that was consistent with having a mixture of bound Ins(1,4,5)P_3 and Ins(1,4)P_2. Reprinted from *Cell*, Vol. 105, Tsujishita Y, Guo S, Stolz LE , York JD, and Hurley JH, Specificity determinants in phosphoinositide dephosphorylation: Crystal structure of an archetypal inositol polyphosphate 5-phosphatase, pp. 379–389, Copyright 2001, with permission from Elsevier.

the Rac1 GTPase. The COOH-terminus of Synj2A interacts with the PDZ domain of the mitochondrial outer membrane protein OMP25, thereby localizing this isoform to mitochondria. Synj2B, which undergoes further alternative splicing, more closely resembles the Synj1 proteins, with the longer isoform, Synj2B2, having binding sites for both endophilin and amphiphysin and the shorter isoform, Synj2B1, having a binding site only for amphiphysin. Synj2B has been localized to both nerve terminals and the spermatide manchettes in testes. The overlapping biochemical properties and localization of Synj2B and Synj1 may account for some of the residual synaptic vesicle recycling capability observed in Synj1-deficient neurons.

In worms and flies, the synaptojanin ortholog is enriched in nerve terminals, where its localization is controlled by endophilin. Based on this feature as well as analyses of synaptojanin function in these two organisms, it appears that these orthologs may be closely related to mammalian Synj1-145.

Substrate Specificity of Synaptojanins

Synaptojanins are part of the inositol 5-phosphatase family of enzymes, which catalyze the hydrolysis of phosphate groups attached to the 5′ position of the inositol ring in either soluble or lipid-bound inositol phosphates. Whereas the central inositol 5-phosphatase domain removes the phosphate from the 5′ position of PtdIns(4,5)P_2 and PtdIns(3,4,5)P_3, the NH2-terminal Sac1 domain can dephosphorylate a variety of phosphoinositides, such as PtdIns(3)P, PtdIns (4)P, PtdIns(5)P, and PtdIns(3,5)P_2. The 5-phosphatase domain can also dephosphorylate (soluble) inositol polyphosphates on the 5′ position, such as the PI-phospholipase C enzymatic reaction product inositol-1,4,5-trisphosphate [Ins(1,4,5)P_3]. Based on lipid analyses carried out on brain tissue and cultured neurons from Synj1 knockout mice, the main physiological substrate appears to be PtdIns(4,5)P_2, thereby denoting a dominant role for the inositol 5-phosphatase domain. The physiological substrates for the Sac1 domain are unknown, although a study on yeast synaptojanin-like protein 2 (Sjlp1/INP52) suggests that at least one of these substrates may be PtdIn(3)P on endosomal membranes. However, the Sac domain of synaptojanins may function redundantly with that of other Sac domain-containing proteins as well as with other 3-phosphatases, such as myotubularins. Whether synaptojanins can physiologically dephosphorylate inositol polyphosphates, such as Ins(1,4,5)P3, is unclear.

Regulation of Synaptojanin Function

Synaptojanins are soluble (cytosolic) lipid enzymes and thus their recruitment to membranes largely relies on their interaction with other proteins. Generally, the targeting of synaptojanins to cell membranes occurs through an interaction of their COOH-terminal proline-rich tail with a variety of binding partners, specifically with Src homology 3 (SH3) domain-containing proteins. Although synaptojanin 1 was originally identified through its affinity to the SH3 domain of Grb2, it appears that the main physiological interactors of synaptojanin 1 may be endophilin A family members. Other interactors include amphiphysin, syndapin, intersectin, and sorting nexin 9, although the precise roles of such interactions are unclear. Importantly, synaptojanins possess multiple independent binding sites for SH3 proteins via

sequences that contain variations of the canonic proline-rich peptides that determine their affinity for the respective SH3 proteins. For instance, synaptojanin 1 contains independent binding sites for endophilin and amphiphysin, and the alternatively spliced isoforms of synaptojanin 2 possess binding sites for amphiphysin, either alone or in combination with those for endophilin (Figure 1).

The function of synaptojanin 1 is largely controlled by a cycle of phosphorylation/dephosphorylation. This mechanism both modulates its intrinsic catalytic activity and regulates its interaction with SH3 proteins, which in turn mediate the recruitment of synaptojanin to membranes. Synaptojanin 1 belongs to the 'dephosphin' group of proteins, which are constitutively phosphorylated in resting nerve terminals and undergo depolarization-dependent dephosphorylation. This process allows for efficient spatiotemporal control of protein–protein interactions to occur between dephosphins (e.g., dynamin and amphiphysin) as well as other endocytic proteins (e.g., endophilin) and mediates their recruitment to sites of endocytosis. After a cycle of exocytosis–endocytosis has occurred, dephosphins are rephosphorylated during repolarization to allow the next round of exocytosis–endocytosis to occur upon the next stimulation.

Although pharmacological studies indicate that the dephosphorylation of dephosphins, including synaptojanin 1, is largely mediated by the Ca^{2+}-dependent protein phosphatase calcineurin, various protein kinases have been shown to be responsible for their phosphorylation. A key enzyme appears to be cyclin-dependent kinase 5 (Cdk5), which is a proline-directed Ser/Thr kinase that is highly expressed in neurons and in nerve terminals. This kinase has been implicated in the phosphorylation of dynamin, amphiphysin, and Synj1. The 5-phosphatase activity of Synj1 was shown to be reduced as a result of Cdk5-mediated phosphorylation, and Cdk5 inhibitors, which block the phosphorylation of Synj1, were able to prevent this reduction in Synj1 catalytic activity. Ser1144 was mapped as the site of phosphorylation by Cdk5, although additional sites may be present. In addition, Cdk5 phosphorylation of Synj1 decreased its ability to interact with both endophilin 1 and amphiphysin 1, suggesting that its membrane recruitment to sites of endocytosis is regulated by phosphorylation.

Another kinase that is potentially involved in the Ser/Thr phosphorylation of synaptojanin is protein kinase C (PKC). Inhibitors of PKC function, Ro31-8220 and Go7874, were shown to obstruct both dynamin 1 and synaptojanin rephosphorylation upon nerve terminal repolarization, thereby preventing endocytosis after a second stimulus. However, the sites of PKC phosphorylation on dynamin 1 found *in vitro* were shown not be phosphorylated *in vivo* from material isolated from intact synaptosomes. The sites of PKC phosphorylation on synaptojanin and whether these sites are physiologically relevant in synaptic vesicle recycling remain to be determined.

Minibrain kinase/dual-specificity tyrosine phosphorylation-regulated kinase (Mnb/Dyrk1A) is a candidate Ser/Thr kinase implicated in the regulation of endocytic proteins, including Synj1. Mnb/Dyrk1A is found within the Down syndrome critical region of human chromosome 21 and its expression is elevated in Down syndrome patients. This proline-directed kinase has been shown to phosphorylate both amphiphysin and dynamin. It has also been suggested to phosphorylate Synj1, affecting its ability to bind amphiphysin and intersectin with minimal impact on its catalytic activity.

In addition to Ser/Thr phosphorylation, tyrosine phosphorylation of Synj1 may play a critical role, as suggested by a study of the EphB2 receptor signaling pathway. This receptor tyrosine kinase, whose ligand is ephrinB2, is believed to function in modulating the actin cytoskeleton resulting in changes in cell morphology. Synaptojanin 1 was identified as a substrate in a screen of proteins phosphorylated after treatment of cells with ephrinB2. Tyrosine phosphorylation of synaptojanin appears to play an important regulatory role, blocking its ability to bind endophilin and affecting its catalytic activity. A tyrosine phosphatase for synaptojanin has yet to be identified in this process.

Role of Synaptojanins in Neurons

The identification of synaptojanin 1 as a partner for the SH3 domain of Grb2 (and amphiphysin), along with the endocytic fission factor dynamin, indirectly suggested an involvement of this enzyme in endocytosis. However, conclusive evidence for a direct role of synaptojanin in this process derived from a genetic study in the mouse, in which a null mutant was shown to produce defects in synaptic vesicle recycling. At the $Synj1^{-/-}$ synapse, increased PtdIns(4,5)P2 levels correlated with an excess of clathrin-coated vesicles, suggesting a delay in the uncoating reaction (**Figure 3c**). In agreement with defects of recycling, a deeper depression of neurotransmission was observed in hippocampal slices as well as in primary cortical cultures from null mice during a prolonged stimulation. Fluorescent dye (FM1-43) uptake and release assays in cultured neurons confirmed that newly endocytosed vesicles recycle with slower kinetics in nerve terminals, likely reflecting the accumulation of clathrin-coated vesicles (**Figure 3(c)**). Strikingly, endocytic defects resulting from inactivation of synaptojanin function were also observed in other species, such as the budding yeast, the worm, and the fly. In addition, defects in synaptic vesicle trafficking were observed in the ribbon synapses of fish photoreceptors as a result of the Nrc mutation, which targets the synaptojanin gene. Thus, the function of synaptojanin appears to be largely conserved across evolution, thereby implicating its role in fundamental biological processes in eukaryotes. Along with studies showing that key endocytic molecules, such as plasma membrane-associated clathrin adaptors and dynamin, bind PtdIns(4,5)P2, work on synaptojanin has provided strong evidence for involvement of PtdIns(4,5)P2 in endocytosis. Consistent with the ability of this lipid to also promote actin polymerization, abnormally high levels of actin-like cytomatrix were found in nerve terminals from $Synj1^{-/-}$ mice and in the giant synapse from the lamprey following a microinjection of inhibitory antibodies against synaptojanin.

Based on studies of Synj1 function in various organisms as well as the role of PtdIns(4,5)P2 in multiple experimental systems, a main function of synaptojanin appears to be the elimination of PtdIns(4,5)P2 from membranes during the endocytic process. This lipid is essential for multiple processes occurring at the plasma membrane, including signal transduction,

regulation of cytoskeletal dynamics, and ion channel/transporter function as well as exo-endocytosis. To a large extent, the implication of PtdIns(4,5)P2 in these processes reflects its ability to function as a compartment-specific identity tag for the plasma membrane. Importantly, this tag must be eliminated as membrane material flows to other cellular compartments, such as endosomes, during endocytosis. Failure to carry out this PtdIns(4,5)P2 conversion via Synj1-mediated dephosphorylation produces defects in the endocytic phase of the synaptic vesicle cycle, including an accumulation of clathrin-coated vesicles suggestive of an uncoating delay. In yeast, failure to hydrolyze PtdIns(4,5)P2 during endocytosis results in the aberrant accumulation of this lipid in intracellular organelles, where it is normally de-enriched. Thus, the main function of synaptojanin might be to spatially restrict PtdIns(4,5)P2 to the plasma membrane as part of homeostatic mechanisms ensuring the maintenance of membranous compartment identity in cells.

Conclusions

Studies disrupting synaptojanin function in neurons, either genetically or via peptide competition, have shown that this molecule plays a critical role in synaptic vesicle recycling. Whereas the most well-characterized function of synaptojanin is the dephosphorylation of PtdIns(4,5)P2 by the 5-phosphatase domain, the exact site and time of action of this enzyme during the endocytic process are not known. The accumulation of clathrin-coated vesicles in null animals suggests involvement of this molecule at a late stage, although it may also modulate the endocytic process at an early stage (e.g., for the regulation of vesicle fission), as suggested by work on Synj2 in nonneuronal cells.

A fundamental question is whether all the defects present in Synj1 null animals are caused by aberrant PtdIns(4,5)P2 metabolism and, thus, by a defect of the 5-phosphatase activity. Indeed, the Sac1 domain has been shown to contribute to the endocytic process while the proline-rich domain is responsible for interactions with other proteins that help target the molecule to sites of action. Reconstitution experiments from Synj1 knockout cultured neurons have addressed the contribution of the various regions of the molecule to specific stages of the endocytic process. Furthermore, based on the large number of biological phenomena regulated by PtdIns(4,5)P_2 in cells, it will be important to determine the contribution of synaptojanin family members to these processes. For instance, the function of PtdIns(4,5)P2-sensitive ion channels or transporters may be regulated by rapid hydrolysis of PtdIns(4,5)P2, either by dephosphorylation or by phospholipase C. Similarly, synaptojanin may regulate the availability of PtdIns(4,5)P_2 for conversion into active metabolites, such as diacylglycerol/Ins(1,4,5)P_3 and PtdIns(3,4,5)P_3.

Because PtdIns(4,5)P2 metabolism plays an essential role in neurophysiology, it would not be surprising that its dyshomeostasis in humans may lead to behavioral abnormalities, such as cognitive deficits. Importantly, the SYNJ1 gene is mapped to chromosome 21 and is overexpressed in a gene dosage-dependent manner in brain tissue from Down syndrome-affected individuals. Studies in mice have suggested that the trisomy of *Synj1* may contribute to subtle neurobehavioral deficits in tasks assessing spatial memory. Additionally, *Synj1* haploinsufficiency may confer protection against some of the synaptotoxic effects of amyloid beta peptide, which has been recently shown to decrease the levels of PtdIns(4,5)P_2. In addition, the ch21q22 region on which Synj1 is found has also been linked to bipolar disorder, and studies have identified potential Synj1 variants that may be involved in this psychiatric disorder. Work using animal models should increase our understanding of the contribution of synaptojanin dysfunction to brain disorders.

Synaptosomes

I J Weiler, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Definition

Synaptosomes are a subcellular fraction of resealed synaptic junctions prepared from brain tissue. On gentle homogenization of brain cells, lipid bilayers reseal, forming subcellular fragments, some of which contain synapses. The synaptic junction is hardy, making it possible to fractionate the subcellular fragments to enrich for synapse-containing elements on the basis of size or density. Preparations are thus characterized by a large preponderance of resealed pre- and postsynaptic entities.

Modes of Separation

Centrifugation

Initial gentle homogenization is important in the disruption of cell constituents. Glass–glass manual homogenizers and low speeds seem to yield more synaptosomes, as judged by the yield of neurotransmitters such as acetylcholine. Most laboratories employ buffers containing 0.32 M sucrose as the homogenizing medium. Centrifugation is then used to separate particles on the basis of sedimentation rate, in which size plays an important role. Early descriptions by Gray and Whittaker, De Robertis, and others demonstrated by electron microscopy and neurotransmitter analysis that centrifugation procedures could yield a population of subcellular particles largely derived from nerve endings.

In a typical procedure, the homogenate is pelleted at 1000 g for 10 min to remove the nuclear pellet; the supernate is spun for 1 h at 17 000 g to yield a mitochondrial pellet, which is then redispersed on a sucrose density gradient (0.8 M, 1.0 M, 1.2 M, and 1.4 M sucrose), centrifuged at 50 000 g for 2 h to separate mitochondria and myelin fragments from synaptosomes. Centrifugation procedures have been subsequently refined by the use of Percoll and Ficoll gradients that reduce osmotic damage.

Moreover, using synaptosomes as a base material, it has been possible to further purify synaptic vesicles (as a source for neurotransmitters), synaptic plasma membranes, and synaptic junctional complexes. A thorough review of the literature in 1975 was provided by DG Jones in his book *Synapses and Synaptosomes*.

A major issue with all methods, including the synaptoneurosomes (discussed later), is assessing the contamination of the fractions by axonal and glial components of the initial tissue homogenate. Although the close functional association of neurons and glia is basic to intact brain tissue function, fragments of glia can skew the analysis of enzyme levels in preparations of isolated nerve terminals. The assessment of purity is based ideally on electron microscopy of pelleted fractions and depends on recognizing a synapse on the basis of the postsynaptic density and the presynaptic vesicles. Serial sectioning must be used to distinguish particles on this morphological basis, and quantitative determination is difficult because of the complexity of tissue fragments. Most laboratories have reported over 60% purity of the synaptosomes.

Specialized Preparations

Considerable effort has been put into achieving either purer or more active preparations. Percoll gradients have been helpful in reducing contamination by myelin and extrasynaptosomal mitochondria; however, the procedures are lengthy (1 h or more) and inflict stress on the cell membrane by repeated pelleting and pipetting procedures. Phase partition, using dextran T500 and polyethylene glycol 4000, has been reported to yield synaptosomes of 62.9% purity based on morphological criteria. A novel method for purification based on synaptic function is described below.

Synaptodendrosomes

Further subfractionation of synaptosomes to the level of the synaptic plasma membrane and synaptic junctional complex has been undertaken; this method relies on two centrifugations followed by ultracentrifugation through a discontinuous Ficoll gradient, preserving some postsynaptic polyribosomes. Despite the lengthy procedure, the synaptodendrosomes are robust enough to exhibit dendritic protein translation that can be shown not to be due to mitochondrial protein synthesis.

Synaptoneurosomes

Hollingsworth and colleagues made the important step of developing a shorter, milder procedure based on simple size fractionation, eliminating centrifugation entirely. A gently homogenized neuronal tissue suspension is passed through a series of filters, yielding a preparation of synaptosomes unusually rich in attached resealed postsynaptic entities; these were

termed synaptoneurosomes and were found to be more homogeneous than previous types of preparations and to yield a larger proportion of postsynaptic configurations (Figure 1). Because of the mild conditions used, it has been possible to obtain functioning synaptoneurosomes from single rat hippocampal slices and to observe metabolic changes during an hour or more of incubation.

Function-Based Purification

To achieve purification of synaptoneurosomes based on functional criteria, we have taken advantage of a lipophilic dye, FM 1–43. This and similar dyes have been used to tag active synapses and to examine exocytotic release from hippocampal synaptosomes. After release of neurotransmitter and endocytosis by synaptic vesicles, the FM 1–43 molecule is trapped in the lipid layers of synaptic vesicles, at which point its fluorescence becomes 50-fold stronger. It is of an intensity such that it can be used in high-performance fluorescence-activated cell sorters. Presynaptic fluorescence can be distinguished from passive absorption to lipid membranes by its dependence on metabolic processes; thus, poisoning the cells with tetrodotoxin abolishes only the active uptake. The particles are loaded with FM 1–43 in the dark, stimulated by addition of 40 mM K^+, and washed twice in cold phosphate-buffered saline (PBS)/10^{-4}M Cd^{2+} to remove excess dye from the medium. The level of fluorescence remains steady for at least 1 h at 4 °C, during which time the particles are sorted at a velocity of about 1000 s^{-1} by means of fluorescence emission at 625 nm. The population distribution shows a large peak of moderate brightness, with a shoulder representing a smaller population (~15%) that is tenfold brighter (Figure 2). The brightest 15% of particles can be selected, concentrated by centrifugation, lysed, and analyzed. The disadvantage of very small yield is compensated for by the increased purity of the preparation.

Applications

Viability

Depolarization of synaptosomes can trigger enzyme reactions leading to increased protein synthesis, suggesting that many metabolic processes remain intact

Figure 2 Biphasic distribution of synaptoneurosomes sorted according to brightness. Peak 1 contains particles labeled passively by FM 1–43; after K^+ stimulation and incorporation of dye into presynaptic vesicles, a second peak (peak 2), tenfold brighter, appears as a shoulder on the original distribution. Particles harvested from the peaks analyzed on western blots (inset) show either the presence (peak 1) or absence (peak 2) of glial fibrillary acidic protein (GFAP); the postsynaptic marker α-calmodulin-dependent protein kinase II (α-CaMKII) is present in both fractions. Thanks to Soong Ho Kim for assistance.

for several hours. A careful study of synaptosomal viability, based on measurements of lactate dehydrogenase as well as Ca^{2+} regulation, was made in 1988 by Verhage and colleagues, who concluded that viability remains high for up to 4 h when neocortical synaptosomes are stored on ice; it declines rapidly after 30 min at 37 °C.

Synaptosomes have been an important source of information about neurotransmitters, membrane polarization, and ion entry and exit. They maintain a membrane potential that is sensitive to the addition of 40 mM K^+, a treatment that is known to cause both depolarization of neuronal membranes and an increase in permeability to Ca^{2+} ions.

Neurotransmitter Release

Neocortical synaptosomes have been extensively used to monitor the release of neurotransmitters such as glutamate, dynorphin, norepinephrin, met-enkephalin and cholecystokinin-8, as well as insulin, from isolated nerve terminals. Typically, synaptosomes are applied to a filter and superfused with buffer to which agonists can be added in a controlled manner and the rinse volume analyzed for released transmitters. A plasma membrane Ca^{2+}-adenosine triphosphatase (ATPase) extrudes Ca^{2+} and maintains the polarization of the membrane; depolarization may be caused either by an elevated K^+ concentration (activating Ca^{2+} channels) or veratridine (activating voltage-dependent Na^+ channels). The advantage of synaptosomes for studies of the release of neurotransmitters is the relative simplicity of the preparation, combined with homogeneity such that ion transport, membrane potentials, and bioenergetics can be measured in a complex biological system. Nicholls and others, as reviewed in 1989, demonstrated ATP-dependent exocytotic release of glutamate and γ-aminobutyric acid (GABA) in mammals using this system.

Protein Synthesis

Postsynaptic protein translation was demonstrated in several types of synaptosome preparations and correlated with the presence of ribosomes. The surprising longevity of the synaptoneurosomal preparation and the particulate nature of the suspension make this preparation advantageous for the analysis of reaction dynamics based on repeated rapid sampling from the same aliquots.

It had been shown by Scheetz, using frog tectum synaptoneurosomes, that specific mRNAs, such as that coding α-calmodulin-dependent protein kinase II (CaMKII), are gradually translated during the 75 min following *N*-methyl-D-aspartate (NMDA) activation, against a background of decreased translation of total protein. To look at more rapid events, we took advantage of the uniform nature of a neocortical synaptoneurosome suspension to take serial samples from a single preparation, divided into untreated and agonist-treated aliquots. We found that depolarization by 40 mM K^+ rapidly triggered protein translation, as shown by a shift of RNA into polyribosomal fractions within 1 min of stimulation. By applying extracellular and intracellular Ca^{2+} chelators to the aliquots of a single preparation and using agonists and antagonists specific for ionotropic or metabotropic glutamate receptors, we were able to show that the group I metabotropic glutamate receptors are most effective in triggering rapid postsynaptic protein synthesis by activating a protein kinase C (PKC)-centered second-messenger cascade. We next compared the mRNAs found in the polyribosome fractions derived from stimulated and unstimulated synaptoneurosomes and discovered that the fragile X mental retardation protein (FMRP) is among the proteins being rapidly synthesized after synaptic stimulation. Subsequent studies have revealed that rapid synaptic FMRP synthesis is dependent on the activation of mitogen-activated protein kinase (MAPK) signaling pathways and that this pathway does not trigger rapid protein synthesis in neocortical synaptoneurosomes from mice lacking a functional *Fmr1* gene. Thus, at least some translation that takes place at the synapse requires functional FMRP, suggesting that the altered transport and/or translation of the mRNAs regulated by FMRP may underlie some symptoms of fragile X syndrome.

The surprising robustness of synaptosomes makes them an attractive candidate for the analysis of biochemical pathways. The synapse-bound enzyme systems are stable enough that the synaptodendrosome preparation can exhibit phosphorylation of eIF4E and enhanced peptide elongation of α-CaMKII after brain-derived neurotropic factor (BDNF) treatment. The same preparation has also been used to demonstrate synaptic localization of α-CaMKII mRNA and to measure its increase subsequent to high-frequency *in vivo* stimulation of rat dentate gyrus. Synaptosomes from mice lacking a tyrosine phosphatase (PTPα) have been used to dissect the role of NMDA receptor phosphorylation, which affects learning and memory. Chloride fluxes were studied in synaptoneurosomes from different parts of the rat brain; PKC was shown to facilitate synaptic vessel turnover. Moreover, the effectiveness of Ca^{2+} buffering within brain terminals following hypoxia was studied in synaptosomes from neonatal and adult brain. Finally, because of the enrichment of synaptic elements in these preparations, they can be used to

compare levels of key proteins between dendritic arbors and synaptic regions, and their changes after neural activation, either after *in vivo* treatment, such as whisker stimulation, or after neurotransmitter activation of *in vitro* systems.

Synaptotagmins

A Maximov, University of Texas Southwestern Medical Center, Dallas TX, USA

© 2009 Published by Elsevier Ltd.

Introduction

Synaptic transmission plays a central role in interneuronal communications. In nerve terminals, fast release of neurotransmitters is mediated by synaptic vesicles, intracellular trafficking organelles that rapidly fuse with the plasma membrane in response to action-potential-driven Ca^{2} influx. Over the past two decades, soluble *N*-ethylmaleimide-sensitive factor attached protein receptor (SNARE) proteins and synaptotagmins have emerged as critical components of the release machinery that mediates synaptic vesicle fusion and exocytosis.

Synaptotagmins: Calcium Sensors for Membrane Fusion

Synaptotagmins is a family of membrane-trafficking proteins composed of a short N-terminus, a single transmembrane domain, a variable linker domain, and two C_2 domains (the C_2A and C_2B domains; Figure 1). The mammalian synaptotagmin family includes 16 genes, whereas the *Caenorhabditis elegans* and *Drosophila melanogaster* genomes encode eight and seven synaptotagmin genes, respectively. In *Drosophila* and mice, the expression of most synaptotagmin isoforms is restricted to the nervous system. Despite the similarity in their principal domain organization, different members of the synaptotagmin family display distinct expression patterns, subcellular localizations, and biochemical properties. Of the 16 synaptotagmins identified in the mouse genome, four isoforms, synaptotagmins-1, -2, -9, and -12, are localized on the synaptic vesicles, whereas the remaining isoforms are likely to be targeted to the various intracellular membrane compartments. The prototypical member of the synaptotagmin family, synaptotagmin-1, was originally identified in a monoclonal antibody screen for synaptic vesicle proteins. Subsequent genetic and functional studies showed that synaptotagmin-1 acts as a Ca^{2} sensor for fast synaptic vesicle exocytosis. In *Drosophila* and mice, deletion of the synaptotagmin-1 gene results in lethal phenotypes associated with the specific loss of fast (synchronous) Ca^{2} -triggered neurotransmitter release (Figure 2); whereas the mutations in the mouse synaptotagmin-1 gene that alter overall synaptotagmin-1 Ca^{2} -binding affinity produce a similar shift in a Ca^{2} sensitivity of transmitter release. Recent studies showed that, similar to synaptotagmin-1, synaptotagmins-2 and -9 act as Ca^{2} sensors for fast synaptic vesicle exocytosis. However, the functional roles of most nonsynaptic vesicle synaptotagmin isoforms remain controversial.

Biochemistry and the Mechanism of Action of Synaptotagmin-1

The average synaptic vesicle contains approximately 15 synaptotagmin-1 molecules that are oriented with their N-termini facing the vesicle lumen and their C_2 domains facing the cytosol. The intraluminal domain of synaptotagmin-1 contains a site for N-glycosilation that is essential for vesicular targeting. The structure of synaptotagmin C_2 domains consists of a compact β-sandwich composed of two four-stranded β-sheets and the top loops that form the sites for Ca^{2} binding (Figure 1(b)). The Ca^{2} binding sites of C_2 domains are coordinated by several negatively charged residues that are widely separated in the primary sequence. The C_2A domain binds three Ca^{2} ions, whereas the C_2B binds two Ca^{2} ions. The intrinsic Ca^{2} affinities of the synaptotagmin-1 C_2 domains are low because the coordination spheres for the Ca^{2} ions are incomplete. The apparent Ca^{2} affinity of the C_2 domains increases dramatically when the C_2 domains bind to phospholipids whose negatively charged head groups provide additional coordination sites for the bound Ca^{2} ions. Apart from Ca^{2} -dependent phospholipid binding, C_2 domains of synaptotagmin-1 mediate Ca^{2} -dependent and Ca^{2} -independent interactions with the SNARE proteins syntaxin-1 and synaptosomal-associated protein of 25 kDa (SNAP-25) and with assembled SNARE complexes. In addition, a number of studies using recombinant and native proteins reported interactions between synaptotagmin-1 and the various components of the presynaptic active zone and proteins implicated to regulation of synaptic vesicle cycle.

Substantial evidence has accumulated that Ca^{2} -dependent binding of synaptotagmin-1 to the lipid membranes and SNARE complexes plays a central role in the function of synaptotagmin-1 in triggering fast synaptic vesicle exocytosis. In reconstituted systems, the C_2 domains of synaptotagmin-1 accelerate the rate of SNARE-mediated lipid mixing in the presence of Ca^{2} , suggesting that the SNAREs and synaptotagmin-1 may cooperate in mediating vesicle fusion. This model is supported by the notions that the purified C_2B domain of synaptotagmin-1 is able to bring the lipid vesicles into close proximity by simultaneously binding to two membranes in a Ca^{2} -dependent manner. Analysis of Sr^{2} -induced

Figure 2 Fast synaptic transmission in wild-type (WT) cortical neurons and neurons isolated from synaptotagmin-1 knockout (Syt 1 KO) mice. Excitatory postsynaptic currents were triggered by single-action potentials and recorded in a whole-cell mode in the presence of 2 mM extracellular Ca^{2+}.

synaptic transmission in cultured hippocampal neurons indicates that synaptotagmin-1 binding to phospholipids may alone be sufficient for triggering synaptic vesicle exocytosis. However, an independent reconstitution study concluded that synaptotagmin-1 triggers fusion by direct interactions with the SNAREs and not solely through the aggregation of vesicles. This conclusion is supported by functional studies of synaptic transmission in neurons isolated from the mutant synaptotagmin-1 mouse line that carries a single-point mutation that alters the affinity of Ca^{2+}-dependent synaptotagmin-1 binding to SNAREs complexes without affecting its phospholipids binding activity. The later study has shown that the enhanced affinity of synaptotagmin-1-SNARE binding (D232N mutation in the C_2A domain) leads to an increase in the probability of evoked neurotransmitter release. Most likely, interaction between synaptotagmin-1 and SNAREs occurs during the last step of synaptic vesicle priming with the plasma membrane, when Ca^{2+}-bound synaptotagmin-1 competes for SNARE complex binding with complexins, small soluble proteins that have been shown to promote the full assembly of the SNARE complexes. In summary, the possible mechanism of synaptotagmin-1 action in triggering fast synaptic vesicle exocytosis involves Ca^{2+}-dependent phospholipid binding and displacement of complexins from the fully assembled SNARE complexes, followed by cooperation with SNAREs in completing the fusion reaction.

Synaptotagmins-1, -2, and -9: Fast Calcium Sensors with Distinct Kinetic Properties

Apart from synaptotagmin-1, three additional synaptotagmin isoforms are localized on the synaptic vesicles. Two of these isoforms, synaptotagmins-2 and -9 (also called synaptotagmin-5), contain functional Ca^{2+}-binding sites in their C_2 domains and display Ca^{2+}-dependent phospholipid and SNARE-binding activities. In the mouse brain, expression patterns of synaptotagmins-1, -2, and -9 are partially segregated, with synaptotagmin-1 being predominantly expressed in the forebrain; synaptotagmin-2 in the cerebellum, brain stem, and spinal cord; and synaptotagmin-9 in the limbic system and striatum. Recent genetic analyses have shown that deletions of the synaptotagmin-2 and -9 genes in mice impair fast Ca^{2+}-triggered neurotransmitter release in the synapses of the Calyx of Held, neuromuscular junctions, and cultured striatal neurons. In rescue experiments, lentiviral-mediated expression of synaptotagmins-2 and -9 restored the fast synaptic responses in cortical neurons lacking synaptotagmin-1, indicating that synaptotagmins-2 and -9 act as Ca^{2+} sensors for fast synaptic vesicle exocytosis. Interestingly, the evoked synaptic responses triggered by three different synaptotagmin isoforms displayed substantial differences in kinetics and Ca^{2+} sensitivity. When compared to synaptotagmin-1, fast synaptic responses triggered by synaptotagmin-2 displayed similar Ca^{2+} dependence but had significantly faster rise and decay times. In contrast, synaptic responses triggered by synaptotagmin-9 displayed much slower rise and decay times and lower Ca^{2+} dependence. Hence, in

subsets of neurons, distinct release properties may be defined by differential expression of fast Ca^{2+} sensors.

Conclusion and Perspectives

Combinations of biochemical, structural, genetic, and electrophysiological approaches advanced our understanding of the functional roles of several members of synaptotagmin family in triggering Ca^{2+}-dependent vesicle fusion. However, a number of questions remain to be answered. First, the interplay between the fast (synchronous) and slow (asynchronous) forms of synaptic vesicle exocysotis needs to be established. Indeed, the synapses of neurons lacking synaptotagmis-1 and -2 exhibit a dramatic increase in the magnitude of delayed asynchronous release and in the frequency of miniature neurotransmission, suggesting that fast Ca^{2+} sensors may regulate asynchronous vesicle exocytosis and minis. Second, the physiological roles of other members of synaptotagmin family need to be clarified. Several nonsynaptic vesicle synaptotagmin isoforms contain functional Ca^{2+}-binding sites and have been implicated in regulating various forms of membrane fusion. For example, synaptotagmin-7 was proposed as mediating Ca^{2+}-triggered exocytosis of dense-core vesicles in PC12 cells and acting as a Ca^{2+} sensor in lysosome exocytosis in nonneuronal cells, whereas synaptotagmin-4 has been recently shown to serve as a Ca^{2+} sensor for postsynaptic vesicle exocytosis in *Drosophila*. Despite these initial clues, the exact subcellular localizations and the functional roles of various nonsynaptic vesicle synaptotagmin isoforms need to be further elucidated.

Key Molecules: SynCAM Proteins

Synapses in the central nervous system (CNS) are asymmetric sites of interneuronal adhesion at which the presynaptic release machinery is localized opposite the postsynaptic receptor apparatus. Both pre- and postsynaptic specializations are tightly aligned with each other. The proper formation of synaptic contacts is endpoint to a highly complex process. It is preceded by signaling and guidance steps at multiple levels, including axonal pathfinding, physical contact of pre and postsynaptic neurons, and interactions between neurons and glia cells surrounding synaptic sites. Once intercellular contact of an incoming axon with a target neuron is achieved, specific signals are necessary to instruct both pre- and postsynaptic neurons to assemble specializations capable of controlled neurotransmitter release and detection. These instructive signals need to be specific both spatially and temporally to achieve the concomitant formation of overlapping pre- and postsynaptic specializations. Cell adhesion molecules are likely candidates to mediate this signaling as they are both capable of demarcating a membrane area as a nascent synapse and of mediating signaling between cells. It can be hypothesized that these activities of synaptic cell adhesion molecules assemble the appropriate intracellular molecular machinery at demarcated sites of synaptic contact.

At mammalian central synapses, several transsynaptic interactions have been described. Roles for adhesion molecules at synapses include stabilization and maturation of synaptic contacts, as described for N-cadherin, and long-term potentiation, in which neural cell adhesion molecule is involved. Receptors such as Eph receptors and their ephrin ligands have been implicated in dendritic spine morphogenesis and synapse differentiation. However, only two transsynaptic adhesion systems are known to play instructive roles in the organization of nascent synapses; these are the neuroligin/neurexin cell adhesion pair and the SynCAM (synaptic cell adhesion molecule) proteins. The four SynCAM proteins are encoded by cell adhesion molecule genes 1–4 and have also been named nectin-like molecules and tumor suppressor in lung cancer (TSLC) proteins as a result of their identification in different contexts. It is likely that additional adhesion molecules are involved in this process, and it will ultimately require detailed studies of each of the proteins to distinguish their roles in synapse formation, stabilization, and maintenance. This article reviews current knowledge of the roles the recently identified SynCAM proteins play in these processes.

Identification and Basic Properties of SynCAM Proteins

SynCAM 1 was initially identified in a bioinformatic search for proteins containing both extracellular immunoglobulin (Ig)-like domains and intracellular PDZ-domain interaction sequences. The search for proteins with this domain organization was motivated by research on the invertebrate proteins fasciclin II in *Drosophila* and apCAM in *Aplysia*, which contribute critically to proper synapse formation and share the presence of these domains and sequences with SynCAM 1. No related proteins had been investigated at vertebrate synapses prior to the identification of SynCAM 1. This domain organization is well suited for a synapse-organizing adhesion molecule as extracellular Ig-like domains are known to mediate homo- and heterophilic adhesion, while the intracellular PDZ interaction sequence is capable of tethering the adhesion molecule to scaffolding molecules found abundantly in the postsynaptic density and the presynaptic active zone. SynCAM 1 is the founding member of a small family of four SynCAM proteins that all share this domain organization.

SynCAMs are single-pass transmembrane proteins of relatively small size (just over 400 amino acids, about 45 kDa in predicted molecular weight depending on family member identity and splice variant). SynCAM proteins contain three extracellular Ig-like domains of the V-set, C1-set, and I-set subclasses (Figure 1(a)). Intracellularly, SynCAM proteins have a short cytosolic tail similar to the cytosolic tails of neurexins, another family of synaptic adhesion molecules involved in synaptogenesis (Figure 1(b)). The cytosolic tails of SynCAMs and neurexins share two motifs. One motif allows for interactions with proteins containing type II PDZ domains, which include a number of synaptically localized adaptor molecules. This motif is located at the extreme C-terminus of SynCAM proteins. The second motif is a sequence of amino acids that can bind members of the protein 4.1 family, which promote assembly of actin/spectrin filaments. One isoform, protein 4.1N, is neuronally expressed and could constitute a molecular link for SynCAMs with the actin cytoskeleton. This motif is located in the N-terminal part of the cytosolic tail, near the transmembrane domain.

Figure 1 Domain map of synaptic cell adhesion molecule (SynCAM) 1 and sequence alignment of SynCAM 1 with neurexins. (a) Domain map of SynCAM 1. SynCAM proteins contain three extracellular Ig-like domains that are N-glycosylated and mediate its adhesive contacts. Positions of N-glycosylation sites are shown as they are located in SynCAM 1. Following the single transmembrane region, SynCAM 1 has a short cytoplasmic sequence which mediates interactions with protein 4.1 family members and with PDZ domain-containing proteins. (b) The C-terminal sequences of SynCAM proteins and neurexins are highly similar, suggesting that the proteins share converging signaling pathways. Interaction sequences with protein 4.1 and PDZ type II domain-containing adaptor molecules are indicated. Ig, immunoglobulin; PM, plasma membrane; TMR, transmembrane region.

The SynCAM protein family is encoded by four *CADM* (cell adhesion molecule) genes designated *CADM 1–4*. SynCAM orthologs are highly conserved throughout the vertebrate phylum. In addition, individual SynCAM family members are highly related to each other and share up to 70% amino acid similarity. No genes encoding SynCAM proteins are found in invertebrates, suggesting the function of the encoded proteins is specific to vertebrates. A protein family with comparable domain organization, the nectins, has been described in vertebrates. Nectins also contain three extracellular Ig-like domains and a short cytoplasmic tail, but they lack sequence similarity to the SynCAM proteins and are not homologous. Most significantly, SynCAMs and nectins have distinct cytoplasmic sequences and interact with different sets of adaptor proteins. SynCAMs have at times been included in a group of proteins called nectin-like proteins, but this nomenclature is not sufficiently suitable as the term nectin-like molecule subsumes multiple proteins not homologous to each other, is not functionally descriptive, and does not clearly distinguish SynCAMs from the nonhomologous nectins. Other nomenclatures for SynCAM 1 have also been utilized as a result of its identification in different contexts. These include RA175, as named after identification in a screen for retinoic acid inducible proteins, TSLC1, for its role in tumor suppression in lung carcinoma, and spermatogenic IGSF, being a member of the immunoglobulin superfamily expressed in testis. Of these, TSLC1 is the only alternative name that describes a function of a SynCAM protein. This function is performed outside the nervous system and is only briefly referred to in this article (see the next section).

Expression and Localization Studies of SynCAM Proteins

All four SynCAM proteins are expressed in the CNS. SynCAM proteins 1 and 4 are also expressed in nonneuronal tissue. In addition to its expression in the CNS, SynCAM 1 is expressed in lung and was identified as a tumor suppressor in non-small-cell lung cancer. SynCAM 1 is also expressed in testes, where it is necessary for proper spermatid adhesion and maturation, and in T cell zone dendritic cells of the immune system. SynCAM 4 is also expressed in the immune system, where its role is unclear. SynCAMs 2 or 3 have been identified exclusively within the CNS.

The expression of SynCAMs 2, 3, and 4 in mouse brain begins early after birth and increases over the next 2 postnatal weeks, an expression profile consistent with a role in synapse formation. SynCAM 1 is expressed already in late embryonic stages, and its expression continues throughout postnatal development into adulthood, indicating that it may have

functions preceding synapse organization in the brain. It is interesting that SynCAM 1 is differentially expressed as two distinct molecular weight species at different developmental stages, suggesting that different splice variants and/or glycosylation patterns occur for SynCAM 1 in a regulated manner. The molecular and functional consequences of altered SynCAM 1 splicing and posttranslational modification are not yet understood.

Biochemical, immunohistochemical, and immunoelectron microscopy studies demonstrate that SynCAMs are synaptically localized. Biochemical fractionation of total brain shows that all four SynCAM proteins strongly enrich in synaptic plasma membrane preparations. Co-localization studies with synaptic marker proteins confirm that SynCAM proteins are synaptic. By means of immunoelectron microscopy, SynCAMs have been shown to localize to both pre- and postsynaptic specializations. These immunohistochemical and immunoelectron microscopy studies used an antibody that recognizes SynCAMs 1, 2, and 3, and as such, no data are yet available for SynCAM 4. However, the synaptic enrichment of SynCAM 4 in biochemical preparations, in addition to its domain organization and interaction motifs shared with other SynCAM proteins, suggests that it will likely be sorted to the same subcellular compartments and confirmed as synaptic protein as well.

The regional expression patterns of SynCAM in the developing CNS are distinct, suggesting that they exert differing functions in the developing brain. Expression studies have been carried out using *in situ* hybridization, RT-PCR, and immunoblotting. Notably, those subsets of SynCAM proteins interacting strongly *in vitro* (see next section) also are co-expressed in the same brain regions during development. One example are SynCAMs 1 and 2, which are both strongly expressed in the cortex and hippocampus during the early postnatal period. This suggests that pairs of SynCAMs may interact not only biochemically but also functionally *in vivo*. Detailed analysis of protein localization at the cellular and synaptic level in conjunction with functional studies will be necessary to determine whether cognate pairs of SynCAMs are in physical proximity and capable of mediating intercellular adhesion to promote synapse formation of neighboring neurons.

Extracellular Interactions of SynCAM Proteins

Heterophilic Interactions of SynCAM Proteins

The adhesive interactions of the extracellular domains of SynCAM proteins have been studied with a number of different techniques. Clustering assays, in which cells or beads display the extracellular domain of different family members, suggest that all four SynCAM proteins are capable of mediating homophilic interactions, but to differing degrees. While homophilic binding of SynCAMs 1, 2, and 3 can be readily demonstrated, SynCAM 4 homophilic interactions appear much weaker. Heterophilic interactions within the family have been studied using both affinity chromatography experiments and in cell overlay assays, in which the soluble extracellular domain of one SynCAM is allowed to adhere to a cell expressing another membrane-bound SynCAM. While SynCAM proteins are capable of interacting homophilically, these studies suggest that they preferentially engage in heterophilic interactions between family members. In these assays, strong binding occurs between SynCAMs 1 and 2 and between SynCAMs 3 and 4. These interactions are summarized in Table 1. The interaction of SynCAM 1 and 2 is affected by glycosylation, indicating regulation of this adhesion complex by posttranslational modification. As the extracellular interactions of SynCAM 1 are necessary for its activity to induce synapses, these studies of SynCAM interactions with each other will be critical to address their roles in synapse formation.

Table 1 Extracellular interactions of the SynCAM family

Protein	*Homophilic interaction*	*Other known interaction partners*
SynCAM 1	Yes	SynCAM 2, SynCAM 3, CRTAM, nectins
SynCAM 2	Yes	SynCAM 1, SynCAM 4
SynCAM 3	Yes	SynCAM 4, SynCAM 1, nectins
SynCAM 4	Very weak	SynCAM 3, SynCAM 2

SynCAM, synaptic cell adhesion molecule; CRTAM, class-1 restricted T cell-associated molecule.

Interactions of SynCAM Proteins with Non-SynCAM Proteins

SynCAM proteins also interact with other immunoglobulin superfamily members outside the SynCAM family, both in the nervous system and in nonneuronal tissues. The extracellular domains of SynCAMs 1 and 3 have been demonstrated to interact with members of the nectin family of proteins in cell clustering assays. However, since it is not known whether these two protein families share subcellular localization, it is unclear what the functional significance of these interactions is. In the immune system, SynCAM 1 is expressed in dendritic cells, where it interacts with the cell adhesion molecule 'class-1 restricted T cell-associated molecule (CRTAM),' as shown by cell overlay assays.

Intracellular Interactions of SynCAM Proteins

Compared to the extracellular analysis of SynCAM binding, the interactions of the cytoplasmic domains of the SynCAM proteins are less well characterized. In part, the promiscuity of the type II PDZ interaction sequence, which SynCAM proteins feature at their extreme C-termini, can mediate *in vitro* interactions with a number of partners that may or may not occur or be significant *in vivo*. Affinity chromatography studies have demonstrated that the cytoplasmic tail of SynCAM 1 is capable of interacting with the brain expressed adaptor molecules CASK, Mint1, and syntenin, all of which are PDZ domain-containing proteins found to differing extents at central synapses. Signaling of SynCAM 1 in the nervous system is plausibly mediated through these adaptor proteins as these are also synaptically enriched. It is likely that these interactions partners of SynCAM 1 also bind cytoplasmic sequences of the other SynCAM family members, but this remains to be confirmed. As expected, SynCAM 1 does not interact with type I PDZ domain-containing proteins such as PSD-95. Further, SynCAM 1 does not bind the nectin-interacting PDZ domain-containing protein afadin.

Interactions of SynCAM 1 cytoplasmic sequences have also been studied outside the CNS. SynCAM 1 interacts with DAL1, a member of the protein 4.1 family expressed in the lung. This interaction was confirmed with both biochemical and cell biological techniques. In addition, the PDZ domain-containing protein called 'protein associated with Lin7–2' was identified from testes as a protein capable of interaction with SynCAM 1 in a yeast two-hybrid screen.

The sequence similarity of the cytoplasmic domains of SynCAMs and neurexins (Figure 1(b)) suggests they function by engaging similar adaptor molecules on the presynaptic side. SynCAMs and neurexins share a protein 4.1 interaction sequence and a PDZ type II interaction motif. Notably, protein 4.1 is also capable of interaction with the scaffolding molecule CASK, providing for the potentially preferred formation of a trimeric complex of SynCAMs, protein 4.1, and CASK (Figure 2). A similar complex has been described for the neurexin proteins. The SynCAM cytoplasmic domains can therefore be imagined as multivalent nucleation sites for scaffolding and cytoskeletal molecules, which, when clustered, assemble molecular complexes such as the vesicle release machinery. This clustering mechanism provides an attractive hypothesis for the way cell adhesion molecules mediate assembly of synaptic membrane complexes.

Figure 2 Model of protein–protein interactions of the synaptic cell adhesion molecule (SynCAM) family. SynCAM 1 interacts with different immunoglobulin (Ig) superfamily members through its extracellular domains. Intracellularly, SynCAM 1 interacts with PDZ domain-containing adaptor molecules such as CASK and forms a trimeric complex with p4.1N which could nucleate cytoskeletal structures at synapse. PM, plasma membrane.

Functional Characterization of SynCAM Proteins in Synapse Organization

Multiple lines of evidence show roles of SynCAM 1 in synapse organization. The first of these is based on a co-culture assay for studying synaptogenesis in a reduced system. Here, expression of SynCAM 1 in epithelial cells co-cultured with hippocampal neurons causes the neurons to form functional synapses atop the epithelial cells. This has been demonstrated by three different approaches. First, immunostaining for presynaptic marker proteins, including synaptic vesicle proteins, shows a specific induction of puncta of presynaptic marker proteins formed by axonal membranes atop the surface of SynCAM 1-expressing epithelial cells (Figure 3). These results suggest that SynCAM 1 is capable of instructing neurons to recruit the synaptic vesicle release machinery to sites of contact. Further, by means of live cell imaging in fluorescent marker dye-recycling assays, it has been demonstrated that these specializations formed by neurons atop SynCAM 1-expressing epithelial cells indeed contain recycling synaptic vesicles. Notably, the synaptic vesicle recycling properties of these SynCAM 1-induced presynaptic specializations are indistinguishable from those of interneuronal synapses. Thus, SynCAM 1-induced presynaptic specializations

Figure 3 Synaptic cell adhesion molecule (SynCAM) 1 induces presynaptic specializations. Three-dimensional reconstruction of a confocal image of an epithelial-like HEK293 cell expressing SynCAM 1 (top left) that was co-cultured for 2 days with hippocampal neurons (not shown). The HEK293 cell is identified by co-expression of ECFP. The co-culture was stained for the presynaptic marker synaptophysin (red). Contact of an axon with the SynCAM 1-expressing HEK293 induces the axon to form multiple punctate presynaptic specializations (filled arrowheads). An axon extending toward the HEK293 cell is visible due to diffuse synaptophysin staining (arrow). Reproduced from Biederer T (2006) SynCAM in formation and function of synaptic specializations. In: Dityatev A and El-Husseini A (eds.) *Molecular Mechanisms of Synaptogenesis*, ch. 8, pp. 125–136, figure 3B. Copyright Springer Science and Business Media, with permission of Springer Science and Business Media.

are capable of evoked vesicle fusion and recycling. In this co-culture assay, SynCAM 1 has also been tested for the capability of recruiting postsynaptic protein clusters, a property demonstrated for the neurexins through their interactions with neuroligins. However, SynCAM 1 is not capable of assembling postsynaptic densities on contact with dendrites, suggesting that SynCAM 1-mediated transsynaptic signaling occurs in a single direction or does not occur through homophilic contacts.

The most direct demonstration that SynCAM 1-induced presynaptic terminals are functionally active utilized electrophysiological recordings from an artificial postsynaptic element. Electrophysiological recordings were obtained from epithelial cells co-expressing SynCAM 1 and a glutamate receptor formed by GluR2 subunits that were co-cultured with dissociated hippocampal neurons. These studies revealed that evoked excitatory neurotransmitter release occurs from the SynCAM 1-induced presynaptic specializations onto the surface of the SynCAM 1-expressing epithelial cell. Excitatory miniature events could be reconstituted as well. The similarities of SynCAM 1-induced presynaptic terminals to those of interneuronal synapses suggest that this reconstitution approach of neurotransmission might serve as a useful general approach on which the roles of other synaptic proteins might be studied.

Functions of SynCAM 1 in synapse formation and synaptic transmission have also been studied using overexpression analysis in cultured neurons. Overexpression of full-length SynCAM 1 in dissociated neurons increases frequency but not amplitude of excitatory miniature potentials that can be recorded from the neurons, suggesting an increase in release sites formed atop the SynCAM 1-overexpressing neurons. Alternatively, existing release sites may undergo plastic changes on postsynaptic overexpression of SynCAM 1. This effect was abrogated by the removal of the three extracellular Ig-like domains of SynCAM 1, demonstrating that its transsynaptic interactions are necessary for this effect. In a converse loss-of-function approach, overexpression of the cytoplasmic domain of SynCAM 1 in cultured hippocampal neurons reduces the number of presynaptic terminals compared with control neurons. This effect is abrogated when the C-terminal three amino acids are removed from the cytoplasmic tail, suggesting that PDZ interactions are critical to SynCAM 1 function. Since the cytoplasmic domains of neurexins and SynCAMs are similar, this experiment suggests that the interactions of scaffolding molecules with these intracellular adhesion molecules are critical for synapse formation. It is likely that the presynaptic signaling mechanisms of neurexins and SynCAMs converge by interaction with the same downstream partner proteins.

The activities of SynCAM 1 likely involve its interactions with SynCAM 2. Both proteins assemble into a heterophilic synaptic adhesion complex during the peak period of synaptogenesis, and can recruit each other across the synaptic cleft to form this SynCAM 1/2 complex. Concurringly, SynCAM 2 promotes functional synapses as it increases the number of active presynaptic terminals and enhances excitatory neurotransmission similar to SynCAM 1. Interestingly, both proteins are differentially expressed in hippocampus, indicating that they may contribute to specifying pre- and postsynaptic interactions in synapse formation.

The roles of SynCAMs at mature synapses have not yet been investigated. However, fractionation studies on SynCAM proteins are consistent with their synaptic localization in adult animals. Given the known

importance of adhesion molecules in the maturation and plasticity of synapses, it may be that SynCAM proteins play roles in these processes as well. Alternatively, SynCAMs might play an active role only in the initial induction of synapses and afterwards assume a static, structural function in synapse maintenance. These questions will need to be addressed in future experiments using mouse models.

Functions of SynCAM 1 *In Vivo*

Analysis of SynCAMs *in vivo* requires the use of mouse models in which the expression of one or more SynCAMs is altered. Thus far, only SynCAM 1 has been studied in this manner. SynCAM 1 knockout mice have been generated, and the main phenotype noted is infertility in the male homozygotes due to lack of retention of maturing spermatids at Sertoli cells. This condition is characterized by low sperm number and motility and aberrant sperm morphology (oligo-astheno-teratozoospermia) and is consistent with SynCAM 1's mediating cell adhesion during spermatid maturation. Similar phenotypes in testes have been noted for other Ig superfamily members.

No obvious phenotypes were noted for mice lacking SynCAM 1 in brain and lung, where it has characterized functions as synapse-inducing molecule and tumor suppressor, respectively. However, further studies will be needed to rigorously characterize synapse formation in mice deleted for SynCAM 1. It is plausible that SynCAM 1 knockout mice show no obvious defect in synapse formation because of redundancy *in vivo* between SynCAM 1 and other SynCAM proteins and because of compensatory mechanisms mediated by other synaptic adhesion molecules. In these cases, multiple knockouts will be necessary to probe the role of SynCAMs *in vivo*.

Summary and Outlook

SynCAM proteins form a family of four adhesion molecules belonging to the Ig superfamily. SynCAM 1 functions in synapse organization of developing neurons. Additional roles for SynCAM 1 exist outside the neurons. The expression of each SynCAM is unique during brain development, suggesting nonredundant roles for all four isoforms in the formation of central synapses. It is important to note that SynCAM proteins preferentially engage in heterophilic interactions with each other, suggesting these may be the key interactions involved in synapse formation. To date, only SynCAMs 1 and 2 have been studied extensively in synapse formation, and their role *in vitro* is well established. The interaction of SynCAM family members *in vitro* is also well understood, as is their basic expression. In order to understand the relevance of these described SynCAM interactions, more detailed expression analysis and functional studies will need to be performed. Such studies will likely provide leads for specific roles of each SynCAM protein in the developing CNS. Ultimately, it will be necessary to develop animal models to truly understand the role of these SynCAM proteins in synapse organization.

Synfire Chains

M Abeles, Bar-Ilan University, Ramat-Gan, Israel

What Is a Synfire Chain?

A synfire chain is essentially a feed-forward network of neurons with many layers (or pools). Each neuron in one pool feeds many excitatory connections to neurons in the next pool, and each neuron in the receiving pool is excited by many neurons in the previous pool. When activity in such a cascade of pools is arranged like a volley of spikes propagating synchronously from pool to pool, it is called a synfire chain. Figure 1 is an illustration of the connectivity in a synfire chain. The mean number of neurons in each pool is the width (w) of the chain. The mean number of synapses that each neuron in one pool receives from neurons in the previous pool (or by which it connects to neurons in the next pool) is the multiplicity of connections (m). In Figure 1, $w = 6$ and $m = 4$. In real cortical networks, w and m are assumed to be much larger, with $w \approx 100$ and $m \approx 50$.

In principle, one may envisage that activity along a synfire chain may propagate in either a synchronous or an asynchronous mode. In the asynchronous mode, an elevated firing rate in one pool will summate over space and time and cause an elevation in the firing rate in the next pool. In the synchronous mode, a synchronous volley in one pool will elicit a synchronous volley in the other after one synaptic delay. Abeles argued that the only stable mode of transmission is the synchronous mode. This was shown to be true theoretically, by numerical calculations, by simulations, and in the slice.

Thus, in most circumstances, in a multilayered feed-forward network of spiking neurons, the only stable mode of transmission is by synchronous volleys. Within each volley there is a small random dispersion of spike times, but this dispersion does not increase as the volleys propagate along the chain. This is so because at the transmission from pool to pool, the dispersion averages itself so that the distribution of firing times remains stable.

A synfire chain is a very simplified structure. There might be other structures, with less specific connections, which can generate precise firing sequences. Indeed, any network that can produce and recognize precise firing sequences would have all the advantages of a synfire chain. In a random diluted network, if one chooses w and m appropriately, one can find an almost infinite number of connectivity schemes similar to synfire chains by chance. However, the activity in such a network is not reproducible. If we start the activity by activating the same w neurons twice, even a very small amount of noise will cause the activity patterns to diverge very fast.

Historical Notes

The term synfire chain was coined by Abeles to account for the appearance of precise firing sequences with long interspike delays which resisted explanation in terms of the known properties of cortical physiology. This structure, with every neuron in one pool exciting all neurons in the second pool, was suggested 20 years earlier by Griffith as a structure that could guarantee a fixed level of activity in a network of excitatory neurons. He called this structure a complete transmission line. Griffith did not study its properties in any detail. Similar structures were presumably also used by Grossberg to learn and reproduce complicated space–time patterns. Bienenstock suggested that the transmission delays need not be equal. In such a system, a connection with a long delay may skip over one or more pools. He called such a network synfire braids. The governing rule for synchronous transmission in such a braid is that for any two neurons along the braid, the sum of all delays along each of the multitude (multineuronal) trajectories, by which one neuron may excite the other, adds up to the same value. A very simplified version of the synfire braid, in which each neuron is activated by a few strong excitatory inputs, was termed polychrony by Izhikevitch.

Memory Capacity for Synfire Chains

A single neuron may take part in more than one synfire pool. When activated with its members in a pool of one synfire chain, it will participate in activating the neurons of the next pool in this chain. When activated within a pool of another chain, it will activate the next pool in the other chain. Obviously, if all the neurons take part in all the pools of a network, we end up with an all-to-all connectivity. The problem of how many synfire pools can be embedded in a network of N neurons without interfering with the reproducibility of the activation was examined by Bienenstock and also by Herz and collaborators. Although they used two very different approaches, both came to similar conclusions: that the number of pools (P) is proportional to the network size (N), it decreases when the average firing rate in the network increases, and it depends on the width (w) of the pools. A cortical network with N neurons, an average

Figure 1 A synfire chain. Each neuron is depicted as a circle (the cell body), with a dendrite protruding to the left and a branching axon to the right. Synapses are symbolized by small triangles. The boldfaced drawing at the top left depicts one neuron. The neurons of each pool are drawn one under the other. The layout of the chain does not represent the anatomy but, rather, the order of activation in time. The same neuron can be part of more than one pool. For example, the two red neurons may be physically the same neuron. Repeated participation of the same neurons can occur up to the limit of the synfire chain's memory capacity.

firing rate of $5\,s^{-1}$, and with $w = 100$ may sustain N synfire pools ($P = N$). This means that each neuron can take part in 100 synfire pools.

These pools can be concatenated into one huge synfire chain or into many shorter chains. As noted by Maass, any structure that can be wired from individual neurons could just as easily be composed of synfire pools. The advantages would be more reliable operation, shorter input–output delays, and immunity to fallout.

Thus, an average cortical hypercolumn of 20 000 pyramidal neurons may contain 200 synfire chains, each 100 pools long and 100 neurons wide. At 5 spikes per second per neuron, this column would have 300 neurons firing every 3 ms. If the average transmission time between two pools is 3 ms, there could be three synfire waves active concomitantly. These may be distributed over three synfire chains or confined to repeated activation of one chain or any combinations thereof.

Although appealing, this idea failed to materialize when tested in a simulation of a large network of integrate and fire neuromimes, in which excitation and inhibition are balanced. Even when only one synfire chain was embedded in such a balanced network, the network went into a mode of synchronous oscillations. Attempts to remedy this failure took two forms. One solution was to also include inhibitory neurons in each pool. The output of these inhibitory neurons was not exclusively fed forward to the subsequent pool but, rather, fed back to the entire network. The other solution, put forward by Diesmann, was to use dispersed parameters for the neuromimes. In particular, using dispersed thresholds, synaptic potential sizes, and delays for the inhibitory neurons was very useful in avoiding global synchronization. It is interesting that in the past, anatomists classified cortical neurons into more than 60 types, only one or two of which were excitatory neurons (comprising 70–90% of cortical neurons), whereas all the others were nonpyramidal cells – almost all of which are the inhibitory neurons in the cortex.

When the same neuron participates in several pools within the same synfire chain, the chain is not a strictly feed-forward network anymore. At some level of such feedback connections, activity may start to reverberate within the synfire chain. However, here too, the reverberating activity is organized in synchronous volleys.

Computing with Synfire Chains

There have only been a few applications using synfire chains, including finding invariances in a picture, parsing an auditory scene, and parsing French sentences. However, the main application seems to lie in Bienenstock's suggestion to use synfire chains for implementing 'compositional' systems. He posits that only a few cross-links between two synfire chains that obey appropriate timing constraints are necessary to ensure that both synfire chains will act as a wider and more stable synfire chain. This wider synfire chain can in turn lock-in to activities of other synfire chains, etc. Thus, a large structure of synfire chains can be dynamically generated to represent binding of many simple components into a meaningful composite mental representation. This type of binding is dynamic so that a single synfire chain may, under different conditions,

lock-in to a number of other chains and therefore be part of numerous distinct composite representations. In Bienenstock's view, the most important feature of such dynamic binding is that it can be 'vertical,' in which a higher level concept binds to the lower level elements that comprise it.

Hayon has shown by way of simulation and by numerical analysis that hierarchical systems of synfire chains can be used to separate figure from ground, to implement a minimal description length principle, and to exhibit the property of compositionality. However, these demonstrations were for 'toy problems.' It remains to be shown whether synfire chains can efficiently solve such problems in real-world situations.

Abeles showed by way of simulations that two synfire chains with random connections may learn to lock-in to each other if activated synchronously several times and if the synaptic modifications follow a time-dependent synaptic plasticity (i.e., synapses are strengthened if the presynaptic spike precedes the postsynaptic one, and they are weakened if the time order is reversed). Such learning rules were experimentally reported and are dubbed TDSP. It should be noted that to a limited extent even a single neuron can learn to recognize specific spatiotemporal firing patterns, as demonstrated by Gutig and Sompolinsky's tempotron.

Self-Organization of Synfire Chains

Bienenstock and Doursat found that in a random network of excitatory neurons, with simple learning rules, if one seeds synchrony by occasionally exciting w neurons synchronously, a synfire chain will spontaneously be formed. In their model, the total synaptic strength that a neuron can produce or accept was limited. However, other researchers have had difficulties in growing synfire chains in a random network. Typically, one obtains short cyclical structures even with fine-tuning of the model parameters. Levy and Horn called the activity in such cyclic synfire chains distributed synchrony. Apparently, the optimal solution is to use the TDSP learning rule and limit the total cumulative synaptic strength that neurons may produce and receive to spontaneously grow long synfire chains. This was recently achieved by Jun and Jin. Itzhikevich easily grew a synfire braidlike structure in a random network when synapses were very strong so that synchronous excitation by very few neurons (two to four) was enough to reach threshold in the postsynaptic neuron. He called activity in such a network polychrony.

Experimental Evidence

Direct experimental support for the existence of synfire chains requires simultaneous recording of several neurons from one pool and several from the next pool under conditions in which the synfire chain is repeatedly activated. Using current techniques, one can simultaneously record up to approximately 100 neurons; however, these will be dispersed over a few cortical hypercolumns. This sampling is far too diluted. Thus, the most one can hope for is to record a few neurons from the same chain simultaneously. In this case, whenever this chain is activated, one expects to see a precise firing sequence of these neurons. Indeed, there have been multiple reports in the literature about observations of precisely repeating firing patterns.

With the synfire memory capacity described previously, each neuron may take part in up to 100 chains within a hypercolumn, which contains 200 chains. Thus, the chance that a given neuron will participate in a given chain is approximately 0.5. The chance that three neurons will participate in this chain is 0.125. Considering the fact that there are many different synfire chains and that one can record from more than three neurons simultaneously, there could be numerous different precise firing sequences in any recording site. This was reported to be the case in the slice and in behaving monkeys.

It should be noted that activity in synfire chains must result in precisely repeating firing patterns, but the existence of such patterns does not prove that activity is organized along synfire chains. There could be other networks that produce precise firing patterns. When recording intracellular activity from a neuron that is strongly affected by a repeatedly activated synfire chain, one expects to see repeating patterns of membrane voltage fluctuations. This was reported by Yuste to be the case in the slice.

Criticism

The claim that the reported precise firing patterns and repeated voltage fluctuations were real was challenged by several research groups that argued that the statistics used to detect such a pattern were flawed. An elegant solution was provided by Bienenstock and Geman. In their approach, the null hypothesis to be tested is that there is nothing precise about spike timing to within a time window of W ms. If true, then any statistic derived from the spike trains should not be significantly different from the same statistic derived after teetering each spike at random within W ms.

In order to test the null hypothesis, the spike trains need to be teetered many times, a preferred statistic must be computed after each teetering, and a histogram of the statistics must be built. If the statistic of the real data falls within the α percentile of the teetered values, then the null hypothesis can be rejected with a significance level of $1-\alpha$. This method also

Figure 2 Estimating the precision of spikes. A statistic based on the most prominent peaks in cross-correlations was extracted to describe the time precision in the data sets. (a) The distribution of 5000 estimations of the statistic when times were teetered within 10 ms and the statistic of the actual data. Clearly, the probability of obtaining the statistic for real data by chance is less than 1 in 5000. (b) The probability that the statistic was obtained by chance as a function of the teetering window for 5 recording days.

allows for estimating the time precision of the spikes. By making the teetering window W increasingly smaller, one reaches a critical W at which the null hypothesis can no longer be rejected. This critical W is an upper bound for precision. Potentially, with another statistic, better precision could be found. Figure 2, based on the work of Shmiel et al., illustrates these ideas.

Gerstein suggested that a better method of teetering is to use the joint interspike interval for teetering each spike while considering the timing of the spike that preceded it and the spike that followed it. All types of teetering destroy precise timing relations; thus, hasty conclusions about precise firing patterns should be avoided. For example, a perfectly periodic spike train will contain a multitude of multispike patterns that repeat, and their number will be reduced considerably by random teetering.

Summary

Classical anatomy and physiology of the cortex support the idea that activity may be organized in synfire chains. Synfire chains generate and can learn to recognize sequences of coactivated neurons. Therefore, one can create compositional systems from synfire chains. It remains to be determined if, when, and where cortical activity is organized in synfire-like modes and whether real-world problems can be solved by synfire chains.

Synucleins

S Chandra, Yale University, New Haven, CT, USA

© 2009 Elsevier Ltd. All rights reserved.

Identification of Synucleins

The synuclein family is made up of three distinct genes, α-synuclein, β-synuclein, and γ-synuclein. The cardinal member, α-synuclein, was initially discovered in *Torpedo California*, by expression cloning, using antibodies against cholinergic synaptic vesicles. It was named as such as it was localized to presynaptic nerve terminals and artifactually to nuclei. Later, α-synuclein was also identified as the non-amyloid-β component of Alzheimer's disease plaques. Subsequently, a 14 kDa phosphoprotein identified in bovine and rat brains was shown to be another member of the synuclein family, namely β-synuclein. More recently, γ-synuclein was identified as breast cancer-specific gene 1, a gene upregulated in breast carcinomas.

Gene Organization

Synucleins are a vertebrate-specific gene family with no known members in other phyla. Human α-synuclein is located on chromosome 4q21.3–q22, β-synuclein on chromosome 5q35, and γ-synuclein on chromosome 10q23.2–q23.3. Phylogenic analyses of all synucleins show that α- and β-synucleins are more closely related to each other than to γ-synuclein. Still, all three genes have five coding exons. The human α-synuclein gene has two additional 5′ noncoding exons; the β-synuclein gene, one 5′ noncoding exon; and the γ-synuclein gene none. Human β- and γ-synuclein are not alternatively spliced. In contrast, human α-synuclein is alternatively spliced at the first two noncoding exons and at exons 4 and 6. The function of these splice forms is not yet known.

Tissue Expression Pattern

Synucleins are mainly found in neural tissue. Synucleins are abundant proteins and by some estimates account for 0.1% of total brain proteins. Both α- and β-synuclein are mainly found in brain, where they are enriched in presynaptic nerve terminals. They have a wide expression pattern and are expressed in the neocortex, hippocampus, striatum, thalamus, and cerebellum. In songbirds, α-synuclein expression is specifically increased, during periods of song acquisition, in key nuclei that control song learning. Meanwhile, γ-synuclein has a distinct expression pattern and is mainly found in peripheral nervous system, that is, in sensory, sympathetic, and motor neurons as well as the retina. Expression of γ-synuclein is also seen in breast carcinomas. This atypical expression is used as marker of progression of breast cancers as it is especially upregulated in metastatic cancers.

At a subcellular level, all synucleins are found in soluble synaptic fractions as well as associated with synaptic vesicle fractions. Immunoelectron microscopic analysis shows that antibodies to synucleins clearly decorate synaptic vesicles. The sequences that target synucleins to presynaptic terminals are currently unknown.

Structural Characteristics

Human α-synuclein has 140 amino acids, β-synuclein 134, and γ-synuclein 127 amino acids. Synucleins are natively unfolded proteins; that is, they have no secondary or tertiary structure in solution and hence are heat stable. The unusual biophysical properties of synucleins are rooted in their characteristic primary sequence (Figure 1). All synuclein proteins have a highly conserved N-terminal domain with an 11-residue repeat and a less conserved, highly acidic C-terminal domain. The seven imperfect 11-residue repeats have the consensus sequence XKTKEGVXXXX and are highly reminiscent of amphipathic helices of apolipoproteins (class A2). The only divergence from this N-terminal repeat structure occurs in β-synuclein, which has an 11-amino-acid deletion (amino acids 73–83), with profound consequences to its aggregation properties (see the section titled 'Oligomerization and fibrillization'). The central portion of α-synuclein is hydrophobic and corresponds to a fragment known as non-amyloid component (amino acids 61–95; Figure 1), previously isolated from Alzheimer's diseased brains. The C-terminus of synucleins is highly acidic and has many prolines.

Though synucleins are natively unfolded proteins, synucleins can bind and fold on acidic phospholipid surfaces via their N-terminal domain. This folding can also be replicated in anionic detergents such as sodium dodecylsulfate. The structure of the folded conformation of human α-synuclein has been determined using protein nuclear magnetic resonance and electron paramagnetic resonance methods. On sodium dodecylsulfate micelles, the folded conformation consists of two amphipathic α-helices with an unfolded C-terminus. The two α-helices are oriented in an antiparallel arrangement. Recently, human β- and γ-synuclein were also shown to fold into this two-helix conformation on sodium dodecylsulfate

Figure1 Sequence alignment of human α-synuclein, β-synuclein, and γ-synuclein protein sequences. Residues are colored gray to indicate identity across all three synucleins. The green lines outline the seven 11-amino-acid repeats, and the arrowheads show exon boundaries. The stars indicate the position of the three known PD mutations, A30P, A53T, and E46K and the arrow indicates position of the break between the two helices in the α-helical conformation of human α-synuclein.

micelles. On liposomes which have a shallower curvature, human α-synuclein still adopts this two-helix conformation. In this conformation, the inner surface of the helices is apolar, with the basic residues pointing sideways from the helix. This allows the inner surface to interact with apolar detergent/lipid tails and concomitantly for the basic side chains to interact with the acidic head groups. These interactions explain the acidic lipid specificity of α-synuclein binding. In this structure, the C-terminus does not bind lipids/detergents and remains unfolded. As this conformation is conserved among all synucleins, it is likely to be relevant for their physiological functions.

α-Synuclein is phosphorylated, most prominently at Ser 129, which increases its ability to aggregate and form fibrils. α-Synuclein and β-Synuclein are also O-glycosylated. The function of this modification is not well understood.

Oligomerization and Fibrillization

Human α-synuclein can readily oligomerize to higher-order species: first to dimers, then trimers, and then oligomers, culminating in large fibrils or amyloids. Conditions that promote the helical conformation of α-synuclein, such as acidic lipids and polyunsaturated fatty acids, also promote oligomerization of α-synuclein. Posttranslational modifications such as phosphorylation and C-terminal truncations, incubation with metal ions such as iron, and oxidative/nitrative challenges also accelerate fibril formation. It is interesting that human γ-synuclein oligomerizes very slowly, and human β-synuclein does not oligomerize or aggregate. In fact, addition of β-synuclein decreases the rate at which α-synuclein oligomerizes. Sequence divergences, such as the 11-amino-acid deletion in the non-amyloid component region of β-synucleins, have been shown to underlie these differences. Another interesting observation is that mouse α-synuclein oligomerizes very poorly. There are seven amino acid changes between these two species that probably account for this difference.

Protofibrils are transient β-sheet-containing oligomers that are formed during fibrillization. Protofibrils have heterogeneous morphologies, including spherical, annular, porelike, tubelike, and chainlike structures. Protofibrils are the precursors to stable macroscopic β-sheeted fibrils or amyloids seen in α-synuclein pathology (see the sections titled 'Alpha-synuclein and Parkinson's disease' and 'Synucleinopathies'). Protofibrillar α-synuclein, in contrast to the monomeric and the fibrillar forms, can bind liposomes via a β-sheet-rich structure and may even act as pores in the membrane. This finding has led to the hypothesis that α-synuclein protofibrils are neurotoxic.

Thus, human α-synuclein is unique among synucleins in the distinct conformational states it can occupy. Several of these conformations are physiological while others are pathological (Figure 2).

Alpha-Synuclein and Parkinson's Disease

Strong genetic and pathological evidence links the human α-synuclein gene to Parkinson's disease (PD). Three independent mutations in the human α-synuclein gene, namely the A30P, A53T, and E46K, have been linked to early-onset familial PD. These mutations are dominant in nature and hence represent a 'gain of function.' Recently, families with duplication and triplication of the α-synuclein locus have also been identified. Even though these patients have a normal wild-type gene, they develop an autosomal dominant

Figure 2 Model for fibrillization pathway of human α-synuclein. Unfolded monomeric α-synuclein folds on synaptic vesicles in a helical conformation. α-Synuclein can also oligomerize to higher-order species including β-sheeted protofibrils. Conditions that promote the helical conformation of α-synuclein also promote its oligomerization. Eventually, these oligomers form large β-sheeted fibrils or amyloids such as those seen in Lewy bodies.

form of PD. The severity and onset of the disease in these patients appears to depend on levels of α-synuclein protein. The discovery of these mutations and duplications has prompted the search for genetic polymorphisms within the α-synuclein locus and the subsequent testing to determine whether these are risk factors for the disease. So far the data are partly contradictory and far from conclusive.

α-Synuclein is a component of Lewy bodies, the defining pathological hallmark of PD for both familial and sporadic cases. Lewy bodies are eosinophilic cytoplasmic inclusions containing α-synuclein, usually in its ubiquitinated form, and synuclein-interacting proteins such as synphilin, as well as heat shock proteins. Lewy bodies may represent end points in a neuron's attempt to cope with an aggregation-prone protein. There is much debate in the literature over whether Lewy bodies themselves are toxic to dopaminergic neurons. Increasingly, recent data suggest that soluble oligomers of α-synuclein (protofibrils) are the culprits and not large aggregates, as represented by Lewy bodies. One of the strongest pieces of evidence is that the A30P mutation actually slows fibrillization, while the A53T mutation accelerates fibrillization *in vitro*. However, both the A53T and A30P mutants promote protofibril formation, compared with wild-type α-synuclein. Interestingly, dopamine reacts with α-synuclien to form covalent adducts that slow the conversion of protofibrils to fibrils, giving further credence to this hypothesis.

The identification of point mutations in the human α-synuclein gene that cause familial PD has led to many of animal models for PD overexpressing wild-type and parkinsonian mutants of α-synuclein. These models have been generated in a variety of organisms, such as mouse, rat, *Drosophila*, *C. elegans*, zebra fish, and even yeast. It should be noted that several of these lower organisms do not have the α-synuclein gene in their genomes. These models have had mixed success in replicating the characteristics of PD, namely, the dopaminergic neuron selectivity, the α-synuclein pathology, and age dependence. The murine models, depending on the promoter used, show late-onset neuronal cell death and some synuclein pathology/inclusions, but the selectivity of nigrostriatal loss is largely absent. It is interesting that in one such α-synuclein transgenic mouse line, co-expression of β-synuclein inhibited aggregation of α-synuclein, mirroring the *in vitro* oligomerization data. Surprisingly, the best model to date that replicates all three characteristics is the Drosophila model that overexpresses human α-synuclein. Co-expression of the chaperone Hsp70 or pharmacological upregulation of heat-shock factors in this model ameliorates dopaminergic cell loss but does not affect inclusion formation.

In addition to transgenics, viral expression systems have also been used to introduce the α-synuclein gene to specific regions of the midbrain. Lentiviral-based expression of human α-synuclein in rat substantia nigra resulted in selective dopaminergic toxicity with nonfibrillar inclusions. Thus transgenic and viral expression systems, in spite of their limitations, have been very useful to test various hypotheses on the causes of PD, such as protein aggregation, mitochondrial dysfunction, and oxidative stress. These models will continue to be very useful as drug discovery platforms.

The last decade has been very fruitful in finding genes linked to rare familial forms of PD. Starting with the identification of the A53T mutation in α-synuclein, several genes, such as parkin, PINK, DJ-1, and LRRK2, have been shown to cause both recessive and dominant forms of PD. These genes have diverse functions in neurons; for example, parkin is an E3 ubiquitin ligase; PINK, a mitochondrial kinase; LRRK2, a leucine-rich-repeat containing tyrosine kinase; and DJ-1 appears to be a mitochondrial redox sensor. These discoveries have renewed interest

in understanding the ubiquitin–proteasome and mitochondrial pathways and their relationship to the nigrostriatal dopaminergic loss seen in PD. The challenge is to determine whether the various PD genes interact with α-synuclein and lead to a pathway of dopaminergic neuron death.

Synucleinopathies

α-Synuclein aggregates, and pathology is associated with a variety of neurodegenerative disorders besides PD. These diseases include Alzheimer's disease, especially the Lewy body variant, dementia with Lewy bodies; multiple system atrophy; Down syndrome; and Halloverden–Spatz disease. Pathologically, these diseases are now known as synucleinopathies. The pathology seen in these patients' brains is diverse and includes Lewy bodies, amyloid-β plaques, and Lewy neurites. In many of these lesions, synuclein is ubiquitinated or nitrosylated or exists as adducts of dopamine. In spite of their diversity, these pathologies represent common pathogenic pathways and as such are useful to study mechanistically.

Physiological Functions

The presynaptic localization of synucleins and the fact that they are vertebrate-specific suggest that synucleins have a modulatory, rather than an essential, synaptic function. The initial discovery of α-synuclein as a gene upregulated in key nuclei that control songbird learning also suggests that synucleins are important for synaptic plasticity. This premise has been tested in single- and double-knockout mice for α-synuclein and β-synuclein. While, some of the data are contradictory, the overall consensus is that synucleins are not essential for neurotransmission but negatively regulate dopamine transmission in certain paradigms. In keeping with this, α- and β-synuclein double-knockout animals have decreased levels of striatal dopamine levels.

The dopaminergic neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes parkinsonism in both humans and mice. MPTP is transported via the dopamine transporter into nigrostriatal neurons, where it inhibits mitochondrial electron transport. Strikingly, all synuclein knockout mice tested to date (α- and γ-synuclein) are completely resistant to MPTP. Unearthing the mechanisms of this resistance will greatly help in understanding synuclein function and may also shed light on the dopamine selectivity of PD.

Surprisingly, the best clues to the physiological function of synucleins have come from analyzing transgenic mice that overexpress α-synuclein. Paraquat is a herbicide that when administered to mice causes the formation of cytosolic α-synuclein aggregates and the degeneration of nigrostriatal neurons. Mice that express human α-synuclein driven by the tyrosine hydroxylase promoter have been shown to be resistant to the herbicide paraquat. These data were the first to hint at a neuroprotective function of synucleins. More recently, in a genetic study, transgenic overexpression of α-synuclein was shown to completely rescue the neurodegeneration and lethality of knockouts for the presynaptic cochaperone CSPα. Phospholipid binding of synucleins was shown to be important for this rescue. Conversely, deletion of endogenous synucleins exacerbated the CSPα knockout phenotypes. Biochemical analysis of these crosses revealed that synucleins function downstream of CSPα to stabilize/fold substrates of CSPα. These data collectively support a neuroprotective role for synucleins and suggest that the involvement of α-synuclein in human neurodegenerative diseases arises not only from a gain of toxic function but also from a loss of synapse-protective properties.

Prospects

Future research on synucleins needs to address aspects of both their physiological and their pathological functions. In particular, it should (1) define the neuroprotective function of synucleins mechanistically, (2) elucidate the pathological conformations of human α-synuclein, and (3) determine the interplay between human α-synuclein and other familial PD genes.

Syringomyelia

S Sgouros, Birmingham Children's Hospital, Birmingham, UK

© 2009 Elsevier Ltd. All rights reserved.

Introduction

Syringomyelia is the cystic cavitation of the spinal cord extending over a distance greater than two spinal segments (see Figure 1). Often the cavity is referred to with the term 'syrinx,' an ancient Greek word meaning 'tube,' also used for an ancient Greek wooden musical instrument similar to a flute. The syringomyelia cavity contains fluid with a consistency similar to cerebrospinal fluid (CSF). Although the condition was described in 1876 by Leyden and in 1891 by Abbe and Coley, the pathophysiology surrounding the formation of the syrinx and its propagation is still unclear. The advent of magnetic resonance imaging (MRI) has contributed greatly to the understanding of syringomyelia, and its wide use has resulted in an apparent increase in the incidence of diagnosis in adults and children.

Syringomyelia is most frequently associated with hindbrain herniation. Hindbrain herniation, or Chiari I malformation, is the prolapse of the cerebellar tonsils for 5 mm or more beyond the foramen magnum (see Figure 1). In large clinical series, 50–80% of patients with symptomatic Chiari I malformation have syringomyelia. In most patients, Chiari I malformation is regarded as congenital. Acquired Chiari I malformation can develop following lumbar or ventricular shunting. Syringomyelia may be associated also with various other conditions, such as spinal cord tumors, spinal arachnoid cysts, traumatic paraplegia, postinfectious or postinflammatory meningitis (tuberculous meningitis, chemical insults such as antibiotics or Myodil (Pantopaque), epidural abscess, Pott's disease, or idiopathic meningeal fibrosis), various forms of spinal dysraphism (diastematomyelia, spinal lipoma, and recurrent tethering after myelomeningocele repair), and rare malformations affecting the foramen magnum region (achondroplasia, posterior fossa arachnoid cysts, Chiari II malformation, and syndromic craniosynostosis). Syringomyelia commonly affects the cervical and upper thoracic spinal cord, although it can extend throughout the entire spinal cord, and in that case is called holocord syringomyelia. If untreated it follows a progressive course over a number of years. The neurological function of arms and legs is at threat, and patients may eventually become quadriplegic if the syringomyelic cavity continues to extend despite treatment. The cavity may extend both proximally and distally, and the tension of the fluid inside it continues to increase. Long-standing syringomyelia provokes gliosis formation in the cavity walls and the surrounding cord, seen in postmortem examinations. Gliosis inside the cord may lead to progressive neurological loss even after successful surgery and collapse of the cavity. The syringomyelic cavity can reach the upper cervical cord and medulla, in which case the condition is called syringobulbia (see Figure 2), and eventually affect the function of the lower brain stem, producing respiratory failure and death.

Epidemiology

The incidence of Chiari I malformation in the general population is estimated at 7% although not all patients are symptomatic. Syringomyelia has a prevalence of 8.4 cases per 100 000 population. The incidence of posttraumatic syringomyelia is around 1–3% of all paraplegics; most of these patients are male and relatively young. The average time between spinal injury and symptomatic presentation is 7 years (range: 3 months to 30 years).

Pathophysiology of Syringomyelia

In the majority of patients, syringomyelia is associated with an obstruction of CSF flow in the subarachnoid space. Surgical treatments are designed to remove such a subarachnoid obstruction. The block in CSF flow is in most patients in the region of the foramen magnum due to hindbrain hernia (Chiari I mostly, Chiari II infrequently) or in other sites in any of the other conditions mentioned already.

The mechanism of formation of syringomyelia has not been adequately explained yet. In experimental studies, dye injected in the spinal subarachnoid space has been found in the central canal and is believed to have traveled there along the Virchow-Robin spaces beside the vessels of the cord. There have been reports of a presyringomyelic state, seen in MRI scans of patients with Chiari I malformation and upper cervical spinal cord swelling, which subsequently developed syringomyelia. Several theories have been proposed on the formation and propagation of syringomyelia. The most notable ones, in chronological order, are Gardner's hydrodynamic theory, Williams's theory of 'pressure dissociation,' and Oldfield's theory of increased subarachnoid CSF pressure.

Figure 1 MRI scans of a 14-year-old girl presenting with clumsy walking, occipital headaches, and scoliosis. (a) Sagittal T1w image. There is a Chiari I malformation with tonsillar descent down to the arch of C1 vertebra and a large syringomyelia cavity extending from the C5 vertebra to the lower thoracic region. (b) Coronal body view showing marked scoliosis. (c) Sagittal T2w image through the spine. Because of the scoliosis, the spinal cord cannot be visualized in one sagittal image. The syringomyelia cavity is seen but the exact lower end of it cannot be estimated. (d) Still image from the cine phase contrast magnetic resonance imaging loop: abnormal CSF flow can be seen at the craniovertebral junction and inside the syringomyelic cavity.

Figure 2 Sagittal T1w magnetic resonance imaging scan of an 11-year-old boy with previously treated Chiari I malformation and syringomyelia who represented with double vision and unilateral facial palsy. There is recurrent arachnoiditis at the foramen magnum, and the syringomyelia has extended upwards and invaded the medulla, becoming syringobulbia.

- In the 1960s Gardner observed that in patients with hindbrain hernia, the foramen of Magendie was partially obstructed by membrane. He believed that fluid entered the central canal in the obex at the floor of the fourth ventricle due to the 'water hammer' effect of the arterial pulsations on CSF flow. Fluid accumulated inside the central canal, creating the syringomyelic cavity – a condition called 'communicating syringomyelia' or 'hydromyelia.' This led to the operative concept of obex plugging, in which a piece of muscle or cotton wool was used to plug the obex. Syringomyelia not communicating with the central canal was called noncommunicating. MRI studies have shown that in most patients, there is no direct communication between the obex and the syringomyelic cavity. Cardiac-gated cine phase contrast MRI (PC-MRI) studies have shown that during systole, the syrinx cavity contracts, whereas if Gardner's theory were correct, it should expand under the force of inflowing CSF. Gardner's theory is regarded as unsatisfactory nowadays, and the term 'communicating syringomyelia' has been abandoned.
- In the early 1980s, Williams described the concept of 'pressure dissociation' between the head and the spine secondary to the block of hindbrain hernia, based on *in vivo* CSF pressure measurements and *in vitro* biomechanical studies. Every time a Valsalva maneuver takes place (e.g., coughing), the pressure from the chest and abdomen is transmitted to the spinal canal through the valveless venous plexus around the vertebral bodies. Normally pressures are equalized rapidly within the spine. In the presence of a partial subarachnoid block, fluid is forced upwards past the block more efficiently than it can run down again. This leads to a collapsed theca below the block, which exerts a suction effect on the spinal cord (the 'suck' mechanism). Fluid that has entered the cord cavity can extend the cavity (the 'slosh' mechanism). Williams's theories were partly verified by MRI scan observations. Cine PC-MRI has shown that in the presence of hindbrain hernia, CSF movement in the region of the foramen magnum differs between systole and diastole. Williams's observations of pressure differential were not confirmed by other studies of intraoperative CSF pressure measurements, however, and is believed that the sitting position his patients used when he obtained his readings contributed to exaggerated cranial-spinal pressure difference readings due to CSF leakage from the site of the spinal measuring needle.
- Using preoperative PC-MRI scanning and intraoperative CSF pressure measurements in patients with syringomyelia and Chiari I malformation, Oldfield's group observed that CSF velocity was increased at the foramen magnum but CSF flow was decreased, cervical subarachnoid CSF pressure was increased, spinal CSF compliance was decreased, and syrinx CSF flowed caudally during systole and cranially during diastole. The group surmised that the prolapsed cerebellar tonsils act like a piston, partially occluding the subarachnoid space and create a state of increased subarachnoid pressure waves, which compress the spinal cord from without and force CSF into the syrinx cavity and propagate it with each heartbeat.

All these theories do not explain exactly how and where CSF enters the cord and the mechanism of formation of septations inside the syringomyelic cavity.

In patients who suffer spinal cord trauma, cord contusion leads to edema, blood effusion, and subsequent liquefaction, leading in up to 50% of patients to cavity formation, the 'primary cyst.' Commonly the cyst at the site of the injury is separated from the syringomyelia by an intact septum. The syrinx may go flat above and below the injury site following treatment, and the primary cysts may remain unchanged. As the acute injury settles, inflammation is followed by adhesions in the subarachnoid space and gliosis in the cord. Obstruction of the CSF pathways may be compounded by narrowing of the bony spinal canal due to the spinal fracture. Fluid may enter the cord at the fracture site, where the cord is usually thin-walled.

For forms of syringomyelia associated with other pathologies (dysraphic states, spinal cord tumors, and spinal arachnoid cysts), there has been no satisfactory explanation of how CSF enters the spinal cord, and an analogy to hindbrain-related syringomyelia is currently accepted. The presence of arachnoid adhesions appears important in the formation of syringomyelia.

Posterior Fossa Volume

It is postulated that hindbrain hernia is caused by a small posterior fossa. Early studies on lateral skull radiographs and later studies on computed tomography or MRI scans showed that posterior fossa volume and dimensions are smaller than normal in patients with Chiari I malformation due to presumed maldevelopment of the occipital enchondrium. A recent study focusing on children demonstrated that patients with Chiari I and syringomyelia have posterior fossa volume significantly smaller than normal whereas those without syringomyelia have normal posterior fossa volume, especially in the first 10 years of life. These findings challenge the view that the development of syringomyelia represents an evolutionary stage of the Chiari I malformation.

Clinical Features

Presenting Symptoms

Patients with hindbrain-related syringomyelia often present with symptoms of Chiari I malformation, and the syringomyelia is discovered on MRI scan. The symptoms can be grouped into those of pain, sensory and motor deficits, and disordered autonomic functions. Severity of symptoms can vary, and there are patients who remain completely symptom free for long periods.

Symptoms associated with Chiari I malformation include headaches that are usually, but not always, occipital and that worsen on physical exertion and straining; occasional clumsiness and poor coordination with hands; and ocular symptoms such as blurred vision, diplopia, or oscillopsia. Other, rare symptoms are dizziness, unsteadiness (disequilibrium), tinnitus, vertigo, hyperacusis, nystagmus, dysphagia, sleep apnea, dysarthria, tremor, facial pain or numbness, shortness of breath, and syncopal (drop) attacks.

Symptoms related to syringomyelia include weakness or clumsiness in arms and legs, paresthesia, dysesthesia and pain, unsteady gait, and muscle atrophy and spasticity. Pain is commonly a prominent feature. In a small percentage of patients there may be urinary and fecal incontinence and impotence in male patients. Syringobulbia commonly presents with spreading facial numbness. Swallowing and voice may also be affected, then vision, hearing and finally respiratory function.

Clinical Examination Findings

In patients with Chiari I malformation or syringobulbia, clinical examination findings include lower cranial nerve and cerebellar signs. A small minority have impaired visual acuity, extraocular muscle palsy, nystagmus, and papilledema. Other signs from lower cranial nerves include facial sensory loss, sensorineural or conductive hearing loss, impaired vestibular function, vocal cord palsy, and impaired gag reflex. Cerebellar signs such as dysmetria or truncal ataxia are not uncommon.

In patients with syringomyelia, long tract signs are common. Patients can have sensory deficit over arms and/or legs of spinothalamic and/or dorsal column type, not always following dermatomal distribution. It is usually unilateral and tends to involve the upper limb early. The traditionally described pain–temperature dissociation due to loss of pain and temperature sensation with preserved light touch and joint position sense is rare. Patients can have weakness of arms and/or legs, often unilateral, not always following a myotomal distribution. In advanced cases, there may be claw deformity in the hand with wasting of all the forearm and arm musculature and fasciculations. Dystrophic (Charcot) joints can be seen. Hyper- or hypo-reflexia can be present, often asymmetrical. Spasticity can affect any limb. Scoliosis is common in children and young adults with syringomyelia. Short neck and low hair line are seen in patients with basilar invagination. Horner's syndrome is seen infrequently. Gross disturbance of sweating can occur, either dry skin or hyperhidrosis.

In patients with spinal cord injury, incomplete paraplegia that deteriorates or ascends and the development of new autonomic features may imply syringomyelia. In complete paraplegia, improvement of leg spasms, alteration of sweating patterns, and impairment of other autonomic functions such as bladder and bowel control and sexual function could imply downward extension of the syrinx. Pain is common in posttraumatic syringomyelia; a paraplegic complaining of severe pain has syringomyelia until proven otherwise. Syringomyelia can be confused with chest or abdominal pathology.

Radiology

MRI scan is the investigation of choice and confirms the diagnosis in most cases. Computed tomography myelography, acquiring late views to visualize contrast in the syringomyelia cavity, remains useful in patients

with severe claustrophobia or magnetic implants. Plain radiographs of the spine are useful in patients with scoliosis, bony malformations, or posttraumatic kyphosis. Flexion–extension views can provide information on possible spinal instability.

MRI scanning shows the Chiari malformation and the extent of the syringomyelia cavity and septa, especially T2-weighted sequences (see Figure 1). Around 15% of patients have hydrocephalus. Other pathologies are clearly demonstrated. Children with profound scoliosis can be difficult to visualize in MRI scanning. As the curvature of the spine can be extensive, it may not be possible to have the entire spinal cord in a single sagittal view, and it may be difficult to correctly count the vertebral levels and identify the full extent of the syrinx (see Figures 1(b) and 1(c)). Children with significant scoliosis can have syringomyelia in the absence of Chiari I malformation. Posttraumatic syringomyelia and its relation to primary cysts shows well in MRI scans (see Figure 3), although in some patients with extensive spinal fractures, it may be difficult to identify the complexity of the bony injury. Diastematomyelia and spinal lipomas are clearly seen, and commonly the syringomyelia cavity is not extensive (see Figure 4). Spinal cord tumors are clearly identified in contrast-enhanced MRI sequences. Whenever a patient is found to have syringomyelia in the absence of a clearly identifiable associated lesion, contrast-enhanced sequences should be obtained to exclude the presence of spinal cord tumors. In a small minority of patients, no associated lesion is identified. Information relating to CSF circulation can be obtained with cardiac-gated cine PC-MRI (see Figure 1(d)), and its correlation with clinical outcome investigated. Sequential MRI imaging is useful in assessing the results of treatment or in observing patients over time.

Figure 3 Sagittal T1w magnetic resonance imaging scan of a quadriparetic 24-year-old man who suffered a cervical spine fracture during a car accident. His arm function deteriorated 2 years later. There is a wedge fracture of the body of C5 vertebra. There is a large syringomyelia cavity extending from C4 to T1 vertebrae.

Neurophysiological Tests

Nerve conduction studies, brain stem evoked potentials (BSEP), and somatosensory evoked potentials (SSEP) have not proved very useful in clinical practice as usually they are abnormal after clinical symptoms or signs have been established. BSEP and SSEP can be useful intraoperatively in selected patients, such as patients with spinal cord tumors.

Natural History of Hindbrain Hernia and Syringomyelia

Controversy still surrounds the management of hindbrain hernia and syringomyelia, largely due to the lack of prospective studies outlining their natural history. Nobody has ever followed 'asymptomatic' patients with hindbrain hernia for several years to see when they will develop symptoms and how many of them will develop syringomyelia. Experience suggests that completely asymptomatic patients with Chiari I malformation only do not develop symptoms meriting operation later and do not develop syringomyelia.

The general consensus is that a completely asymptomatic patient with hindbrain hernia does not need surgery. The controversy focuses on what constitutes asymptomatic hindbrain hernia. Most patients, on close questioning, present clear evidence of cough-induced headache or occipital pain. Some even admit to arm pain on exertion. In small children, mild motor developmental delay is frequently seen. Other, more subtle symptoms and signs can go unnoticed. There is

Figure 4 Sagittal T1w magnetic resonance imaging scan of a 4-year-old girl with newly presented limp and a hairy patch at the bottom of her spine. There is a diastematomyelia peg at the level of L3 vertebral body tethering the spinal cord. There is a syringomyelia cavity at T11-L1, which did not alter significantly after a cord untethering operation. Scale is in centimeter.

a spectrum of symptom intensity, and the surgeon's expertise in the field will influence which patients would benefit from surgery.

Although sudden neurological deterioration has been described, the percentage of patients with syringomyelia who deteriorate and the time frame involved are not known. Subtle symptoms and signs are easy to miss. This problem is more serious in young children, in whom mild scoliosis and subtle motor developmental delay are difficult to evaluate. Considering that long-standing syringomyelia leads to gliosis inside the spinal cord and irreversible damage, it would make sense to have a low threshold for surgical treatment. Often, though, mild or moderate syringomyelia cavities can stay unchanged for months or even years.

Indications for Surgical Treatment

- In patients with Chiari I malformation with or without syringomyelia, the presence of relevant symptoms and clinical findings indicates craniovertebral decompression. A tense syrinx occupying the cervical cord, even if asymptomatic, merits surgical treatment as it potentially threatens vital neurological functions. In contrast, the patient with a small, two-level cavity and no relevant symptoms can be watched with repeat MRI scans annually.
- The presence of scoliosis in children, even in the absence of other neurological symptoms, requires surgical treatment to stabilize the progress of scoliosis. Most orthopedic surgeons would not contemplate surgical correction of scoliosis in the presence of untreated syringomyelia as the risk of postoperative paraplegia or quadriplegia is significant.
- Patients with posttraumatic syringomyelia merit early surgery as syringomyelia can silently and insidiously threaten their residual neurological function. Surgical decompression is performed on the site of the subarachnoid block, which is commonly the fracture site.
- In patients with dysraphic states, syringomyelia rarely constitutes a problem and an indication for surgery and remains unchanged after successful cord untethering.
- Patients with spinal cord tumors usually require surgical excision for their tumor, which leads to reduction of the syringomyelia cavity. Recurrence of syringomyelia commonly implies tumor recurrence.
- Patients with spinal arachnoid cysts commonly have neurological symptoms from cord compression and require surgical excision of the cyst.
- Patients with postinflammatory syringomyelia usually have significant neurological deficits even before syringomyelia develops, and it is not always easy to determine whether the development of syringomyelia is associated with the development of new symptoms. In general, these patients merit early surgery to avoid clinical deterioration. They need careful radiological evaluation to determine the site of the subarachnoid block and tailored surgical strategy.
- Patients with recurrent syringomyelia and unclear neurological signs require careful assessment. Repeat surgery for such patients often has poor results, and caution should be exercised. Often an initial period of observation and twice yearly MRI scans is a good strategy, with surgery for clear clinical or radiological deterioration.

Surgical Management of Hindbrain Hernia–Chiari I Malformation

Craniovertebral decompression for Chiari I malformation includes occipital craniectomy and removal of the arch of C1 at least, depending on the extent of the hindbrain hernia. This aims to remove the block of CSF flow in the craniovertebral junction due to the

prolapsed tonsils. This technique leads to radiological improvement in up to 80% of the patients. Syringopleural or syringosubarachnoid shunts, when used as primary treatment, have a very poor long-term success rate in the presence of an active subarachnoid block, which acts as a filling mechanism for the syringomyelia.

Controversy exists over whether the arachnoid matter should be opened. Most neurosurgeons prefer to open the arachnoid. The proponents of opening the arachnoid maintain that dissection of the arachnoid adhesions on the foramen of Magendie safeguards against recurrence. The proponents of leaving the arachnoid intact believe that breaching the arachnoid can promote creation of further adhesions due to the intraoperative spillage of blood. Recently, intraoperative ultrasound scanning has indicated that absence of CSF flow at the foramen of Magendie after craniectomy may be an indication for opening the arachnoid membrane.

Another controversial issue is the use of grafting to enlarge the cisterna magna. Most neurosurgeons in North America are in favor of grafting because of a lower incidence of CSF leak. Arguing against grafting, however, is the observation that grafts promote adhesion formation in the cisterna magna. This can be worse in young children, who tend to regrow part of the removed foramen magnum.

Surgical Management of Posttraumatic Syringomyelia

In the 1970s and 1980s, syringosubarachnoid and syringopleural shunts were used widely, but in the past decade, their long-term effectiveness has been questioned. Mechanical complications and infection have been observed. The drain functions for some time, but then the cord collapses around it, and the draining holes become occluded by gliotic tissue. Subsequently the syringomyelia recurs if the filling mechanism has not been corrected. The current treatment of posttraumatic syringomyelia is decompressive laminectomy and subarachnoid space reconstruction by adhesiolysis at the fracture site. This technique results in radiological improvement of the syrinx in 80% of patients.

Surgical Management of Residual or Recurrent Syringomyelia

When failure to reduce syrinx size or recurrence has been observed, reexploration of the craniovertebral junction and extensive dissection of the arachnoid adhesions in all the foramina of the fourth ventricle are necessary. Stents can be placed in the foramen of Magendie to avoid recurrent adhesions. The use of endoscopy to break down septations inside the syrinx cavity was employed in the 1990s but has been abandoned. Recurrent posttraumatic or postinflammatory syringomyelia requires repeat exploration and adhesiolysis. Syringopleural or syringosubarachnoid shunts can be reserved for patients who show poor syrinx response despite adequate surgical decompression.

Management of the Associated Hydrocephalus

The connection between hydrocephalus and syringomyelia has not been elucidated fully yet. Traditionally, hydrocephalus is treated first, before a craniovertebral decompression. Cine PC-MRI evidence suggests that hydrocephalus is due to fourth ventricle obstruction. In practice, though, the ventricles commonly do not decrease in size after craniovertebral decompression. On the other hand, when ventricular shunting is performed first, the syrinx cavity reduces in size, but the need for craniovertebral decompression is not avoided. Recently, endoscopic third ventriculostomy has been used to treat hydrocephalus, with good results for syrinx resolution.

In patients with a ventriculoperitoneal shunt and syringomyelia that has been controlled, recurrence of the syringomyelia implies shunt obstruction until proven otherwise. Shunt revision should be performed before any other surgery is contemplated.

Complications

The complication rate for craniovertebral or spinal decompression is low. Perioperative mortality is rare nowadays. Low rates of wound infection, CSF leak, meningitis, subdural hematoma, urinary tract infection, and thromboembolic complications have been observed. Self-limiting sterile meningitis affects many patients after craniovertebral decompression, most often when the arachnoid has been opened. A very small percentage of patients suffer catastrophic complications such as posterior fossa hematoma, transverse sinus thrombosis, or brain stem infarction due to posterior inferior cerebellar artery damage. Cerebellar sag or slump has been reported as a delayed side effect of craniovertebral decompression. It was more common in the 1980s and 1990s and presented with intractable headaches and lower cranial nerve signs. In recent years there has been a tendency for smaller occipital craniectomy, which has reduced the incidence of this complication.

Treatment Outcome

Up to 80% of patients with hindbrain-related syringomyelia experience clinical and radiological improvement after craniovertebral decompression. Most symptoms improve, but an unfortunate minority of patients experience long-standing incapacitating chronic headaches. Established neurological deficits such as sensory loss and weakness improve little. Muscle wasting and severe lower cranial nerve palsies do not improve. Early myelopathy improves variably. Established spasticity improves little, and often other surgical options have to be used (e.g., intrathecal Baclofen).

In paraplegics, several problems may persist despite resolution of syringomyelia. Loss of pain sensitivity leads to trophic changes in skin or joints. Damage to joints without pain sensation may be severe, leading to neuropathic or Charcot joints. In the shoulder, the head of the humerus may rapidly absorb. The elbow joint can develop osteophytes and limitation of movement. Paraplegic patients have increased risk of developing cervical spondylosis, possibly related to increased use of their arms as a result of the paraplegia.

Up to 15% of patients do not experience postoperative radiological resolution of their syringomyelia. Most of them end up having reexploration of the craniovertebral junction or the spinal decompression site and division of residual arachnoid adhesions, with variable result. Patients with recurrent syringomyelia and/or recurrent arachnoiditis in the foramen magnum or the spinal decompression site tend to deteriorate with time. Despite radiological control of the syrinx, a significant number of patients continue to deteriorate clinically, possibly due to progressive gliosis around the syrinx walls.

Intracranial Hypertension and Syringomyelia

Intracranial hypertension in the absence of hydrocephalus may be more common among these patients than previously realized. There have been reports of incidence of papilledema up to 13% in patients with hindbrain hernia, and some patients have intracranial hypertension without papilledema. It is possible that those who do not demonstrate resolution of syrinx following successful surgery may harbor intracranial hypertension.

Future Development

Advances in imaging and noninvasive methods of measuring increased intracranial pressure may help the neurosurgeon better identify which patients need surgical treatment. Patients with syringomyelia benefit from support systems and help groups.

Tactile Coding in Peripheral Neural Populations

A W Goodwin and H E Wheat, University of Melbourne, Parkville, VIC, Australia

The sense of touch is used by humans to provide a vast array of information about objects in the environment. There are many features, such as the compliance or softness of an object, that can only be determined by using touch. Other features, such as the texture of a surface, can be determined visually, but resolution is greater with touch, which is thus the preferred mode.

Invariably tactile perception requires hand movements. In some cases, the motor control component is relatively simple, principally providing contact with the object or providing relative motion between the skin and the surface; an example is determining the texture of a surface by rubbing the fingers over the surface. Such touch is often termed active because the relative motion is generated by the observer, but tactile sensation is also possible via passive touch, in which the relative motion is generated by a machine or a second person. In contrast, many operations are true sensorimotor tasks in which tactile sensation and hand movements are interdependent; two simple examples are operating a computer mouse or inserting a catheter into a vein.

During complex manipulations, tactile input may give rise to conscious sensation and perception or it may be used by the motor control system without conscious sensation. In general, the sensory signals lead to both perception and motor control.

The Sensors

The palmar (front) surface of the hand is covered by specialized skin called glabrous skin (Figure 1). The more superficial epidermis and the deeper dermis are arranged in an interlocking pattern of grooves and ridges. This undulating pattern is visible in the thick layer of keratin that covers the epidermis, particularly on the fingertips, where it forms the characteristic fingerprint patterns which vary from individual to individual.

There are four classes of mechanoreceptors in glabrous skin; these are the sensors that mediate touch. Two of the receptor types, Meissner corpuscles and Merkel complexes, are located relatively close to the surface of the skin. Meissner corpuscles are located in the most superficial part of the dermis, in the crests of the waves called the dermal papillae. Merkel complexes are located at the epidermal–dermal junction at the base of the downwardly protruding limiting ridges of the epidermis. The remaining two receptor types are located further from the skin surface. Ruffini organs are located within the dermis and Pacinian corpuscles are located both deep within the dermis and also below the dermis in subcutaneous tissues. This difference in the depth of the receptors is reflected in a difference in their spatial properties.

Based on their structure, the mechanoreceptors can be divided into two groups. Each Meissner corpuscle and Pacinian corpuscle is surrounded by a capsule, and within the capsule the structure is laminated with layers of nerve terminals or connective tissue separated by layers of fluid. In contrast, the Ruffini organs and Merkel complexes do not have a laminated structure. This structural difference between the two groups results in a difference in their temporal characteristics.

The mechanoreceptors are the terminations of sensory neurons with somas or cell bodies located in the dorsal root ganglia. The axons which extend from the receptors to the cell bodies form the sensory component of the peripheral nerves. These fibers, sometimes referred to as primary afferent fibers, are large myelinated fibers ($\sim$5–12 μm in diameter) which conduct action potentials rapidly ($\sim$30–70 m s^{-1}). A single fiber may end in a single mechanoreceptor, but more commonly it will innervate many mechanoreceptors. Conversely, a single mechanoreceptor may be innervated by a single fiber or by more than one fiber.

Single-Fiber Responses to Simple Stimuli

Recording responses in single peripheral nerve fibers, in both monkeys and humans, is relatively straightforward. In anesthetized monkeys, the peripheral nerve is exposed surgically and microdissected, or successively split, until a single functional axon can be draped over an electrode and its action potentials recorded. In awake humans, a sharpened microelectrode is inserted through the skin into the peripheral nerve and positioned so that action potentials can be recorded from a single axon.

In early studies of cutaneous mechanoreceptors, the stimulus consisted of a handheld probe indented into the skin surface. Sometimes the probe was rigid, such as a glass rod, but more commonly it was a monofilament (von Frey hair), which provided some rudimentary control over contact force.

Limited though these stimuli were, they did enable classification of the primary afferent fibers into four unambiguous groups. Two classes respond during the dynamic phase, when the probe is indented or

Figure 1 A cross section through glabrous skin. The upper layer, or epidermis (b), is covered in thick keratin (a). Both the epidermis and the underlying layer, the dermis (c), have a wave-like structure. Peripheral nerve fibers, shown in blue, terminate on four types of mechanoreceptors: the Meissner corpuscles (d), the Merkel endings (e), the Ruffini organs (f), and the Pacinian corpuscles (g). Reproduced from Darian-Smith I (1984) The sense of touch: Performance and peripheral neural processes. In: Brookhart JM, Mountcastle VB, Darian-Smith I, and Geiger SR (eds.) *Handbook of Physiology, Vol. 3: The Nervous System,* pp. 739–788. Bethesda, MD: American Physiological Society, used with permission from American Physiological Society.

withdrawn from the skin, and during the static phase, when the probe is in contact with the skin without change in indentation. These are termed slowly adapting (SA) afferents. One class, with small well-defined receptive fields, is termed SAI ,and the second class, with larger less well-defined receptive fields, is termed SAII. The remaining two classes of afferents respond only during the dynamic phase of stimulation and are silent during the static phase. These are termed fast-adapting (FA) afferents; FAI afferents have small receptive fields, and FAII afferents large receptive fields. There is clear evidence that SAI afferents terminate in Merkel complexes and strong evidence that FAII afferents terminate in Pacinian corpuscles. There is reasonable evidence that FAI afferents terminate in Meissner corpuscles and, by exclusion, it is generally accepted that SAII afferents terminate in Ruffini organs. The more superficial receptors (Meissner corpuscles and Merkel complexes) give rise to small well-defined receptive fields (type I afferents), and the deeper receptors (Pacinian corpuscles and Ruffini organs) are associated with larger less well-delineated receptive fields (type II afferents). The receptors with a laminated structure (Meissner and Pacinian corpuscles) result in a transient response in their innervating axons.

The introduction of electronically controlled stimulators enabled the temporal profile of the probe indentation to be varied accurately and also allowed for the indentation amplitude or the contact force to be controlled. Using such stimulators, it was shown that FA afferents responded to the velocity as well as the depth of indentation and therefore responded well to vibrating probes. For any stimulus parameter, individual afferents differ in their sensitivity. For example, individual SAI afferents show a range of indentation thresholds and individual FAI afferents show a range of velocity thresholds.

A key factor that limits tactile resolution is the density of the mechanoreceptors and, more critically, the innervation density of the associated primary afferent fibers that convey the tactile information to the central nervous system. Density varies with the afferent type and with the location on the hand. Density of the FAI and SAI afferents increases distally, reaching a maximum on the fingertips of approximately 1.4 and 0.7 afferents mm^{-2}, respectively. Density of the FAII and SAII afferents is significantly lower, approximately 0.14 afferents mm^{-2}, and is fairly uniform over the hand.

Coding of Simple Stimuli

Accurately controlled indenting probes allowed afferent responses to be characterized quantitatively and allowed human perception to be quantified in matching psychophysics experiments. By comparing the neural and psychophysical responses, conclusions were drawn about how the characteristics of the simple probe stimuli were coded in the neural responses. As an illustration, at frequencies around 10 Hz the human threshold for detecting vibration on glabrous skin matches FAI afferent thresholds and is well below FAII afferent thresholds. Conversely, at 300 Hz the human threshold matches the FAII afferent thresholds and is below the FAI afferent thresholds. Thus, it can be concluded that high-frequency tactile vibration is coded by FAII afferents and low-frequency vibration (sometimes called flutter) is coded by FAI afferents.

Although they are seminal and extremely useful, it is important to recognize that studies such as this only scratch the surface of the highly complex issue of coding. The next step requires measuring the statistical distribution of the afferent properties (in this case, threshold), some model of how the responses of the many responding afferents are combined, an allowance for noise or neural variability, and finally a precise comparison of the combined neural responses with the human performance. An obvious and perhaps more important limitation of these early studies is the nature of such stimuli. They cannot readily be related to the tactile stimuli we encounter daily and rely on for successful perception and manipulation of objects.

The Nature of Tactile Stimuli

When we handle objects in everyday life, there are a number of properties of those objects that we are aware of and that we can make judgments about should we wish to. Three of the more obvious are: surface texture (which encompasses roughness), size, and shape. This is true for immobile objects that we explore with active touch, such as a large statue, and also for mobile objects that we manipulate, such as a piece of fruit. When we manipulate a mobile object, several additional parameters affect the cutaneous mechanoreceptor responses; these include the grip forces (normal to the skin) that we employ, the load forces (tangential to the skin) imposed by gravity, and the distribution of the contact points on the hand. All commonly encountered tactile stimuli have both temporal and spatial components.

These properties of the manipulated object are far more complex than the simple indenting probes that were used initially to study the mechanoreceptors. In order to gain a more realistic appreciation of the nature of mechanoreceptor responses, it is therefore necessary to employ complex stimuli that can be directly related to real, everyday tactile events.

How is it possible for the cutaneous mechanoreceptors with apparently simple transduction properties to convey information about such complex stimulus properties, and how do they convey, simultaneously, multiple properties without ambiguity? As discussed next, such rich information is contained in the responses of whole populations of afferents.

What Is a Population Response?

If all the active neurons had identical responses to the stimulus and there was no variability in the neural responses, then a single neuron would convey as much information as a group of neurons. But this is never the case. There is always some degree of neural noise or variability, and the statistical reliability of the combined (summed or averaged) responses of a group of neurons is greater than the reliability of the individual neural responses. This improvement in signal-to-noise ratio is the simplest way in which information transmission by a single neuron is enhanced by a population of multiple neurons.

In most cases, the power of the population response is much greater than a simple enhancement of statistical reliability. Rather, the spatial and temporal patterns within the population contain a wealth of information about the stimulus and can simultaneously encode multiple stimulus parameters.

To measure a population response experimentally, it would be necessary to record the single-unit activity of all the responding neurons simultaneously. This is not possible with existing technology. Therefore, the only way to study population responses currently is to model them in some way by reconstructing the population response from individual single-unit recordings.

A Simple Population Model

In the tactile system, the earliest examples of population models stemmed from mapping the spatial characteristics of receptive fields of primary afferent fibers with an indenting probe. A typical receptive field, for an SAI afferent, is illustrated in Figure 2. The neuron

Figure 2 The receptive field profile of a single SAI afferent mapped using an indenting probe with a spherical tip of radius 1.44 mm (curvature 694 m^{-1}). The probe was positioned successively at 1 mm intervals on a line through the receptive field center. Alternatively, the profile may be viewed as the response of a population of identical SAI afferents with their receptive fields located along a line on the skin. imp, impulses; SAI, slowly adapting type I.

is most responsive to indentation at the center of the receptive field, and the response reduces successively as the probe is applied at points on the skin successively further from the center. This is the receptive field profile of a single SAI afferent, measured at 1 mm intervals, but it can also be interpreted as a population profile as follows. Consider an array of identical SAI fibers, with receptive field centers separated by 1 mm, on a region of skin in contact with an indenting probe. The afferent with a receptive field center directly under the probe responds most vigorously, and afferents with receptive field centers successively further from the probe respond successively less vigorously.

Texture

Sometimes we wish to determine the texture of an object's surface, and we do so by scanning our fingertips over the surface. We can make fine discriminations, for example in the roughness of a piece of wood we are sanding. Texture is also an important parameter for the motor control system in object manipulation because of the relationship between texture and the effective coefficient of friction between a surface and the skin.

For experimental purposes, surfaces with controlled and easily quantifiable textures are readily achieved by gratings of alternating grooves and ridges or by embossed patterns of raised dots, both of which are easy to manufacture. Commonly, the peripheral neural population response for such textures is approximated by reciprocally interpreting a single afferent's receptive field properties. The approach is analogous to that illustrated in **Figure 2,** except that, instead of stepping the stimulus across the receptive field, it is scanned over the receptive field at constant velocity. The embossed dots in **Figure 3(a)** are scanned over the afferent's receptive field along the surface's long axis (i.e., in the direction of the arrow), with small shifts between scans at right angles to this axis. In this way, the entire pattern is scanned over the receptive field center. Corresponding two-dimensional plots of evoked action potentials (**Figure 3(b)**) can be interpreted as a simplified population response. At a qualitative level, such plots show the extent to which the population of that afferent class represents the stimulus. In addition, some quantitative analysis can be used to compare these neural responses to psychophysical measures of human perception when the same surfaces are scanned over the subjects' fingertips.

Notwithstanding the power of this approach, it is important to recognize the substantial difference between these response plots and the true population response. First, these plots imply infinite innervation density but, in reality, they are sampled by the afferents with a finite density of some 1.4 or 0.7 mm^{-2} for the FAI and SAI populations respectively. Second, the inherent assumption in such representations is that all the afferents have identical properties. In particularly, no account is taken of the varying sensitivities of afferents, even though it has been shown that SAI sensitivities vary by a factor of around 5. Third,

Figure 3 Responses to a textured surface: (a) surface of embossed dots of graded size; (b) two-dimensional plot of evoked action potentials; (c) plot of degrees of spatial variation in afferent impulse rate. In (a), the surface of embossed dots is scanned across an afferent's receptive field in the direction of the arrow; between scans the stimulus is shifted a small amount in a direction at right angles to the scanning direction. In (b), each dot in the two-dimensional plot marks an impulse evoked in an SAI afferent by the surface. In (c), parts of the surface with different dot sizes produce different degrees of spatial variation in the SAI afferents' impulse rates; this correlates with the human perception of the roughness of those parts of the surface. imp, impulses; SAI, slowly adapting type I. Adapted from Blake DT, Hsiao SS, and Johnson KO (1997) Neural coding mechanisms in tactile pattern recognition: The relative contributions of slowly and rapidly adapting mechanoreceptors to perceived roughness. *Journal of Neuroscience* 17: 7480–7489.

response variability or neural noise is not accounted for, but that will have an obvious impact on resolution in the population.

Shape

When we touch an object, the cutaneous mechanoreceptors relay precise information about the local shape of the object. When we touch the mouse and keyboard during typing, it is very obvious that the key surfaces are concave and the mouse surfaces convex. It is also obvious that the central wheel of the mouse is more convex than the buttons. In human psychophysics experiments, the resolution of the cutaneous mechanoreceptors for such shapes can be measured by using a machine to apply variously shaped stimuli to an immobilized fingertip so that only those receptors are activated. In such experiments humans can discriminate two spherical surfaces that differ in curvature by approximately 10%. We may use such shape information consciously, but it is also important for the motor control system because the characteristics and consequences of load and grip forces vary with the shape of a grasped object. Also, for manipulations in which the fingers move over the object, the trajectories of finger movements depend on the object's shape.

To reconstruct a simplified SAI afferent population response to a sphere, the sphere is indented into the skin at contact points over the two-dimensional receptive field (Figure 4(a)); this is the two-dimensional equivalent of Figure 2. Comparing Figures 4(a) and 4(b), we see how a change in the curvature (shape) of the sphere results in a change in the shape of the population response. In contrast, comparing Figures 4(a) and 4(d), we see how changing a different parameter of the stimulus, namely the contact force between the spherical object and the finger, does not affect the curvature of the population response but results in a corresponding scaling of the response. A third independent parameter of the stimulus is the position of contact of the sphere on the skin. When this parameter is changed (compare Figures 4(a) and 4(c)), neither the curvature nor the scale of the population response is affected but the entire response is shifted, within the population, by a corresponding amount.

In Figure 4 three different parameters have been varied: the curvature (shape) of the sphere, the force between the sphere and the skin, and the position of contact on the skin. From these idealized population

Figure 4 Representation of multiple stimulus parameters in the SAI afferent population response: (a) sphere has a curvature of 694 m^{-1} (radius 1.44 mm); (b) stimulus shape changes to a curvature of 256 m^{-1} (radius 3.9 mm); (c) shifting the stimulus by 1 mm results in the population response shifting by 1 mm (compare to arrow and arrow in (a)); (d) a reduction in contact force scales the entire response correspondingly. ΔCurv, change in curvature (shape); ΔForce, change in contact force; ΔPosn, change in position of contact; SAI, slowly-adapting type I. Adapted from Goodwin AW and Wheat HE (1999) Effects of nonuniform fiber sensitivity, innervation geometry, and noise on information relayed by a population of slowly adapting type I primary afferents from the fingerpad. *Journal of Neuroscience* 19: 8057–8070.

Figure 5 Idealized slowly adapting type I (SAI) afferent population response to a cylinder contacting the skin (radius 5.8 mm, curvature 172 m^{-1}) for two orientations of the cylinder: (a) 0°; (b) 15°. Adapted from Dodson MJ, Goodwin AW, Browning AS, and Gehring HM (1998) Peripheral neural mechanisms determining the orientation of cylindersgrasped by the digits. *Journal of Neuroscience* 18: 521–530.

responses, it is clearly evident how a single population can provide unambiguous information about the three stimulus parameters. The brain can extract the shape of the sphere from the shape of the population response, the contact force from the overall magnitude of the response, and the position on the skin from the location of the response. All three parameters can be extracted independently.

In a similar way, Figure 5 shows how a cylinder in contact with the skin will result in a cylindrically shaped population response. A change in the orientation of the cylinder is evident from a corresponding rotation of the population response. As was the case for the sphere in Figure 4, changing the curvature, position, or contact force of the cylinder will uniquely change the curvature, position, or scaling of the population response. All four parameters of the cylindrical stimulus are clearly and independently signaled to the brain.

Population Codes

So far we have drawn only qualitative conclusions from the population responses. This has been possible because of their isomorphic nature; for example, the impulse pattern in Figure 3(b) resembles the pattern of dots in the stimulus. In order to quantify the population responses and compare them with human performance, it is necessary to extract some response measure relating to each stimulus parameter. Such a measure may be thought of as a population code for that stimulus parameter. How does the pattern of impulses in Figure 3(b) encode the roughness of the textured surface evoking it? Experimental data show that the smoother the surface, the more uniformly the impulses are distributed across the two spatial dimensions of the response. Thus, one potential code for surface roughness is the spatial variation in impulse density. As we see in Figure 3(c), this code corresponds well with the measured human perception of the surface roughness. In a similar way, an inspection of Figures 4(a) and 4(c) suggests that a potential code for the position of the stimulus on the skin is the centroid of the population response. The centroid is independent of the curvature of the sphere and independent of the contact force and adequately explains the human capacity to discriminate differences in position of less than 0.5 mm.

More Realistic Population Responses

Although useful, the population responses shown so far may overestimate the precision of stimulus representation because of their idealistic nature. A neural code extracted from such a population may match human performance and therefore be deemed a viable code, whereas in a more realistic population that same code may not have sufficient resolution to explain human performance and must therefore be rejected as a potential code.

Building on the underlying profiles shown in Figure 4, mathematical and statistical modeling, often in the form of computer simulations, can be used to generate credible population responses and potential codes for the stimulus parameters. A powerful feature of such modeling is that it enables a systematic analysis of the effect of the inherent properties of the population.

One problem with idealized population profiles is the assumption of equal sensitivity or responsiveness for all afferents within a class, which is not the case. In computer models, it is simple to randomly assign a sensitivity to each afferent using estimates derived from experimental data of the sensitivity distribution for a specific afferent class. One set of random sensitivities for afferents with receptive fields along a line through the center of the stimulus is shown in Figure 6(a). The distorting effect this has on the ideal response profile is shown in Figure 6(b). The two-dimensional contour plot in Figure 6(c) shows the

Figure 6 Variation in sensitivity distorts the SAI afferent population response to a sphere contacting the skin: (a) sensitivities along the line $y=0$ were randomly allocated according to the experimentally measured distribution; (b) plot of the resultant distortion (solid line) of the ideal response profile (dashed line); (c) contour plot showing the distorted population response (in impulses s^{-1}) in two dimensions. Adapted from Goodwin AW and Wheat HE (1999) Effects of nonuniform fiber sensitivity, innervation geometry, and noise on information relayed by a population of slowly adapting type I primary afferents from the fingerpad. *Journal of Neuroscience* 19: 8057–8070.

distortion of the ideal profiles of Figure 4. When we view the ideal population profile, it might seem reasonable to propose the position of the peak response as a potential code for the position of the stimulus on the skin. However, when variation in afferent sensitivity is included, the position of the peak shifts and is an unreliable predictor of human performance. The centroid is a more robust measure which averages out the individual afferent sensitivities. Modeling also allows more speculative schemes to be considered. For example, could the brain compensate for varying afferent sensitivity using some prior knowledge or estimate of each afferent's sensitivity? Such knowledge could be accurate or could have varying amounts of uncertainty.

Neural noise, or variability in responses to the same stimulus, is an intrinsic property of all neurons. In reality, the response of each afferent in Figure 4 has a random, or noise, component added, which will distort the profile. If the same stimulus is presented many times, each time the noise component on each neuron will be different and the resultant profile will be different to an extent dependent on the magnitude of the noise. Little is known about the magnitude of such noise in the multitude of neural populations in the nervous system. An additional complication, which is difficult to measure experimentally, is the degree of interdependence of noise or covariance among the members of a population. These are important considerations because different neural codes will be affected differently by different types of noise and different degrees of covariance. An interesting outcome of simulations which incorporate noise is that neural codes akin to population averages, such as the total volume under the curve in Figure 4, are degraded by covariance of noise among the constituent neurons, whereas codes of a spatial nature, such as the centroid, benefit from covariance.

An additional factor that limits resolution in the population response is the finite innervation density of the afferents. Profiles such as those in Figure 6 are not continuous but rather are sampled by the afferents. The best estimates of innervation density for the fingertip are 1.4 and 0.7 afferents mm^{-2} for the FAI and SAI afferents, which are equivalent to a separation between receptive field centers of 0.85 and 1.2 mm, respectively, assuming a uniform pattern of innervation. However, there is some uncertainty about these figures; the estimates are based on a single study in humans and a single study in monkeys, and they result from indirect calculations necessitating a number of assumptions. Moreover, the pattern of innervation is unknown. The Meissner corpuscles and Merkel complexes conform to the pattern of fingerprints (Figure 1), which vary over the fingertip and vary between individuals, but the pattern of convergence between

receptors and innervating afferents is unknown. Models can sample the simulated response profiles at any desired density and in any desired pattern to explore the effect on the stimulus representation and on the resolution of any putative codes. This is particularly pertinent in common neurological diseases, such as diabetic neuropathy, in which some of the afferents cease to function, perhaps in a patchy pattern.

An alternative approach to the computational analysis of neural populations is to simulate a neural network of some sort. One advantage of neural networks is that they can be trained, with known inputs and outputs, without knowledge of or assumptions about the details of the intervening neural processes. This, of course, is also a disadvantage. A more serious criticism of neural networks is that the constituent neurons do not behave like real neurons and the simulation may therefore be of limited value for understanding the human nervous system.

Tactile Texture

C E Chapman and A M Smith, Université de Montréal, Montreal, QC, Canada

© 2009 Elsevier Ltd. All rights reserved.

Tactile surface texture varies along a continuum from smooth to rough. Surface asperities are absent for smooth surfaces such as polished glass or fabrics like satin or silk; rougher surfaces (abrasive papers or burlap), in contrast, are characterized by the presence of surface asperities. The term 'rough' is defined in the Oxford English Dictionary as a "surface diversified with small projections, points, bristles etc; not even or smooth." Roughness is thus a function of multiple tactile elements which may vary in their size, shape (pointed vs. round), and distribution (periodic vs. nonperiodic; distance between elements) on the surface. The material properties of the surface (hardness/softness or stiffness/elasticity) can also contribute to the overall impression of texture: some surfaces are nondeformable (abrasive papers); others are deformable (human skin, textiles). Yet, deformability is not a key element for roughness perception since subjects can scale the roughness of a continuum of abrasive papers or fabrics.

The importance of the physical characteristics of the surface to the perception of roughness has been investigated experimentally using surfaces with randomly disposed tactile elements (abrasive papers) and also simple periodic patterns (gratings formed by alternating ridges and grooves, raised dots similar to Braille dots). The latter approach has an advantage in that the size and spacing, and so the density, of the tactile elements can be varied independently. In contrast, particle diameter, spacing, and density all change with grit value across a range of abrasive papers ('grit' refers to the number of openings per inch (2.54 cm) in the sieves used to produce abrasive papers).

Tactile Roughness Psychophysics

In everyday life, impressions about surface texture are normally obtained by exploring the surface or object with your hand/fingers, using what is termed active touch. The first systematic evaluations of perceived roughness employed abrasive papers. These studies demonstrated that roughness increases with a decrease in the grit value of abrasive surfaces, corresponding to larger particle diameters and lower particle densities. The relationship between perceived roughness and particle diameter has been described as a power function with a slope of approximately 1.5. The Weber fraction (the minimal difference that can be discriminated relative to the magnitude of the standard stimulus) is approximately 0.30 for very fine abrasive papers. This relatively high Weber fraction, which corresponds to an ability to discriminate a 3 μm change in particle density and/or size for a standard surface of 2000 grit (average particle size, 9 μm), may reflect the well-known tendency of the Weber fraction to increase at very low intensities.

As particle density, size, and spacing covary across abrasive papers, however, such studies cannot determine the relative importance of each factor to the perception of roughness. For this reason, subsequent studies have used simple manufactured patterns (grooved metal plates, etched arrays of gratings, or raised dots) to systematically determine the contribution of various physical parameters to roughness appreciation.

Using grooved metal plates, in which case a single dimension can be varied independently, it has been shown that roughness increases as a function of groove width (ridge width constant). In contrast, perceived roughness declines modestly as ridge width is increased (groove width constant). Early experiments were restricted to a small range of surfaces (groove or ridge widths of 0.125–1 mm). In these early studies, spatial period (SP, distance center-to-center between adjacent ridges) *per se* was not the determining factor for roughness because the range of SPs in each series (varying groove or ridge width) was identical (0.375–1.25 mm). These results have since been extended to larger spacings, up to a SP of 3.1 mm, and also finer spacings (0.1 mm SP). The Weber fraction for discriminating gratings is ~0.05, corresponding to a 50 μm threshold for a standard SP of 1 mm. As with fine abrasive papers, the Weber fraction is higher for smaller SPs (0.30–0.50 for a 40 μm SP standard), corresponding to finely textured surfaces.

Further studies to determine the contribution of the physical structure of the surface to perceived roughness have been undertaken using patterns of raised dots, the spacing of which can be varied in one dimension, as with mechanical gratings, or in two dimensions. When spacing is increased in a single dimension, along the direction of scanning, then subjective tactile roughness shows a linear relationship with SP up to 8.5 mm (Figure 1(a)). This relationship is similar to that seen with mechanical gratings, extending the results to a wider range of SPs. When, in contrast, dot spacing is changed in two dimensions (tetragonal patterns), then an inverted U-shaped relation between perceived roughness and dot spacing is obtained (Figure 1(b)): roughness increases with

Figure 1 (a) Mean normalized roughness estimates (± SEM) as a function of longitudinal SP for raised dot surfaces displaced under the finger tip (passive touch). SP was increased in one dimension, corresponding to the direction of the scan (see representative surfaces). A monotonic relation between roughness and SP was found, and this was independent of the scanning speed (trials intermixed during acquisition). (b) Mean normalized roughness estimates ($n = 21$) plotted as a function of the dot spacing of tetragonal arrays of raised dots (active touch). Dot spacing was increased in two dimensions (see representative surfaces). Roughness showed a U-shaped relation with dot spacing. (a) Adapted from figure 4 in Meftah E-M, Belingard L, and Chapman CE (2000) Relative effects of spatial and temporal characteristics of scanned surfaces on human perception of tactile roughness using passive touch. *Experimental Brain Research* 132: 351–361, and reproduced with kind permission of Springer Science and Business Media. (b) Adapted and reprinted, with permission, from the *Annual Review of Neuroscience*, Volume 15 ©1992 by Annual Reviews.

increased dot spacing up to 3.2 mm, and thereafter declines. The apparent discrepancy between the two sets of results reflects, in large part, the fact that the height of the dots in the tetragonal arrays was very low (0.35 mm vs. 1.8 mm for the one-dimensional arrays in A), and it is known that subjective roughness increases with increased dot height (see below). Thus, there may be a family of curves relating roughness perception to the spacing of regular arrays of raised dots.

Several factors related to the physical characteristics of the raised dot surfaces modify overall roughness. Thus, when dot diameter is increased then perceived roughness declines. The latter observation is consistent with the decrease in roughness found when the ridge width of mechanical gratings is increased. In addition, as mentioned above, roughness increases with the height of the raised dots. This observation likely reflects both decreased contact between the skin and the smooth surface forming the floor between the dots and increased mechanical deformation of the skin by the raised dots as the skin penetrates more deeply into the spaces between adjacent raised dots. Finally, lubricating the surface decreases its subjective roughness.

Importance of the Mode, and Parameters, of Touch

One key consideration for tactile roughness is that discrimination of surface roughness is better when there is tangential movement between the skin and the surface, or what can be termed dynamic touch, as compared to no movement or static touch. For example, roughness discrimination thresholds are approximately doubled when using static touch as compared to dynamic touch. The superiority of dynamic touch over static touch can be explained by several factors. First, dynamic touch recruits rapidly adapting mechanoreceptors (RA and PC or Pacinian afferents) as well as slowly adapting mechanoreceptors (SA types I and II), while static touch only activates SA receptors. Second, the discharge rates for SA afferents are higher for dynamic stimuli than for static stimuli, so that the signal-to-noise ratio is increased. Finally, neurons in primary somatosensory cortex show a bias for dynamic as opposed to static stimuli, so that the population of neurons contributing to the processing of the tactile input is potentially larger for dynamic inputs.

There has been a long-standing debate in the literature as to whether or not tactile perception is equivalent with active touch (movement made by the subject; the stimulus remains stationary) and passive touch (surface moved over the skin by an external agent; the subject remains stationary). Intuitively, it seems obvious that active touch should show an advantage, in that the exploration is controlled and presumably optimized by the subject. Passive touch, in contrast, is restricted by the parameters of stimulation imposed by the external agent. Nevertheless, current evidence indicates that if exploration conditions

are suitably matched, then roughness discrimination and magnitude estimates of surface roughness are similar for active and passive touch.

Systematic changes in roughness perception can, nevertheless, be produced by changing the physical parameters of the movement. For example, the psychophysical curve for perceived roughness of mechanical gratings is shifted up when contact force is increased from very light (<0.3 N) to very heavy (~7 N) contact forces. Intermediate estimates are obtained with a contact force closer to that employed during active tactile exploration (~1.5 N). This observation, along with the fact that roughness is a function of multiple tactile elements and that roughness increases with increased dot height (above), leads to the possibility that the change in friction (ratio of the tangential to normal force) offered by the surface contributes substantially to roughness. Recent results indicate that while subjective roughness decreases when kinetic friction (i.e., the friction observed during the actual scanning movement) is reduced by lubricating the surface, the most important variable appears to be fluctuations in tangential force, as reflected in the root mean square of the first derivative of the tangential force, dF/dt. Tangential force variations likely also contribute to the human ability to detect a single raised dot of 1–3 μm on a smooth background.

Another important parameter of exploration, scanning speed, has little influence on roughness estimates, at least for coarser textures. As shown in Figure 1(a), there is perceptual constancy for roughness over a range of scanning speeds (50 and 95 mm s^{-1} here; 10 to 100 mm s^{-1} in other studies). To situate these speeds, fair to good Braille readers scan text at 60–125 mm s^{-1}, while excellent Braille readers use faster scans of up to 190 mm s^{-1}. When very rapid scanning speeds are employed (~200 mm s^{-1}), roughness estimates show a modest decline, likely reflecting the fact that the stimulus is less effective, as there is less time for mechanical deformation of the skin by the tactile elements.

Neuronal Codes Underlying Tactile Roughness

The neuronal codes underlying tactile roughness have been the subject of a number of investigations, mostly concentrating on characterizing the responses of the cutaneous mechanoreceptive afferents in the monkey, and relating these to the results of human psychophysical experiments. This is a difficult task because roughness is critically dependent on surface structure, and this in a number of ways, so that no single physical parameter can describe surface roughness. Moreover, surface texture is a continuum from the micron to the millimeter level. Indeed, it may be overly optimistic to expect that a single neuronal code can explain the subjective impression of roughness across the entire range.

A number of candidate neuronal codes exist. One of the simplest is mean discharge rate, often referred to as an intensive code. Experimental evidence in favor of such a code has been obtained using fabrics, mechanical gratings, and raised dot surfaces. These data are, necessarily, restricted to a consideration of three types of mechanoreceptive afferents – SAI, RA, and PC – because glabrous skin in the monkey lacks SAII innervation. For fabrics, there is limited information suggesting that RA afferents but not SAI afferents show a linear relation between firing rate and surface texture. For gratings displaced sinusoidally over the skin, the mean cyclic discharge rate of all three types of afferent increases with groove width, as does perceived roughness. SAI afferents appear to be particularly important for the tactile roughness of gratings, an observation recently extended down to very fine gratings. But, only PC afferents, and not SAI and RA afferents, show a decrease in discharge rate with increased ridge width as required to explain the decrease in roughness with increased ridge width. This leaves open the possibility that ridge width may be signaled by another code, specifically the temporal frequency (speed/SP) of discharge of the population of afferents activated by moving gratings. For raised dot arrays with two-dimensional changes in spacing, in contrast, the mean discharge frequencies of SAI, RA, and PC afferents take a U-shaped form with increased dot spacing, similar to the psychophysical curve shown in Figure 1(b). But these neural functions all peak at a smaller spacing value than the peak in perceived roughness, so that the correlations with subjective roughness are relatively poor. This observation has been interpreted as suggesting that an intensive code may not be applicable to these surfaces, and by extension to other textured surfaces. An alternative explanation is, however, that the shift in the peak of the U-shaped function may reflect species differences related to differences in the size of the stimulated digit relative to the dot patterns (humans vs. monkeys).

Another candidate is a modal code whereby roughness reflects some combination of inputs from the various mechanoreceptive afferents activated by textured stimuli, an interesting idea since all major types of afferents found in monkey glabrous skin (SAI, RA, and PC) are activated when a textured surface is displaced over the skin. One variant of this, based principally on psychophysical data, is the duplex theory whereby spatial cues are thought to contribute to the appreciation of coarser surfaces (see below),

but vibratory cues (presumably via PC afferents with their exquisite sensitivity to mechanical vibration) are thought to be critical for the appreciation of finer surfaces. Unfortunately, recordings from PC afferents have not confirmed that PC discharge covaries with the subjective roughness of fine textures.

Another possibility is some form of temporal code, an observation consistent with the demonstration that peripheral afferents fire in phase-locked bursts to the temporal frequency of mechanical gratings, and that this periodicity is preserved within the firing pattern of both thalamic and somatosensory cortical neurons. The observation that the subjective roughness of ridge-varying gratings is critically dependent on temporal and not spatial variables suggests that a temporal code may well contribute to roughness appreciation. The close correlation between tangential force variations and roughness also supports the importance of a temporal code. A temporal code is not likely to be exclusive since it is difficult to reconcile with the observation that roughness estimates are independent of scanning speed. Nevertheless, temporal coding could complement an intensive code.

Finally, a spatial code has also been proposed, and is supported by the results of a number of studies. This hypothesis was developed to explain the inverted U-shaped relation between subjective roughness and two-dimensional raised dot arrays (**Figure 1(b)**). The spatial code is defined as the mean absolute difference in firing rate between afferent fibers separated by 2 mm. Such a neuronal code has the interesting property of being insensitive to changes in scanning speed, and so consistent with observations that roughness perception is independent of scanning speed (**Figure 1(a)**). According to the spatial variation hypothesis, differences in the firing rates of SAI afferents innervating skin regions separated by 2 mm are converted centrally, at some unspecified location, into an intensive code that signals roughness independent of the scanning conditions. Critical to this hypothesis, the required fine-grained spatial detail is indeed preserved in the discharge of neurons in area 3b of primary somatosensory cortex. Other studies have, on the other hand, also shown the existence of neurons, including in area 3b, whose mean discharge rate covaries with the SP of either gratings or raised dot surfaces, as predicted by the intensive code. At present, it is not clear if such cells reflect the result of the central transformation suggested for the spatial code, or a simpler intensive code.

The SAI spatial code has been extended to other types of surfaces (gratings, random raised dot surfaces). While SAI spatial variation may be the neuronal code employed across the smooth-rough continuum, SAI mean impulse rate may also contribute since there is evidence that SAI mean impulse rate, as well as SAI spatial variation, both covary with the perceived roughness of fine textures.

Remote Sensing of Roughness

The coding mechanisms described above are applicable to textures explored with the bare finger, that is, direct contact. There is now a growing body of knowledge about remote sensing of texture, using a hand-held probe, particularly important for new technical applications such as haptic interfaces for the remote operation of instruments and training surgical skills within virtual-reality environments. The various approaches taken all share a common theme in using force-feedback through a hand-held tool or implement to guide the operator in interacting with the remote or virtual environment. When using a probe, roughness discrimination has variously been reported to be unaffected or impaired. In contrast, subjective roughness is increased when surfaces are explored with a probe as compared to the bare finger. It is evident that a spatial code cannot account for the appreciation of roughness through a hand-held probe. Instead, roughness must be dependent on vibrations transmitted to the hand through the probe. Vibration sensitivity is highest for PC afferents. They act as high-pass filters and have a threshold of $<1\,\mu m$ for frequencies of 250–300 Hz. RA afferents are also sensitive to vibration, but for lower frequencies corresponding to the flutter range of 2–50 Hz. Their threshold for activation is higher than for PC afferents (10–100 μm). The challenge for the future will be to determine the respective roles of each type of afferent to the remote sensing of roughness.

Summary

Tactile roughness is a rich and varied sensation, dependent on numerous parameters of surface geometry, so that no single parameter can precisely define roughness. The dynamics between the explored surface and the skin contribute to subjective roughness, but these have not as yet been fully characterized. A number of peripheral neuronal codes for roughness have been proposed, and the SAI spatial code has received considerable experimental support. Nevertheless, while a single, parsimonious explanation for tactile roughness is a very attractive idea, alternate hypotheses need to be more fully explored, and this using a variety of different surfaces, covering the entire range from the micron to the millimetre level.

Target Selection for Pursuit and Saccades

R J Krauzlis and L Chukoskie, Salk Institute for Biological Studies, La Jolla, CA, USA

Introduction

When we visually inspect our surroundings, we typically direct our line of sight to objects or features of particular interest, even when those items move. These eye movements are under voluntary control and involve selectively sampling the visual environment because tracking one visual object typically causes the retinal images of other objects to become blurred. Accordingly, these voluntary eye movements are found only in animals that have retinal specializations, such as the primate fovea, that can be used to examine a limited region of visual space at a higher spatial resolution.

There are two types of voluntary eye movements used by animals with foveal vision (illustrated in Figure 1). The first type is saccadic eye movements, which act to quickly move the image of a visual target from an eccentric retinal location to the center of the retina, where it can be seen best. Saccades are rapid movements, reaching peak speeds of several hundred degrees per second and lasting only tens of milliseconds. Consequently, although saccades are typically evoked by stimulus events at latencies of 150–250 ms, the trajectory of saccades is not guided by sensory feedback. Instead, saccades follow a stereotyped profile that depends on the amplitude of the movement. Saccades are typically trigged by visual stimuli, but they can be evoked and guided by other stimulus modalities and can also be directed toward the location of imagined or remembered targets.

The second type of voluntary eye movements is called smooth pursuit, which slowly rotates the eyes to compensate for any motion of the visual target and thus acts to minimize the blurring of the target's retinal image that would otherwise occur. Smooth pursuit is a relatively slow movement whose trajectory is determined by the moving stimulus. Pursuit is triggered by visual stimuli at latencies similar to, but somewhat shorter than, the latencies of saccades (typically 100–200 ms) and generates eye velocities up to approximately $50\,^{\circ}s^{-1}$, continuously adjusted by visual feedback about the target's retinal image. Unlike saccades, pursuit cannot be generated in the absence of a stimulus, although moving targets that are sensed through modalities other than vision can also guide pursuit.

As this brief overview indicates, saccades and pursuit have very different properties. The neural mechanisms for the two types of movements have also been conventionally viewed as involving distinct neuroanatomical circuits. However, during normal behavior the two types of movements are tightly coordinated and almost always act to stabilize the same visual stimulus on the retina (Figure 1). Results from recent behavioral and physiological studies have provided insights into how the coordination between these two motor systems is achieved.

Gating of Pursuit and Saccades

The initiation of both pursuit and saccades involves a break from the state of fixation, which otherwise keeps the eyes from shifting to the new target. This break from fixation is controlled by similar factors for pursuit and saccades, and can be either facilitated or inhibited, depending on the circumstances. In the gap paradigm, the break from fixation is facilitated by manipulating the temporal sequence in which the visual stimuli are presented. In a typical simple eye-movement task, a second target is presented at an eccentric position immediately after the initial foveated target has been extinguished, and saccades and pursuit are evoked at latencies of approximately 150–200 ms. However, in the gap paradigm, the initial foveated stimulus is turned off a few hundred milliseconds before the eccentric target appears, and this simple change consistently reduces the latencies of saccades and pursuit, typically by approximately 20 ms. The decreases in pursuit and saccade latencies show the same dependency on the duration of the gap, suggesting that the release of fixation for the two movements depends on a shared preparatory signal.

Conversely, the inhibition of pursuit and saccades also appears to involve a shared mechanism. In the countermanding paradigm, the break from fixation is inhibited by presenting a stop signal indicating to the subjects that they should cancel the movement that had been previously planned. By varying when this stop signal is presented relative to the go signal (e.g., the appearance of the eccentric visual target), it is possible to calculate how much time is required to cancel the movement. The calculation is complicated by the fact that the final motor pathways for pursuit and saccades are different – in particular, the generation of saccades appears to include an approximately 20-ms ballistic interval that is not present for pursuit. However, once these differences are taken into account, it has been found that the time

Figure 1 The selection of targets for saccades and pursuit is normally tightly coordinated. In this example, the observer's initial eye position is aligned on a quail standing in the grass. To stabilize the image of the dove flying overhead, the observer makes a coordinated combination of saccadic and pursuit eye movements. The saccade rapidly changes eye position (in this case, primarily vertically) based on the position of the new target, as highlighted in green in the traces of eye position and velocity. The pursuit movement smoothly adjusts the velocity of the eyes (in this case, primarily horizontally) based on the velocity of the same selected target, as highlighted in red in the traces.

taken to stop either a pursuit or saccadic eye movement is approximately 50–60 ms. Moreover, both movements show an effect of trial sequence. Pursuit and saccade latencies are longer if the previous trial contains a stop signal than if it does not. These differences occur regardless of whether the previous trial involves the same or different type of eye movement response, showing that the effect involves a shared inhibitory mechanism.

Target Selection for Pursuit and Saccades

In addition to determining whether and when to break fixation, saccades and pursuit also depend on selecting one visual target from among the various candidates within the visual scene. It is well established that the latencies of saccades increase when observers must search the visual field for a unique target among a set of stimuli and that these increases depend on the difficulty in finding the target. Similar increases in latency have been observed for pursuit eye movements when an observer must choose between two stimuli moving in opposite directions. These latency effects suggest that a target selection process might precede the initiation of both pursuit and saccades, but they do not resolve whether these effects are due to a single process or to similar but independent processes. To address the linkage between the two movements, it is necessary to consider the two movements together during the process of selection. Recent studies have addressed this challenge and have produced evidence in favor of two different hypotheses about how target selection for pursuit and saccades is coordinated.

One possibility is that target selection for pursuit is determined by the generation of saccades. When

pursuit of a moving target is initiated, it is typically accompanied by saccades that eliminate the mismatches between eye and target position that were left uncorrected by the pursuit movement. The pursuit eye velocity after the corrective saccade is usually much closer to target velocity than it was prior to the corrective saccade and higher than that observed at comparable times in trials without corrective saccades. This postsaccadic enhancement of pursuit suggests that the execution of the saccade improves the ability of the pursuit system to track the target. A closely related finding occurs when subjects initiate pursuit in response to two stimuli that move in orthogonal directions but subjects are not told at the outset which of the two will be the target. Because the target identity is not known initially, subjects begin smooth pursuit in a direction that tends toward the average of the two motions. After a brief period of this vector-average pursuit, subjects make a saccade toward one stimulus or the other and then pursue that one selectively. Once again, the execution of the saccade is closely related to the ability of the pursuit system to selectively track the target, supporting the suggestion that pursuit target selection is serially linked to the execution of the saccade.

Another possibility is that targets are selected in common for pursuit and saccades. By using a discrimination task that requires subjects to select the target using a combination of horizontal pursuit and vertical saccades, it is possible to compare the pursuit and saccade choices on a trial-by-trial basis. Even though they are aimed in orthogonal directions, pursuit and saccade choices agree on the target much more frequently than expected by chance. In the minority of trials in which they initially disagree (1–13%), pursuit eye velocity reverses direction producing turn-around pursuit that anticipates the choice made by the saccade that follows. These findings suggest that the two choices are guided by the same decision process but that saccades might use a somewhat more stringent decision criterion. Consistent with this view, when performance (e.g., discriminability) is considered as a function of reaction time, pursuit and saccades exhibit nearly the same trade-off between speed and accuracy but saccades tend to be delayed and somewhat more accurate.

How can this evidence of a shared decision process be reconciled with the observations of postsaccadic enhancement of pursuit? One possibility is that the decision signal evolves fairly abruptly but stochastically during single trials. In this case, the occurrence of the saccade provides a temporal marker for when the decision signal reaches a critical level, and we would expect the selectivity of pursuit to increase markedly at about this same time if it is guided by the same decision signal but used different criteria. As expected from this interpretation, there is a telltale correlation between the absolute latencies of the saccades and the differences in latency between pursuit and saccades on each trial. This correlation between relative and absolute latencies is what is expected if two different response thresholds were applied to the same decision signal. On the other hand, it is evident that saccades are not strictly necessary for pursuit target selection because pursuit can selectively follow one stimulus in the presence of distracters even when no corrective saccades are generated.

It may not be initially evident how such a shared decision signal operates because saccades depend on selecting the correct stimulus location, whereas pursuit depends on selecting the correct stimulus motion. However, there is evidence that spatial information has a surprisingly large influence on target selection for pursuit, even though stimulus motion is the crucial signal for driving pursuit eye movements. When subjects are given prior information about the location of the target but not its motion, this reduces the latencies of pursuit much more than when subjects are given prior information about the motion of the target but not its location (Figure 2). Thus, for triggering pursuit eye movements, it is more important to know where the target will be than to know in which direction it will be moving. These findings suggest that spatial attention may play a prominent role in target selection for eye movements. They also provide hints about the likely neural sites and mechanisms involved in coordinating target selection for pursuit and saccades.

Neural Mechanisms of Target Selection for Pursuit and Saccades

The neural mechanisms of target selection for saccades have been studied for many years and involve cortical areas such as the frontal eye fields, lateral intraparietal area, and subcortical brain regions such as the superior colliculus (SC). The mechanisms of target selection for pursuit have not been as thoroughly studied. The middle temporal (MT) area provides the visual motion signals that are most important for driving pursuit, and although neurons in MT area show a preference for the motion of the target, this effect appears to be too small to fully account for the selectivity of the pursuit eye movement. The pursuit area in the frontal eye fields also plays an important role in the control of pursuit and is the only area identified in the cerebral cortex where electrical stimulation can directly evoke smooth eye movements.

Figure 2 Spatial information influences target selection for pursuit more than motion information: (a) trial in which subjects were given prior spatial information; (b) trial in which subjects were given prior motion information. On trials with prior spatial information, a single stationary gabor patch indicated the location of the upcoming target but not its direction of motion. On trials with prior motion information, two stationary gabor patches both displayed drifting gratings that indicated the direction of motion of the upcoming target but not its location. Surprisingly, the average latency on trials with prior spatial information was shorter (~180 ms) than on trials with prior motion information (~220 ms), even though visual motion is the primary driving signal for pursuit. This effect demonstrates the primacy of spatial information in target selection for pursuit eye movements. Adapted from Adler SA, Bala J, and Krauzlis RJ (2002) Primacy of spatial information in guiding target selection for pursuit and saccades. *Journal of Vision* 2: 627–644.

However, in none of these areas is there clear evidence of a mechanism for coordinating the outputs of the pursuit and saccadic eye movement systems. In fact, although many of the same cortical areas are involved in the control of pursuit and saccades, each area contains largely nonoverlapping subregions for the two types of eye movements. How are the outputs from these two different eye-movement systems coordinated? One possibility is that the coordination is accomplished by the same selection mechanisms that control visual attention. There is emerging evidence from physiological experiments supporting the idea that the selective processing of visual stimuli (i.e., visual attention) and the preparation of voluntary eye movements involve overlapping mechanisms. Another possibility, not necessarily excluding the first, is that the coordination is accomplished by subcortical brain regions. The brain stem pathways for pursuit and saccades have long been believed to remain separated until the final motor steps, but recent physiological experiments have identified two regions where signals from the two eye movement systems coincide: the reticular formation and the SC.

The brain stem reticular formation contains the special classes of neurons that make up the saccadic burst generator – the circuit that forms the motor command for saccades. However, parts of this classic brain stem circuit for saccades also appear to be involved in the control of pursuit. For example, one well-known type of neuron in this circuit emits a burst of activity that is related to the pulse of velocity that defines the saccade trajectory. Some of these burst neurons have activity that is related to the velocity of the eyes during pursuit as well as during saccades. The function of this activity related to pursuit velocity is not yet understood, but it might be related to the mechanisms that determine when to trigger corrective saccades during pursuit eye movements.

Even more surprising is the finding of pursuit-related modulation in the activity of omnipause neurons (OPNs). It is well known that OPNs discharge steadily during fixation but stop firing during all saccades. Because this pause in activity is believed to disinhibit the saccade burst generator, OPNs are considered to act as the gatekeepers for saccade initiation. Surprisingly, approximately half of the OPNs also decrease their activity during the onset of pursuit – they do not completely pause their activity but reduce their activity depending on the speed of pursuit. Moreover, microstimulation in the region of the OPNs not only stops saccades but also strongly decelerates pursuit eye movements. These results suggest that the brain stem reticular formation contains an inhibitory mechanism that acts on both pursuit and saccadic eye movements.

The intermediate and deep layers of the SC contain neurons that have long been implicated in the selection of targets for saccades. During the preparation

of saccades, many SC neurons show increases in activity that begin hundreds of milliseconds before the movement, and these increases appear to play a role in representing the possible targets. When the probability that a visual stimulus will be the target is changed, for example by adding extra distracter stimuli, the level of preparatory activity changes in ways that reflect the altered target probability. During a visual search task, when subjects search for a uniquely colored target stimulus amid other colored distracters, many SC neurons discriminate the target from the distracter with a delay that is time-locked to the stimulus onset (rather than saccade onset), suggesting that they play a role in target selection for saccades.

Many of these saccade-related neurons also show modulation in activity during pursuit eye movements. The SC has not classically been viewed as part of the pathways for pursuit eye movements, but this modulation was noted in passing in some of the earliest studies of the SC, and more detailed studies have shown that it depends on where the neurons are located within the retinotopically organized SC map. During pursuit eye movements, each neuron may show a somewhat complicated temporal pattern of activity, but this pattern can be explained fairly simply by considering the position of the tracked target within the neuron's response field. The distribution of activity across the SC map thus provides a real-time estimate of the position of the target in oculocentric or retinotopic coordinates, not restricted to saccades but for orienting movements in general. This target position map hypothesis provides a parsimonious alternative to the widely discussed fixation zone/saccade zone hypothesis, although the issue has not yet been definitively settled.

In addition to indicating the position of the target, the activity of these SC neurons also reflects its behavioral relevance. During a visual search task, many SC neurons exhibit a preference for the rewarded stimulus over irrelevant (i.e., unrewarded) stimuli, and this preference emerges over the course of approximately 100 ms prior to the initiation of pursuit and saccades. By interpreting this preference for the rewarded target as a decision signal, it has been shown that this SC activity can account for the target

Figure 3 Experiment showing that subthreshold stimulation of the superior colliculus biases target selection for pursuit: (a) the site of stimulation matches the position of the visual target; (b) the site of stimulation is opposite the position of the visual target. An electrode placed in the intermediate layers of the superior colliculus is used to apply subthreshold electrical stimulation (i.e., currents too weak to directly evoke an eye movement) during a target selection task requiring a luminance discrimination. When the site of stimulation matches the position of the visual target (a), the percentage of correct responses increases (compared to no-stimulation control trials) and the latency of those correct responses decreases. In contrast, when the site of stimulation is opposite the position of the visual target (b), the percentage of correct responses decreases and the latency of the responses increases. Thus, activation of the superior colliculus biases target selection for pursuit eye movements, even though the required eye movements are directed away from the stimulation site. This experiment therefore demonstrates that the effect of stimulation in the superior colliculus is based on the location of the target and not the direction of the eye movement needed to acquire the target. Adapted from Carello CD and Krauzlis RJ (2004) Manipulating intent: Evidence for a causal role of the superior colliculus in target selection. *Neuron* 43: 575–583.

choices made by pursuit and saccades. Consistent with the behavioral results cited earlier, these results also imply that saccades use a more stringent decision criterion than pursuit, perhaps because errant saccades are more costly than mistakes by pursuit. These physiology results show that activity in the SC provides a neural correlate of target selection for both pursuit and saccades.

There is also recent evidence that the SC plays a causal role in target selection for pursuit and saccades. During a visual search task in which the subject should saccade to the oddball stimulus, it has been shown that, when the region of the SC representing the target is focally and reversibly inactivated, saccades are often misdirected to distracters appearing in unaffected areas of the visual field. During a luminance discrimination task, it has been found that electrical stimulation of the SC – at currents too weak to directly evoke an eye movement – nonetheless biases the selection of targets toward the stimulated location, regardless of whether the target is acquired with a pursuit or saccadic eye movement. The results for pursuit are especially revealing (**Figure 3**). Because the targets for pursuit initially appear at a location opposite to its direction of motion, the experimental design is able to identify effects based on the position of the target (i.e., which stimulus to follow) as distinguished from effects based on the motor commands (i.e., which direction to move). The results provide strong support for the idea that the SC plays a causal role in target selection itself, regardless of the type or direction of eye movement used to acquire the target.

Conclusion

Although pursuit and saccadic eye movements have been conventionally described as separate systems, their outputs are tightly coordinated during normal behavior. Recent findings indicate that this coordination is achieved by shared mechanisms for gating the movements and for selecting the visual target. The neural basis of these shared mechanisms includes the SC and possibly parts of the brain stem saccade generator. It is left for future work to clarify how these mechanisms of target selection for eye movements are related to other types of visual selection, such as the allocation of spatial attention.

Task Switching

Introduction

Task switching is widely considered to be at the nexus of executive control in the human cognitive system. The ability to switch tasks is thought to require extensive high-level cognitive processing, ranging from instantiating abstract representations to preparing task-specific processes and monitoring response selection and execution. The behavioral outcome of this processing is a robust switch cost – slower and more error-prone performance when switching tasks than when repeating tasks.

Switch costs are frequently interpreted as reflecting the duration of time-consuming executive control processes that reconfigure the cognitive system when switching tasks, although this idea is debated in the behavioral literature on task switching. Some researchers have questioned whether switch costs are valid indices of executive control processes, whereas others have challenged the very notion that task switching involves executive control. There is abundant evidence indicating that basic psychological processes subserving attention, memory, and perception contribute to switch costs, compromising the interpretation of many behavioral effects as diagnostic evidence of executive control. Given that the cognitive architecture underlying switch costs and related effects is a matter of debate, it is important to exercise caution when interpreting proposed linkages between neural activity and specific cognitive processes putatively involved in task-switching performance.

With or without full appreciation of this point, many researchers have begun to explore the neural correlates of task switching. An increasing focus on identifying the neural substrates of various components of task-switching performance has produced a wealth of knowledge about task representation, selection, preparation, and switching. However, the quest to identify switch-specific neural mechanisms has proven to be challenging, with mounting evidence indicating that a distributed frontoparietal cortical network underlies task-switching performance.

Task Representation

To perform a task, it is necessary to have access to a representation of the associations between relevant stimuli and responses (i.e., task or stimulus–response mapping rules). A task representation can be considered part of a broader configuration of the cognitive system known as a task set, which includes task-specific processes that act on these representations. Many researchers propose that switching tasks requires reconfiguring the existing task set, in part to instantiate different task rules.

A brain area that is strongly implicated in task representation is prefrontal cortex (PFC). It has been proposed that PFC is involved in the acquisition, representation, and maintenance of abstract task rules for goal-directed behavior. These task rules are assumed to be extracted from past experience, in part through myriad connections to and from sensory and motor areas throughout the brain. The strongest evidence that PFC encodes task rules comes from single-cell recordings in monkeys performing different tasks. When monkeys are cued to adopt a specific task rule for responding to a stimulus, a substantial proportion of single neurons in PFC have been found to fire selectively for a given task rule. These neurons were considered rule selective because they fired after cue onset or during the delay period following the cue, regardless of the specific cue used to signal the task rule. Moreover, monkeys were able to generalize the rule to new, unseen stimuli. Such rule-selective neurons have been identified throughout dorsolateral, ventrolateral, and orbital PFC.

Task rule-selective neurons have also been found in parietal cortex. There is evidence that single neurons in the lateral bank of the intraparietal sulcus (IPS) and on the angular gyrus may encode task rules. These neurons had markedly increased firing approximately 400 ms after cue onset and fired regardless of the perceptual cues associated with each rule, suggesting that abstract task information (rather than the sensory features of the cues) had been encoded.

The evidence implicating prefrontal and parietal cortices in task representation suggests that these brain areas should be active when switching tasks, based on the proposal that task switching involves changing the existing task representation or task set. This suggestion is supported by several studies on task selection, preparation, and switching.

Task Selection, Preparation, and Switching

The primary goal in many task-switching situations is the selection and performance of a relevant task in the face of irrelevant, competing tasks. Task selection becomes crucial when stimuli are multivalent (i.e., associated with more than one task), creating

ambiguity about which task to perform. Such ambiguity can be resolved by presenting a task cue prior to or in conjunction with the imperative stimulus, enabling researchers to investigate the neural underpinnings of how tasks are selected, prepared, or switched in advance or during task execution.

Much of our knowledge concerning task switching has come from studies involving event-related functional magnetic resonance imaging (fMRI), in which researchers measure changes in the blood oxygen level-dependent (BOLD) signal elicited by different types of trials. The basic analytical strategy has been to contrast task switches with task repetitions (or other baselines) to determine which brain areas are more 'active' (i.e., generate stronger BOLD signals) when switching tasks. Although there are potential problems with this strategy (discussed later), it has yielded a large body of knowledge about the neural basis of task switching.

Neural Correlates of Task Switching

As with task representation, there is evidence that PFC underlies task selection, preparation, and switching. There is a general consensus that PFC is involved in various activities related to executive control, such as selective attention, task management, goal maintenance, and the regulation of on-line processing involving the contents of working memory. Evidence suggesting that PFC is involved in goal maintenance in dual-task and task-switching situations has come from several fMRI studies. For example, dual-task performance that involves keeping a single goal in mind activates dorsolateral PFC (Brodmann area (BA) 9), whereas keeping a primary goal in mind while performing concurrent subgoals tends to activate dorsal frontopolar PFC (BA 10). Some researchers have proposed that goal activation in PFC may bias or configure processing in other brain areas to enable implementation of the relevant task set, implying top-down control over task processing. Direct evidence in support of this proposal comes from single-cell recordings in split-brain monkeys performing a cue–stimulus association task; activity in inferior temporal cortex related to task processing was found to be modulated by activity in PFC.

The notion that PFC is involved in selecting and maintaining goals in preparation for performing or switching tasks is the main conclusion from many studies. Bilateral dorsolateral PFC (BA 9/46) activation has been observed following different types of task cues in task switching, suggesting that cue-based selection of task goals is subserved by PFC. Evidence indicates that a similar type of cue-elicited task preparation may occur in an area at the junction of the inferior frontal sulcus and inferior precentral sulcus – the so-called inferior frontal junction (which includes parts of BA 6, 8, and 44). Activation in the inferior frontal junction is separate from that associated with cue encoding and is thought to reflect task management or the updating of task representations in preparation for task switching. However, activity associated with task-switching performance extends to other regions of PFC, such as frontopolar, ventrolateral, and medial PFC.

Regarding the medial surface of the frontal lobes, researchers have also focused on the role of anterior cingulate cortex (ACC; BA 24/32) in task-switching performance. ACC is thought to play an important role in resolving conflict situations and monitoring for errors; therefore, it is likely involved in task selection when stimuli are multivalent and there is a chance of performing the wrong task. In dual-task performance, ACC activation has been interpreted as reflecting response selection among competing alternatives. In task-switching performance, ACC activation has been observed when switching between Stroop color–word tasks, which are thought to require executive control processes to resolve stimulus-induced conflict (e.g., the word 'green' printed in the color red). Even in non-Stroop task-switching situations, ACC is sometimes active and tends to be accompanied by activity in dorsolateral PFC, especially when tasks occur unpredictably and stimulus onset is uncertain. This latter point has received some attention in studies on the effects of manipulating task predictability, either by contrasting fixed and randomized task orders or by comparing cues that either specify the upcoming task or only indicate whether to switch or repeat tasks. These studies have led to the emerging idea that PFC is organized along an anterior–posterior axis, with activation becoming more anterior as task performance requires more endogenous (i.e., internal) control.

Another anterior–posterior axis figures prominently in neuroimaging research on task switching, although this axis extends across the brain from prefrontal to parietal cortex. Consistent with some of the studies on task representation, there is evidence that areas of parietal cortex are highly active when switching tasks. One such area is the IPS (BA 39/40), which has been found to be more active for task-switching than dual-task performance. The IPS is more active when task order is unpredictable rather than predictable, although there is also evidence of its involvement in cue-elicited task preparation. Moreover, there is emerging evidence for possible functional dissociations in parietal cortex, with posterior areas being more active when switching between task-relevant dimensions, and anterior areas being more active when switching between stimulus–response mapping rules.

These activations in parietal cortex tend to be interpreted in relation to activations in PFC. As mentioned previously, PFC is thought to provide top-down control signals for coordinating neural activity in other brain areas. Some researchers have interpreted activation in PFC as reflecting the selection of task-relevant neural pathways or instantiation of the appropriate task representation, with concurrent activation in parietal cortex reflecting the organization or implementation of task-specific stimulus–response mapping rules. In other words, PFC is viewed as the source of preparatory signals for biasing activation in parietal cortex and other brain areas.

Although much of the neuroimaging literature tends to emphasize the involvement of the frontal and parietal cortices in task-switching performance, many other brain areas have been found to be more active when switching than when repeating tasks, such as the cerebellum and various regions in the temporal and occipital cortices. The consistency of these activations across studies is unclear, and functional interpretations of their roles in task switching are lacking, in part because researchers have been more captivated by the frontal and parietal cortices. An important avenue for future research on task switching will be to delve into these relatively unexplored brain areas to determine if and how they contribute to the broader network of neural activity underlying task-switching performance.

Rule Switching

Given that task switching is often thought to require changing task (or stimulus–response mapping) rules, it is useful to search for neural correlates of rule switching in related experimental paradigms. One such paradigm is the Wisconsin Card Sort Test (WCST), which was a precursor to some of the modern research on task switching. In the WCST, subjects are given a set of cards on which stimuli of varying number, color, and shape are printed. The task is to learn to sort the cards into piles related to a specific stimulus dimension (e.g., color), based on feedback from the experimenter. After many consecutive correct responses (indicating that the sorting rule has been learned), the relevant stimulus dimension is surreptitiously changed, and subjects have to discover the new sorting rule (e.g., shape). The process of adopting a new sorting rule is thought to require changing the existing task set; hence, the neural correlates of WCST performance should be similar to the neural correlates of task-switching performance.

There is abundant evidence implicating PFC in WCST performance. Early neuropsychological studies revealed that patients with lesions of dorsolateral PFC performed worse than control subjects. fMRI studies have examined different components of WCST performance within PFC. Activation of the posterior part of the bilateral inferior frontal sulci (BA 45/44) increases as the number of relevant sorting dimensions increases. The right anterodorsal part (BA 46) and bilateral posteroventral parts (BA 8/44) of PFC tend to be more active when a change in the task rule requires shifting attentional set (e.g., to a different stimulus dimension), but only the latter areas are activated when the task rule is merely reversed. Although these findings of bilateral activation in PFC indicate that both cerebral hemispheres are involved in WCST performance, evidence suggests that there is functional specialization, with regions of right lateral PFC activated in response to negative feedback (when the sorting rule changes) and regions of left lateral PFC activated when updating the existing task set. Collectively, these findings of PFC activation, as well as reports of parietal cortex activation, are consistent with the neuroimaging results of many task-switching studies, suggesting that the brain areas involved in WCST performance may overlap with those involved in task-switching performance. Indeed, this suggestion is supported by a meta-analysis of WCST and task-switching studies that revealed a common pattern of distributed frontoparietal cortex activation across these paradigms.

Task-Set Inhibition

The preceding review may convey the misconception that task switching is only about the activation of task representations or stimulus–response mapping rules, but it is important to consider some of the neuroimaging evidence for inhibition in task-switching performance. When switching between different tasks (denoted A, B, and C) across a series of trials, performance is slower on the third trial of an ABA task sequence than a CBA task sequence. This impairment in performance of a recently abandoned task has been attributed to task-set inhibition – the inhibition of a previously relevant (but now irrelevant) task set when performing a different task.

Studies have found evidence suggesting that task-set inhibition involves right PFC, consistent with findings associated with other types of inhibition. Contrasting ABA and CBA task sequences in fMRI work has revealed activation in right lateral PFC (BA 45, 9/46) as well as left inferior temporal cortex (BA 37) and occipital cortex (BA 19). However, these results have been interpreted as reflecting increased task-set engagement in response to inhibition rather than task-set inhibition *per se*. Further evidence for the involvement of right PFC in task-set inhibition comes from the finding that patients with focal lesions of right PFC exhibit no behavioral manifestation of

task-set inhibition, unlike patients with lesions of left PFC and control subjects.

Correlations between Neuroimaging and Behavioral Data

If the various inferences about the roles of different brain areas in task switching are valid, then it should be possible to identify correlations between activations in specific regions and behavioral measures of task-switching performance. A positive correlation has been observed between activation of the left inferior frontal junction (as well as the presupplementary motor area) and the magnitude of a behavioral cuing effect (i.e., the decrease in response time with an increased cue–target interval), which has been interpreted as evidence of cue-elicited task preparation. When switching between Stroop color–word tasks, activation of left dorsolateral PFC is strongest for those subjects who exhibit the weakest behavioral effects related to conflict, suggesting a role for this brain area in task preparation, whereas activation of ACC is strongest for those subjects who exhibit the strongest conflict effects, suggesting a role for ACC in performance monitoring. A finding that is related to the aforementioned results concerns a region encompassing parts of the presupplementary motor area and ACC: as activity in this region increases, switch cost increases. This finding has been interpreted as evidence of neural activity increasing in parallel with the degree of interference at the time of task performance, consistent with the observation of increased switch costs with increased activity in task-irrelevant brain areas. However, there have been some reported failures to observe correlations between switch cost and neural activity, which may reflect the fact that multiple brain areas contribute to task-switching performance, a point discussed later.

Switch Specificity

Research on task representation, selection, preparation, and switching implicates an extensive fronto-parietal cortical network and many other brain areas in task-switching performance. This distributed neural basis for task switching raises an important question that has motivated many neuroimaging studies: are there any brain areas that are specific to switching tasks? This multifaceted question can be approached from three angles: analytical, empirical, and conceptual.

The Analytical Angle

Identifying a switch-specific brain area in neuroimaging research usually requires contrasting task switch trials with appropriate baseline trials. A common baseline used in fMRI studies is the pattern of activation on task repetition trials, resulting in a task switch–task repetition contrast. When a specific brain area is reliably more active (i.e., generates a stronger BOLD signal) when switching tasks than when repeating tasks, this contrast will tend to be significant. Although some researchers have used this contrast to identify brain areas involved in task switching, an important point that is sometimes overlooked is that the contrast indexes relative, not absolute, activation across different types of trials. In other words, a specific brain area may be active on both task switch and task repetition trials but exhibit stronger activation on task switch trials, yielding a significant contrast. It is clearly inappropriate in this situation to claim that the brain area associated with the contrast is switch specific (i.e., it is only involved in switching tasks), and this problem extends to region-of-interest analyses that are based on the pattern of activation associated with task repetition trials.

This issue can be partially addressed through the use of multiple baselines. For example, some researchers have supplemented the task switch–task repetition contrast with a task repetition–fixation contrast in an effort to separate out those brain areas that are active on task repetition trials. There are two potential problems with this strategy. First, the processing required for nontask events such as fixation may differ substantially from that required for task repetition trials, obfuscating the interpretation of any brain areas that yield significant task repetition–fixation contrasts. Second, application of this strategy requires making the assumption that task switch trials not only include switch-specific processes but also all of the processes engaged on task repetition trials, which may not necessarily be the case. This second problem also applies to the use of other tasks (e.g., Stroop color–word tasks) and situations (e.g., dual-task performance) as comparison conditions for task switch trials. Although these tasks and situations may be comparable to task switching (in that they are thought to require executive control processing), the differences between complex tasks may complicate any inferences regarding switch-specific brain areas.

The Empirical Angle

Analytical issues aside, there is little empirical evidence of switch-specific brain areas. Through the use of multiple baselines, some researchers have found that the same brain areas are active on both task switch and task repetition trials, suggesting that task-switching performance is not restricted to a single brain area and that there is no brain area specifically

involved in task switching. This suggestion is supported by contrasts of task-switching performance with other situations (e.g., dual-task performance), which have revealed activation of a common bilateral prefrontoparietal cortical network. Similar findings have emerged from integrative meta-analyses of Stroop and task-switching performance and different types of attention shifting (which included task switching and rule switching). For example, meta-analyses of attention-shifting studies have revealed substantial activation overlap in areas such as medial PFC, medial, superior, and inferior parietal cortex, and premotor cortex (as well as bilateral dorsolateral PFC and bilateral anterior insula, but to a lesser extent); these results have been interpreted as evidence that different types of attention shifting all depend on a similar set of working memory and executive control processes.

Some researchers have argued against the notion of switch-specific brain areas on the basis of other evidence. For example, the lack of a relationship between switch-related neural activity and behavioral measures of task-switching performance has been interpreted as evidence against a switch-specific neural mechanism. An electrophysiological study of changes in the electrical brain potential over frontal cortex, supplemented with fMRI data, did not yield any clear markers of task-switching performance. On a related note, there is evidence that changes in event-related electrical brain potentials following a single task switch trial can persist over a subsequent run of task repetition trials, suggesting that activity on task repetition trials may not be pure (in the sense of not reflecting task switching). A direct implication for fMRI studies of task switching – which typically involve measuring changes in cerebral blood flow over several seconds – is that task repetition trials may not represent an appropriate baseline for task switch trials in standard contrasts.

The Conceptual Angle

The lack of evidence for switch specificity is not surprising if one considers the broader conceptual issue of what is likely involved in task switching. In the behavioral literature, many component processes have been proposed to account for task-switching performance, and it is unlikely that all of these processes are exclusive to task switching or implemented in the same brain area. The idea that task switching requires the integration of various perceptual, attentional, mnemonic, and motor processes is supported by the abundant evidence implicating an extensive frontoparietal cortical network in task-switching performance and the conjecture that frontal areas integrate and coordinate information that is then transmitted to parietal areas for task-specific processing. For these reasons, it may be difficult to find robust correlations between switch cost and neural activity, and the search for switch-specific brain areas may be in vain. Indeed, some authors have argued that attempts to localize any complex cognitive processes in the brain may be misguided because such processes likely involve a distributed, interacting network of brain areas. If this is the case, then perhaps cognitive neuroscientists should focus their efforts on identifying and understanding the functional linkages between different brain areas involved in task-switching performance rather than seeking evidence of switch-specific neural mechanisms.

Conclusion

Despite the fact that the cognitive neuroscience of task switching is only approximately 7 years old, much progress has been made toward identifying the neural correlates of task-switching performance. Research on task representation, selection, preparation, and switching suggests that myriad brain areas – stretching from prefrontal to posterior parietal cortices – are involved in task switching. Although there has been interest in isolating switch-specific neural mechanisms, careful consideration from analytical, empirical, and conceptual angles suggests that no single brain area underlies performance. As researchers continue to delve into the multifaceted nature of task switching, a clearer picture of the intricate functional connections between brain areas will likely emerge, hopefully providing insight into the cognitive architecture of task switching and a window to the broader realm of executive control in human cognition.

Taste: Vertebrate Central Pathways

D V Smith[†] **and J D Boughter Jr.** University of Tennessee Health Science Center, Memphis, TN, USA

© 2009 Published by Elsevier Ltd.

Introduction

The sense of taste provides an important gateway to the body's internal environment by monitoring the ingestion of foods and fluids. This function is reflected in the reciprocal connectivity of central taste nuclei with forebrain areas involved in motivation and homeostatic regulation. The taste sensory organs, called taste buds, are situated at the entrance to the alimentary canal, on the tongue, palate, pharynx, and larynx. Transduction of sweet, salt, bitter, acid, and umami (i.e., L-type amino acids such as glutamate) stimuli occurs via G-protein-coupled receptors and ion channels located on the apical processes of taste receptor cells (TRCs). TRCs make synaptic connections with gustatory fibers of three cranial nerves: VII, IX, and X. These afferents terminate in the nucleus of the solitary tract (NST). From this nucleus, taste information is conducted to either local brain stem circuits, or into higher forebrain pathways.

Gustatory Nuclei

Afferent Nerves

TRCs, contained within taste buds, make synaptic connections with nerve fibers of one of three cranial nerves: VII, IX, or X. Separate branches of the facial (VII) nerve innervate taste buds on the anterior tongue and the soft palate. The cell bodies of these afferent neurons are located in the geniculate ganglion. The chorda tympani branch of VII also provides innervation for a small percentage of taste buds located on the lateral aspect of the posterior tongue. However, the majority of these taste buds, as well as all of those contained in the vallate papilla on the dorsal surface of the posterior tongue, receive innervation from the glossopharyngeal (IX) nerve. The cell bodies of the IXth nerve are located within the petrosal ganglion. Taste buds distributed on the laryngeal surface of the epiglottis receive innervation from the superior laryngeal branch of the vagus (X) nerve, whose cell bodies are found in the nodose ganglion. Both the IXth and Xth nerves are probably involved in the innervation of taste buds on the nasopharynx and esophagus, although the exact distribution of this innervation in either humans or rodents is not well understood. The oral mucosa and lingual epithelium are also innervated by general sensory or general visceral fibers mediating touch, thermal sensitivity, and pain, transmitted via the trigeminal nerve (V), as well as the IXth and Xth nerves.

Nucleus of the Solitary Tract

The NST is located in the medulla, and comprises an important brain structure, largely involved in modulating autonomic function. It is also the site of the first central synapse for taste information. Gustatory and visceral input from cranial nerves VII, IX, and X terminates within the medulla in the NST, in an overlapping rostral to caudal distribution. The most rostral pole of the NST receives afferent input from both the anterior tongue and palate via the VIIth nerve. Input from the IXth nerve overlaps with the more caudal portion of the VIIth nerve distribution within the NST, although it extends to more caudal levels. Similarly, the gustatory input from the Xth nerve, although overlapping somewhat with that of the VIIth and IXth nerves, is distributed more caudally still. The most caudal aspect of the NST receives vagal afferent input from the viscera. A schematic diagram of the ascending and descending connections of the rodent gustatory system, including the NST, is shown in Figure 1.

The ascending gustatory pathway originates primarily from neurons in the rostral central and rostral lateral subnuclei of the NST. The ascending pathway is responsible for the conscious awareness of taste quality, taste hedonics (pleasantness or unpleasantness), and the integration of sensory activity associated with eating and drinking. This projection from NST terminates in the taste area of the parabrachial nucleus (PbN). Other NST neurons, mostly in the rostral ventral region, project ventrally and/or caudally to adjacent somatic and visceral premotor or motor areas, including the caudal NST, the reticular formation, or the hypoglossal nucleus. These projections are responsible for the modulation of ingestive circuits and reflexes such as mastication, licking, swallowing, coughing, and salivation.

The gustatory NST contains several morphologically distinct types of neurons, including fusiform, stellate, or ovoid in shape, although there is as yet no obvious correlation between morphology and function. Transmitters involved in synaptic processing in the NST include γ-aminobutyric acid (GABA), which produces inhibition of activity in NST neurons, and the excitatory amino acid glutamate, which likely acts as a neurotransmitter between

[†]Deceased.

Figure 1 Schematic diagram of the ascending and descending gustatory pathways. Solid blue lines show ascending connections of the rodent gustatory system within the central nervous system (CNS); dashed red lines indicate descending projections. Black lines indicate local circuit projections from NST to medullary nuclei. IC, insular cortex; VPMpc, ventral posterior medial nucleus of the thalamus, parvicellular division; BST, bed nucleus of the stria terminalis; CeA, central nucleus of the amygdala; LH, lateral hypothalamus; PbN, parabrachial nucleus; NST, nucleus of the solitary tract; RF, reticular formation; VII, V, and XII, facial, trigeminal, and hypoglossal motor nuclei; VIIth, IXth, and Xth, axons of peripheral gustatory fibers in these cranial nerves.

gustatory afferent fibers and taste-responsive cells in the NST. Evidence also indicates that taste-responsive cells in the NST are excited by substance P (SP) and inhibited by met-enkephalin, and there exists a potential functional role in taste processing for cholinergic receptors (AChRs), found expressed in NST neurons.

Electrophysiological studies have shown that there is convergence of gustatory input onto neurons of the NST, both within and across receptive fields, including from different taste bud populations such as anterior tongue and palate. Single taste buds on the anterior tongue converge onto chorda tympani (CT) nerve fibers, which converge even further as those afferent fibers innervate neurons of the NST. In addition, there is evidence that axons from different peripheral nerves also converge onto single neurons of the NST. Physiological examination of the gustatory sensitivities of either afferent fibers or NST neurons demonstrates that these cells respond to taste stimuli of different qualities. Investigators have often classified taste neurons according to 'best stimulus' (Figure 2), although this organization is subject to modulation by stimulus type and concentration.

Parabrachial Nucleus

About 80% of gustatory neurons in the NST of rodents send second-order projections to the PbN of the pons, which serves as an obligate relay in the taste system of most mammals. This gustatory projection parallels that of the visceral afferent system. In primates, including humans, there is a direct projection from the rostral NST to the ventral posterior medial nucleus of the thalamus; only the visceral portions of the NST appears to possess a relay in the primate PbN. As in the NST neurons, PbN neurons tend to be broadly responsive to gustatory stimuli of multiple qualities, and in fact electrophysiological evidence in rodents suggests that there is a further convergence of afferent taste information onto cells of the PbN. Studies of conditioned taste aversion suggest that taste-responsive neurons in the PbN play a key role in this form of simple associative learning.

From the PbN, two divergent pathways carry gustatory information into the forebrain. The thalamocortical pathway contains axons from the PbN that terminate in the ventral posterior medial nucleus of the thalamus, parvicellular division (VPMpc), from where axons arise to project to the primary gustatory cortex. Other cells of the PbN project into areas of the limbic forebrain, including the lateral hypothalamus (LH), the central nucleus of the amygdala (CeA), and the bed nucleus of the stria terminalis (BST). Double-labeling studies demonstrated that the vast majority of PbN neurons project into either the VPMpc or CeA, but not both. The PbN projects bilaterally to the VPMpc. The PbN projections to the limbic areas are extensive and reflect the substantial interactions between the gustatory and general visceral sensory systems, as well as the interconnectivity between taste and feeding behavior.

Thalamocortical Pathway

Gustatory thalamus Like other sensory systems, taste projects into a thalamic nucleus. The gustatory thalamic relay is located in the VPMpc of the thalamus, which is a medial extension of the ventral posterior

Figure 2 Across-neuron patterns of responses to six taste stimuli applied to the anterior tongue (0.1 M sucrose, 0.03 M NaCl, 0.003 M HCl, 0.001 M QHCl, 0.1 M KCl, 10 μM amiloride) in 48 individual cells in the nucleus of the solitary tract (NST) of the golden hamster. The concentrations were chosen on the basis of their half-maximal integrated response in the CT nerve. Responses are adjusted for spontaneous rate (impulses per 5 s), displayed at the bottom of the figure. Neurons are grouped from left to right into best-stimulus classes, and ranked within each group according to the magnitude of the response to the best stimulus. Response of any one neuron can be read vertically. Neurons 1–16, sucrose-best (shown in blue); 17–35, NaCl-best (shown in green); 36–48, HCl-best (shown in red). Although these neurons can be grouped according to best stimulus, it can be seen that they are generally broadly tuned, responding to stimuli of more than one quality. Reproduced from Boughter JD Jr., St. John SJ, and Smith DV (1999) Neural representation of the taste of NaCl and KCl in gustatory neurons of the hamster solitary nucleus. *The Journal of Neurophysiology* 81: 2636–2649. Used with permission from The American Physiological Society.

medial nucleus of the thalamus (VPM), the thalamic relay for trigeminal somatosensory information from the head. Therefore, taste representation is found adjacent to tongue somatosensory representation. Additionally, neurons in the VPMpc tend to be responsive to multimodal stimuli such as taste and oral tactile input. Therefore, the activity of these neurons encompasses all forms of sensory stimulation of the oral cavity. Ascending gustatory fibers from the PbN also cross over at the level of VPM to terminate in the contralateral VPMpc, accounting for bilateral responses of thalamic neurons to taste stimuli.

Insular cortex In rodents, gustatory thalamic neurons project to agranular insular cortex, located on the lateral convexity of the cerebrum, dorsal to the rhinal fissure. In contrast, oral somatosensory input to primary somatosensory cortex is targeted to granular cortex, immediately dorsal to the agranular gustatory cortex. In primates, the primary gustatory neocortex corresponds to both the frontal operculum and the buried insular cortex toward the rostral portion of the lateral fissure. Both of these areas receive major input from VPMpc. A second gustatory cortex in primates is located within orbitofrontal cortex of primates but does not receive direct projections from VPMpc. In gustatory cortex, the activity of single neurons tends to be multimodal. Recent studies suggest a role for interactions between ensembles of gustatory cortical neurons recruited during taste discriminations.

Insular cortex has widespread descending projections to subcortical taste and taste-related nuclei, including VPMpc, amygdala, LH, and NST. These descending projections may modulate the processing of ascending gustatory information. Corticofugal input to the NST appears to differentially inhibit gustatory afferent activity through GABAergic mechanisms. This modulation is often bilateral, and there is also evidence for excitatory corticofugal inputs to the NST.

Limbic Forebrain

Cells within the PbN project to the LH, CeA, BST, and substantia innominata. These are brain areas important in food and water regulation, responses to stress, conditioned taste-aversion learning, and mechanisms of reinforcement, reward, and drug addiction. Electrophysiological studies have shown the existence of taste-responsive neurons in several of these areas, including the LH and the CeA. Each of these forebrain targets sends centrifugal axons to both the PbN and the NST and have been shown to produce modulation of brain stem taste activity in the NST and/or the PbN.

Stimulation of the LH produces increases in food intake and alterations in taste preference behavior, whereas damage to this area has opposite effects. About half of the taste-responsive cells in the NST are modulated by LH stimulation. This input from LH tends to be contralateral and excitatory; recent studies indicate responses to taste stimuli were more than doubled by this excitatory influence, with no alteration of spontaneous activity. These effects may in fact enhance taste discriminability by increasing the signal-to-noise ratio of taste-evoked activity. The CeA contains neurons that respond differentially to hedonically positive and negative taste stimuli, and both the CeA and the basolateral amygdala are involved in conditioned taste-aversion learning. Projections from CeA to NST are predominantly bilateral and excitatory. In contrast, descending modulation of the PbN by either LH or CeA is largely inhibitory. Stimulation of the BST produces inhibition of gustatory NST neurons. Collectively, these limbic forebrain targets form an extensive neural substrate that no doubt underlies the modulation of taste activity by physiological and experiential factors. These pathways may be engaged by alterations in blood glucose, gastric distension, conditioned taste-aversion learning, and other physiological conditions known to alter taste sensitivity.

Taste Quality Coding

Historically, there have been two opposing views of how taste information is represented in the activity of gustatory neurons. The across-fiber pattern theory postulates that taste quality is represented by the pattern of activity across the afferent population. Stimuli with similar tastes produce similar patterns of activity. An example of this type of sensory coding is found in the olfactory system, where different odorants activate distinct populations of glomeruli in the olfactory bulbs. The opposing view is that activity in a few distinct neuron types codes taste quality in a labeled-line fashion, that is, neurons responding best to NaCl would code 'saltiness.' An example of this type of sensory coding is found in the somatosensory system, where unique fiber and neuron types transmit information about touch, pain, and temperature. However, neurons higher in the afferent pathway, such as those in the thalamus and cortex, are typically multimodal and integrative in terms of sensory quality and receptive field. For taste, temporal aspects of the neural response may also encode information about quality, especially in populations of cortical gustatory neurons.

The gustatory sensitivities of peripheral axons and central neurons in rodents are well established. At each step of the gustatory pathway, from afferent fiber to cortex, neurons tend to be broadly tuned, or responsive to stimuli from multiple qualities: sweet, salt, acid, and bitter (Figure 2). Taste neurons may be classified

according to the stimulus, among a set representative of each quality, that evokes the strongest response. Within each best-stimulus group, response profiles for gustatory neurons tend to be similar, suggesting a certain amount of homogeneity within groups. Hierarchical cluster analyses of responses of taste fibers in the CT nerve, and among gustatory neurons in the NST or PbN, provide strong support for the classification of these neurons into types, based on similarities and differences in their response profiles. However, the broad tuning means that taste-evoked activity in one cell alone cannot unambiguously represent taste quality. Rather, neuron types play a critical role in establishing unique patterns of neural activity that distinguish among taste stimuli. An example of this type of neural substrate for discrimination concerns the responses to salts such as NaCl and KCl in the rodent NST. Patterns of neural activity evoked by these two stimuli at isomolar concentrations across all cell types are distinct, resulting in a low across-neuron correlation. Yet within particular subgroups, such as HCl-best or sucrose-best neurons, the correlation is high, suggesting that discrimination can only occur when the relative response across all cell types is considered.

Introduction

Narrowly viewed, taste is the perception of sweet, salt, sour, bitter, and possibly umami (meaty savory flavor of some amino acids) sensations. However, colloquially, taste refers to oral sensations from foods and beverages, in which taste combines with other sensory inputs to produce a complex sensation. Recently, interest in taste as a field has increased with the discovery of genes that encode receptors for bitter and sweet compounds and provide better understanding of taste transduction. Equal progress has been made in taste psychophysics – the study of the relationship between physical stimuli and the perceptions they induce. Modern psychophysical methods permit the characterization of normal variation in taste as well as variation associated with aging and environmental insult. Appropriate taste psychophysical methods are needed to fully understand genetic, molecular, and neurochemical processes involved in taste sensation. Through taste psychophysics, scientists and clinicians can determine how normal and abnormal variation in taste influences what we like to eat, what and how much we choose to consume, and ultimately our health and quality of life.

Methodologies

Called the father of psychophysics, Gustav Theodor Fechner (1801–87) established the basis of our classic methods for determining detection thresholds, the lowest level at which a stimulus is perceived. However, when given an ambiguous stimulus, an observer may classify it as a signal ("yes, something is there") or as noise ("no, it was nothing"), and this criterion depends on the context and potential outcome. Informed by cold war radar research that resulted in Signal Detection Theory, psychophysicists developed criterion-free methods that use probability to isolate observer bias from the detection of a signal within a noisy background. These procedures use repeated trials to narrow in precisely on the level at which the individual can detect the stimulus. Typically, participants are given two samples – a target and a blank – and forced to identify one as the target (a forced choice task). In one common protocol, correctly choosing the stimulus, usually in two successive trials, results in a more difficult task (i.e., a lower stimulus concentration) or a reversal. With an incorrect choice, the concentration is increased – also a reversal. Threshold value is the geometric mean of all reversals (usually six reversals).

Threshold measurements are labor and time intensive, requiring precise control of the target and blank and sufficient reversals to dampen oscillations around the true threshold. Precise control allows the assessment of factors that can change taste thresholds within an individual (e.g., medications, physiological state) or account for threshold differences across individuals (e.g., genetic variation in receptors). However, threshold represents a narrow window of the perceptual experience and thus has minimal relevance for explaining complex behaviors such as response to foods and beverages. Threshold is frequently used to assess the connection between a tastant and a specific molecular receptor yet it fails to provide insight into how the receptor functions at higher taste concentrations or the combined influence of multiple receptors to affect perceived intensity or behavioral responses to the tastant (e.g., liking/disliking).

Today, suprathreshold scaling techniques are increasingly popular since they provide much more information about sensory experience and are relevant to understanding taste-related behaviors such as eating and are more easily used outside the laboratory setting. Scaling techniques describe how perceived intensity varies across the entire dynamic range, from threshold to the strongest sensations possible, producing a psychophysical function. Gustav Fechner used difference thresholds to generate a method of measuring suprathreshold perceived intensity. He proposed that the unit of sensation be the 'just noticeable difference' (jnd), the amount a stimulus had to be raised to produce a perceptible increase. To scale perceived intensity, one needed only to count the number of jnds from threshold to the sensation of interest. A century later, SS Stevens argued that the jnd did not have the properties desirable for a unit of sensation. For example, if one stimulus is X jnds above threshold and a second stimulus is 2X jnds above threshold, then the second stimulus should be twice as intense as the first. However, Stevens showed that this second stimulus is often perceived as more intense than it should be; the subjective size of the jnd grows as the stimulus grows.

In 1969, Stevens proposed 'magnitude estimation,' which asks participants to assign numbers to sensations such that one sensation that is twice as intense as another is assigned a number twice as large (i.e., the

scale has ratio properties). Magnitude matching, used by Marks and others, extends the utility of magnitude estimation for comparisons of intensity judgments. The experimenter or clinician asks the participant to use the same scale to judge the intensities of both a tastant and a standard (perceived or remembered). For example, the saltiness of sodium chloride in chicken broth has been compared across men and women. Both groups were asked to rate a given concentration of sodium chloride in broth along with a 98 dB tone on the same scale (cross-modality matching). Assuming that the perception of loudness is independent of taste, taste can be compared across women and men as follows. The women, on average, rated the saltiness of the NaCl to be about equal to the loudness of the 98 dB tone, while men rated the saltiness to be only about two-thirds as intense as the tone was loud. Thus we can conclude the men perceived the saltiness to be about two-thirds as salty as did the women did. Women tend to have more taste buds than do men, which would explain the heightened saltiness sensation. In practice, using several standards is prudent. The standards should be independent of taste. Sound standards are commonly used although there may be associations between taste and sound through middle ear pathology (see the section titled 'Taste changes with environmental insults and across the life span').

Labeled scales (e.g., category and visual analog scales (VASs)) have historically been used to compare groups; however, such comparisons are invalid unless the experimenter can show that the labels on these scales denote the same perceived intensities, on average, to all groups to be compared. Since this is often not true, conventional labeled scales can provide erroneous comparisons. This problem can be corrected in much the same way it was corrected for magnitude estimation; devise labeled scales that permit ratings from multiple sensory continua and that thus permit magnitude matching. For example, Green and colleagues devised a scale to measure oral sensations (the Labeled Magnitude Scales or LMS). This scale used a series of intensity labels (weak, moderate, strong, etc.) and spaced them to give the scale ratio properties (a very important advancement for labeled category scales). However, as with all conventional category scales, the minimum and maximum intensities were oral sensations. By simply expressing the minimum and maximum labels in terms of all sensory experience, the scale can be used to rate taste and nontaste standards on a common scale. This generalized LMS is called the general LMS or gLMS; the gLMS produces psychophysical functions equivalent to those produced by magnitude matching using magnitude estimation.

One potential concern with the gLMS involves confusion over the intermediate labels (e.g., weak, moderate, etc.). One can think of labeled scales as elastic. The relative position of intensity descriptors appears to be essentially the same no matter the domain to which a labeled scale is applied. As this elastic scale is compressed to fit a weak domain (e.g., the odor of roses) and stretched to fit a stronger domain (e.g., pain), the relative positions of the descriptors remains the same. This means that a given intensity descriptor denotes different absolute intensities depending on the domain. For example, a woman who has just experienced a difficult childbirth may describe her pain is 'very strong.' She may also describe the odor of the roses in a bouquet presented to her to celebrate the birth as 'very strong.' One understands that she does not mean to equate the intensity of the rose odor with the intensity of her pain. Thus, there is some utility in dispensing with the intermediate descriptors in favor of a scale from 'zero' to 'strongest sensation of any kind.' A line with such labels is essentially a global VAS or gVAS. However, the experimenter may still find adjective labels useful in communicating the intensities of the sensation (e.g., strong vs. weak as compared to 37 vs. 15).

Taste Quality

Before the introduction by Henning in 1916 of the taste tetrahedron, with sweet, sour, salty, and bitter at the vertices, the number of gustatory qualities was heavily disputed. Bravo had nine classes in 1592, Linnaeus 11 in 1751, and Haller 12 in 1751, which he later reduced to six. As late as 1892, acid (sour) and salt were controversial enough that their inclusion by Shore warranted both theoretical and empirical justification. In his epic history, the eminent psychologist Edwin Boring reported the "matter was settled" by Henning's tetrahedron, although today there is still a lack consensus on exactly which qualities should be included. Almost all investigators today accept Henning's four (sweet, sour, salty, and bitter); the contention arises over whether this list is complete. Umami, the meaty, savory quality of certain amino acids, has been recognized as a fifth quality in the Japanese scientific literature for a full century, although some skeptics in the West remain unconvinced. As a sixth quality, metallic is the most common contender, with recent work suggesting that while metallic sensations rely in part on an olfactory component, taste input certainly plays a role. Notably, direct electrical stimulation of the tongue can produce metallic sensations, and these sensations are a frequent complaint in taste pathologies, which

suggests that metallic sensations may occur when patterns of taste input are altered. Finally, it should be noted that two other oral sensations are well accepted and widely recognized – oral astringency (red wine) and oral burn (chilies) – but are considered nontaste sensations as they are carried centrally to the brain by a different set of nerve fibers.

Psychophysically, two phenomena, adaptation and mixture interactions, support the independence of sweet, sour, salty, and bitter from each other. Complete adaptation can occur in taste. That is, with constant stimulation, taste sensations can completely disappear. Concentrations just above the adapting concentration will still produce the expected taste quality, albeit at a lower than expected intensity, whereas concentrations lower than the adapting concentration take on an untypical taste called a 'water taste.' (At concentrations well above the adapting concentration, intensity will rebound to expected levels due to recruitment, analogous to what occurs in audition.) The artichoke provides a dramatic example of water taste for some individuals. After exposing the tongue to globe artichokes (or to the isomers of caffeic acid from the artichokes), water tastes sweet for several minutes. Cross-adaptation refers to the ability of adaptation to one substance to affect the taste intensity of a different substance. Classic theory argued that if cross-adaptation occurred between two stimuli, then they must share receptor sites. Cross-adaptation does not occur across substances with different taste qualities. It also fails to occur across some sweet stimuli and some bitter stimuli, leading to the conclusion that sweetness and bitterness are mediated by multiple, distinct receptor sites. Mixture interactions also support the independence of the four common taste qualities. In taste mixtures, although the perceived intensities of the components may be reduced (in fact this is usually the case), the qualities remain recognizable (unless one is reduced so much that it disappears). New qualities do not emerge in taste mixtures.

Tongue Map

Contrary to popular belief, various taste qualities can be detected over the entire surface of the tongue wherever there are taste receptors. That is, the classical tongue map showing that sweet is perceived on the tip of the tongue, bitter on the back, and so forth, is entrenched in texts but is, in fact, wrong. In the history mentioned above, Boring replotted data found in Hänig's doctoral dissertation and, in doing so, did not label the ordinate axis. This omission led readers to mistakenly conclude that the small differences were, in fact, all-or-none differences. Hänig, a student of Wundt, had found that all four qualities could be tasted around the perimeter of the tongue with only some minor variability in threshold, a finding that was reconfirmed by Collings in 1974. While the classic tongue map is incorrect, we now believe that variability in taste perception associated with environmental insult (see the section titled 'Taste changes with environmental insults and across the life span') has implications for perception of food flavor, food preference, and dietary-related disease risk.

Genetic Variation

Human psychophysical data are vital to provide meaning to taste receptor genetics and taste gene expression. The most-studied genetic trait involves variation in response to phenylthiocarbamide (PTC) and 6-*n*-propylthiouracil (PROP), members of the thiourea family. Taste blindness to PTC was an accidental finding by the chemist Fox in 1931. PROP is preferred today as a taste stimulus as it is safer and lacks an odor. PROP is not found in the food supply, leading to questions of its ecological validity; however, related natural thioureas (e.g., 1-5-vinyl-2-thio-oxazolidone) are widely found in foods. Studies using PROP as a phenotypic marker have revealed associations with dietary and lifestyle behaviors and health outcomes.

PROP has become a marker for differences in overall oral sensation, probably not because of some unique receptor attribute, but because it shows large variability across individuals and because it highlights the importance of taste in the central integration of oral sensation. Some individuals live in a neon orosensory world (supertasters), and others live in a more pastel one (nontasters). Characterizing genetic variation in oral sensation could move to an expanded number of taste markers and emerging taste genotypes. For example, greater taster intensity has been characterized by other phenotypes, including response to some irritants and thermal stimulation.

Historically, PROP tasting was measured via threshold procedure, separating those who are insensitive from those who are tasters. Polymorphisms on the long arm of chromosome 7 for the *TAS2R38* gene correspond well with PTC/PROP threshold classifications. Two homozygous and a heterozygous form are seen commonly in the population: The AVI/AVI homozygote corresponds to the PROP nontaster phenotype, while the PAV/AVI heterozygote and the PAV/PAV homozygote correspond to the taster phenotype. The perceived intensity of PROP or suprathreshold response corresponds less well with *TAS2R38*, not sufficiently differentiating individuals who taste PROP as bitter (i.e., medium tasters) from those who taste PROP as exceedingly bitter (i.e., supertasters). It is interesting that some AVI/AVI individuals taste concentrated

PROP as bitter, which suggests with a high enough concentration, the hT2R38 receptor responds to PROP or that a second taste receptor is involved in PROP tasting. Some of the heightened bitterness of PROP can be explained through greater numbers of fungiform papillae, the type of taste papillae found on the anterior tongue. Those who taste PROP as bitter and extremely bitter have a high number of fungiform papillae, yet the heightened number of papillae may not fully explain PROP supertasting. Identification of other factors that may contribute to supertasting is an area of active research.

Supertasters of PROP perceive greater intensities to salty, sweet, sour, and bitter compounds. Because supertasters tend to have more fungiform papillae and these papillae hold pain and touch fibers as well as taste fibers, those who taste PROP as more bitter also experience more chemesthetic sensations from irritants (e.g., chili peppers, black pepper, ginger, carbonation, alcohol) and tactile sensations (e.g., creamy sensations from fat). PROP supertasters also experience greater retronasal sensations, especially if these sensations are congruent with taste sensations (e.g., sweet taste of sucrose with sweet odor of strawberries in strawberry jam). Thus, the term 'supertaster' could be operationalized as an individual who tastes PROP strongly bitter or has a high number of fungiform papillae, as well as a heightened response to other oral sensations.

Taste Changes with Environmental Insults and Across the Life Span

Total loss of the sense of taste, or ageusia, is rare because of the redundancy in the taste system. Branches of three cranial nerves (CNs) innervate taste buds, transmitting the electrical impulses to the central nervous system: The chorda tympani nerve (CN VII) innervates fungiform and anterior foliate papillae, and the lingual nerve (CN IX) innervates the posterior foliate and circumvallate papillae. Taste buds on the soft palate are innervated by the greater superficial petrosal nerve (CN VII), and those on the epiglottis are innervated by the superior branch of the vagus nerve (CN X). These peripheral taste messages are integrated with oral somatosensation and retronasal olfaction by the orbitofrontal cortex, which acts as a 'sensory packaging center.'

Decreased taste from one region of innervation is relatively common (i.e., spatial taste loss). Loss from one or more taste inputs alters the sensations from foods or beverages and/or may lead to phantom sensations in the absence of stimulation. Localized loss can increase signals from unaffected systems. However, losses in multiple systems can depress overall oral sensations. For example, loss of taste on the anterior tongue (chorda tympani nerve) releases the normal inhibition of other taste nerves (CN IX, X) to maintain or heighten whole-mouth taste perception. A poignant and historical example was described by Brillat-Savarin in *The Physiology of Taste*: A prisoner, after recovering from having his anterior tongue cut off for punishment, reported no loss of taste sensations and, in fact, had intense or painful sensations from very sour or bitter substances. The damage removed chorda tympani input to the CNS, releasing the inhibition from CNs IX and X to preserve most sensations and heighten others.

In the current medical literature, surgical treatments of middle-ear tumors can damage taste from the chorda tympani nerve, and tonsillectomies can damage taste from the glossopharyngeal nerve, heightening sensations from undamaged nerves. Spatial taste loss can result from exposure to common pathogens. For example, pathogens associated with middle ear infections (i.e., otitis media) can damage taste because the chorda tympani nerve passes through the middle ear on its way to the brain. As shown clinically (or temporarily with anesthesia), spatial taste loss may be the basis of dysgeusia (taste in the absence of apparent stimulation) or altered taste sensations in response to foods or beverages. Spatial taste losses affect other oral sensory inputs, including diminishing retronasal flavor perception but intensifying oral somatosensory sensations. A hypothetical example demonstrates this phenomenon. After temporary bilateral anesthesia of the chorda tympani nerve, strawberry jam would have limited sweetness and diminished strawberry flavor yet have heightened thickness and prickly sensations from the acid in the strawberry (i.e., enhanced somatosensations). This is an acute response to an experimental procedure, but it nonetheless suggests that spatial damage to taste could have implications for overall sensations from foods and beverages and resultant dietary behaviors (discussed in the section titled 'Nutritional implications of variation in taste and oral sensation'). Damage to taste from the chorda tympani nerve has also been implicated in increasing the risk of burning mouth syndrome – a phantom pain syndrome. There is growing support for the hypothesis that spatial taste damage, especially among those with high numbers of fungiform papillae (i.e., more trigeminal innervation) increases the chance for heightened response to oral irritants and, in severe cases, phantom oral pain.

Taste changes have been noted with changes in female sex hormones. Bitter response may be regulated during childbearing ages to support a healthy pregnancy. Bitter perception rises to its peak during the first trimester, helping women avoid ingesting

toxins, tetratogens, and abortifacients, and falls to its lowest in the third trimester, helping women consume a varied diet. Changes in the hedonic responses to salt may help women ingest sufficient sodium to build the blood volume to support fetal blood supply. Taste varies across the menstrual cycle and for young women. Bitterness may decline across menopause and with aging in general – a potential advantage for acceptance of bitter and nutrient-rich fruits and vegetables among the older population.

Nutritional Implications of Variation in Taste and Oral Sensation

Consumers report that 'taste' is an important determinant of what they consume. Taste integrated with other oral sensations affects hedonic responses to foods and beverages. Variation in taste and oral sensations can be linked to differential dietary risk of chronic disease by affecting food preference and possibly appetite and satiety responses. Through use of improved scaling techniques, the impact of variation in taste and oral sensations on dietary risk of obesity and other chronic diseases is now being realized.

Oral Sensation, Vegetable Intake, and Cancer Risk

One dietary strategy to lower cancer risk is through consumption of up to nine servings of fruits and vegetables per day. Fruits and vegetables contain cancer chemopreventive agents that are often bitter. Individuals who taste PROP as more bitter experience less positive (e.g., sweetness) and more bitter sensations from vegetables and thus consume fewer vegetables. Preliminary data support a link between PROP bitterness and colon cancer risk; in older men, the number of colon polyps measured during routine colonoscopies was associated with PROP bitterness.

Oral Sensation and Risk of Cardiovascular Disease

PROP nontasters, as well as those with spatial taste losses, may show greater risk of cardiovascular disease because of dietary intake, body weight, and lifestyle behaviors. In the 1960s, Fischer postulated that individuals with high PROP and quinine thresholds (insensitivity) tended to have a heavy body type whereas those with low PROP and quinine thresholds tended to have thin body types. Current literature has tended to examine associations between PROP and body weight; those tasting PROP as less bitter tend to be heavier, as seen in children, adults, and older people, although the size of the effects is small and not seen in those who are very obese. Taste damage from the chorda tympani nerve, either from reported exposure to otitis media or as functionally measured by depressed quinine bitterness on the tongue tip, appears to provide a stronger risk of overweight and obesity. Support for the spatial taste damage–obesity relationship comes from community-based research, survey data, laboratory-based data, and emerging longitudinal data from national surveillance. Laboratory studies find that those with lower quinine bitterness on the tongue (or elevated whole-mouth quinine related to the release of inhibition) report greater preference for sweet and high-fat foods and alcoholic beverages, dietary behaviors that could support overconsumption of energy and energy imbalances.

Nontasters of PROP and/or those with spatial taste damage may have elevated dietary risk of cardiovascular disease through higher intakes of alcoholic beverages and sodium as well as smoking behaviors. Nontasters perceive more positive (sweet) and less negative (bitter, irritating) sensations from alcoholic beverages; they also report consuming alcoholic beverages most frequently. Alcohol intake and risk of alcoholism have also been linked with *TAS2R38* and *TAS2R16* receptor genotypes in laboratory-based studies as well as in multicenter family studies of alcoholism. Through unpleasant oral sensations from alcoholic beverages, especially during early exposures to these beverages, when alcohol drinking habits are established, supertasting may confer some protection from overconsumption. The same supertasting protection may be observed for smoking: Chronic smokers are more likely to be nontasters. Preliminary evidence also links nontasters, particularly male nontasters, to greater risk of higher sodium intakes. Compared with supertasters, nontasters perceive concentrated NaCl as less intense and less unpleasant; they are also more likely to consume high-fat sodium foods and to report adding salt to foods more frequently.

Conclusions

Human variation in taste and oral sensation has implications for dietary and lifestyle behaviors that influence risk of chronic diseases. Taste psychophysics has allowed basic taste research to be translated into implications for overall health and quality of life, which is a promising future for work in chemosensation and neuroscience.

Introduction and Overview

Our sense of taste guides our consumption of nutrients, prevents us from ingesting deleterious substances, and helps our bodies maintain a Na^+ and pH balance. Also, and what is sometimes overlooked, taste initiates the physiological processes that are necessary for digesting and absorbing food efficiently; that is, taste stimulates 'cephalic phase digestion.' The sense of taste also conveys hedonic qualities and, as such, contributes to an individual's overall feeling of well-being and comfort. These gustatory functions are carried out by 5000 to 10 000 peripheral sensory organs – taste buds – in the oral cavity. This article reviews how sensory signals are initiated in taste buds, how taste information is processed in taste buds, and how taste information ascends from peripheral receptor cells to higher cortical centers where taste perceptions of sweetness, sourness, bitterness, saltiness, and umami arise.

Taste Stimuli

Sugars elicit sweet taste and identify foods rich in carbohydrates. (Certain proteins, as well as Pb^{2+} salts, also evoke sweet taste.) Although we now know a good deal about how sugars certain other sweet-tasting compounds stimulate taste receptors, the biological significance of detecting sweet-tasting proteins and lead salts is obscure. The human detection threshold for sucrose to stimulate sweet taste receptors is $\sim$1 mmol^{-1}, but there is great individual variability and age dependence. This relatively high sucrose concentration (as far as ligand–receptor activation is concerned when compared with, e.g., hormone and transmitter receptors) ensures that sweet taste is generated only by nutritionally significant amounts of sugar.

Sodium (and lithium) salts evoke salty taste. Certain potassium salts also stimulate salty taste, albeit poorly, and have been used as salt substitutes to reduce dietary Na^+ intake. Saltiness measures the mineral content of foods and controls the consumption of Na^+, the predominant ion helping maintain the body's fluid volume and blood pressure. The prototypic salty taste is table salt (NaCl), which has a threshold detection of about 1 mmol^{-1}. Many commercially available soups contain NaCl at $\sim$150 mmol^{-1}, a concentration which tastes mildly salty to many individuals.

Sour taste is generated by acids and presumably is important in regulating dietary intake of H^+. Restricting the consumption of protons aids in maintaining the body's pH balance and ensures that the body's intracellular and extracellular buffering systems are not overly taxed. Acid taste, which normally is aversive, also protects against consuming foods that have become rancid and sour. Sourness has a threshold of about pH 4 (e.g., 0.7 mmol^{-1} acetic acid). Commercial vinegar ($\geq$700 mmol^{-1} acetic acid) has a pH of $\sim$2.5. However, the proton concentration (i.e., pH) is not the sole determining factor for sour.

Bitter is mostly an aversive taste and is elicited by an enormous variety of compounds with diverse chemical structures. Many bitter compounds are toxic, and it is believed that bitter taste functions to warn against consuming potentially harmful substances. Newborns innately reject bitter compounds, but later in life many individuals gain an acceptance for certain bitter-tasting compounds, such as caffeine and quinine. Bitterness can be evoked by micromolar concentrations of some compounds, such as strychnine and quinine (e.g., the detection threshold of quinine is 1.4 μmol^{-1}). This (relatively) low threshold ensures that potentially toxic compounds will be detected at concentrations that would be harmful if ingested.

Monosodium glutamate (MSG) and certain other amino acids, especially when paired with the nucleotide 5′ inosine monophosphate or 5′ guanine monophosphate, stimulate a taste named umami, now recognized as a fifth taste quality independent of sweet, sour, salty, or bitter. The detection threshold for MSG is $\sim$10 mmol^{-1}. Umami is a preferred taste, and MSG is a common additive to foods for animal and human consumption. MSG occurs naturally in many foods and is particularly abundant in protein-rich foods, notably cheeses and meats.

There are likely taste qualities in addition to the five above, such as fatty, astringent, spicy, and others, but it is unclear how much of these perceptions is due to their somatosensory components mediated by trigeminal activation in contrast to gustation *per se*. Sweet, salty, sour, bitter, and umami are commonly accepted by the majority of chemosensory neuroscientists as basic tastes.

Taste Buds

There may be as many as 5000 taste buds in most individuals, although approximately 25% of the population may have twice this number. These latter individuals are the so-called supertasters, people who are genetically endowed with an unusually large number of taste buds and consequently have a heightened sense of taste. (A very crude analogy might be made between

the gustatory sensory epithelium of supertasters and the olfactory epithelium of canines, insofar as canines possess a keen sense of smell largely due to their extensive, enfolded olfactory epithelium – and thus the increased number of olfactory sensory receptor cells – within their noses.)

Taste buds are situated in the oral epithelium, with the majority in the lingual epithelium. Taste buds reside in fungiform papillae on the anterior tongue and in foliate and circumvallate papillae on the posterior tongue. Taste buds are also found on the soft palate and the epiglottis. Taste buds are onion- or pear-shaped collections of elongate cells surrounded by stratified squamous epithelium. Sapid stimuli reach the taste bud through a narrow taste pore into which the apical chemosensitive tips of gustatory sensory receptor cells extend.

Each taste bud is a separate sensory organ populated with up to 100 cells, some of which are sensory cells and others of which are believed to have other functions related to taste. Specifically, recent experiments have shown that perhaps only 20% of the cells within a typical taste bud are sensory receptor cells for sweet, bitter, or umami (the taste of certain amino acids). A different population of cells, representing a smaller fraction of cells in taste buds appear to respond to sour (acid) stimuli and perhaps to salty tastes. (Taste bud cells that transduce salty stimuli remain to be identified confidently.) The remainder of the taste bud is populated with supporting and stem cells. Historically, various nomenclatures for taste bud cells have been proposed – 'dark cells' and 'light cells,' from an early era of light microscopy of taste buds, and 'type I, II, III, and IV cells,' on the basis of ultrastructural characteristics observed in electron microscopic analyses of taste buds. Presently, research using molecular and cellular biological approaches is focusing on determining which proteins different types of taste bud cells express. The goal of this research is to identify functional classes of taste bud cells that may correlate with the morphotypes recognized by light and electron microscopy. Recent studies indicate that there is a group of cells (corresponding approximately to type I taste bud cells) that expresses proteins such as nucleoside triphosphate diphosphohydrolase-2 (an ectoadenosine triphosphatase (ecto-ATPase)) and the glutamate aspartate transporter (GLAST). These cells are believed to be supporting cells. There is another group of cells (corresponding approximately to type II taste bud cells) that expresses G-protein-coupled receptors (GPCRs) involved in sweet, bitter, and umami taste. These cells also express downstream partners and effectors (G-proteins, phospholipase Cβ2, inositol triphosphate (IP3) R3 receptors, and transient receptor potential (TRP) M5 channels; see the section titled 'Intracellular cascades downstream of taste receptors, cyclic adenosine monophosphate and Ca^{2+}') for taste GPCRs. Presumably these cells are the primary gustatory sensory receptor cells for sweet, bitter, and umami. Finally, there is subset of cells (corresponding approximately to type III) that express proteins associated with synapses, such as SNAP25 and NCAM (**Figures 1 and 2**). These cells are the only cells that have been shown to form synapses with primary afferent fibers, as determined by electron microscopy. Many of these type III presynaptic cells are serotonergic; an evolving concept is that this group subserves an aminergic synaptic pathway in taste buds: type III cells are also the taste cells that respond to sour(acid) taste.

Figure 1 Taste buds contain different populations of cells. This figure is a micrograph of a taste bud in a thin section of the vallate papilla of a mouse. (Left) Gustatory sensory receptor cells express phospholipase Cβ2 (PLCβ2), a downstream effector for taste G-protein-coupled receptors, shown here as green fluorescence. The fluorescence was produced by the expression of green fluorescent protein driven by the PLCβ2 promoter in transgenic mice. (Middle) Other cells in the taste bud form synapses with afferent fibers and express synaptic proteins such as synaptosomal-associated protein 25 (SNAP25), shown here as red immunofluorescence (same taste bud photographed with excitation–emission filters appropriate for the red immunofluorescence of SNAP25). (Right) A merged micrograph of this taste bud, showing the separate populations of gustatory sensory receptor cells (green, ~type II cells; see text and **Figure 2**) and synaptic cells (red, ~type III). Modified from DeFazio RA, Dvoryanchikov G, Marugama Y, et al. (2006) Seperate populations of receptor cells and presynaptic cells in mouse taste buds. *Journal of Neuroscience* 26: 3971–3980, with permission from Society for Neuroscience.

Nerves that Innervate Taste Buds

Taste buds are innervated by primary afferent fibers originating in the sensory ganglia associated with cranial nerves VII, IX, and X (Table 1). It has been claimed that the different regions of the oral cavity, and in particular the tongue, convey different taste qualities (sweet, bitter, etc.), but this notion stems from a mistranslation of the original findings into English and subsequent incorporation and replication in textbooks. There is no well-defined 'tongue map.' Instead, there is a tendency for the anterior tongue to respond better to certain tastes, such as sweet, and the posterior region to others, such as bitter, but any given area on the tongue can and does respond to sweet, sour, salty, and bitter (the situation for umami remains to be explored).

Figure 2 Schematic drawing of a taste bud showing type I supporting cells (gray/green), type II gustatory sensory receptor cells (yellow), and a type III synaptic cell (cyan). Nerve fibers (black) are shown passing near type II cells where presumed synaptic interactions mediated by adenosine triphosphate (ATP) occur. Afferent fibers come into close contact type II (gustatory sensory receptor) cells but do not form any ultrastructurally recognizable synapses. Instead, conventional synapses are present between the type III cell and a nerve fiber. This synapse may be serotonergic, but definitive evidence about these synapses is presently lacking.

Sensory Afferent Terminals and Information Coding

Sensory afferent fibers running in the gustatory nerves summarized above distribute themselves throughout the oral cavity and penetrate individual taste buds at their bases at the boundary between the epithelium and the lamina propria. Recent studies in mice have shown that axons from relatively few (four or five) sensory ganglion cells innervate a single taste bud, at least for taste buds in fungiform papillae and sensory cells in the geniculate ganglion. Thus, several taste bud cells must converge onto a single sensory afferent fiber insofar as there may be up to 100 cells in a taste bud, of which at least 20% are receptor cells.

As stated earlier, the only synapses that are recognized at the electron microscopic level in taste buds are formed between type III synaptic cells and sensory afferent fibers. It presently is uncertain how type II gustatory sensory receptor cells, which make no morphologically identifiable synapses with sensory afferent fibers, transmit signals to the afferent fibers. ATP has been proposed as a principal neurotransmitter between taste buds and sensory afferent terminals. The best evidence is that type II gustatory sensory receptor cells secrete ATP via unconventional, nonvesicular synaptic mechanisms and that ATP stimulates postsynaptic P2X2 and P2X3 receptors on primary sensory afferent fibers. Such synaptic interactions would not necessarily require recognizable structures, thus explaining the lack of synapses observed in electron micrographs of taste buds. ATP secreted from type II cells also appears to stimulate nearby type III synaptic cells within the taste bud and excites them to release serotonin (Figure 3). The function of these latter cells is under scrutiny, and the role of biogenic aminergic neurotransmitters in information flow within taste buds is currently being investigated.

Table 1 Nerves innervating taste buds

Cranial nerve	*Cranial ganglion*	*Name of nerve innervating taste buds*	*Region innervated*	*Name(s) of papillae innervated*
VII (Facial)	Geniculate ganglion	Chorda tympani	Anterior tongue (fungiform); lateral tongue (foliate)	Fungiform and foliate papillae
IX (Glossopharyngeal)	Inferior (petrosal) glossopharyngeal ganglion	Greater petrosal Glossopharyngeal	Soft palate Posterior tongue	Palate Circumvalate papillae
X (Vagus)	Inferior (nodose) vagal ganglion	Vagus	Upper pharynx Epiglottis, larynx, esophagus	

Figure 3 Model for information flow in the taste bud. Gustatory sensory receptor (type II) cells express G-protein-coupled receptors (GPCRs) for sweet, bitter, and umami tastants, and secrete adenosine triphosphate (ATP). ATP stimulates sensory afferent fibers expressing P2X2 and P2X3 receptors. ATP secreted by receptor cells also stimulates P2Y receptors on adjacent presynaptic (type III) cells. Presynaptic (type III) cells form synapses with afferent fibers. Many, but not all, type III cells are serotonergic and release serotonin (5HT) in response to ATP secreted by receptor cells.

The lack of discrete synaptic connections between gustatory receptor cells and sensory afferent fibers may help explain why afferent fibers are rarely highly 'tuned' to specific taste qualities such as sweet, bitter, and so forth. That is, when the electrical activity in single afferent fibers has been recorded during taste stimulation in experimental animals, the usual finding is that individual fibers often respond to two or more taste qualities, such as sweet and salty, with one being predominant. Thus, in this case, the fiber would respond robustly, but not exclusively, to sugars. Such a recording might arise from a sensory afferent that within the taste bud courses near gustatory receptor cells that express sweet receptors as well as near a salt-sensitive taste cell. If both cells secrete neurotransmitter and there are no discrete, point-to-point synapses between the cell and the fiber, the afferent fiber will be excited by activation of the sweet-sensitive taste cell, the salt-sensitive taste cell, or both, with the intensity of the fiber's activation governed by its proximity to the sites of transmitter secretion.

Such a lack of narrow tuning in individual sensory afferent fibers has given rise to the concept that information about taste quality (sweet, sour, salty, etc.) is encoded by the concurrent excitation of numerous sensory afferent fibers. Information encoded by activity in any given single fiber would be ambiguous because a single fiber can be excited by more than one taste stimulus. However, when activity of several fibers is integrated – so-called combinatorial coding or cross-fiber coding – coherent information would emerge. Most investigators believe that this is how taste information is coded and transmitted to the brain, in contrast to the notion that there are highly-tuned, individual, specific lines for sweet, sour, bitter, and so forth – a notion called the 'labeled line' theory of coding.

Molecular Receptors for Taste Stimuli

The molecular basis for detecting taste stimuli has been determined, in part, for sweet, bitter, and umami, but details remain elusive for sour and salty. Sweet, bitter, and umami are transduced by GPCRs embedded in the apical chemosensitive tips of gustatory sensory receptor cells (~type II cells). GPCRs for these tastes have been identified and are unique to gustatory sensory receptor cells. The GPCRs for sweet include the heteromeric dimer T1R2 plus T1R3. There may be additional sweet receptors, as suggested by ongoing investigations. Umami is transduced by the dimer T1R1 plus T1R3 and by additional receptors that have not been completely characterized. These additional receptors may include GPCRs that are modified synaptic metabotropic glutamate receptors (mGluRs), specifically a modified mGluR4 and mGluR1. Molecular receptors for bitter are named T2Rs. A family of approximately 25 T2R genes transduces bitter substances in the human. Current research is aimed at identifying the ligands for each of the T2R GPCRs. It is highly likely that there are additional, less-explored molecular mechanisms for bitter taste, including direct actions of bitter ligands on ion channels.

The molecular transducers for salty and sour (acid) tastes have eluded identification to date. There is considerable evidence that ion channels, not GPCRs, subserve these qualities and that the amiloride-sensitive epithelial sodium channel transduces Na^+ taste, at least in rodents. Even less is known about mechanisms for acid taste. Recent research has implicated TRP-like channels, specifically PKD1L3 and PKD2L1, in contributing to sour taste transduction but the evidence is not yet conclusive. It is important to note that the proximate stimulus for sour (acid) taste appears to be an increase in intracellular (not extracellular) protons, that is, intracellular acidification. Accordingly, solutions of organic acids such as acetic and citric acids are more intensely sour than are mineral acids such as hydrochloric acid when all are presented at the same pH. The protonated (undissociated) molecules of organic acids (HA) readily penetrate the cell membrane and dissociate inside the cell to lower the cytosolic pH. In contrast, the extracellular protons of a fully dissociated acid

($HCl \rightarrow H^+ + Cl^-$) only penetrate the plasma membrane (Figure 4). Intracellular acidification occurs throughout the taste bud and possibly the entire lingual epithelium during sour stimulation, but only a subpopulation of acid-sensitive taste sensory cells respond to this intracellular pH shift by activating transduction mechanisms specific for sour taste. Sour-responsive taste cells have recently been identified as type III taste cells, but the details of how acid taste is transduce by these cells is not yet known. It is not known what characterizes this population of acid-sensitive sensory cells or how they signal sour taste.

The principal receptor for sucrose and other sugars appears to be a dimer of class C GPCRs: T1R2 plus T1R3. Class C GPCRs are characterized by lengthy extracellular N-termini which form a hinged binding pocket, akin to the carnivorous leaves on the Venus fly trap plant; hence the name for this portion of the receptor is the Venus fly trap domain. This motif seems to be the primary binding site for sucrose and glucose. However, there are at least two other binding pockets elsewhere in the T1R2–T1R3 dimer, including a site for the artificial sweetener cyclamate, and another for the sweet protein brazzein (Figure 5). The cyclamate pocket is tucked between transmembrane (TM) regions 3, 5, and 6 of T1R3 and situated within the TM depths of the molecule, as is found for the binding pocket of other GPCRs, such as the β adrenergic receptor. The binding site for brazzein is found in a cysteine-rich region near where the large extracellular N-terminus joins the first TM domain of T1R3. Considerably less is known about the structural details of GPCRs for umami and bitter.

Figure 4 Proposed mechanism for sour (acid) taste. A sour-sensitive cell is shown responding to a mineral acid (HCl), left, and to an organic acid (acetic acid), right, both at a pH of 2.4. Left, HCl is virtually totally dissociated into protons and Cl^- in solution, and at pH 2.4, concentration of $H^+ \sim 4\,mmol^{-1}$. Protons weakly permeate the plasma membrane (dotted line) and acidify the cytosol, which is believed to be the proximate stimulus for sour taste. Right, acetic acid (HAc) at $0.7\,mol^{-1}$ (i.e., about that of commercial vinegar) has a pH of ~2.4, and thus, concentration of H^+ in solution also is $\sim 4\,mmol^{-1}$. However, at pH 2.4, >99% of acetic acid is undissociated ($Ka = 1.76 \times 10^{-5}$), and thus the concentration of the neutral, protonated species HAc $\sim 700\,mmol^{-1}$. The plasma membrane is relatively permeable to the uncharged protonated acid (i.e., HAc; solid line), which enters the cell and dissociates inside to acidify the cytosol. This may explain why organic acids such as acetic acid are more sour than mineral acids such as HCl when both are presented at the same pH. The relatively abundant, uncharged, protonated form of the organic acid 'transports' protons into the cell interior and effectively acidifies the cytosol.

Intracellular Cascades Downstream of Taste Receptors, Cyclic Adenosine Monophosphate and Ca^{2+}

Two general schemes exist for the consequence of activating taste GPCRs (Figure 6). Early studies focused on the second messenger, cyclic adenosine monophosphate (cAMP), and G-proteins such as the taste-specific G_α protein, gustducin, that directly modulate intracellular cAMP levels. Bitter and umami stimuli reduce intracellular cAMP, possibly via a G_α gustducin-activated phosphodiesterase, by analogy with the actions of the closely related G_α protein found in photoreceptors, transducin. In contrast, sweet stimuli increase cAMP, likely via $G_{\alpha s}$-coupled mechanisms. However, greater attention has been drawn in the recent past to IP3-mediated increases in another second messenger, calcium, inside taste receptor cells. Sweet, bitter, and umami stimuli all elicit phospholipase C (PLC) → IP3-mediated Ca^{2+} release from intracellular stores in the gustatory sensory receptor cells. Downstream of Ca^{2+} release appears to be the TRP channel TRPM5. All the relevant molecular participants – G_α gustducin, PLCβ2, IP3, IP3 receptors, and TRPM5 – have been identified in type II taste gustatory sensory receptor cells. It has been speculated that the intracellular release of Ca^{2+} during taste receptor activation (by way of PLCβ2, IP3, and IP3 receptors) opens TRPM5, allowing influx of cations and consequently membrane depolarization. Genetic knockout of many of the genes for these transducer elements, namely G_α gustducin, PLC β2, and TRPM5, profoundly reduces, but does not eliminate, taste sensitivity. How cAMP, Ca^{2+}, and the downstream cascades interact, if at all, is unknown.

Central Processing of Taste Signals

Signals from taste buds enter the hindbrain and reach the nucleus of the solitary tract (NTS). From the NTS, information is relayed to the thalamus and from there ascends to the primary cortex for gustation, located in the insular cortex. In some species, such as rodents,

Figure 5 Schematic drawing of the sweet receptor, a G-protein-coupled receptor dimer T1R2 + T1R3, showing the multiple ligand-binding sites. T1R2 is shown on the left, T1R3 is on the right. Details of the interactions, if any, between the extensive N-termini of T1R2 and T1R3 are not known. The N-termini possess one or more binding pockets for sucrose and other sugars. Another ligand-binding pocket, located in T1R3 near the first transmembrane (TM) region, exists for certain sweet-tasting proteins such as brazzein. A third ligand pocket, embedded in the TM regions of T1R3, is comprised of portions of TM3, 5, and 6. This site binds the artificial sweetener cyclamate but is also the binding site for antagonists such as saccharin (which at high concentrations is a sweet receptor antagonist) and lactisole. Modified from Roper SP (2007) *Pflügers Archiv* 45: 759–776, with permission.

Figure 6 Chemosensory transduction pathways for G-protein-coupled receptor (GPCR)-mediated tastes. Activation of taste GPCRs initiates (a) changes in intracellular cyclic adenosine monophosphate (cAMP), shown on the left branch, and (b) changes in intracellular Ca^{2+}, shown on the right branch. The final steps in the transduction pathways are transmitter release and stimulation of primary sensory afferent pathways. How changes in cAMP and Ca^{2+} lead to transmitter release is currently under investigation. IP3, inositol triphosphate; PDE, phosphodiesterase; PLC, phospholipase C; TRP, transient receptor potential channel.

the parabrachial nucleus (PBN) is interposed in the taste axis between the NTS and the thalamus. At each stage, there is feedback to lower centers as well as feed-forward to the next higher level (Figure 7).

Taste information processed in the insular cortex is transmitted to association cortices, especially the orbitofrontal cortex, where inputs from olfaction (and other sensory modalities) converge, presumably to generate the more complex perceptions of 'flavor' (which contrast to the more basic taste quality sensations, such as sweet, salty, etc.). Studies from functional magnetic resonance imaging (fMRI) and microelectrode recordings suggest that the primary (insular) cortex in taste encodes taste intensity and perhaps taste quality (sweet, sour, salty, etc.) but that the orbitofrontal cortex is more important for interpreting hedonic aspects, especially pleasure, that would guide food consumption. Other association

Figure 7 Outline of the information flow from taste buds to the brain in humans. At every level after the taste bud, there is information feed-forward (→) and feedback (←). Whether there is central feedback to the taste buds is not established. NTS, nucleus of the solitary tract.

areas include parts of the limbic system, such as the amygdala, which are important in establishing taste memories and conditioned food aversions.

Researchers are presently investigating specifically how information is encoded at each stage of the taste axis, from peripheral end organs (taste buds) to higher cortical areas. There is no consensus in the field as yet. As discussed above, it is unlikely that there are simple labeled lines of information leaving taste buds. The situation becomes even more complex as taste signals ascend to the cortex. Where it has been measured electrophysiologically, central neurons are increasingly broadly tuned to taste qualities as one ascends the taste axis to the cortex; there are no 'sweet-selective' or 'bitter-selective' central nervous system taste neurons. Measurements of the breadth of tuning, the entropy in the gustatory signal, show increases from the NTS to the thalamus to the cortex.

One concept is that information about sweet, sour, and so forth is coded by the particular combination of primary afferent fibers that are activated. This is akin to combining individual notes on a piano keyboard to form chords that as readily distinguish Schubert from Stravinsky as we distinguish sweet from salty. Individual piano keys taken alone cannot identify a composer any more than the single fibers of a supposed 'labeled line' can identify a taste quality. In higher centers, this concept can be extended: different combinations of central nervous system neurons are excited to represent the different taste qualities. Evidence to date suggests that if this is the case, the neurons that underlie a particular taste quality do not form readily distinguishable clusters that can be observed with fMRI. There is no well-defined cluster of sweet-sensitive neurons that is distinguishable from a 'bitter' cluster. If taste is coded in this manner, the 'grain' of the pattern for each taste quality might be too fine to be resolved with fMRI.

Another, related concept is that the temporal pattern of firing in different groups of neurons encodes sweet, sour, salty, and so forth. A crude analogy would be telegraphic Morse code, with taste information conveyed along neither a labeled line nor a combination of parallel lines but instead as a time-varying pattern of signals. In the case of taste, the time-varying signals would be occurring in thousands of parallel lines, whether primary sensory afferent fibers or tracts of central neurons. Sensory coding in general, and gustatory coding in particular, is an area of current investigation.

Tay–Sachs Disease

E H Kolodny, New York University School of Medicine, New York, NY, USA

© 2009 Elsevier Ltd. All rights reserved.

Historical Background

In 1881, Warren Tay, a British ophthalmologist, general surgeon, and dermatologist, reported to the Ophthalmology Society of the United Kingdom the case of a 12-month-old infant who had become increasingly weak since the age of 2 or 3 weeks. The mother thought the baby was not as visually alert as other babies. Tay noticed in the macula of each eye a conspicuous, large, somewhat circular white patch containing within its center a brownish red spot, a finding which has become known as a cherry-red spot. An autopsy performed 6 months later showed only a large cavity containing an old blood clot near the left lateral ventricle. Three years later, Tay reported that three children in this original family had by then had a similar condition.

Unaware of Warren Tay's findings, the New York neurologist Bernard Sachs reported in 1887 a case of 'arrested cerebral development' in a girl with progressive neurodegeneration from the age of 2 or 3 months until her death at age 2 years. The ophthalmologist Herman Knaap, having seen the child at 2 or 3 months, described within the 'Fovea centralis' the appearance of a 'cherry red color surrounded by an intense grayish white opacity.' When he saw the child again at age 22 months, the child was totally blind with the 'disk as white as paper with scarcely any trace of blood vessels.' According to Sachs, similar fundal appearances had been reported by Magnus and Goldzieher in 1855. Sachs described the child's hearing as very acute with unusual hyperexcitability to auditory and tactile impressions. His report in 1887 included two drawings by van Giesen showing a distorted shape of small and large pyramidal cells. The same year, another case was described by Wadsworth, and the next year in another case report Kingdon mentioned Jewish parentage.

By 1896, Sachs had seen 19 cases and was aware of its familial nature and its predilection in Jewish children. He gave it the name 'amaurotic family idiocy.' Kingdon and Russell, in their 1896 publication, first used the eponym Tay–Sachs.

Studying the chemistry of brain tissue from children with amaurotic family idiocy, the German biochemist Ernst Klenk in the 1930s isolated sialic acid-containing glycosphingolipids. Because of their high concentration in nerve cells, he termed them 'gangliosides.' The specific ganglioside stored in Tay–Sachs disease (TSD) was identified in 1962 by the Swedish neurochemist Lars Svennerholm as G_{M2} ganglioside, and its chemical structure was published the following year by Makita and Yamakawa.

The early 1960s also ushered in a period of investigation into the pathology and epidemiology of TSD. The group led by Terry and Korey showed, with the aid of the electron microscope, an abundance of multilamellar membraneous granules within the cytoplasm of swollen Tay–Sachs nerve cells. Contemporaneously, Myrianthropoulos and Aronson were documenting the relatively high heterozygote frequency of TSD (1:33–1:45) among Jews of Eastern European origin.

The discovery of acid hydrolase deficiencies in several other lysosomal storage diseases in the mid-1960s fostered the belief that TSD might also result from an enzyme deficiency, possibly in the cleavage of the terminal β-linked *N*-acetylgalactosamine residue. However, assays of hexosaminidase activity in TSD were either normal or showed increased, not decreased activity. In 1968, Sandhoff, Andrae, and Jatzkewitz reported finding a generalized deficiency in β-*N*-acetylhexosaminidase in a non-Jewish patient. This case was unusual in that the patient had storage within visceral tissues of increased amounts of the asialo derivative of G_{M2} ganglioside (G_{A2}) and of another hexosamine-containing glycolipid, globoside. The following year, Okada and O'Brien, using an electrophoretic technique devised by Stirling and Robinson, showed that one of two components of hexosaminidase was missing from the serum of patients with TSD. Whereas the A component was absent, the B component was increased in amount, therefore explaining why the total activity of the two components was normal in Tay–Sachs patients. A small subgroup of non-Jewish patients were later shown to be deficient in both components of hexosaminidase. This variant is now known as Sandhoff disease in recognition of the findings of Sandhoff et al. in their 1968 report. Subsequently, it was recognized that a specific protein cofactor was needed for hexosaminidase A (Hex A) to act on G_{M2} ganglioside. In the very rare AB variant, this cofactor is missing. The term G_{M2} gangliosidosis, introduced by Suzuki and Chen in 1967, is now used to refer to all diseases in which G_{M2} ganglioside accumulates because of a defect in its hydrolysis.

In 1970, Schneck and colleagues reported the first prenatal diagnosis for TSD. With the possibility of

in utero detection and the development of a test for carriers of the Tay–Sachs trait, prospective screening to prevent TSD became feasible.

During the 1970s, the subunit structure, chemical composition, substrate specificity, and chromosomal localization of the hexosaminidases were elucidated. Investigations in the 1980s revealed the steps involved in their intracellular processing and targeting to lysosomes, and by the end of the decade the genes encoding both the α and β subunits of hexosaminidase and the G_{M2} activator protein were isolated and sequenced. Many different molecular defects causing TSD and its variants have now been described, animal models have been devised, and various therapeutic approaches are being examined.

Clinical Features

The infant with classical TSD may appear normal at birth but within a few weeks may become less visually attentive, hypotonic, and easily startled by sound, light, or touch stimuli. By age 6–8 months, developmental delay becomes obvious when the infant fails to consistently roll over and is unable to sit. At an early stage, fundiscopic examinations of the retina will reveal a whitish halo surrounding the retina due to lipid deposition in the perifovial retinal bipolar ganglion cells.

By 1 year of age, there is a marked reduction in purposeful movements and the child becomes spastic and increasingly lethargic. Vision deteriorates, although the pupillary light reaction may persist, and seizures become more frequent. These may be short, subtle complex–partial or absence attacks and are separate from the episodes of extensor rigidity associated with the exaggerated startle reflex. Bouts of unmotivated laughter also occur. Macrocephaly and optic atrophy supervene and by age 2 years the child is in a vegetative state and requires constant nursing care. Common clinical signs at this stage are feeding difficulty, drooling, microaspiration leading to bronchopneumonia, constipation, and episodes of autonomic dysfunction with unexplained fevers and spells of rubor, pallor, or cyanosis and irregular breathing.

In the advanced stage, the cherry-red appearance of the macula tends to disappear as retinal ganglion cells degenerate, and seizures diminish in frequency and severity. There is progressive cachexia and recurrent pneumonia, with death occurring between age 3 and 5 years in most cases.

The electroencephalogram progresses from high-voltage slowing to multifocal spikes, then to a more diffuse slow wave pattern, and finally to a low-voltage tracing. The electroretinogram is normal but visual-evoked potentials are abnormal early in the disease, and the signal from the visual cortex is lost by 12–16 months.

Neuroimaging studies disclose on computerized tomography low density in the basal ganglia and cerebral white matter, and on T2-weighted magnetic resonance imaging (MRI) high signal intensity in these same areas. The T2 signal in the thalamus may be decreased. The caudate nuclei are enlarged, and in a late stage of the disease cerebral atrophy is found. The pattern on magnetic resonance spectroscopy of increases in myoinositol and a decrease in *N*-acetylaspartate is consistent with demyelination of central white matter, axonal injury, and neuronal cell loss.

Pathology

The brain of an infant with classical TSD surviving beyond 2 years of age is increased in weight and size compared to normal but shows generalized atrophy due to a marked reduction in neurons and loss of central white matter. Widespread lipid storage within surviving neurons of both the central and peripheral nervous systems causes these cells to enlarge, lose Nissl substance, and displace the nucleus to the periphery of the neuronal perikarya. Their cell bodies stain positive with the periodic acid Schiff stain and luxol fast blue but stain negative after treatment with lipid solvents and paraffin embedding.

Electron microscopic examination reveals the ballooned neuronal perikarya to be filled with discrete concentrically arranged multilamellated cytoplasmic bodies (MCBs) approximately 1 μm in diameter contained within lysosomes and consisting of cholesterol, phospholipid, G_{M2} ganglioside, and protein. Cortical pyramidal cells lose their angular shape and develop fusiform enlargements of the proximal axonal segment termed 'meganeurites' that contain spine-like processes. Aberrant synaptic contacts are created which are believed to cause neuronal hyperexcitability. Such ectopic dendritogenesis appears to be driven by an excess of G_{M2} ganglioside which occupies a pivotal role as a regulator of dendritic sprouting in cortical pyramidal neurons.

The cerebellum is also atrophic and in older patients there is a marked reduction in cerebellar Purkinje and granule cells. Antler-like expansions are notable at bifurcations of Purkinje cell dendrites.

Reduction in central myelin is due to both arrested myelinogenesis and loss of cortical neurons. Gliosis is present in the cortical gray matter as well as in cerebral white matter.

Gene expression profiles in TSD brain indicate a decrease in the expression of neuron-specific genes

and overexpression of genes related to the inflammatory process. This suggests that macrophage/microglia and astrocyte activation contribute to neuronal apoptosis in TSD and trigger a reactive gliosis.

Within the TSD fetus aborted at midterm, abnormal storage can be shown in phylogenetically older areas of the central nervous system (CNS), including anterior horn cells of the spinal cord, dorsal root ganglia, motor nuclei of the midbrain, and thalamic neurons. Lamellar membranous bodies are present but less compact than in affected infants.

Biochemistry

As much as 80% of the ganglioside content of brain in TSD is G_{M2} ganglioside, which normally comprises less than 5% of total brain gangliosides. Svennerholm first reported this sialic acid-containing glycolipid in 1962, and its structure was confirmed in 1965 by Ledeen and Salsman. It comprises four carbohydrate residues linked to ceramide, including two *N*-acetylated sugars, *N*-acetylgalactosamine and *N*-acetyl neuraminic acid, both linked to a penultimate galactose residue. The primary cause of classical TSD was shown in 1970 to be a deficiency of the acid hydrolase necessary to cleave the *N*-acetylgalactosamine residue from G_{M2} ganglioside.

Molecular Genetics

The hydrolysis of G_{M2} ganglioside requires the concerted action of three gene products: the α and β subunits of β-hexosaminidase A and the G_{M2} activator protein. The α and β subunits are encoded by two evolutionarily related genes, *HEXA* on chromosome 15q23–q24 and *HEXB* encoded on chromosome 5q13, and share a large degree of primary structure homology. The G_{M2} activator protein gene G_{M2A}, encoded on chromosome 5q31.3–33.1, is a much smaller, structurally different glycoprotein.

In 1968, Stirling and Robinson showed that lysosomal β-*N*-acetylhexosaminidase activity could be separated into two forms, an acidic Hex A and a basic Hex B form, each with a different extent of migration in an electrophoretic field. Okada and O'Brien subsequently showed that infants with classical TSD lacked Hex A. Hex A is a heterodimer comprising an α and a β subunit; Hex B is composed of two β subunits. Both enzymes are involved in degradation of glycolipids, glycoprotein-derived oligosaccharides, and glycosaminoglycans, but only Hex A can catalyze the hydrolysis of the β-linked GalNAc residue from G_{M2} ganglioside. Both enzymes will also cleave the artificial fluorogenic substrate 4-methylumbelliferyl-β-*N*-acetylglucosamine (4MUG), whereas the sulfated form of this substrate (4MUGS) is hydrolyzed only by Hex A and Hex S, the latter of which is an unstable α dimer. Because Hex B is heat stable while Hex A is heat labile, the proportion of each in serum, leukocytes, or cultured cells can be determined by assaying enzyme activity before and after heat treatment (usually 50 °C for 2 h).

As of March 2007, 109 mutations had been reported in the α polypeptide of Hex A, of which 97 were associated with TSD. Among Ashkenazi Jews, the most common mutation is a 4-base pair insertion in exon 11 ($+TATC_{1278}$), accounting for approximately 80% of mutated alleles. The second most common in Ashkenazim is a splice junction mutation at the 5′ end of intron 12 (+1 IVS-12) found in another 13% of Tay–Sachs alleles. A 7.6-kb deletion at the 5′ end of the Hex A gene is characteristic of French–Canadian patients with infantile TSD. In the case of these three mutations, enzyme activity is undetectable. Many other Hex A mutations causing TSD are restricted to small populations or single pedigrees.

Two missense mutations, Arg247Trp and Arg249Trp, cause the lack of Hex A activity in apparently healthy individuals when assayed with 4MUG but not in the presence of 4MUGS. The Arg247Trp alteration is present in 32% of non-Jewish enzyme-defined carriers, but only 2% of Jewish enzyme-defined carriers. The Arg249Trp mutation is seen in 4% of non-Jewish carriers but not at all in Jewish carriers. The presence of these pseudodeficiency alleles in the non-Jewish population explains the apparent discrepancy between the carrier frequency in this population based on disease incidence (1/300) and that observed by enzyme assay (1/167).

Five mutations have been found in G_{M2A}, the G_{M2} ganglioside activator protein gene. These mutations produce very little protein and therefore are associated with the severe TSD phenotype known as the AB variant. When assayed with artificial substrates, normal levels of Hex A and Hex B are obtained, but no activity results when assays are done using G_{M2} ganglioside as the substrate.

Clinical Heterogeneity

TSD is but one of a group of autosomal recessive lysosomal storage diseases known as the G_{M2} gangliosidoses. The development of routine assays for Hex A and Hex B activity and the spread of large-scale population screening programs for carriers of TSD have revealed a spectrum of phenotypic variants, including chronic and later onset forms. In general, the higher the residual enzyme activity, the later the onset of the disease and the milder the clinical manifestations.

Sandhoff Disease

Sandhoff disease is distinguished by the absence of both Hex A and B activity due to defects in the *HEXB* gene encoding the β subunit. Because this polypeptide is a component of both enzymes, total hexosaminidase activity is severely reduced, with only the rare Hex S ($\alpha\alpha$ dimer) present. A total of 32 mutations have been reported in the *HEXB* gene.

The clinical course of infantile Sandhoff disease is similar to that of TSD. In patients age 12–18 months, brain MRI reveals mild cortical atrophy, a thin corpus callosum, and abnormal signal intensities in the caudate, globus pallidum, putamen, cerebellum, and brain stem. Due to the additional storage of globoside and other hexosamine-containing glycolipids and oligosaccharides within systemic organs, foam cells may appear in the bone marrow and slight hepatomegaly may be recognized.

These signs and the presence of an excess of hexosamine-containing glycoprotein fragments within the urine of patients with Sandhoff disease help distinguish infantile Sandhoff disease from classical TSD.

AB Variant

Few clinical reports are available that describe the phenotypic appearance and pathology of patients with the AB variant. At least two patients with American Indian ancestry are known. The clinical manifestations and brain pathology are similar to those of classical TSD. G_{M2} ganglioside concentration in the cerebrospinal fluid (CSF) is elevated and MCBs can be found within a conjunctival biopsy. The diagnosis is confirmed by finding G_{M2} activator protein deficiency and mutations within the G_{M2A} gene.

B_1 Variant

The B_1 variant of G_{M2} gangliosidosis is due to mutations that affect the active site in the α subunit without affecting its ability to associate with the β subunit. Therefore, normal catalytic activity is obtained using 4MUG as the substrate, but hydrolysis of the sulfated derivative (4MUGS) and G_{M2} ganglioside is deficient. This is because the catalytic site of the β subunit of Hex A can act on 4MUG but the α subunit catalytic site is required for cleavage of 4MUGS and G_{M2} ganglioside. Carriers of a B_1 variant allele will demonstrate normal Hex activity with 4MUG and half-normal activity with 4MUGS. Compound heterozygotes for a B_1 allele and a null mutation will appear as carrier with 4MUG but deficient in Hex A activity with 4MUGS as the substrate.

Infantile, juvenile, and late-onset forms of G_{M2} gangliosidosis have been found with a B_1 allele. The Arg178His mutation, also known as the DN allele, is the most frequent cause of the B_1 form of disease and is especially common among patients of Portuguese origin. In one series, onset appeared between 1.5 and 2.5 years and in another between ages 3 and 7 years. The course was rapid in some and slow in others, allowing survival into the second decade. Manifestations include ataxia and pyramidal signs leading to gait difficulty and dysarthria progressing to anarthria. The brain MRI findings are similar to those in other variants, with basal ganglia injury and severe demyelination in the infantile form progressing to cerebellar atrophy and no supratentorial abnormalities in the adult form.

Juvenile/Subacute G_{M2} Gangliosidosis

Juvenile or subacute onset of G_{M2} gangliosidosis has been associated with both α subunit (TSD variant) and β subunit (Sandhoff variant) mutations. A review of 134 previously described patients reported the onset at 5.4 ± 4.0 years, with gait disturbances (58.2%) as the most common symptom at onset. Other symptoms were speech problems (37.3%), incoordination (36.5%), intellectual impairment (29.1%), and behavior or psychiatric disturbances (11.9%). Optic atrophy occurred in 15.4% of patients, and 4 patients (4.6%) had a macular cherry-red spot. Dysphagia and sphincter incontinence occurred earlier in the TSD variants. Spasticity, rigidity, seizures, and dementia have also been observed in juvenile-onset cases. Mean survival was 19.0 ± 2.1 years in the 40% of patients whose status was known. The most common cause of death was respiratory tract infection (43.4%).

Late-Onset (Chronic Adult) G_{M2} Gangliosidosis

Patients with late-onset chronic or adult G_{M2} gangliosidosis retain a small amount of residual enzyme activity ($\sim$5% of normal) due to a mild mutation in compound heterozygosity with a more severe nonexpressing mutation. The prototypic example is the Gly269Ser mutation in exon 7 of the *HEXA* gene which is most often found in Ashkenazi Jews. Of the TSD carriers in this population, 2% carry this mutation.

Phenotypically, patients with the Gly269Ser mutation may present in childhood or adolescence with subtle signs and symptoms, including learning disabilities, clumsiness, and/or dysarthria. Proximal muscle weakness develops in adolescence with progression to a slightly broad-based ataxic gait in the third or fourth decade. The onset of overt disease may be heralded by an acute psychiatric disturbance with anxiety, depression, or a psychotic episode. Fasciculations, muscle cramps, easy startle, and fine tremor of the outstretched hands become evident. Saccadic pursuit of the eyes is slowed, muscle atrophy develops,

knee reflexes are lost, and Babinski signs appear. Autonomic disturbances develop, including painful ankle edema and cool, purple-colored feet. Brain MRI studies reveal marked cerebellar atrophy. Neuropsychological testing demonstrates impairment in executive functioning and memory, although dementia is not part of the usual disease pattern. This cohort of patients responds poorly and may worsen neurologically if treated with tricyclic antidepressants or major neurolepties such as haloperidol, risperidone, or chlorpromazine.

Late-onset patients with other mutations may present with seizures, dementia, and a rapidly progressive course. Patients in their 50s or older with either *HEXA* or *HEXB* mutations have also been reported with esophageal and gastrointestinal motility problems (achalasia and diarrhea) and other evidence of autonomic dysfunction.

Diagnosis and Carrier Testing

Formerly the diagnosis of TSD was based on the typical clinical presentation in combination with histologic evidence of lipid storage (i.e., rectal biopsy for myenteric plexus neurons). Patients with the Sandhoff variant will often have vacuolated lymphocytes and monocytes in their peripheral smear and foam cells in the bone marrow. Moreover, chromatography of their urine will reveal an excess of *N*-acetylglucosaminyl oligosaccharides.

Enzymatic assays utilizing synthetic substrates are now in widespread use for detecting Hex A and Hex B deficiency. Assays employing the fluorogenic compound, 4MUG, can be used with readily available sources of enzyme, such as serum, leukocytes, tears, cultured skin fibroblasts, amniocytes, and chorionic villus tissue, to detect Hex A and B after electrophoretic separation or before and after selective thermal denaturation of Hex A. Under specific conditions, Hex B remains heat stable, whereas Hex A is heat labile. The amount of Hex A present is obtained by subtracting the activity obtained after heat treatment of the sample, typically 2 h at 50 °C, from the total activity prior to thermal exposure. Typically, assays on specimens from carriers of mutations in the α subunit gene will show half the normal amount of Hex A activity, whereas carriers of β subunit gene mutations will have reduced activity of both Hex A and Hex B.

Certain exceptions may cause problems in rare individuals. Carriers as well as homozygyous affected individuals with the B_1 variant allele will appear normal or low normal in routine assays with 4MUG as substrate. Such individuals can be differentiated using the Hex A-specific substrate 4MUGS. Another problem is pseudodeficiency alleles, which can account for as much as one-third of non-Jewish enzyme-defined carriers. In both of these circumstances, DNA-based mutation analysis is a necessary next step. DNA mutation analysis is also necessary for patients with β subunit mutations causing heat lability of Hex B. These individuals will appear with the standard heat denaturation assay to have an increased fraction of Hex A activity.

Up to 10% of Ashkenazi Jewish individuals may carry the delTG(+)619→G haplotype, which causes low serum Hex B activity, possibly masking a TSD carrier state. In such individuals, further testing of leukocyte enzyme activity is required. Leukocytes, and not serum, should also be employed for patients who are pregnant, on birth control medication, on certain other drugs, or who suffer concurrent illness such as hepatitis. Leukocyte enzyme determinations are also done as a backup whenever serum assays suggest a carrier state or are inconclusive.

Enzyme determinations for G_{M2} activator protein deficiency generally require cultured skin fibroblasts and radioactively labeled G_{M2} ganglioside, which is not routinely available. Therefore, DNA mutation analysis of the G_{M2A} gene may be preferred.

In pregnancies at risk for TSD or another variant of G_{M2} gangliosidosis, DNA mutation analysis performed in advance on DNA of the parents and previously affected patient, if there is one, greatly simplifies diagnosis of the fetus. In the case of non-Ashkenazi individuals in particular, this precaution will rule out the possibility of mistaking a pseudodeficiency state as affected.

The American College of Obstetricians and Gynecologists, through their Committee on Genetics, issued a consensus statement in October 2005 recommending that carrier screening be "offered before pregnancy to individuals and couples at high risk, including those of Ashkenazi Jewish, French–Canadian, or Cajun descent and those with a family history consistent with TSD." The committee also advised that genetic counseling and prenatal diagnosis be offered to both partners if they are proven to be carriers. A carrier–carrier couple has a 25% risk with each pregnancy of having an affected fetus. Prenatal diagnosis allows the option for pregnancy termination in the case of an affected offspring. Another approach chosen by a few at-risk couples is preimplantation testing in which normal embryos only are selected through *in vitro* fertilization and molecular analysis of a single cell at the blastocyte stage.

Therapy

Currently, there is no cure. The maintenance of proper nutrition and hydration, prevention of infectious disease, and control of seizures are the main

goals of treatment. Complications such as constipation and joint contractures in the infant and psychiatric disturbances and tremor in late-onset patients require appropriate pharmacological interventions. We favor high-calorie, semisolid or blenderized feedings, if necessary via a gastrostomy tube, laxatives and diazepam for infants, and carbamazepine and propanolol in adults. All clinical variants may benefit from physical therapy.

Experimental approaches include enzyme replacement, bone marrow transplantation, substrate synthesis inhibition, pharmacologic chaperones, and gene therapy. Because the locus of pathology in the G_{M2} gangliosidoses is within the CNS, successful enzyme replacement will require efficient targeting to neuronal lysosomes. Breaching the blood–brain barrier is possible through intrathecal administration or osmotic disruption, but neither technique has achieved sufficient concentration of enzyme within brain parenchyma to be therapeutic. Furthermore, cell media derived from murine fibroblasts overexpressing Hex A activity, when added to cultured Tay–Sachs fibroblasts, does not achieve high enough concentrations to hydrolyze the G_{M2} ganglioside present in these cells.

Following bone marrow transplantation (BMT), donor-derived cells of microglia/macrophage lineage can be found within the CNS. Sandhoff disease mice that have received BMT with wild-type cells show enzyme positivity in the leptomeninges, choroid plexus, and perivascular regions of the cerebrum but not within neurons. Although microglial activation and neuronal apoptosis were suppressed, neuronal storage of ganglioside was not altered. It is therefore not surprising that neurological deterioration has progressed in the few TSD patients who have had a BMT.

Another approach, substrate reduction therapy (SRT), employs an inhibitor of glycolipid synthesis to reduce the influx of substrate into lysosomes. One such compound, *N*-butyldeoxynojirimycin (NB-DNJ), inhibits the enzyme that joins glucose with ceramide to form glucosylceramide, a basic step in ganglioside biosynthesis. With a reduced substrate load, it is assumed that further reduction in G_{M2} ganglioside storage can be achieved through the action of residual enzyme activity. Both TSD and Sandhoff mice treated with NB-DNJ show a significant reduction in brain G_{M2} content. Also, Sandhoff mice have delayed symptom onset and live longer. When treated with both NB-DNJ and BMT, these mice survived significantly longer than those treated with NB-DNJ or BMT alone. On the other hand, according to anecdotal evidence, TSD infants who have received NB-DNJ (as miglustat) continue to deteriorate neurologically. Perhaps this result would be expected since infants with TSD have no residual enzyme activity. However, a controlled open-label trial of miglustat in late-onset patients who do have residual enzyme activity also did not show convincing benefit of the drug. Potential advantages of SRT are its oral route of administration and the presence of significant drug concentrations in the CSF suggesting ready availability to the CNS.

Pharmacological chaperones are yet another means to correct the enzyme deficiency, in this case by stabilizing the confirmation of the mutant Hex A protein. Instead of undergoing premature degradation, it can bypass the quality control system of the endoplasmic reticulum and enter the lysosome to enhance residual enzyme levels. Potential pharmacological chaperones for *HEXA* include NGT (*N*-acetylglucosamine-thiazoline) and pyrimethamine, both of which have been shown to enhance Hex A activity in cultured cells from patients with the late-onset Gly269Ser mutation. Human trials of chaperone therapy are in the planning stage.

Gene therapy represents another attractive alternative for treatment of the G_{M2} gangliosidoses. Trials with recombinant AAV vectors expressing various lysosomal enzymes have proven efficacious in treating a dog model of mucopolysaccharidosis I, mice with mucopolysaccharidosis VII, and a cat model of α-mannosidosis. Stereotaxic intracranial inoculation of recombinant AAV vectors encoding the human hexosaminidase α and β subunit genes into Sandhoff mice led to delay in the onset of the disease with preservation of motor function and reduced G_{M2} ganglioside storage and inflammation. Delivery of the therapeutic protein was widespread despite a single striatal injection. Retroviral constructs have also been used to correct Tay–Sachs cells in culture. It appears necessary for both the α and β subunit genes to be transduced jointly in order to prevent the nondefective subunit from limiting formation of the Hex A $\alpha\beta$ heterodimer.

Animal Models

Animal models of inherited human diseases are a rich resource for the study of disease pathogenesis and therapeutic approaches. Naturally occurring animal species with G_{M2} gangliosidosis have been reported in Muntjak deer and American flamingos (Hex A deficiency), in two feline breeds and a golden retriever (Hex A and B deficiency), and in Yorkshire pigs and Japanese spaniels (G_{M2} activator protein deficiency).

Mouse models have also been created of the three major forms of G_{M2} gangliosidosis by targeted disruption of their hex α and β subunit genes and G_{M2} activator protein gene in embryonic stem cells. Mice

deficient in Hex A appear phenotypically normal, although they accumulate G_{M2} ganglioside within specific regions of the brain. Their asymptomatic state was assumed to result from the availability of an alternative route for G_{M2} ganglioside hydrolysis involving the action of a sialidase not active in humans. However, symptoms have appeared in approximately 60% of these Tay–Sachs mice at an advanced age (i.e., by 18–24 months). The clinical appearance resembles human late-onset TSD. It consists of lordosis, progressing to abdominal dragging, tremor, and hind limb weakness and paralysis. Its appearance can be accelerated in the hex A-deficient females by repeated breeding within their first year. These mice have increased levels of G_{M2} ganglioside storage within the CNS and show symptoms by 13–18 months.

Sandhoff mice deficient in Hex A and B activity develop neurological symptoms at 3 months, including tremor, spasticity, hind limb rigidity, ataxic gait, muscle wasting and weakness, and paralysis, dying 4–6 weeks after disease onset. Because of the absence of Hex B, the sialidase bypass pathway is not available and therefore there is more extensive neuronal storage. In addition, storage material is also present within visceral organs.

A double knockout mouse has also been produced with disruption of both the α subunit and β subunit genes causing complete absence of all forms of lysosomal β-hexosaminidase. These mice are even more impaired than the Sandhoff mice, with a clinical picture resembling a mucopolysaccharidosis phenotype due to the additional accumulation of glycosaminoglycans within the nervous system and viscera.

The mouse model of G_{M2} activator deficiency expresses a phenotype intermediate between the Tay–Sachs and Sandhoff mouse. They have a normal life span but develop severe motor deficits. Unlike the Hex A-deficient mice, they store the glycolipid G_{A2} in cerebellar neurons and glial cells. Intraneuronal lysosomal inclusions and apoptosis are common features of these mouse models. In addition, in the Sandhoff mouse there is evidence of CNS inflammation and altered blood–brain barrier permeability.

Prevention

Tay–Sachs disease carrier screening has become the prototype for genetic disease prevention. It is based on the availability of relatively simple and inexpensive laboratory tests, a defined population subgroup at high risk, and the ability to monitor pregnancies of carrier–carrier couples. Community-based carrier testing programs began in 1970 and spread to high schools, college campuses, and community centers. However, the response among the general Jewish community has been poor, with only approximately 10% of the target population having been screened.

Concerns have been raised about the testing of adolescents in a school setting. These involve issues of informed consent (vs. peer pressure); the potential for stigmatization and discrimination; costs to the school for providing explanatory letters, obtaining parental consent, and protecting students' privacy; and the difficulty of reporting results and providing further genetic counseling in a confidential manner. To address the many obstacles created by carrier screening, the Orthodox Jewish community established the Dor Yeshorim program. It is designed for testing of unmarried young men and women who remain anonymous to the program. They are matched to their blood sample by a number which is randomly generated and stored in a computer together with their test results. When a marriage is proposed within their community, using their assigned number, the results of their testing are compared. If a carrier–carrier situation is found, the matchmaker will search for other potential spouses. At no time is the test result disclosed to either party. Although this system ensures freedom from stigmatization, it requires that each family member of marriageable age and in each generation be tested.

As of 2000, more than 1.4 million individuals had been tested worldwide and approximately 51 000 carriers identified, including 1400 at-risk couples. As a consequence, the number of infants born with TSD has markedly decreased, particularly among the Ashkenazi Jewish population. The development of DNA chip and bioarray technologies to detect multiple mutations should, in time, allow cost-effective screening for the entire child-bearing population. In the meantime, efforts to educate the high-risk population through their physicians and clergy should be enhanced.

Temperature Sensation

A D Craig, Barrow Neurological Institute, Phoenix, AZ, USA

Psychophysics of Temperature Sensation

The normal temperature of human skin is *c.* 32–34 °C (90–94 °F), with hands and face warmest. Temperatures above that are perceived as warm, and temperatures above *c.* 45 °C (113 °F) are perceived as hot and painful. Temperatures below 32–34 °C are perceived as cool, and temperatures below *c.* 15 °C (59 °F) are perceived as painfully cold and burning. These temperature ranges correspond with the sensitivity of distinct classes of thermoreceptors in the skin (see below). Humans can distinguish temperature differences as small as *c.* 0.1 °C within the innocuous range, and we report cooling or warming intensity linearly.

By applying small metal probes with varied temperatures to the skin, individual spots can be found that are uniquely sensitive to warming, to cooling, and to noxious heat and/or noxious cold. Each spot corresponds with the location of a particular thermoreceptor. These spots are most clearly separated on the torso, where large intervening insensitive areas can be found, and they are most densely packed on the lips, nose, and hands. This reveals first the specificity and second the innervation density of the different classes of thermoreceptors.

The German physiologist EH Weber in 1859 described two thermal illusions. In the Thaler (dollar) illusion, a cool silver coin placed on the forehead of a prone individual feels noticeably heavier than a warm one. This can be explained by the nonlinear increment in activity caused by a cool temperature in type 1 slowly adapting (SA1) mechanoreceptors, which thereby elicit an increased sensation of pressure. The second illusion, usually called simply the Weber illusion, occurs as follows: one places both hands first on a lukewarm (thermoneutral) object for 1 min, and then each hand separately on a slightly cooler and a slightly warmer object, respectively, for 1 min, and finally both hands again on the initial neutral object, whereupon different sensations are perceived from the two hands. The neutral object now feels initially cool to the hand that was warmed, and initially warm to the hand that was cooled. This perceptual difference soon fades, and it may not occur if the hands are returned to the neutral object too quickly or if the temperature difference is too great. This illusion demonstrates, first, that warm- and cool-sensitive thermosensory pathways both adapt slowly to ambient temperature, second, that they display a narrow thermal 'dead zone,' and third, that they have a dynamic sensitivity to slight changes in skin temperature.

The 'thermal grill' (first described by Thunberg in 1896) is an illusion of painful (burning) cold that is elicited by placing one's hand on a platform consisting of a series of closely spaced metal bars that are alternately cool (20 °C) or warm (40 °C). The illusion is strongest if the temperatures of the bars are actively altered from an initial thermoneutral value: if, while the hand is held on the platform, one set of bars is first warmed and then (within 2–5 s) the alternate set is cooled, then a feeling of increasing warmth is perceived that blends alarmingly into noxious heat. The same feeling can be elicited most simply by touching a cold object to the veins on the back of a hand immersed in warm water, or most dramatically by pouring warm water on a foot that is numb with cold, or most informatively by applying a cool stimulus during a pressure block of myelinated fiber conduction in a peripheral nerve. A similar feeling of 'synthetic heat' can be elicited with temporally alternating warm and cool pulses presented on the foot or with rapid cooling of small thermodes on the fingers. All of these instances demonstrate that a cool stimulus activates two distinct thermosensory pathways, one responsible for the sensation of cooling and another responsible for the sensation of burning cold, and that the latter is normally inhibited by the former. In the original thermal grill, the cool-sensitive thermoreceptive-specific pathway is inhibited by the presence of the alternate warm bars, thus unmasking the simultaneous activation of the polymodal nociceptive pathway that is responsible for the feeling of burning cold.

Temperature stimuli also elicit a graded affective feeling of pleasantness or unpleasantness that depends on the body's thermoregulatory needs. For example, a cool glass of water feels refreshingly pleasant if one is excessively warm but gnawingly unpleasant if one is 'chilled to the bone.' Conversely, a pricking hot shower feels welcome if one is chilled but painful if one is hot. This valenced affect, which is the perceptual correlate of thermoregulatory behavioral motivation, demonstrates that temperature sensation can be regarded as a homeostatic emotion (i.e., both a feeling and a motivation) that drives behavior, like hunger, thirst, and pain.

Temperature Sensation in Other Species

Virtually all animals thermoregulate and display behavioral thermal sensitivity, and physiological and ethological studies have demonstrated cool and warm sensitivity in bacteria, worms, insects, honeybees, fish, lizards, birds, and mammals. Some animals have specialized thermoreceptive organs. For example, certain snakes have directionally selective pit organs that are highly sensitive to warmth (infrared energy) and are used for detecting and targeting prey. Some fish (e.g., sharks) have unique cool-sensitive ampullae (that are also sensitive to electric currents). Many birds, which like mammals are homeothermic rather than poikilothermic, have dense thermosensors around the bill and the brood patch that are important for behavioral control of egg incubation. All mammals have thermoreceptors similar to humans; for example, cats can be trained to respond to warm or cool differences in floor temperature as small as 0.2 °C, and the nocturnal owl monkey has a unique and highly evolved discriminative thermosensory capacity focused at the nose. Nevertheless, forebrain processing of temperature sensation is crucial for behavior only in highly encephalized primates.

Thermoreceptors

Thermoreceptive afferents have been characterized by physiological recordings from peripheral nerve fibers in many species, including humans. Cool and warm thermoreceptors show both dynamic (transient) and static (steady) responses that represent the rate of change and the absolute level, respectively, of cool and warm stimuli. Individual cool thermoreceptors have thresholds near, above, or below normal skin temperature (~20–40 °C). Some show bell-shaped response curves that peak and then diminish at noxious cold temperatures, and others show sigmoidal curves that increase and then saturate at such temperatures. Similarly, warm thermoreceptors have thresholds that span normal skin temperature (~30–40 °C) and show bell-shaped or sigmoidal response curves that diminish or saturate at noxious heat temperatures. Both types are inhibited dynamically by temperature changes in the opposite direction, and both are sensitive to the absolute temperature at the receptor, rather than the temperature gradient across the skin. In contrast, different types of nociceptors respond to noxious heat and/or noxious cold.

Thermoreceptors have spot-like receptive fields in the skin. Cool receptors are much more numerous than warm receptors in the skin, whereas warm receptors are much more numerous in deep tissues (muscle, viscera, spinal cord), corresponding to the different homeostatic priorities for monitoring temperature in the thermoregulatory core and shell. Cutaneous thermoreceptors are concentrated in orofacial regions (mouth, tongue, nose, lips, eyes, and ears), as well as on the hands and feet. Warm receptive afferents are unmyelinated C-fibers that conduct very slowly, and cool receptive afferents are predominantly thinly myelinated Aδ-fibers that conduct more rapidly. Thus, a pressure block of myelinated fiber conduction in a peripheral nerve interrupts touch and cool sensations, leaving sensations of warm and pain, whereas blockade with a local anesthetic (e.g., lidocaine) interrupts warm and pain sensations, leaving touch and cool. Thermoreceptors are very modality selective and are excited by mechanical deformation very infrequently. Particular temperature-sensitive membrane channels (e.g., TRPM8) are associated with thermoreceptors. Cool thermoreceptors are also sensitive to application of menthol. Cool thermoreceptors are sometimes paradoxically activated by temperatures above 45 °C, corresponding to the brief sensation of cold that can occur when the hand is immersed in hot water. In contrast, the sharp biting sensation elicited by touching an object that is very cold (such as dry ice) is due to the abrupt activation of myelinated nociceptors by the sudden formation of small ice crystals in the skin.

Central Neural Processing

Spinal Level

Thermoreceptive processing begins in the dorsal horn of the spinal cord. Selectively warm- and cool-sensitive spinothalamic cells in the most superficial layer (lamina I) respond to thermal stimuli over large areas of skin; receptive field sizes vary from 2 to 4 cm^2 near the nose to half of the hand to the entire lateral abdomen. The summation produces a mean response profile that aggregates the response curves of individual thermoreceptors. Cool-sensitive lamina I neurons have thresholds at or above normal skin temperature, and they respond very linearly to cooling down to about 15 °C but show constant activity below that temperature (Figure 1). They have ongoing discharge at normal skin temperature that is inhibited by warming. Conversely, warm-sensitive neurons have thresholds at or below normal skin temperature, and they show graded warm responses up to about 45 °C, where their activity becomes constant. They have ongoing discharge that is inhibited by cooling. Thus, the activity of cool- and warm-sensitive thermoreceptive-specific spinal neurons closely parallels human thermosensory capacities and temperature perceptions. Further, thermoreceptive-specific neurons are

Figure 1 Quantitative characterization of cool-sensitive lamina I thermoreceptive-specific spinothalamic neurons: (a) average static response to temperature, (b) linearity of regression against innocuous cool temperatures, (c) examples of individual unit responses to 20 s cooling staircase stimuli showing both the dynamic and the static responses. Reproduced from Craig AD, Krout K, and Andrew D (2001) Quantitative response characteristics of thermoreceptive and nociceptive lamina I spinothalamic neurons in the cat *Journal of Neurophysiology* 86: 1459–1480.

modality selective and are insensitive to other stimuli (except for menthol-like chemicals). They also have unique cell morphologies, unique axonal conduction velocities and projections, and unique responses to activation of descending controls from the brain stem and to pharmacological agents; so, they can be termed 'labeled lines' for temperature sensation. Two subpopulations of cells are sensitive to cooling the epidermis and the dermis, respectively. In contrast, spinal neurons in the deep dorsal horn that receive input from SA1 mechanoreceptors show graded tactile and weak, nonlinear cool sensitivity. In addition, polymodal nociceptive lamina I spinothalamic neurons are sensitive to noxious cold, noxious heat (>45 °C), and noxious mechanical stimulation. These neurons have little ongoing discharge, and their threshold to cold stimulation is *c.* 24 °C (75 °F), the temperature below which environmental cold becomes unpleasant. They are responsible for the sensation of burning pain caused by noxious heat, noxious cold, and the thermal grill.

Thermoreceptive-specific lamina I neurons project to homeostatic regions in the spinal intermediolateral cell column, where sympathetic preganglionic vasoconstrictor neurons are located, and to homeostatic regions in the brain stem, where catecholaminergic pre-autonomic motor centers control blood flow, heart rate, and respiration. Direct access to central autonomic control and thermoregulatory integration centers is provided by way of major projections to the A1 noradrenergic cell group in the caudal ventrolateral medulla (which projects to hypothalamus) and to the parabrachial nucleus (which projects both to hypothalamus and amygdala). Other thermoreceptive lamina I cells project to the contralateral forebrain by way of the lateral spinothalamic tract; surgical interruptions of this pathway in the spinal cord (e.g., to reduce cancer pain) completely eliminates contralateral temperature sensation.

Thalamocortical Level

In monkeys and humans, the ascending lamina I thermoreceptive-specific pathway reaches a compact nucleus in posterolateral thalamus (VMpo). These neurons also show thermoreceptive-specific responses, and they are organized spatially so that there is a segregated, antero-posteriorly organized thermoreceptive map of the body. Microstimulation in this region in awake humans (during neurosurgical procedures for movement disorders or chronic pain) elicits

Figure 2 Functional imaging data showing the location of discriminative thermosensory cortex in the dorsal posterior insula: (a) linear regression of PET data with cooling stimuli; (b) antero-posterior somatotopic organization of regressed cooling activation by stimulation of the hand (red) and neck (green). (a) Reproduced from Craig AD, Chen K, Bandy D, and Reiman EM (2000) Thermosensory activation of insular cortex. *Nature Neuroscience* 3: 184–190. (b) Reproduced from Hau LH, Strigo IA, Baxter LC, Johnson SC, and Craig AD (2005) Anteroposterior somatotopy of innocuous cooling activation focus in human dorsal posterior insular cortex. *American Journal of Physiology. Regulatory, Integrative, and Comparative Physiology* 289: R319–R325.

descriptions of immediate, discrete cooling sensations that are graded with the intensity of stimulation and well-localized on the body. These thalamic neurons topographically relay thermoreceptive activity to a cortical site in the dorsal posterior insula. Functional imaging with positron emission tomography (PET) has confirmed that activation of this area of the human brain is directly correlated with cool skin temperatures (Figure 2), and low-power laser stimulation has similarly indicated that activation in this region correlates with warm skin temperatures. Recent studies using functional magnetic resonance imaging (fMRI) have shown that this region has an antero-posteriorly organized topographic map of thermoreceptive activity (Figure 2). Consonant with these observations, clinical findings indicate that damage to posterolateral thalamus or the dorsal posterior insula interrupts temperature sensation on the contralateral body. Thus, there is a direct thermoreceptive-specific spinothalamocortical pathway that provides a map of temperature sensation over the body within this particular area of the cerebral cortex, and it is responsible for the discrimination and the localization of temperature sensations in humans.

It is important to recognize that the discriminative thermosensory area in dorsal posterior insular cortex of primates and humans is actually part of a set of interoceptive areas that provide a general representation of all aspects of the physiological condition of the body. The same lamina I spinothalamocortical pathway by way of VMpo that conveys thermoreceptive activity also generates topographic maps that represent other distinct feelings from the body, such as first (sharp) pain, second (burning) pain, itch, muscle ache, visceral sensation, and so on, that constitute other aspects of the body's physiological condition. Further, afferent inputs from the vagal and glossopharyngeal nerves cause activity in the adjacent portion of dorsal insula related to hunger, thirst, taste, breathlessness, and cardiovascular condition. Thus, these insular cortical areas serve as a primary homeostatic afferent image of the state of the body. The evolutionary role of these limbic sensory cortical areas is to modulate the activity of regulatory regions in the brain stem and hypothalamus that maintain the health of the body, that is, regions directly involved in homeostatic integration and control. In humans, they also provide a basis for discriminative sensation, and further, for distinct feelings that are related to subjective disposition and emotions (i.e., 'how you feel'). The affective experiences of thermal comfort and discomfort that accompany all temperature sensations are associated with thermosensory activation of anterior frontoinsular and medial frontal cortical regions.

Thermoreceptive-specific neurons are not found within the somatosensory cortical areas that are associated with the sensation of touch. Therefore, whereas it has long been held that temperature sensation is an aspect of the sense of touch, the neuroanatomy of temperature sensation indicates that the discriminative thermosensory capacity of humans has emerged evolutionarily as one distinct aspect of the cortical representation of the physiological condition of the body, which developed along with the enormous encephalization in primates and especially humans. The highly developed sense of temperature in humans provides the capacity to use temperature information not only as a signal of the condition of our bodies, but also as a discriminative sensation useful for recognizing objects and exploring the environment.

Finally, it is noteworthy that damage to primary thermosensory cortex causes not only loss of temperature sensation, but may also cause the so-called central pain syndrome, in which ongoing burning pain is reported in a region of thermanesthesia or

thermosensory dysfunction. The thermal grill illusion is remarkably analagous to the central pain syndrome, suggesting that this syndrome may be regarded as a thermoregulatory dysfunction due to the loss of the cool inhibition of the polymodal pain pathway. Reports that such pain may be alleviated by warming or by drugs that increase tissue perfusion and thermogenic heat production support this hypothesis.

Temporal Processing in the Auditory Pathway

D Oertel, M J McGinley, and X-J Cao, University of Wisconsin, Madison, WI, USA

Acoustic Information Is Carried in the Timing of Firing of Neurons

The vertebrate brain carries information both in the spatial pattern in which neurons are activated and by the timing of their firing. Although often considered separately, they are linked because the determination of a spatial firing pattern requires that firing be integrated over a time period. The time over which spatial activation is monitored is in many cases inherent to the method used and often has a low temporal resolution, for example, in functional MRI or in methods based on glucose metabolism to examine those spatial patterns of activation, so relatively little attention has been given to these issues in the studies of many regions of the brain. In the mammalian auditory system the importance of the relationship between temporal and spatial firing patterns among neurons has long been appreciated and continues to be explored.

The ability of neurons to encode acoustic information in the timing of firing is illustrated especially clearly in the ability of neurons to fire in phase with sounds. In the early 1960s, Nelson Kiang showed that auditory nerve fibers encode the frequency of tones not only in their tuning but also in the timing of their firing. The groups led by Kiang at the Massachusetts Eye and Ear Infirmary in Boston and by Jerzy Rose at the University of Wisconsin in Madison documented, using some of the earliest lab computers, how auditory nerve fibers encode frequency by firing in phase with sounds. In cats and monkeys, low-frequency sounds, sounds below about 4000 Hz, evoke action potentials at a particular phase of the sound cycle. In order to do so, the probability of firing must be greater over one-half of the 250 μs cycle than the other and requires that neurons fire with a temporal precision on the order of 100 μs. Neurons fire in phase with tones, skipping some cycles when sounds are soft or at frequencies too high for neurons to fire with every cycle, as illustrated in Figure 1.

The ability of neurons in the auditory system to encode phase underlies the ability to use interaural time differences to localize sound sources in the horizontal plane. The relative time of arrival of a sound at the two ears is a function of the angle of the sound source with respect to the nose and ears. The maximal interaural time differences are about 0.5 ms for sounds coming from the side of the head in animals such as human beings with large heads and are smaller in animals with smaller heads. Interaural time differences produce corresponding interaural phase differences. Recent work has shown that mammals use every cycle of a sound to measure interaural time differences at low frequencies. To make use of small interaural time and phase differences for localizing sound sources, auditory neurons need to signal with enough temporal precision to resolve these differences.

Precision in the timing of firing is observed across the tonotopic range. Auditory nerve fibers tuned to high frequencies and their targets can be phase-locked to the rate of amplitude modulation. Their targets in the cochlear nucleus, octopus cells, signal the presence of broadband transients with a temporal precision in the range of 100 μs.

The precision of the temporal coding of frequency also plays a role in the detection of pitch. The range of musical pitch, 20–5000 Hz, lies largely in the range of frequencies where there is phase-locking and has been shown in many, but not all, cases to be related to the periodicity of sounds. Pitch, like phase-locking and unlike spatial tuning, becomes increasingly precise as the loudness of sounds increase. Bertrand Delgutte and Peter Cariani have shown that the period of a perceived pitch corresponds to the most common interval between action potentials in the population of auditory nerve fibers in cats, suggesting that differences of tens to hundreds of microseconds in intervals between action potentials in the population of auditory nerve fibers are detected and used to sense pitch. Detecting pitch is required to recognize voices and appreciate music.

The encoding of temporal cues is likely to contribute to understanding speech. Arnold Starr and Feng-Gang Zeng and their colleagues have shown that patients with auditory neuropathy lose the ability to detect brief gaps in noise as they lose the ability to understand speech. Contributions of the encoding of temporal cues for understanding speech have been revealed especially clearly in people with cochlear implants. Processors for cochlear implants generally divide the frequency spectrum into a small number of bands and use the envelopes of those bands to modulate the strength of a very rapid train of shocks. The fine structure of sounds, including phase-locking at low frequencies, is generally not encoded. People with cochlear implants understand speech remarkably well but they cannot hear pitch. Even when the phase of the fundamental frequency is encoded, the perception of pitch does not improve. Perhaps this is because

Figure 1 An illustration of what is meant by phase-locking shows how a neuron in the brain stem can fire (upper trace) in phase with the cycles of a tone (lower trace). Neurons that phase-lock fire at a particular phase in the cycle but can skip cycles. As the period of a cycle becomes shorter with increasing tonal frequency, jitter in the timing of firing reduces the precision of timing with respect to phase; under such conditions the synchronization coefficient is reduced. In the auditory nerve of mammals phase-locking is robust at frequencies lower than 2000 Hz; at higher frequencies, the synchronization coefficient drops off and no phase-locking can generally be detected at frequencies higher than 4000 Hz. Neurons can fire at every cycle in response to low frequency tones but skip more cycles with increasing frequency.

cochlear implants do not reach the apex of the cochlea, so even if phase cues are presented for low-frequency sounds, they can only be presented at inappropriate cochlear locations. The inability to detect pitch leads not only to an inability to appreciate music but also to an inability to distinguish the age or gender of voices that makes it difficult to follow conversations in noisy environments. These observations indicate that pitch probably requires that encoding of temporal fine structure occur within the appropriate location in the tonotopic map.

This article is concerned with understanding how neurons in the auditory system can fire with temporal precision. It is impossible to be complete in reviewing the topic. This chapter will focus on what we have learned about the cellular mechanisms that underlie temporal encoding of acoustic information in the ventral cochlear nucleus (VCN). These findings illustrate both that neurons use common mechanisms to encode timing precisely and also that differences in those properties allow neurons to perform different integrative tasks and to convey different aspects of sensory information.

Temporal Precision Is Greatest in the Brain Stem

Acoustic information that is contained in the timing of firing in the auditory system necessarily comes from the cochlear hair cells that transduce sounds and is conveyed synaptically through chains of neurons that form the auditory pathway. The precision of timing information in the auditory nerve is limited by the ability of voltage changes in hair cells to follow mechanical movements in the cochlea and by the precision whereby those voltage signals are conveyed synaptically to spiral ganglion cells. Auditory nerve fibers in turn convey that information to several different cell types in the cochlear nuclei, each of which forms a separate pathway. In so doing, the auditory pathway is subdivided into multiple, parallel ascending pathways. These cell types and the pathways they form differ in the precision with which they encode temporal information. In some, octopus and bushy cells for example, the precision of timing information is sharpened by convergence whereas in the principal cells of the dorsal cochlear nucleus acoustic information contained in the timing of firing is largely lost.

The major components of the ascending auditory system are illustrated in Figure 2. Every auditory nerve fiber carries acoustic information from the cochlea to multiple groups of neurons whose projection patterns differ and which therefore form separate, parallel, ascending pathways. In the VCN auditory nerve fibers contact T stellate, bushy, and octopus cells. The axons of octopus cells cross the midline to innervate the contralateral superior paraolivary nucleus (SPN) and the ventral nucleus of the lateral lemniscus (VNLL). The axons of bushy cells innervate the superior olivary complex; some innervate the medial superior olive (MSO) bilaterally, others innervate the contralateral medial nucleus of the trapezoid body (MNTB), and yet others innervate the ipsilateral lateral superior olive (LSO). The axons of T stellate cells terminate in the LSO, periolivary nuclei, the contralateral VNLL, and the inferior colliculus. Nuclei that contain neurons with biophysical specializations for encoding timing are indicated with gray in Figure 2. Ultimately,

Figure 2 The major components in the ascending auditory pathways are shown diagrammatically. Sound is transduced in the cochlea. Information is carried through the axons of spiral ganglion cells, the auditory nerve fibers, to the dorsal (DCN) and ventral (VCN) cochlear nuclei. Several parallel pathways are formed from the cochlear nuclei through the brain stem which converge in the inferior colliculus. The principal cells of the DCN project directly to the contralateral inferior colliculus. The VCN contains three types of principal cells, T stellate cells, bushy cells and octopus cells. The axons of T stellate cells innervate the lateral superior olive (LSO) and the ventral nucleus of the lateral lemniscus (VNLL) and continue to the inferior colliculus. Bushy cells innervate the superior olivary complex. One subtype of bushy cell innervates the medial superior olive (MSO) bilaterally. Another subtype of bushy cell innervates the contralateral medial nucleus of the trapezoid body (MNTB), whose principal cells in turn inhibit the LSO. A third subtype of bushy cell innervates the LSO ipsilaterally. At least some of the bushy cells innervate the VNLL. Octopus cells innervate the contralateral superior paraolivary nucleus (SPN) and the contralateral VNLL. The DNLL receives input from the ipsilateral MSO and LSO. Principal cells of the MSO, LSO, SPN, VNLL, and DNLL project to the inferior colliculus. Principal cells of the inferior colliculus project to the medial geniculate body of the thalamus and these in turn project to the auditory cortex. Neurons with low-voltage-activated K^+ conductances that enable them to signal with temporal precision are found in nuclei that are colored gray. In the nuclei that are colored with solid gray, all neurons have those specializations. In nuclei indicated with the patterned gray only some neurons have those conductances. DNLL, dorsal nucleus of the lateral lemniscus.

all parallel pathways through the brain stem lead to the inferior colliculus and thence to the auditory part of the thalamus and auditory cortex. The precision in the timing of firing that is evident at lower levels is not observed in the inferior colliculus or its targets. Information contained in precise timing of firing is either lost or re-encoded in the inferior colliculus.

Biophysical Specializations that Underlie Precision in the Timing of Firing Are Variations on a Common Pattern

The temporal precision with which neurons carry acoustic information differs between cell types. Some neurons (including the spiral ganglion cells whose axons form the auditory nerve, ventral cochlear nuclear octopus and bushy cells, the principal cells of the MSO, MNTB, and some neurons in the LSO and VNLL) are specialized to receive and convey precisely timed signals. These groups of neurons perform differing integrative tasks that are reflected in differences in their shapes, the identity and distribution of their synaptic inputs, in the route taken by their axons, and in their electrophysiological properties. However, specializations for preserving and conveying timing in their signaling have common features. They receive rapidly rising and falling synaptic currents, they have low input resistances and, as a consequence also short

time constants, that allow voltages to rise and fall quickly. Nuclei that contain neurons with such biophysical properties are indicated in gray in Figure 2. In the following section common features and functionally significant differences will be illustrated in the properties of the three major groups of principal cells of the VCN: octopus, bushy, and T stellate cells. Robin Davis and her colleagues have documented the presence of similar features in the auditory nerve. Ian Forsythe and his colleagues revealed them in the principal cells of the MNTB and in some cells in the LSO. Shu Hui Wu and Nace Golding and their colleagues have described similar properties in principal cells of the MSO. Shu Hui Wu and colleagues revealed their presence in the VNLL.

Intrinsic Properties of Principal Cells of the VCN Span a Wide Range

Differences in the way neurons in the brainstem receive and convey timing information are illustrated in the properties of the three major types of principal neurons of the VCN in Figure 3. octopus, bushy, and T stellate cells. Recordings of the intracellular voltage with respect to the extracellular environment, by impaling neurons with sharp microelectrodes, or by recording through a patch in the whole-cell mode, show that neurons have similar resting potentials, near –65 mV. Differences in their biophysical properties are revealed in their responses to identical, depolarizing current pulses delivered through the recording electrodes. Figure 3 illustrates that a pulse of depolarizing current produces a rapid, small change in voltage that falls quickly back to the resting potential at its offset in octopus cells. A similar current pulse injected into a bushy cell produces an action potential; at the end of the current pulse the voltage falls back toward rest more slowly than in octopus cells. A current pulse injected into a T stellate cell causes the cell to fire a train of regularly spaced action potentials; at the end of the pulse the voltage falls back toward rest more slowly than in either octopus or bushy cells. Differences in the responses to current pulses results from differences in morphology as well as differences in number, type, and location of ion channels.

An important determinant of the responses to transmembrane current is the input resistance near

Figure 3 Biophysical properties shape responses to depolarizing current and responses to shocks of the auditory nerve. Left: Responses to pulses of depolarizing current. The response of the octopus cell is subthreshold; a larger current pulse produces an action potential at the onset of a depolarization (not illustrated). The return to rest of the voltage after the end of the current pulse is most rapid in the octopus cell and slowest in the T stellate cell (*). Right: Shocks to the auditory nerve (arrows) evoke EPSPs whose duration is briefest in the octopus cell, intermediate in the bushy cell, and longest in the T stellate cell. The time course of averaged, spontaneous, mineature EPSCs measured from each of the cell types is shown beneath the corresponding EPSPs. The low input resistance of octopus cells makes EPSPs barely longer than the EPSCs whereas in T stellate cells the EPSPs outlast EPSCs. All of the traces are redrawn. Some are adapted, redrawn and idealized, from traces that were recorded by Nace Golding. From figure 30–14, Kandel ER, Schwartz JH, and Jessell TM (2000) *Principles of Neural Science*, 4th edn. New York: McGraw-Hill. Averaged, normalized mEPSCs are derived from data reported by Gardner SM, Trussell LO, and Oertel D (1999) Time course and permeation of synaptic AMPA receptors in cochlear nuclear neurons correlate with input. *Journal of Neuroscience* 19: 8721–8729.

the resting potential. Both the magnitude of the voltage changes evoked by current and their rates of change (Figure 3) reflect the input resistance. The input resistance of octopus cells is on average only about 5 MΩ, so that large currents are required to evoke action potentials but the voltage can rise and fall quickly. Bushy cells have higher input resistances, about 70 MΩ, so that currents produce larger voltage changes and smaller currents are required to reach threshold, but the fall of voltage back to rest is slower. T stellate cells generally have input resistances around 75 MΩ and have correspondingly larger and slower voltage changes. The rate at which voltage changes depends upon the input resistance as well as on the input capacitance which is a function of the size, shape, and surface area of neurons. The fastest rate at which membrane potential can change can be estimated by fitting voltage changes at the termination of a current pulse with a single exponential function and comparing the time constants, τ. The τ varies more than an order of magnitude between cells; it is only about 0.2 ms in octopus cells, about 1 ms in bushy cells, and about 7 ms in T stellate cells.

Responses to synaptic currents, like those to injected current pulses, are shaped by the electrical properties of neurons. In the VCN, release of neurotransmitter from auditory nerve fibers produces excitatory postsynaptic currents (EPSCs) in target neurons that cause excitatory postsynaptic potentials (EPSPs). Stephanie Gardner measured the time course of synaptic currents produced by the spontaneous release of neurotransmitter (mEPSCs) in each of these cell types and found that their time course was similar in octopus, bushy, and T stellate cells as illustrated on the right in Figure 3. Although EPSCs are similar, shocks to auditory nerve fibers (Figure 3, arrow) evoke EPSPs whose shapes vary between cell types (Figure 3). EPSPs are briefest in octopus cells, longer in bushy cells, and still longer in T stellate cells. Timing is encoded most sharply in neurons with the briefest EPSPs.

Glutamate Receptors in the Auditory Brain Stem Nuclei Have Rapid Kinetics

Glutamate receptors vary in their properties as a function of the subunits from which they are formed. Glutamate receptors are ligand-gated ion channels that vary in the rate at which they are activated, deactivated, and at which they desensitize when they are exposed to ligands. The number of possible compositions is large because these receptors are formed from combinations of four subunits, GluR1–GluR4, each of which exists in one of the two alternatively spliced forms, flip or flop. The work of Laurence Trussell and Robert Wenthold and their colleagues has shown that the glutamate receptors in neurons of the VCN are formed from GluR3 flop and GluR4 flop α-subunits and that they are the most rapidly activating, deactivating, and desensitizing glutamate receptors known. The rapid activation, deactivation, and desensitization of these receptors allow synaptic currents to be brief and thus sharply timed.

Voltage-Sensitive Conductances Allow Signaling to be Temporally Precise

Neurons that encode timing in the mammalian auditory pathway contain conventional voltage-sensitive ion channels. Specializations lie in the distribution and density of those channels. The axons of neurons that encode timing produce action potentials that are mediated through voltage-sensitive, and tetrodotoxin-sensitive, Na^+ channels (g_{Na}). Action potentials are repolarized by various K^+ conductances, some activated at relatively negative membrane potentials and others activated at more positive potentials, and in some cells by Ca^{2+}-activated K^+ conductances. The density, distribution, and form of some of the ion channels that mediate these conductances not only vary between types of auditory neurons, giving them distinctive electrophysiological signatures, but in some cell types (spiral ganglion cells and principal cells of the MNTB) have also been shown to vary as a function of position in the tonotopic map.

Cells that signal with temporal fidelity have low-voltage-activated K^+ (g_{KL}) conductances and hyperpolarization-activated mixed-cation conductances (g_h). Paul Manis and colleagues were the first to draw attention to the importance of g_{KL}, showing that neurons that behaved like bushy cells have not only a K^+ conductance that is activated by strong depolarizations (more positive than –40 mV; g_{KH}, carries I_{KH}) but also one that is activated at quite negative voltages (more positive than –70 mV; g_{KL}, carries low-voltage-activated K^+ current, I_{KL}). The neurons that behaved like T stellate cells lacked g_{KL}. Recent experiments show that g_{KL} seems to be present in all neurons in the brain stem auditory pathway that are known to encode timing with precision. Resting outward K^+ currents through g_{KL} are to some extent balanced by inward currents through g_h.

Exceptionally large g_{KL} and g_h endow octopus cells with the low input resistances that make them fast. At rest two opposing conductances, g_{KL} and g_h, are partially activated and balance one another. Figure 4 illustrates that these two conductances are activated by opposite changes in membrane potential and illustrates that at the resting potential both g_h and g_{KL} are partially activated. The channels that underlie g_{KL}

Figure 4 Two opposing conductances affect the resting properties of octopus cells. A low-voltage-activated K^+ conductance (g_{KL}) is activated at depolarizing voltages. The activation curve is scaled to the average peak, maximum conductance (based on data reported by Bal R and Oertel D (2001) Potassium currents in octopus cells of the mammalian cochlear nucleus. *Journal of Neurophysiology* 86: 2299–2311). Its reversal potential (V_{rev}) is near the K^+ equilibrium potential (open circle), identifying it as a K^+ conductance. A mixed cation conductance (g_h) is activated by hyperpolarizing voltages. Its reversal lies between the equilibrium potentials of permeant ions, Na^+ and K^+ (filled circle). The plot is scaled to the average, maximum conductance (based on data reported by Bal R and Oertel D (2000) Hyperpolarization-activated, mixed-cation current (I_h) in octopus cells of the mammalian cochlear nucleus. *Journal of Neurophysiology* 84: 806–817). At the resting potential (V_{rest}) both conductances are partially activated, contributing substantially to the low input resistance of octopus cells. At rest the currents, a function of the conductance and the difference between the resting potential and the reversal potential, through the two conductances are matched.

are opened by positive changes in potential, whereas the channels that underlie g_h are opened by negative changes in potential. Under physiological conditions, the action of each of these conductances feeds back on itself negatively so that each will tend toward its own minimal activation in the steady state. The reversal potential, V_{rev}, is the voltage at which there is no net movement of ions even when channels are open. The current, I_{KL}, reverses near the equilibrium potential of K^+, at −76 mV, confirming that g_{KL} carries K^+ ions (Figure 4, open circle V_{rev}). The reversal potential of I_h lies near −38 mV (Figure 4, filled circle); its position between the equilibrium potentials for Na^+ and K^+ ions reflects the permeability of these channels to both Na^+ and K^+, with P_{Na}/P_K being about 0.2. In octopus cells, at rest the K^+ ions that flow out through g_{KL} are balanced by Na^+ ions flowing in through hyperpolarization-activated, mixed cation channels, g_h. Bushy cells are also endowed with g_{KL} and g_h but the maximum amplitudes of these conductances are smaller. T stellate cells lack g_{KL}.

Under physiological conditions, the voltage of neurons is dynamic and the state of voltage-sensitive ion channels is governed by their voltage sensitivity as well as by their kinetics. Changes in membrane potential result in rapid changes in g_{Na} and g_{KL}, but only slower changes in g_h. The firing of cells can thus be affected by the rate at which they are depolarized. Principal cells of the VCN vary in their sensitivity to the rate at which they are depolarized and consequently in the duration of the time window over which depolarizing current can sum to bring the neuron to threshold. Figure 5 shows that the types of principal cells of the VCN differ in their dynamic properties. Octopus cells fire action potentials when they are depolarized with rapid, but not with slow, ramped currents. In families of currents when ramps were brief, depolarization was rapid and octopus cells fired action potentials even to relatively small currents; when ramps to similar current levels were longer and depolarization was slower, only the largest current brought the cell to threshold (Figure 5(a)). Plots of the cell's response as a function of the subthreshold rate of depolarization show that firing consistently occurred when the rate of depolarization exceeded a threshold. The example shown in Figure 5(a) had a threshold rate of depolarization of about 12 mV ms^{-1}; on an average rate thresholds of octopus cells were about 10 mV ms^{-1}. These properties allow an integration window to be defined operationally. Depolarizing current can contribute to evoking an action potential over a period that is the duration of the slowest suprathreshold ramp to the time at which the action potential is triggered (Figure 5(a), period between the dashed lines on left). Integration windows are very short in octopus cells, about 1.5 ms. In order to fire action potentials, bushy cells, too, must be depolarized faster than at a threshold rate but that threshold rate is slower and the integration window over which depolarizing current can sum is longer (Figure 5(b)). In bushy cells rate thresholds were about 6 mV ms^{-1} on average and integration windows were about 5 ms. In contrast with octopus and bushy cells, T stellate cells are insensitive to the rate of depolarization and have no rate thresholds. Even when they are depolarized very slowly, it appeared that they fire action potentials upon reaching a voltage threshold (Figure 5(c), dashed line). Their integration window is not limited by intrinsic biophysical properties.

The sensitivity to rate of depolarization and the duration of the integration window depend on g_{KL}. Figure 6 shows comparisons of the responses of neurons in the absence and presence of α-dendrotoxin, a toxin from the green mamba snake that blocks g_{KL} with great specificity. Under control conditions, an octopus cell and a bushy cell require depolarization at greater than a threshold rate to fire action potentials (Figures 6(a) and 6(b), left). When those same cells were exposed to α-dendrotoxin, they fired action

Figure 5 Principal cells of the VCN differ in their sensitivity to rate of depolarization. (a) An octopus cell was depolarized with families of current ramps to steady levels as illustrated at the top right. The duration of the ramps was varied between 1 (upper traces) and 1.4 ms (lower traces). The octopus cell fired action potentials only when the rate of depolarization exceeded a threshold. The step in the plot on the lower right shows that this octopus cell had to be depolarized at more than 11 mV ms^{-1} to fire. The longest duration between the onset of a ramp and the initiation of the action potential defines the integration window: the longest period over which depolarizing current can sum and lead to an action potential (period between dashed lines). The integration window of this octopus cell was 1.3 ms. (b) A bushy cell was depolarized at varying rates by varying the duration of current ramps toward 0.2 nA. To fire, the bushy cell had to be depolarized faster than 4.3 mV ms^{-1} and it had an integration window of 4.7 ms. (c) A T stellate cell was depolarized with currents that rose at two different rates. Light trace shows the response to a relatively rapid ramp to 0.3 nA. The cell started to fire when it reached a threshold voltage and then increased the firing rate. When the same cell was depolarized with a very slow ramp, action potentials rose when roughly the same potential was reached. The T stellate cell behaved as if it fired action potentials when it reached a certain voltage (dashed line) even when the peaks of the action potentials were reduced by inactivation of the Na^+ conductance. (a) Traces and plots are reproduced from figure 3, Ferragamo MJ and Oertel D (2002) Octopus cells of the mammalian venteral cochlear nucleus sense the rate of depolarization. *Journal of Neurophysiology* 87: 2262–2270). (b and c) Reprinted from McGinley MJ and Oertel D (2006) Rate thresholds determine the precision of temporal integration in principal cells of the ventral cochlear nucleus. *Hearing Research* 216–217: 52–63.

Figure 6 The low-voltage-activated K^+ conductance (g_{KL}) plays a key role in determining the sensitivity to rate of depolarization. (a) Responses of an octopus cell to ramps show that ramps needed to be rapid to be suprathreshold. When that same cell was bathed in 100 nM α-dendrotoxin, a saturating concentration of a toxin that specifically blocks g_{KL}, action potentials could be evoked even with slow ramps. In the absence of g_{KL}, action potentials became tall and broad, revealing a role of g_{KL} in the repolarization of action potentials. (b) Bushy cells, too, had to be depolarized at more than a threshold rate to fire. In the presence of 66 nM α-dendrotoxin the bushy cell fired repetitively even when depolarized with a slow ramp. Peaks of action potentials were not affected by the toxin, indicating that repolarization depended on a different type of K^+ conductance. (c) The firing of action potentials by T stellate cells is unaffected by 100 nM α-dendrotoxin indicating that they contain little, if any, g_{KL}. (a and c) Reproduced from figures 6 and 8, Ferragamo MJ and Oertel D (2002) Octopus cells of the mammalian venteral cochlear nucleus sense the rat of depolarization. *Journal of Neurophysiology* 87: 2266, 2267. (b) Reprinted from McGinley MJ and Oertel D (2006) Rate thresholds determine the precision of temporal integration in principal cells of the ventral cochlear nucleus. *Hearing Research* 216–217: 52–63.

potentials even in response to slow depolarization (Figure 6(a) and 6(b), right). In octopus cells, but less so in bushy cells, g_{KL} plays a role in repolarizing action potentials because in its absence, action potentials are unusually tall and of long duration. In contrast with octopus and bushy cells, T stellate cells have little or no g_{KL} because they are not affected by α-dendrotoxin and as a result the duration of their integration windows is effectively unlimited (Figure 6(c)).

The duration of EPSPs is matched to the duration of the integration windows in principal cells of the VCN. Synaptic responses to shocks to the auditory nerve are briefest in octopus cells, of intermediate

duration in bushy cells, and longest in T stellate cells (Figure 3). This observation results in part from the fact that the voltage-sensitive conductances that determine the integration window also shape synaptic responses. The voltage sensitivity of g_{KL} is maximally steep over the voltage range over which EPSPs occur. Synaptic depolarization in octopus and bushy cells thus activates g_{KL} which then contributes actively to the repolarization of the EPSP, making EPSPs brief. In T stellate cells, in contrast, the decay of EPSPs is determined by passive decay rate (Figure 3).

Rate of depolarization thresholds and short integration windows enhance the ability of neurons to detect synchrony among subthreshold inputs and to convey the timing of synchronous inputs in their own firing. Octopus cells provide a particularly clear example. Figure 7(a) shows that as shocks to the auditory nerve increased in strength, activating more and more auditory nerve fibers, the rate of rise of the EPSPs increased and the peaks of synaptic responses became larger and occurred only slightly earlier. Octopus cells are innervated by many auditory nerve fibers (>60). Action potentials in any one auditory nerve fiber produce only small EPSPs with slow depolarization so that many auditory nerve fibers must sum to produce a suprathreshold response. To achieve the threshold rate of depolarization, the rising phases of EPSPs from many auditory nerve fibers must sum. The firing of octopus cells signals the activation of populations of auditory nerve fibers whose firing occurs within the integration window. Two other features of synaptic responses of octopus cells are notable. First, the action potentials of octopus cells are conventional in the axon but are strongly attenuated at the cell body where recordings are made. In being attenuated, action potentials interfere minimally with synaptic integration. Second, the timing of the peak is remarkably constant over a wide range of EPSP amplitude. In part that is because the peak is determined not only by the time course of the excitatory, synaptic inward currents but also by the rapid repolarization by g_{KL} that truncates the depolarization. The ability of octopus cells to detect synchronous activation of auditory nerve fibers and to fire with great temporal precision is evident in responses to sound *in vivo*. They respond sensitively and with precision to broadband acoustic transients. These phenomena also occur in bushy cells but they are less exaggerated. Bushy cells detect synchronous activation among a smaller number of auditory nerve inputs (4–20). They also convey the timing of the activation of those inputs with enhanced temporal precision.

The unlimited integration windows make it possible for T stellate cells to signal the presence of very slow signals and it makes it possible for their excitability to be modulated synaptically. Figure 7(b) illustrates responses of one T stellate cell to electrical stimulation of the nerve root. The weakest shocks evoked relatively brief responses like those illustrated in Figure 3 that were suprathreshold. As the strength of shocks was increased, the depolarizations lasted

Figure 7 Synaptic responses in principal cells of the VCN are matched to their biophysical properties. (a) Shocks to the auditory nerve evoke brief synaptic responses in an octopus cell; depolarizing phases last less than 1 ms. As the shock strength was increased, synaptic responses were evoked after a synaptic delay. The responses grew by small increments over wide range, reflecting the recruitment of converging auditory nerve fibers onto a single octopus cell. Action potentials recorded at the cell body are small in octopus cells; the smallest response in the illustration is subthreshold, and all the others are suprathreshold. The timing of the peaks of action potentials varied by about 300 μs over a wide range of shock strengths. (b) In a T stellate cell, shocks to the auditory nerve evoked responses that lasted for up to 100 ms. In this cell weak shocks evoked a suprathreshold EPSP. (The synaptic delay cannot be resolved in these long traces and the peaks of action potentials are truncated.) Stronger shocks evoked not only the rapid suprathreshold EPSPs but also slower, longer-lasting excitation. Even slow and steady depolarization evoked action potentials. (a) Reproduced from figure 3, Oertel D, Bal R, Gardner SM, Smith PH, and Joris PX (2000) Detection of synchrony in the activity of auditory nerve fibers by octopus cells of the mammalian cochlear. *Proceedings of the National Academy of Sciences of the United States of America* 97: 11775. (b) Reproduced from figure 2, Ferragamo MJ, Golding NL, and Oertel D (1998) Synaptic inputs to stellate cells in the venteral cochlear nucleus. *Journal of Neurophysiology* 79: 54.

Figure 8 The range of biophysical properties allows principal cells of the VCN to encode and convey timing information with varying resolution. Principal cells vary in time constant, τ, in large part because they vary in the expression of the low-voltage-activated conductance, g_{KL}. The presence of g_{KL} is associated with high rate-of-depolarization (dV/dt) thresholds and short integration windows. High rate thresholds and short integration windows make synaptic responses sharply timed. The sharp timing can be measured as a small coefficient of variation in the latency of responses to sound (CV latency) and in high synchronization coefficients to the modulation frequency in responses to AM tones. Data are shown as means with standard deviations and are derived from the following sources: τ, octopus and T stellate cells, Golding NL, Ferragamo MJ, and Oertel D (1999) Role of intrinsic conductances underlying responses to transients in octopus cells of the cochlear nucleus. *Journal of Neuroscience* 19: 2897–2905; bushy cells, unpublished results); g_{KLmax} (Bal R and Oertel D (2001) Potassium currents in octopus cells of the mammalian cochlear nucleus. *Journal of Neurophysiology* 86: 2299–2311, Cao X-J, Shatadal S, and Oertal D (2007) Voltage-sensitive conductances of bushy cells of the mammalian venteral cochlear nucleus. *Journal of Neurophysiology* (in press); dV/dt thresholds and integration windows (reprinted from McGinley MJ and Oertel D (2006) Rate thresholds determine the precision of temporal integration in principal cells of the ventral cochlear nucleus. *Hearing Research* 216–217: 52–63); coefficient of variation of latency in responses to tones (Rhode WS and Smith PH (1986) Encoding timing and intensity in the venteral cochlear nucleus of the cat. *Journal of Neurophysiology* 56: 261–286). Synchronization coefficients are compared in responses to sounds at the characteristic frequency of the neurons and modulated at 500 Hz (Rhode WS (1994) Temporal coding of 200% amplitude modulated signals in the ventral cochlear nucleus of cat. *Hearing Research* 77: 43–68).

for increasingly long times (>100 ms) and the duration of excitation was conveyed in its firing. Cholinergic currents, too, can modulate responses of T stellate cells, perhaps modulating the dynamic range of responses to sounds.

Relationship of Biophysical Specializations to Responses to Sound

The three major groups of principal cells in the VCN can be viewed as pathways for carrying different types of timing information (Figure 8). At one extreme, octopus cells sense transients. They signal the presence of broadband transients with exceptional temporal precision. They fail to signal the duration of sounds, however. Bushy cells are intermediate, enhancing the encoding of timing in narrowband transients to some extent yet still conveying information about the fine structure and duration of sounds. T stellate cells are at the opposite extreme in that they encode the duration of narrowband sounds but lose information about its fine structure.

The ranges of physiological parameters that underlie the differences and that determine how these pathways convey temporal information are summarized in Figure 8. Time constants around the resting potentials that reflect the input resistance and input capacitance varied between 0.2 ms in octopus cells and 7 ms in T stellate cells. The presence of g_{KL} is an important determinant both of the input resistance and of the shapes of EPSPs because it is partially activated at the resting potential and is maximally sensitive to voltage in the voltage range of EPSPs. This conductance is particularly large in octopus cells and is either absent or expressed at very low levels in T stellate cells, with bushy cells being intermediate (Figure 8, top panels). To make an analogy with current, octopus cells are at one extreme of the spectrum and detect AC signals and T stellate cells are at the opposite extreme and detect DC signals.

Differences in the expression of g_{KL} lead to differences in sensitivity to the rate of depolarization. Octopus cells require high rates of depolarization to fire action potentials and fire only transiently, whereas T stellate cells respond even to steady depolarizations. Bushy cells, again, are intermediate. Associated with

differences in sensitivity to rate of depolarization are differences in the duration of integration windows. At the one extreme, the rising phases of brief EPSPs must sum to cause octopus cells to fire while at the other extreme T stellate cells respond sensitively to small steady currents (Figure 8, middle panels).

Responses to sound reflect the biophysical properties of neurons. The latency in the timing of the initial responses to tones, for example, reflects the precision with which timing information is conveyed. The latency has a very small coefficient of variation in responses of octopus cells, a larger coefficient of variation in responses of bushy cells, and the largest coefficient of variation in T stellate cells (Figure 8, bottom left). Another measure of the encoding of timing is in the synchronization coefficient of responses to amplitude-modulated sound. The synchronization coefficient is greatest in octopus cells, and smallest in T stellate cells (Figure 8, bottom right).

A comparable analysis of sensitivity to rate of depolarization, of the variation in latency, and of responses to amplitude-modulated tones has not been made in other neurons that are known to encode timing with precision but it is likely to follow the same pattern. The presence of g_{KL} in auditory nerve fibers and in targets of bushy and octopus cells suggests that each of these groups of neurons is sensitive to the rate of depolarization and thus is sensitive to acoustic transients and enhances the precision in the timing of firing of its inputs. Other pathways through the brain stem lack g_{KL} enabling them to encode slower modulation.

Introduction

In 1990, Gail Mandel and David Anderson independently reported the first data suggesting that expression of neuron-specific genes might be under the control of *cis*-acting negative regulator elements within these genes. These insights quickly led to the discovery in 1992 of the sequence of such an element, which was called RE1 by Mandel and neuron-restrictive silencer element (NRSE) by Anderson. Since NRSE/RE1-like sequences were found in at least three genes specifically expressed by neuronal cell types, it was immediately postulated that NRSE/RE1-dependent silencing might be a general mechanism to silence neuronal genes in nonneuronal cell types, mediated by a *trans*-acting silencing factor expressed in nonneuronal cells but not in neuronal cells. Indeed, separate cloning efforts by both groups, published in 1995, led to the identification of this silencer factor as the RE1-silencing transcription factor (REST) or neuron-restrictive silencer factor (NRSF). As had been hypothesized, REST/NRSF expression was observed to be generally high in nonneuronal cells types, with concomitantly low levels of transcripts of genes with an NRSE/RE1 element, and vice versa.

Although REST/NRSF's initially proposed function as a silencer of a large set of neuronally enriched genes has acquired widespread acceptance, evidence has accumulated in the past few years indicating that REST/NRSF plays additional, much more dynamic roles in normal development and adult brain function, as well as in disease. This view is supported by the discovery of a large network of REST/NRSF targets that includes many genes not exclusively expressed in neurons.

In this article, we review the architecture of the REST/NRSF gene and protein, including regulation of REST/NRSF expression, and present the current knowledge of its gene targets. In our discussion of its role in the developing and adult organism, we also briefly touch upon REST/NRSF regulation in neurological disease and cancer. Lastly, because the control of target gene expression by REST/NRSF is critically dependent on the action of its protein interaction partners, we also provide insight into REST/NRSF-recruited cofactors and how these are thought to modulate the function of this transcription factor.

REST/NRSF: Gene Organization, Alternative Splicing, and Protein Structure

The REST/NRSF gene and its exon structure are evolutionarily conserved from human to fugu (pufferfish). The gene is not found in flies or nematodes, suggesting that REST/NRSF is specific to the vertebrate lineage. It consists of three alternative first exons (exons I–III), located in the 5′ untranslated region (5′ UTR); three constitutively spliced exons (IV–VI); and a short (28 base pairs) alternatively spliced internal exon (exon N). The full-length REST/NRSF protein comprises three known functional domains: a DNA-binding domain and two repressor domains, which are located at the N- and C-termini of the protein. The two repressor domains function independently of each other and serve to recruit distinct transcriptional regulation complexes (Figure 1(b)). The protein also has lysine- and proline-rich regions; however, their significance is unknown. REST/NRSF's DNA binding domain encompasses an array of eight highly conserved zinc fingers, small independently folded nucleic acid binding motifs found in many other sequence-specific nucleic acid binding proteins. Thus, with its repressor and DNA binding domains, REST/NRSF shows an architecture typical of most transcription factors.

Although little is known about the function of alternative splicing events that affect the 5′ UTR of the REST/NRSF gene, the splice variant produced by inclusion of exon N, located within the region of the gene that encodes the DNA binding domain, has received a great deal of attention because it is primarily found in neurons. Its protein product, termed REST4, is a truncated version of REST/NRSF that terminates after the fifth zinc finger and therefore lacks the C-terminal repressor domain (Figure 1(a)). Thus, REST4 is likely to have a function distinct from full-length REST/NRSF, which will be discussed later.

NRSE/RE1: The DNA Binding Element of REST/NRSF

REST/NRSF regulates target genes by direct binding to its cognate DNA silencer element, the NRSE/RE1 (Figure 1(c)), which was originally identified in the promoters of the superior cervical ganglia 10 and type II sodium channel. With its long span of approximately 21 base pairs (bp) and its rather low degree of sequence degeneracy (Figure 1(c)), the NRSE/RE1 is a highly unusual transcription factor binding site.

This considerable level of sequence conservation has enabled stringent bioinformatic searches for candidate

Figure 1 (a) Structure of the REST/NRSF gene and alternative isoform REST4. Exons are indicated as boxes and introns as dashed lines. Exon numbers in roman characters from I to VI are shown above the respective exons; the neuronal-specific exon located between exons V and VI is indicated as exon N. Exons I–III are alternative 5′ UTRs that are spliced to exon IV, represented by lines connecting exons at the intron–exon boundaries. Lines above the primary transcript represent the REST/NRSF primary isoform, and lines below the primary transcript represent the REST4 alternative isoform. Arrows indicate termination codons for REST/NRSF and REST4. (b) REST/NRSF protein includes eight zinc fingers near the N-terminal repressor domain and one zinc finger in the C-terminal domain. REST/NRSF contains a lysine-rich and a proline-rich region upstream of the C-terminal repressor domain. REST4 includes exon N, leading to a truncated protein encompassing the N-terminal repressor domain and five zinc fingers. (c) The conserved REST/NRSF DNA binding site, termed NRSE/RE1, is approximately 21 bp of long and contains of two highly conserved half-site motifs that are separated by two non conserved nucleotides and are flanked by several poorly conserved nucleotides. In this depiction of conserved mammalian NRSE/RE1 sites, generated with pictogram (http://genes.mit.edu/pictogram), the degree of conservation at each position is represented by the size of the nucleotide letter.

NRSE/RE1 sites in the genomes of multiple organisms, and several hundred conserved potential REST/NRSF binding sites in mammalian genomes are now known. Although most of these NRSE/RE1 sequences remain to be experimentally confirmed as functional (i.e., occupied by REST/NRSF in cells), they are enriched near the transcriptional start sites of genes typically expressed in neurons, consistent with the canonical role of REST/NRSF to specifically restrict the expression of genes typical of the neuronal phenotype. These neuronal genes encode ion channels, neurotransmitters, growth factors, hormones, and factors involved in axonal guidance and vesicle trafficking, as well as molecules involved in maintenance of the cytoskeleton and extracellular matrix.

NRSE/RE1 sites have also been found proximal to genes of neuronally enriched microRNAs, a class of small noncoding RNAs known to negatively regulate gene expression at the posttranscriptional level. Since these REST/NRSF-regulated microRNAs extend REST/NRSF's influence on gene regulation beyond NRSE/RE1-containing genes, their action is likely to contribute critically to the establishment of proper gene expression patterns during development and in the adult.

REST/NRSF in Development

The prevalence of NRSE/RE1 sites in the promoters of neuronal genes and the observation that REST/NRSF is most highly expressed in nonneuronal cells initially inspired the simple model that in cells in which REST/NRSF is expressed, it acts as a suppressor of the neuronal cell fate and/or silences the expression of neuronal-specific genes. However, REST/NRSF loss-of-function experiments conducted in mouse, chick, and frog revealed that REST/NRSF's role in early development is much more complex.

From these studies, it has emerged that impairment of REST/NRSF function does not always result in widespread neuronal gene expression in nonneuronal cells within the developing organism, nor does it lead to massive precocious expression of these genes in neural progenitors. Thus, the popular 'master neuronal

regulator' hypothesis of REST/NRSF does not appear to apply in early development. This is likely due to the fact that REST/NRSF-independent mechanisms act redundantly with REST/NRSF to control the timing and extent of neuronal gene expression.

However, even in cases in which REST/NRSF might be the sole repressor of a gene, de-repression of that locus by perturbation of REST/NRSF function will lead to robust transcription of that gene only when activators are available and recruited subsequent to departure of REST/NRSF. The failure to observe catastrophic gene deregulation upon REST/NRSF inactivation may therefore be due to the lack of such activator molecules. Indeed, REST/NRSF, when converted into a transcriptional activator by fusing its DNA binding domain to a powerful activator domain from a viral protein, thereby overcoming the requirement for endogenous activators, can guide the differentiation of myoblasts to a physiologically active neuronal phenotype *in vitro*. This experiment impressively demonstrates the vast network of neurogenic and neuronal genes that REST/NRSF controls. It appears that *in vivo*, however, REST/NRSF is not involved in specifying the fate of nonneuronal cells and tissues, and that de-repression of REST/NRSF-regulated genes alone is not sufficient to direct cells toward the neuronal lineage. Support for this view comes from gain-of-function experiments in the developing chick embryo. Here, forced expression of REST/NRSF does not interfere with neurogenesis, although neurons constitutively expressing REST/NRSF show axon pathfinding errors.

The master neuronal regulator hypothesis of REST/NRSF was placed under more scrutiny when NRSE/RE1 sites were discovered in several nonneuronal genes. Indeed, it is now known that aside from functioning in central nervous system development, REST/NRSF is important in the function of the fetal and adult heart, smooth muscle cells, and pancreatic islet cells. These functions are mediated, at least in part, by REST/NRSF-dependent regulation of these NRSE/RE1-containing nonneuronal genes. It is likely that roles for REST/NRSF in the development of other organs will emerge. These insights further substantiate the notion that REST/NRSF function in neurogenesis is just one aspect of this transcription factor's multifaceted role as a master regulator of a diverse set of gene expression programs.

REST/NRSF in the Adult

Several lines of evidence strongly implicate REST/NRSF in regulating the expression of NRSE/RE1-containing genes in mature neurons. Transcripts of several REST/NRSF isoforms, including full-length REST/NRSF, are detectable, albeit at low levels, in mature neurons within several regions of the adult brain, most prominently in the hippocampus. Experiments in animal disease models strongly implicate this limited amount of REST/NRSF protein in regulating gene expression responses to pathological states of the brain. Similarly, *in vitro* studies have hinted at a role for REST/NRSF in activity-dependent modulation of gene expression.

Induction of status epilepticus (seizure) by systemic administration of the glutamate analog kainate triggers an immediate transient elevation of REST/NRSF transcript and protein in the rodent hippocampus. Because the kainate-induced upregulation of REST/NRSF is preceded by upregulation of known targets of REST/NRSF, including brain-derived neurotrophic factor (BDNF) and the AMPA-responsive Ca^{2+} receptor subunit, encoded by the GluR2 gene, it has been suggested that REST/NRSF serves to dampen spiking expression levels of these genes. Indeed, deletion of the NRSE/RE1 in the BDNF promoter results in increased induction of BDNF upon kainate treatment.

Likewise, global ischemia, a brain insult associated with cardiac arrest, leads to transiently increased levels of REST/NRSF in neurons of the CA1 hippocampal subfield. These CA1 pyramidal neurons are known to eventually die following the ischemic insult, and it is thought that cell death is dependent on changes in transcription. Since several genes that have been implicated in mediating this ischemia-induced cell death, such as the μ opioid receptor 1 and GluR2, are directly regulated by REST/NRSF, it is likely that REST/NRSF is involved in controlling the timing and/or extent of cell death. These observations point to a central role of REST/NRSF in neuroprotective cellular responses. They also highlight the rather dynamic nature of REST/NRSF-dependent modulation of gene expression in the adult brain, which contrasts REST/NRSF's role as a stable silencer in most terminally differentiated nonneuronal cells.

Regulation of REST/NRSF

Despite the often dramatically different levels of REST/NRSF transcripts and protein observed in tissues and cultured cells, our knowledge regarding the transcriptional, translational, and posttranslational regulation of REST/NRSF remains limited. Experiments in the developing chick spinal cord indicate that the canonical Wnt pathway, which is critically involved in orchestrating growth and patterning of neural tissue, may directly control the expression of REST/NRSF. The Wnt-activated β-catenin/TCF complex upregulates REST/NRSF by recognizing a sequence element located within the first exon of REST/NRSF. Since this

element is conserved in human and mouse, it is conceivable that this pathway may regulate REST/NRSF expression in mammals as well. In agreement with a conserved role for Wnt in controlling REST/NRSF transcription, human embryonic carcinoma cells, when treated with constitutively active Wnt protein, demonstrate upregulation of REST/NRSF mRNA levels.

Cell culture experiments have shown a mechanistic switch in the downregulation of REST/NRSF during neuronal differentiation. When mouse-derived pluripotent embryonic stem cells are induced to differentiate into neural stem/progenitor cells, the rate of REST/NRSF transcription remains unchanged, yet REST/NRSF protein decreases substantially because it is specifically targeted for degradation by the proteasome. Upon cell cycle exit and further differentiation into mature neurons, however, REST/NRSF is repressed at the transcriptional level through the action of the unliganded retinoic acid receptor repressor complex acting on the REST/NRSF gene. These mechanisms may also regulate REST/NRSF protein levels at corresponding differentiation stages *in vivo*.

The control of subcellular localization of REST/NRSF is emerging as an additional layer of regulation of REST/NRSF activity. Experiments in a rat model of self-sustained status epilepticus show that REST/NRSF accumulates in the nuclei of CA1 hippocampal pyramidal neurons. The mechanism controlling seizure-induced REST/NRSF compartmentalization is unknown. However, a nuclear envelope protein termed RILP has been shown to specifically bind REST/NRSF and control nucleocytoplasmic shuttling of REST/NRSF, making RILP a good candidate for controlling the distribution of REST/NRSF within the cell. Lastly, the huntingtin protein, which is mutated in Huntington's disease, interacts with REST/NRSF and sequesters a portion of the cellular REST/NRSF pool within the cytoplasm. Mutant huntingtin loses its interaction with REST/NRSF, and the resultant increase in nuclear levels of REST/NRSF causes repression of NRSE/RE1-containing genes. Thus, dysregulation of REST/NRSF subcellular localization may contribute to disease phenotypes in some cases, whereas in other cases intracellular REST/NRSF redistribution may be an adaptive cellular response to counter aberrant gene expression patterns induced by pathological insults.

The Splice Variant REST4

As mentioned previously, REST4 is a splice variant of REST/NRSF that lacks the C-terminal repressor domain found in full-length REST/NRSF, and it also has a truncated DNA binding domain. Initially identified in neurons, REST4 is now known also to be expressed in many cancer cells lines. Although the precise mechanisms that regulate alternative splicing of the REST/NRSF gene are unclear, evidence suggests that protein kinase A regulates as yet unidentified splicing factors responsible for promoting the alternative splicing of the REST/NRSF transcript to produce REST4.

Despite extensive studies, the biological function of REST4 remains controversial. Although *in vitro*, REST4 has much reduced affinity to DNA compared to REST/NRSF, this residual binding activity might nevertheless be sufficient to allow REST4 to occupy DNA sites *in vivo*, especially in cells in which REST4 is highly expressed. REST4 and REST/NRSF can interact with each other directly *in vitro*, so REST4–REST/NRSF hetero-oligomerization may have a function *in vivo*, for example, by sequestering REST/NRSF in an complex that is incapable of binding to DNA. Alternatively, the REST4–REST/NRSF complex might bind NRSE/RE1 sites in a conformation that impairs its ability to recruit corepressors.

Supporting evidence for an antagonistic effect of REST4 on REST/NRSF function comes from experiments in which introduction of REST4 into cells can block REST/NRSF-dependent repression of NRSE/RE1-containing genes. Likewise, expression levels of some NRSE/RE1-containing genes in neuroblastoma- and small cell lung cancer-derived cell lines that also express REST/NRSF is inversely correlated with their levels of REST4 expression, lending further credence to the notion that REST4 might de-repress REST/NRSF-regulated genes.

REST/NRSF and Cancer

In addition to increased expression of REST4 and similar truncated forms of REST/NRSF in cell lines derived from neuroblastomas, aberrantly high levels of REST/NRSF have also been found in these cancers of the sympathetic nervous system. In keeping with a REST/NRSF-antagonistic role for REST4, the expression of the neuroendocrine character typical of these malignancies despite high levels of REST/NRSF has been suggested to be due to the de-repressive action of REST4.

REST/NRSF dysregulation is a hallmark of several other cancers. Medulloblastoma, the most common brain tumor, is thought to originate from neuroectodermal stem/progenitor cells in the cerebellum. Primary tumors and cell lines derived from them express extremely high levels of REST/NRSF, and it has been suggested that the failure to downregulate REST/NRSF in undifferentiated normal brain cells contributes to their malignant transformation. However, since REST/NRSF overexpression by itself has been

shown to be insufficient to induce tumorigenesis in several animal and cell culture models, it appears that the additional deregulated expression of oncogenes, such as c-myc, is required.

Other cancers, however, show markedly reduced and sometimes undetectable levels of REST/NRSF, including breast, colon, and small cell lung cancers. Moreover, a significant number of tumors and cell lines have deletions of the chromosomal locus encompassing the REST/NRSF gene. Consistent with this observation, REST/NRSF was found to be a candidate in a stringent unbiased screen for tumor suppressors in a mammary epithelial cells.

REST/NRSF-Mediated Transcriptional Repression and Silencing

These apparently contradictory observations make formulating a unifying hypothesis for REST/NRSF function a daunting task. Downregulation of REST/NRSF is seen both in terminally differentiated postmitotic neurons and in rapidly dividing cancer cells. Likewise, REST/NRSF has properties of a tumor suppressor but is observed to be dramatically upregulated in some cancers and is high in proliferating stem cells. The answer to these conundrums is likely to be found in the fact that different cellular environments contain different relative levels of available cofactors that REST/NRSF relies on to exert its function. It is therefore imperative that we examine more closely the proteins that REST/NRSF recruits and the chromatin changes that are induced by them (Figure 2).

In embryonic stem cells, REST/NRSF occupies NRSE/RE1 sites in promoters and introns of genes and is associated with the corepressors mSin3a and CoREST, recruited by its N-terminal and C-terminal repressor domains, respectively (Figure 1(b)). These corepressors exist in the nucleus as separate complexes, both of which harbor the class I histone deacetylases (HDACs) 1 and 2. By catalyzing the deacetylation of specific lysine residues within the N-terminal tails

Figure 2 REST/NRSF recruits celltype-dependent complexes to gene regulatory regions, thereby altering chromatin status and transcriptional activity. (a) In terminally differentiated non-neuronal cell types and tissues, genes containing an NRSE/RE1 element are in a REST/NRSF-dependent stably silenced state. In addition to mSin3a/b-mediated recruitment of histone deacetylases (HDACs) and the methyl-DNA-binding protein MeCP2, the REST/NRSF–CoREST complex recruits chromatin modification enzymes associated with long-term silencers (green ovals) (left). These include the histone H3 lysine 9 (H3K9) methyltransferases G9a and SUV39H1, the H3K4 demethylase LSD1, and probably the DNA methyltransferase DNMT1. Methylation (red spheres) of H3K9 and DNA recruits heterochromatic protein 1 (HP1) and MeCP2, respectively. These modifications lead to heterochromatic compaction of chromatin and long-term silencing (middle). RNA polymerase II (pink) is absent from promoters and/or transcriptionally inhibited through phosphorylation (blue spheres) of its C-terminal domain (CTD) by small CTD phosphatases (SCPs) (right). (b) In multipotent embryonic stem cells and neuronal progenitors, NRSE/RE1-regulated genes are in an inactive but permissive state, characterized by the absence or low occupancy levels of long-term silencers but the presence of HDACs, which are generally considered as mediators of dynamic repression (left). Chromatin shows markers of actively transcribed genes, such as hypermethylated H3K4, but is kept in a repressed state by histone deacetylation (middle). RNA polymerase II is found at promoters, albeit at low levels, leading to limited but detectable transcript levels. The role of SCPs at this stage is unknown (right). (c) In most terminally differentiated neurons, REST/NRSF has been downregulated, leading to its departure from most NRSE/RE1-controlled genes (left). Chromatin is highly acetylated and found in a transcriptionally permissive, relaxed state (middle). Transcriptional activators recruit the RNA polymerase II complex to promoters. Downregulated nuclear SCPs levels lead to increased CTD phosphorylation levels of pol II, thereby relieving inhibition of transcription (right).

of histones, HDACs create a chromatin state that is transcriptionally repressive. Because deacetylation can be readily reversed by the action of histone acetyltransferases, this modification is generally considered transient and associated with a dynamically regulated chromatin environment.

In contrast to the situation in terminally differentiated nonneuronal cells, REST/NRSF occupancy at NRSE/RE1 sites is not accompanied by complete silencing of genes in embryonic stem cells (Figure 1(b)). Instead, this transcriptional 'twilight state' near NRSE/RE1 sites is characterized, on the one hand, by rather low levels of other epigenetic markers of repressed chromatin, such as methylated DNA, methylated lysine 9 of histone 3 (H3-meK9), and the histone methyl transferase G9a, which creates this modification. On the other hand, the histones in these regions of the genome are associated with active chromatin marks, such as H3meK4. Polymerase activity at these loci is small but detectable, and the net result of these opposing forces is a low level of transcriptional output that may be further reduced by the action of REST-recruited small CTD phosphatases, which remove regulatory phosphate marks on the C-terminal domain of RNA polymerase II and thereby interfere with transcriptional elongation. Thus, in pluripotent cells REST/NRSF maintains a chromatin signature and transcriptional state that is sufficiently repressive to prevent manifestation of the neuronal phenotype but is dynamic enough to allow de-repression upon neuronal differentiation cues.

As embryonic stem cells transition toward a neuronal lineage via a neuronal progenitor stage, REST/NRSF occupancy at NRSE/RE1 sites is gradually relieved. This process is initiated by REST protein degradation and subsequently by repression of the REST gene transcription. In most terminally differentiated neurons, REST can no longer be detected at promoters, the chromatin has changed to a permissive state, and transcription is activated (Figure 1(c)). Some gene promoters retain subsets of REST-recruited corepressors, despite REST departure from NRSE/RE1 sites, thus maintaining a responsive chromatin state that can be modulated in response to extracellular stimuli. This subset of genes is likely to be involved in the REST/NRSF-dependent regulation of neuronal plasticity described previously.

In terminally differentiated nonneuronal cell types, REST/NRSF maintains a stably repressed chromatin state by recruiting, via CoREST, not only the aforementioned HDACs but also additional complexes that confer a long-term silenced state on the surrounding chromatin (Figure 1(a)). CoREST binds to at least three histone modification enzymes: G9a and SUV39H1, which are both H3-K9 methyl transferases, and LSD1, which is an H3-K4 demethylase. The chromatin modifications created by these enzymes, in turn, serve as binding sites for repressive chromatin binding proteins, such as heterochromatic protein 1 (HP1), which binds to methylated H3-K9. CoREST also recruits the methyl-CpG binding protein 2 (MeCP2), a chromatin regulator protein whose dysfunction is implicated in several neurodevelopmental disorders, most prominently in Rett syndrome. These chromatin modifiers act in concert to maintain a stably repressed transcriptional state at NRSE/RE1-containing neuronal genes.

REST/NRSF as an Activator

The observation in embryonic stem cells that gene transcription can occur despite promoter occupancy by REST/NRSF is surprising given its canonical role as a repressor or silencer of transcription. However, several lines of evidence show that the presence of REST/NRSF at promoters is not incompatible with active transcription. In fact, REST/NRSF might even act as the activator of transcription in some contexts. In transgenic mouse experiments using a reporter gene construct, mutation of the NRSE/RE1 element of the gene that encodes the L1 cell adhesion molecule led to loss of L1 reporter expression in several adult brain structures, including cortex, striatum, and hippocampus. Likewise, expression of a β_2-nicotinic acetylcholine receptor reporter was lost in several structures of the peripheral nervous system upon introduction of a point mutation into its NRSE/RE1. Similar observations have been made in cell culture experiments in which NRSE/RE1 elements in the several other genes were disrupted.

In differentiating neural stem/progenitors cells from the adult brain, a small noncoding double-stranded RNA containing an NRSE/RE1 sequence initiates a switch in the cofactor composition of the REST/NRSF-recruited complex. This process is presumably dependent on the association of the RNA with DNA-bound REST/NRSF and is characterized by a reduction of HDAC association, concomitant with recruitment of proteins and acquisition of histone modifications characteristic of actively transcribed loci. Consequently, these genes are transcribed.

Consistent with these observations, *in vitro* experiments show that REST/NRSF can associate with factors of the basal transcription machinery as well as with the SWI/SNF chromatin remodeling complex, which is capable of remodeling chromatin into both active and repressed states. Since activator properties of REST/NRSF are most often observed in cells and brain structures in which REST/NRSF levels are relatively low, it is likely that REST/NRSF mode of function – activator, repressor, or silencer – is

dependent on its abundance in the nucleus. Clearly, additional parameters, particularly the balance of cofactors recruited by REST/NRSF, are critical in determining the net effect of REST/NRSF promoter association on transcription.

Conclusions

Since its discovery as a silencer of terminal neuronal genes more than a decade ago, REST/NRSF has come to be appreciated as a regulator of a much more complex set of gene expression programs. Advances in the knowledge of the genes targeted by REST/NRSF and the diversity of REST/NRSF-recruited cofactors have contributed to this development. It has also become clear that a quantitative approach toward studying REST/NRSF is invaluable because its function is likely to be critically dependent on both the concentration of available REST/NRSF and that of its cofactors. Large-scale screens aimed at elucidating changes in REST/NRSF promoter occupancy at target genes as well as spaciotemporally targeted REST/NRSF gain- and loss-of-function experiments during development and in the adult will undoubtedly help to build a parsimonious model of REST/NRSF function.

Thalamic Mechanisms in Vision

S M Sherman, The University of Chicago, Chicago, IL, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The thalamus is a paired structure, roughly the size of a walnut, lying along the midline near the center of the brain. Thalamus proper can be divided into dorsal thalamus, which contains the relay nuclei that project to cortex, and ventral thalamus, the major part of which is the thalamic reticular nucleus (TRN). (Dorsal and ventral here represent embryonic relative locations that change during development. Unless otherwise specified, thalamus used by itself refers to the relay nuclei of the dorsal thalamus.) The TRN is a thin shell of neurons that lies generally lateral to the dorsal thalamus, like a shield, extending somewhat dorsally, ventrally, and anteriorly. A number of cytoarchitectonically distinctive zones of dorsal thalamus can be recognized, and these are the various thalamic relay nuclei. Each nucleus is reciprocally connected with cortex, and most do so with one or a small group of cortical areas. Although not divided into cytoarchitectonically clear zones, nonetheless the TRN can be functionally divided into zones, each of which is reciprocally connected with one or a small group of thalamic relay nuclei. Reticular cells target thalamic relay cells and are not known to project outside of thalamus.

An important fact to keep in mind is that effectively all information reaching cerebral cortex is relayed via thalamus. Thus, all information that reaches consciousness does so by being successfully relayed through thalamus, and if such a relay is blocked, the affected information is not consciously recognized or acted upon. An equally important fact is that, as far as we know, every cortical area receives a thalamic input. A number of thalamic nuclei innervate telencephalic targets other than cortex, examples of such targets being the basal ganglia and amygdala, but this will not be considered further here: only cerebral cortex will be regarded among thalamic targets.

The main thalamic relays of visual information are the lateral geniculate nucleus (LGN) and pulvinar. (Strictly speaking, this includes the lateral posterior nucleus and is often referred to as the lateral posterior/pulvinar complex, but for the sake of brevity, we shall refer to this simply as the pulvinar.) Until fairly recently, the LGN was viewed as a trivial, machine-like relay of retinal information to primary visual cortex, and the pulvinar was regarded as a rather mysterious entity that innervates extrastriate visual areas; one specific theory for its function is that it is somehow involved in attention. The purpose of the present account is twofold: to demonstrate that the complex cell and circuit functions of the thalamus, including the LGN, belie any simple relay functions, and instead affect the nature of information relayed in a manner that reflects behavioral state, including attention; and to suggest a relatively new hypothesis for the function of pulvinar as a central element in information transfer between cortical areas involving a cortico-thalamo-cortical route. Finally, the point shall be emphasized that all thalamic relays share most basic cell and circuit functions, but certain differences between the LGN and pulvinar identify them as members of two different kinds of relay found throughout thalamus.

The LGN

We know most about the cell and circuit properties of the LGN, particularly in the cat. The details learned from this nucleus seem broadly applicable to the rest of thalamus in all mammals. Certain differences are elaborated later. This section focuses on how retinal information to be passed on to cortex is modulated by the cell and circuit properties of geniculate relay cells.

Parallel Processing

Relay cells, at least in the LGN, are not homogeneous but can actually be divided into at least three functional classes. Each of these geniculate classes represents a thalamic link in separate streams of retino-geniculo-cortical processing; that is, there are equivalent distinct classes of retinal ganglion cells that project to the LGN, and each retinal class seems to innervate a single class of geniculate relay cell to maintain separate, parallel streams of information to cortex. In general, the receptive field properties that distinguish these cell types are similar for retina and the LGN, because geniculate receptive fields are essentially the same as their retinal inputs. These classes have been best studied in the cat, where they are called X, Y, and W cells, and in the monkey, where they are called magnocellular (M), parvocellular (P), and koniocellular (K).

The cat LGN

1. *X and Y cells*. X and Y cells are fairly homogeneous classes. Anatomically, in the retina, X cells are equivalent to the anatomical class known as 'beta,' and Y cells as 'alpha.' Compared to retinal Y cells,

X cells have smaller cell bodies with smaller dendritic arbors and thinner caliber axons. Similar relationships exist for geniculate X and Y cells, and Figure 1 summarizes some of these anatomical differences. The X cells have smaller cell bodies with thinner axons, and their dendritic arbors are elongated perpendicular to the geniculate laminar borders (see below for geniculate layers), whereas those of Y cells are organized into a roughly spherical shape. Also, X cells tend to have grape-like appendages near proximal dendritic branch points, whereas Y cell dendrites are generally smooth (see Figure 1). This is interesting, because these appendages on the X cells mark the postsynaptic target of the retinal inputs; on Y cells, retinal inputs terminate directly onto proximal dendritic shafts. The receptive fields of both cell types in retina and the LGN are organized into classic center/surround regions with roughly equal numbers of on and off center cells. However, X cells have smaller receptive fields and respond to higher spatial and lower temporal frequencies.

Figure 1 Tracings of an X and Y cell from the A layers of the LGN of the cat. The cells were first identified during *in vivo*, intracellular recording, and then horseradish peroxidase was iontophoresed from the recording pipette into the cells. After appropriate histological processing, the procedure provides a dense stain, allowing visualization of the morphology of the cell body and entire dendritic arbor. The dendritic arbor of the X cell is elongated and oriented perpendicular to laminar borders, while the Y cell dendrites show a stellate distribution with an approximately spherical arbor. The X cell also has prominent clusters of grape-like appendages near proximal dendritic branch points. These are hard to see in the cell reconstructions, so three examples are shown at greater magnification, with dashed lines indicating their dendritic locations (the scale is 50 μm for the cell reconstructions and 10 μm for the dendritic appendage examples). Adapted from Sherman SM and Guillery RW (2006) *Exploring the Thalamus and Its Role in Cortical Function*, 2nd edn. Cambridge, MA: MIT Press.

Based on receptive field properties, hypotheses have been developed for the distinct function of the X and Y pathways. X cells are thought to provide maximum acuity for detail vision, while Y cells are more important for motion detection and processing of low spatial frequencies.

2. *W cells.* W cells are probably a heterogeneous group with several distinct classes, but for convenience and because the final classification and functional correlates of W cells remains to be done, they are treated together here. More details of these cells can be found elsewhere (see 'Further reading'). Retinal W cells generally have small- to medium-sized cell bodies with long, sparsely branched dendrites, but the morphological features of this group are so varied that any generality must be considered limited. W cells so far described in the LGN have medium-sized cell bodies and dendritic arbors oriented parallel to the layers. The receptive fields of these cells, both in retina and the LGN, are also quite varied but tend to be large and poorly responsive (some have named them 'sluggish'): some have center/surround configuration; others have poorly defined borders with on/off responses throughout, some have directional selectivity, and some have limited wavelength sensitivity. To date, there has not been much speculation regarding the function of the W pathway(s), which remains a mystery.

The monkey LGN Details of the organization of the parallel pathways in the monkey are less well understood than those in the cat, but the same general principles apply. At least three parallel pathways start in the retina and are relayed separately through the LGN. These have been called the P, M, and K pathways. Relationships of these pathways to those in the cat has been a source of confusion and controversy, but a consensus seems to be developing that the P, M, and K cells and pathways are homologous, respectively, to the cat's X, Y, and W. However, homology does not mean functional equivalence, only that a common ancestral form is shared, and, indeed, evolution works to create functional differences between homologous structures. An example is our fingers and the wings of bird: these are homologous structures that have evolved quite different functions. In contrast, the fins of a fish and whale are examples of nonhomologous structures that have evolved similar functions.

1. *P and M cells.* In the retina, P cells (called midget cells) are smaller than M cells (called parasol cells), and this size differential also holds in the LGN,

as the names (parvocellular and magnocellular) imply. In both structures, their receptive fields are organized into center/surround configurations, but P cells have smaller receptive fields. M cells are much more sensitive to luminance contrast and moving stimuli, but, while M cells show no wavelength sensitivity, P cells show sensitivity for green and red wavelengths. One exception to this is the owl monkey, which is crepuscular and thus not so reliant on color vision. For these animals, P cells show little wavelength sensitivity.

As is the case for the cat, there has been much speculation concerning the role of these cell types in the monkey. Common suggestions are that P cells are important for color discrimination, especially for red/green distinctions, and may also be involved in high-acuity vision, whereas M cells provide for better luminance contrast sensitivity and are also important for motion detection. Naturally, the role of P cells in monkeys without much color vision, such as the owl monkey, would be different. This would be another example of evolution working on homologous systems to create different functions.

2. *K cells*. Like W cells, K cells probably include many distinct cell classes but are grouped together here, because their complete classification remains to be done. As the name (koniocellular) implies, these are smaller than M or P cells in both the retina and the LGN. Not much is known of their receptive field properties, but some of these cells are thought to be responsible for yellow/blue-wavelength discrimination.

Laminar Relationships

Lateral geniculate nucleus The LGN in all mammals so far studied has distinct zones that in cats and monkeys have evolved to separate layers, and each of these layers receives an input from one or the other eye. Geniculate laminar patterns vary greatly among species, but this ocular division between sets of layers seems to be one constant.

In addition to ocular dominance, the various cell types are distributed with varying levels of laminar specificity. For instance, in the cat, X and Y cells commingle in the dorsal two layers (called the A layers), and the next ventral layer (layer C) has only Y cells, and the ventral few layers have only W cells. For the rhesus monkey, P and M cells are completely separated into four dorsal parvocellular layers and two ventral magnocellular layers. The K cells are found in all the interlaminar zones but also extend dorsally to commingle with P cells in the ventral portions of the parvocellular layers.

Figure 2 summarizes the laminar patterns for cats, monkeys, and some other species to illustrate the sort of bewildering variation in patterns present. Note that two closely relayed carnivore species like the cat versus the ferret or mink differ in that the cat has its on- and off-center cells mixed together in the layers, while the ferret and mink have further divided the dorsal two layers into four to separate on and off center cells. The bottom line here is that geniculate lamination does correlate with cell type, but the nature and extent of this correlation varies widely across species, and it is difficult to discern any special significance to these correlations.

Visual cortex There is also a laminar correlation regarding the target zones of the various cell types. In the cat, geniculate X cell axons innervate the ventral part of layer 4, while those of Y cells innervate the upper part. Most W cells innervate layer 3. A similar arrangement holds for the monkey: P cells innervate the ventral half of layer 4 (sometimes called layer 4Cβ), M cells innervate the dorsal half of layer 4

Figure 2 Schematic rendering of layers and distribution of cell types in the LGN of six different species. The shaded boxes show layers innervated by the contralateral eye (contra), and the unshaded boxes show the input from the ipsilateral eye (ipsi). The X, Y, and W pathways are shown for cat, ferret, mink, tree shrew, and squirrel, and the magnocellular (M), parvocellular (P), and koniocellular (K) pathways are shown for macaque and galago. Where there is a clear segregation of on- and off-center (on, off) cells, this is also indicated. Adapted from Sherman SM and Guillery RW (2006) *Exploring the Thalamus and Its Role in Cortical Function*, 2nd edn. Cambridge, MA: MIT Press.

(sometimes called 4Cα), and K cells mostly innervate layer 3. Thus, through the first stage of processing, the three parallel pathways are kept fairly independent through this first stage of cortical processing, although what happens further centrally with regard to these pathways is not at all clear.

Thalamic Cell Types

There are three basic thalamic cell types related to the LGN: relay cells (which in the LGN can be further divided into W, X, and Y; K, P, and M; etc.), interneurons, and cells of the TRN. Relay cells are glutamatergic, and the latter two cell types are GABAergic, providing a major inhibitory input to relay cells. Interneurons are located within the main geniculate layers, intermixed with relay cells, and the ratio of relay cells to interneurons is roughly 3:1. This ratio is similar throughout thalamus in all mammals with a peculiar exception. That is, outside of the LGN, the thalamus of rats and mice are essentially devoid of interneurons, but, curiously, the LGN in these animals does have a normal complement of interneurons. This is not a property of rodents, because hamsters, guinea pigs, squirrels, etc., have interneurons throughout thalamus. However, this point has been questioned recently by evidence that the lateral posterior nucleus of the rat has a substantial fraction of interneurons.

Cell Properties

All thalamic relay cells, like cells throughout the central nervous system, exhibit a number of voltage-gated ionic membrane conductances. Geniculate relay cells serve as a typical example. The best known of these ubiquitous conductances is the voltage-gated Na^+ conductance underlying the action potential. Other examples include various voltage-gated K^+ and Ca^{2+} conductances. A detailed listing of these is beyond the scope of this article. The presence of these conductances means that membrane voltage, which determines if and when each of these becomes activated, plays an important role in cell excitability and thus the gating of retinogeniculate information flow. Most of these conductances are garden-variety properties found in neurons everywhere, but one in particular, a voltage-gated Ca^{2+} conductance that operates via T-type Ca^{2+} channels, is worth further consideration.

When T-type Ca^{2+} channels are open, Ca^{2+} flows into the cell, depolarizing it via a current known as I_T. However, the T channel can only be opened by depolarization from a relatively hyperpolarized level. That is, depolarization initially activates the channel, but after about 100 ms or so, inactivates it. Once inactivated, it takes about 100 ms or so of subsequent hyperpolarization to remove the inactivation of (i.e., de-inactivate) IT, so that it can again be activated. Actually the opening or closing of the inactivation gate is a complex function of voltage and time so that the more depolarized (or hyperpolarized) the more quickly the gate closes (or opens), but the important point is that under normal conditions, roughly 100 ms is required for these activations.

Once activated, however, the depolarization initiated by I_T becomes an all-or-none Ca^{2+} spike, much like the conventional Na^+/K^+ action potential, and it propagates throughout the dendrites and soma. This is often known as the low-threshold spike, which is tens of millivolts in amplitude and thus large enough to evoke a cluster of action potentials that rides its crest; typically, there are 2–10 such action potentials with interspike intervals <4 ms or so. Such burst firing is ubiquitous for relay cells: every relay cell of every thalamic nucleus of every mammalian species so far tested shows this property. T channels, however, are found in neurons throughout the brain, but what makes thalamic relay cells relatively unique is the density of T channels they express: in relay cells, this density is high enough to support an all-or-none Ca^{2+} spike, while in most other neurons, T channel density is too low for this and can thus underlie only a graded depolarization.

From the above, the voltage-dependent properties of the T channel can be characterized by two gates, an activation gate and an inactivation gate. The activation gate opens with depolarization and closes with hyperpolarization, and it does so with very fast kinetics, typically requiring <1 ms for opening or closing. The inactivation gate has the opposite voltage relationships, since it opens with hyperpolarization and closes with depolarization; also, it operates much more slowly, taking about 100 ms for either action. This slow action is important to how the channel is controlled by thalamic circuitry, which is considered below.

Figure 3 illustrates and summarizes many of these features of the T channels. Activation of T channels requires that they be first de-inactivated, which in turn requires hyperpolarization. The more hyperpolarization that occurs, the more T channels are de-inactivated and can thus participate in the subsequently evoked low-threshold spike, and the larger the evoked low-threshold spike. This is shown in Figure 3(a) for two relay cells. Thus, the size of the low-threshold spike can vary depending on the history of the cell's membrane voltage, and, as might be predicted, the number of conventional action potentials evoked from such a low-threshold spike is correlated with its amplitude (Figure 3(a)). However, for any given level of T channel de-inactivation, the low-threshold spike is all-or-none (Figure 3(b)).

Figure 3 Properties of I_T and the low-threshold Ca^{2+} spike (LTS). All examples are from relay cells of the cat's LGN recorded intracellularly in an *in vitro* slice preparation. (a) Voltage dependency of amplitude of LTS and extent of burst response. Examples for two cells are shown. The more hyperpolarized the cell before being activated (initial membrane potential), the larger the LTS (filled squares and dashed curve) and the more action potentials (APs) in the burst (open circles). The number of APs were first measured, and then tetrodotoxin (TTX) was applied to isolate the LTS for measurement. (b) All-or-none nature of the LTS measured in the presence of TTX in another geniculate cell. The cell is initially hyperpolarized, and current pulses were injected starting at 200 pA amplitude and incremented in 10 pA steps. Smaller (subthreshold) pulses led to pure resistive–capacitative responses, but all larger (suprathreshold) pulses led to an LTS. Much like conventional APs, the LTSs are all the same amplitude regardless of how far the depolarizing pulse exceeded activation threshold, although there is latency variability for smaller suprathreshold pulses. (c, d) Voltage dependency of the LTS. Responses are shown to the same depolarizing current pulse delivered intracellularly but from two different initial holding potentials (–59 and –70 mV). When the cell is relatively depolarized (c), I_T is inactivated, and the cell responds with a stream of unitary action potentials as long as the stimulus is suprathreshold for firing. This is the tonic mode of firing. When the cell is relatively hyperpolarized (d), I_T is de-inactivated, and the current pulse activates an LTS with eight action potentials riding its crest. This is the burst mode of firing. (e) Input–output relationship for one cell. The input variable is the amplitude of the depolarizing current pulse, and the output is the firing frequency of the cell. To compare burst and tonic firing, the firing frequency was determined by the first six APs of the response, since this cell usually exhibited six APs per burst in this experiment. The initial holding potentials are shown, and –47 and –59 mV reflect tonic mode, whereas –77 and –83 mV reflect burst mode. (a) Redrawn from Zhan XJ, Cox CL, and Sherman SM (2000) Dendritic depolarization efficiently attenuates low threshold calcium spikes in thalamic relay cells. *The Journal of Neuroscience* 20: 3909–3914. (e) Redrawn from Zhan XJ, Cox CL, Rinzel J, and Sherman SM (1999) Current clamp and modeling studies of low threshold calcium spikes in cells of the cat's lateral geniculate nucleus. *The Journal of Neurophysiology* 81: 2360–2373.

Properties of burst and tonic firing T channel activity determines two very different response modes, tonic or burst, for the relay cell. This has important implications for relay of information for a number of reasons. Note that the only signal relayed to cortex is via conventional action potentials. However, the same retinal excitatory postsynaptic potential will evoke a very different response in the relay cell dependent

on the cell's response mode (see Figures 3(c) and 3(d)). During tonic firing mode, the action potentials rise directly from the excitatory postsynaptic potential, and thus a larger excitatory postsynaptic potential evokes a higher rate of firing. However, the action potentials during burst firing mode arise indirectly from the excitatory postsynaptic potential. Here, the excitatory postsynaptic potential evokes the low-threshold spike, which is all-or-none, and thus a larger excitatory postsynaptic potential will not evoke a larger low-threshold spike, meaning that the size of the burst is not linearly related to the size of the retinal excitatory postsynaptic potential. What this all means is that there is a fairly linear input/output relationship during tonic firing, but this relationship is very nonlinear during burst firing (Figure 3(e)).

The advantage for tonic firing is pretty clear: if cortex is to reproduce faithfully the visual scene, the sort of nonlinear distortion seen during burst firing would hamper this process. What, then, is the advantage for burst firing? There are at least two of them. First, burst firing is associated with low spontaneous activity but the burst itself represents a high rate of firing; together, this means that burst firing is associated with a higher signal-to-noise ratio and thus better stimulus detectability. Second, the combination of the nature of the thalamocortical synapse and the different pattern of action potentials between firing modes leads to a much greater postsynaptic response in cortex for burst firing. Two related observations support this second point. First, there is evidence that the first action potential in a burst evokes a much greater response in cortex than does a tonic action potential. Second, many cortical cells operate in an 'up' or 'down' state in which up state is relatively depolarized and responsive to thalamic input, whereas the more hyperpolarized down state is much less responsive to thalamic input; recent evidence indicates that tonic firing is relatively ineffective in switching a cortical cell from the down to the up state, but burst firing brings about this switch quite readily. The overall implication is that while tonic firing is better for stimulus reconstruction, burst firing is better for the detection of novel stimuli, and associated with this improved detectability is a much stronger cortical response.

Hypothesis for burst and tonic firing This difference between burst and tonic firing has led to the following hypothesis. Because burst firing is better for stimulus detection, it could be the mode more often seen when the receptive field of the geniculate neuron covers an unattended part of the visual field, unattended because the subject is drowsy, is attending to another sensory modality or part of the visual field, etc.; under these conditions, the burst evoked by a novel stimulus would more likely get through to cortex and be recognized as a signal than if the cell were firing tonically. In this sense, the burst is a sort of 'wake-up call' that something has changed, and that something should be attended to so that its importance can be evaluated. The idea here is not necessarily that bursting provides a stronger overall signal to cortex than does tonic firing, but rather that bursting overcomes any disadvantage regarding stimulus detectability or cortical activation imposed by inattention. Once the burst activates cortical circuits, the relay cell would then switch to tonic firing so that the novel stimulus can be properly evaluated.

Consistent with this hypothesis are several observations. Both tonic and burst firing are seen in behaving animals and humans, with switching occurring between modes. Bursting is seen relatively rarely in the alert animals and more commonly in drowsy animals. Studies of behaving cats show that a relatively common pattern of response of geniculate cells to a repeating stimulus (e.g., a flashing spot) would be to respond to the first cycle of stimulation, then switch to tonic firing in response to subsequent cycles. Finally, recent receptive field studies show that the type of visual stimulus most likely to evoke a burst is one that switches from an inhibitory one to an excitatory one, such as a dark region covering the receptive field of an on-center cell that is then switched to a bright spot; this indicates that the burst signals a significant change in the form of a novel stimulus just appearing. However, these observations, while supporting the hypothesis, do not constitute proof of its validity. Much more research will be needed to accept or reject the hypothesis.

Other cellular properties of relay cells While much is known about T channels and their significance for thalamic relays, many other voltage-sensitive ionic currents exist that affect these relays. These include a variety of voltage-gated K^+, Na^+, and other Ca^{2+} channels and also a hyperpolarization-activated cation channel known as I_h. While we understand much of the voltage-sensitive properties of each of these, much more work needs to be done to appreciate how these interact among themselves and also with I_T.

Circuit Properties

Figure 4 schematically shows the main inputs to geniculate relay cells. This circuitry is generally repeated, with some variations, throughout thalamus.

Anatomical features An important point shown in Figure 4 is that retinal input is one of the several inputs to relay cells. Other prominent input derives

Figure 4 Circuitry of the LGN with related receptors present on relay cells. Other thalamic nuclei seem to be organized along the same pattern. The key to the left indicates the major transmitter systems involved. The retinal input activates only ionotropic receptors (circles), whereas all nonretinal inputs activate metabotropic receptors (stars) and often ionotropic receptors as well. The question mark related to input from interneurons indicates uncertainty whether metabotropic receptors are involved. Thick solid and thin dashed lines indicate driver and modulator inputs, respectively. Filled and open icons for synaptic terminals indicate excitatory and inhibitory inputs, respectively. ACh, acetylcholine; GABA, γ-aminobutyric acid; Glu, glutamate; LGN, lateral geniculate nucleus; PBR, parabrachial region of the brain stem; TRN, thalamic reticular nucleus. Adapted from Sherman SM and Guillery RW (1998) On the actions that one nerve cell can have on another: Distinguishing 'drivers' from 'modulators'. *Proceedings of the National Academy of Sciences of the United States of America* 95: 7121–7126 and Sherman SM and Guillery RW (2001) *Exploring the Thalamus*. San Diego: Academic Press.

from local GABAergic sources (interneurons and reticular cells), layer 6 of cortex, which provides a feedback, glutamatergic input, and ascending input from the brain stem, mostly from cholinergic cells in a midbrain area known as the parabrachial region. (Another term often applied to this area is 'pedunculopontine tegmental nucleus.' We prefer 'parabrachial region,' because the cells that innervate thalamus from this area do not have a clear nuclear boundary, and they are found scattered around the brachium conjunctivum.) Not shown for simplicity are other small inputs also seen widely throughout thalamus, such as serotonergic input from the dorsal raphé nucleus of the brain stem, noradrenergic inputs from the parabrachial region, and histaminergic inputs from the tuberomamillary nucleus of the hypothalamus. However, we focus here on the inputs shown in Figure 4, because these are the best understood.

Thus, the main extrinsic, nonretinal inputs to geniculate relay cells derive from cortex and brain stem. There are also local, GABAergic inputs, but these are also innervated by the same cortical and brain stem sources that innervate relay cells. Thus, these extrinsic inputs can affect relay cells directly or indirectly via local GABAergic circuitry.

Functional features

1. *Ionotropic and metabotropic receptors*. Figure 4 also shows the neurotransmitters used by various afferents to relay cells as well as the postsynaptic receptors involved. These receptors are critical in understanding how this circuit works, because the inputs to relay cells operate via conventional chemical synapses, meaning that they release transmitters that affect the relay cell via postsynaptic receptors. The receptors, which determine the final postsynaptic response of the relay cell, come in two main flavors: ionotropic and metabotropic. Examples of the relevant ionotropic receptors are α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) for glutamate, nicotinic for acetylcholine, and the $GABA_A$ receptor (GABA, γ-aminobutyric acid). For metabotropic receptors, examples are various metabotropic glutamate receptors, various muscarinic receptors for acetylcholine, and the $GABA_B$ receptor.

Differences between ionotropic and metabotropic receptors are many, and only certain ones are considered below. Ionotropic receptors are simpler in construction and function, and the receptor itself usually contains the ion channel it controls. Generally, the binding of the transmitter to the receptor changes the shape of the receptor, exposing and thus opening the ion channel. Opening the channel allows ions to flow into or out of the cell, leading to an excitatory or inhibitory postsynaptic potential. Typically, the postsynaptic potential occurs with a brief latency (<1 ms) and duration (mostly over in 10 ms or a few tens of milliseconds). The story with metabotropic receptors is more complicated.

Here, the receptor is only indirectly linked to the relevant ion channel. Typically, binding of the transmitter to the receptor causes release of a G-protein that interacts with an effector protein, setting off a cascade of biochemical reactions with many effects on the cell, one of which ultimately is on the ion channel. For thalamic relay cells, these are typically K^+ channels. Thus when the channel opens, K^+ flows out of the cell, leading to an inhibitory postsynaptic potential; when the channel closes, leakage of K^+ is stopped, leading to an excitatory postsynaptic potential. However, these postsynaptic potentials with metabotropic receptors typically have a long latency (~10 ms or so) and duration (hundreds of milliseconds to several seconds).

Given these differences between receptor types, particularly with regard to duration of the resultant postsynaptic potential, it is particularly interesting to note the pattern of postsynaptic receptors as they relate to various inputs onto relay cells (**Figure 4**). What is striking is that retinal inputs activate only ionotropic (mostly AMPA but also NMDA) receptors, whereas all nonretinal inputs activate metabotropic as well as ionotropic receptors. One obvious conclusion is that the nonretinal inputs, by activating metabotropic receptors, can achieve sustained changes in membrane potential and thus relay cell excitability, thereby modulating the gain of retinogeniculate transmission.

There is a further, more interesting implication of this pattern that involves control of the T channels. Recall that to inactivate the T channel (i.e., to close the inactivation gate) requires 100 ms or so of sustained depolarization; similarly, to de-inactivate it (i.e., to open the inactivation gate) requires 100 ms or so of sustained hyperpolarization. This means that the fast excitatory or inhibitory postsynaptic potentials seen with ionotropic receptors are ill suited to affect the inactivation gate; even action potentials, despite their amplitude, are terminated too quickly to effectively inactivate the T channel. In contrast, the sustained postsynaptic potentials of metabotropic receptors are ideally suited to inactivate or de-inactivate T channels. It thus follows that retinal input by itself, with its fast excitatory postsynaptic potentials, is less likely to directly affect T channels. This seems appropriate in the sense that burst or tonic firing is thought to be dependent on behavioral state.

One would expect that to be mainly the function of inputs to relay cells that do not carry the main information to be relayed. However, the fast retinal excitatory postsynaptic potentials means that each can represent a specific retinal action potential up to high rates of firing, thus preserving temporal information. Put another way, if retinal inputs activated metabotropic glutamate receptors, the resultant long excitatory postsynaptic potentials would act like low-pass temporal filters, and higher-frequency temporal information would fail in the relay. From this reasoning, it falls to the nonretinal inputs via activation of metabotropic receptors to provide the main control of T channels and determine whether the response to retinal input is in tonic or burst firing mode.

In addition, there is clear evidence that visual stimuli can also affect firing mode: for instance, a visual stimulus that inhibits a geniculate cell for a sufficient time (e.g., a dark stimulus falling on the center of an on-center cell) can de-inactivate the T channels, and when this stimulus is replaced by an excitatory one (e.g., a bright spot), a burst is evoked. Note that this is likely due to inhibitory circuits involving interneurons or reticular cells, or both, and perhaps also involving $GABA_B$ receptors and is not likely to represent retinal inputs alone.

Indeed, evidence exists that metabotropic glutamate receptors activated from layer 6 of cortex and muscarinic receptors activated from the parabrachial region produce long, slow excitatory postsynaptic potentials that inactivate the T channels and switch relay cells from burst to tonic firing mode. Similarly, activation of $GABA_B$ receptors from reticular inputs does the opposite: it produces a sustained inhibitory postsynaptic potential that switches firing modes from tonic to burst. Interneurons may also participate in this, but as indicated by the question mark in **Figure 4**, it is not yet known whether or not these inputs activate $GABA_B$ receptors on relay cells.

2. *Role of parabrachial and cortical inputs.* Further inspection of **Figure 4** shows that, as parabrachial inputs become more active, relay cells become more depolarized and responsive. This is because the main effect of parabrachial input onto relay cells is depolarizing, via activation of nicotinic and M1 muscarinic receptors (activations of M1 receptors closes K^+ channels), and its main effect onto the local GABAergic cells is hyperpolarizing, via activation of another (M2?) muscarinic receptor that opens K^+ channels. Thus, parabrachial input directly depolarizes relay cells and also disinhibits them. Not only does parabrachial input excite relay cells, but the resultant depolarization also inactivates T channels, biasing relay cell responses to tonic mode. Consistent with this scenario is the further observation that parabrachial neurons become more active and relay cells become less bursty with increasing vigilance, from slow-wave sleep through drowsiness to full attention.

Understanding the consequence of the layer 6 cortical input is much more difficult. **Figure 4** suggests that this input directly excites relay cells while it indirectly inhibits them, but, in fact, the actual effect of this input depends on details of the circuit that are generally unknown. This is illustrated in **Figure 5**,

Figure 5 Two patterns among others possible for corticothalamic projection from layer 6 to cells of the TRN and geniculate relay cells. (a) Pattern of simple excitation and feedforward inhibition. (b) More complicated pattern in which activation of a cortical axon can excite some relay cells directly and inhibit others through activation of reticular cells. For further details, see text. LGN, lateral geniculate nucleus; TRN, thalamic reticular nucleus.

which shows two variants of the many possible for the relevant circuit. (The example of Figure 5 includes just reticular cells, but one can easily imagine a similar circuit involving interneurons.) In Figure 5(a), individual corticogeniculate axons innervate a reticular cell and relay cell, with the reticular cell innervating the same relay cell. The consequence of increased corticogeniculate activity might be of little or no effect on the relay cell's membrane voltage (and T channel inactivation or de-inactivation) if the excitatory and inhibitory inputs are balanced. However, while this may not affect membrane voltage, the increased synaptic conductance among other factors will reduce relay cell excitability to other (i.e., retinal) inputs, and thus reduce the gain of retinogeniculate transmission. Thus, the more active the corticogeniculate inputs in the circuit of Figure 5(a), the lower the gain of retinogeniculate transmission.

The circuit of Figure 5(b) has very different consequences. Here, activation of the corticogeniculate axon purely excites one or a few relay cells (e.g., cell 2) and purely inhibits others (e.g., cells 1 and 3). Also, note that the final effect on relay cell membrane voltage is such that activation of the corticogeniculate axon would promote tonic firing in cell 2 and burst firing in cells 1 and 3. This means that layer 6 corticogeniculate can have very different and localized effects. Figure 5 illustrates the importance of a much better understanding of these functional circuits at the single-cell level than we have at present.

Drivers and Modulators

Figure 4 also partly demonstrates a fundamental observation, namely, that all inputs to geniculate relay cells are not equal. That is, the retinal input alone represents the main information actually relayed to cortex. Among other factors, a consideration of receptive field properties demonstrates this fact, because the responses of the relay cell to visual stimulation does, in fact, identify the information relayed. In this regard, the receptive fields of geniculate relay cells are remarkably like those of their retinal afferents, having the same center/surround configuration and with only minor, subtle differences. If we consider the other extrathalamic inputs, receptive fields of corticogeniculate afferents, which show selectivities for orientation and often direction typical of cortical cells, are utterly unlike geniculate receptive fields, and parabrachial inputs are not plausible sources of such clear center/surround properties. If it is the retinal input that provides the information to be relayed, then the nonretinal inputs must have another function. This, plus a number of morphological, pharmacological, and physiological differences that distinguish retinal and nonretinal afferents to relay cells, has led to the idea that these can be functionally divided: the retinal inputs are the drivers (so called because one of its properties is the very strong postsynaptic drive of their target relay cells; see Table 1), while all the nonretinal inputs are the modulators, the idea being that the driver input is the information-bearing input, while the modulators serve to modulate retinogeniculate transmission. Modulation can take many forms, including, for example, the above-mentioned consequences of metabotropic receptor activation that lead to overall changes in relay cell excitability and that serve to control the tonic/burst transition; also, as indicated above, the circuit suggested by Figure 5(a) can operate to control the gain of retinogeniculate transmission.

There is actually an extensive list of properties that distinguish drivers from modulators in thalamus, and this list will likely increase in size as we learn more about this issue. Table 1 summarizes the most important features but is not meant to be exhaustive. Layer 5 drivers (the second column in Table 1) are considered below. The 13 criteria in Table 1, in a roughly decreasing order of importance, are as follows:

1. As already noted, drivers determine the main receptive field properties of the relay cell; modulator input does not.
2. Also as already noted, drivers activate only ionotropic receptors; modulators activate metabotropic as well as ionotropic receptors.
3. Drivers evoke very large excitatory postsynaptic potentials; modulators generally evoke much smaller excitatory or inhibitory postsynaptic potentials.

Table 1 Drivers and modulators in LGN plus layer 5 drivers

Criteria	*Retinal (driver)*	*Layer 5 to HO (driver)*	*Modulator: layer 6*	*Modulator: PBR*	*Modulator: TRN & Int*
Criterion 1	Determines relay cell receptive field	[a]Determines relay cell receptive field	Does not determine relay cell receptive field	Does not determine relay cell receptive field	Does not determine relay cell receptive field
Criterion 2	Activates only ionotropic receptors	Activates only ionotropic receptors	Activates metabotropic receptors	Activates metabotropic receptors	TRN: Activates metabotropic receptors; Int:[b]
Criterion 3	Large EPSPs	Large EPSPs	Small EPSPs	[b]	TRN: small IPSPs; Int:[b]
Criterion 4	Large terminals on proximal dendrites	Large terminals on proximal dendrites	Small terminals on distal dendrites	Small terminals on proximal dendrites	Small terminals; TRN: distal; Int: proximal
Criterion 5	Each terminal forms multiple contacts	Each terminal forms multiple contacts	Each terminal forms single contact	Each terminal forms single contact	Each terminal forms single contact
Criterion 6	Little convergence onto target	[a]Little convergence onto target	Much convergence onto target	[b]	[b]
Criterion 7	Very few synapses onto relay cells (~5%)	Very few synapses onto relay cells (~5%)	Many synapses onto relay cells (~30%)	Many synapses onto relay cells (~30%)	Many synapses onto relay cells (~30%)
Criterion 8	Often thick axons	Often thick axons	Thin axons	Thin axons	Thin axons
Criterion 9	Glutamatergic	Glutamatergic	Glutamatergic	Cholinergic	GABAergic
Criterion 10	Synapses show paired-pulse depression (high *p*)	[a]Synapses show paired-pulse depression (high *p*)	Synapses show paired-pulse facilitation (low *p*)	[b]	[b]
Criterion 11	Well localized, dense terminal arbors	Well localized, dense terminal arbors	Well localized, dense terminal arbors	Sparse terminal arbors	Well localized, dense terminal arbors
Criterion 12	Branches innervate subtelencephalic targets	Branches innervate subtelencephalic targets	Subcortically known to innervate thalamus only	[b]	Subcortically known to innervate thalamus only
Criterion 13	Innervates dorsal thalamus but not TRN	Innervates dorsal thalamus but not TRN	Innervates dorsal thalamus and TRN	Innervates dorsal thalamus and TRN	TRN: both; Int: dorsal thalamus only

[a]Very limited data to data.
[b]No relevant data available.

4. Drivers form very large terminals on proximal dendrites; modulators usually form small terminals, and these can be on proximal or distal dendrites.
5. Each driver terminal forms multiple large synapses; each modulator terminal usually forms a single, small synapse.
6. Driver inputs show little convergence, meaning, for example, that one or a small number of retinal axons converge to innervate each geniculate relay cell; where evidence is available, modulator inputs show considerable convergence.
7. Driver inputs produce a small minority (~5%) of the synapses onto relay cells; many modulator inputs produce larger synaptic numbers (e.g., the cortical and parabrachial modulator inputs in Figure 4 each produces about 30% of the synapses).
8. Drivers have thick axons; modulators have thin axons.
9. Drivers are glutamatergic; modulators can use a variety of neurotransmitters.
10. Driver synapses show high release probability and paired-pulse depression, meaning that a given action potential is likely to result in transmitter release, and that, with the initiation of a train of action potentials, there is a period after each evoked postsynaptic potential lasting for tens of milliseconds that the next one will be smaller (depressed); modulator synapses that have been tested so far show the opposite properties of low release probability and paired-pulse facilitation.
11. Driver terminal arbors are well localized with a dense array of terminals; modulator terminal arbors can be either well localized and dense or relatively poorly localized and sparse.
12. Branches of driver axons tend to innervate extrathalamic targets as well as thalamus (e.g., many or all retinogeniculate axons branch and also

innervate midbrain targets); those modulator inputs so far tested innervate thalamus only.

13. Driver inputs innervate relay cells and interneurons in dorsal thalamus but do not innervate the TRN; modulator inputs innervate relay cells, interneurons, and reticular cells.

This driver/modulator distinction is clear not just in the LGN but also in other thalamic relays for which sufficient information is available, such as the ventral portion of the medial geniculate nucleus (the primary auditory thalamic relay) and the ventral posterior nucleus (the primary somatosensory thalamic relay). The main point, again, is that not all anatomical pathways are functionally equivalent, acting in some sort of anatomical democracy, and if one is to understand the functional organization of the thalamus and what it is that is being relayed, one must identify and characterize the driver input. This may also apply outside of thalamus.

This point can be underscored with a consideration of criterion (7) above. It may seem surprising at first that driver input, which provides the main information to be relayed, is responsible for such a small percentage of the synapses onto relay cells, but there are two factors to be considered. First, despite the small number of inputs numerically, these are especially powerful and do manage to drive the relay cells effectively. Second, it may only take a relatively small number of synapses to get the basic information to the relay cell, provided these are powerful synapses, but to provide a wide range of subtle modulatory effects, it also makes sense to have many more, individually weaker synapses that can be combined in myriad ways.

One last point should be made regarding the driver/modulator distinction with regard to the LGN. If one had only anatomical information, such as numbers of synapses from subcortical sites, the number from the parabrachial region (~30%) is considerably greater than that from retina (5–10%). Such anatomical data in isolation would suggest the conclusion that the parabrachial input is the more important and thus represents the information being relayed, while the retinal input, being so small, performs some vague, lesser function that might not even merit inclusion in some schematic illustrations of geniculate circuitry. The key lesson here is that anatomical data, on their own, can be very misleading when trying to unravel functional circuits. With regard to information processing through thalamus, the most important issue is to identify what is being relayed, and to do so, it is potentially misleading to treat all pathways as equal: one must instead separately identify drivers from modulators.

Usually, one is likely to find examples of schematically illustrated circuits that are based on anatomy alone, as if all inputs were drivers in the sense the term has been used here. If the concept of drivers and modulators has validity beyond thalamus, many of these suggested circuits need to be reconsidered.

First- and Higher-Order Relays: The LGN and Pulvinar

There are two ways to think about the function of the thalamus. One is to consider the properties of thalamic circuitry as they affect relay functions; that is, how do the modulators affect relay cell responses to their driver input? The other is to consider what it is that the thalamic nucleus is actually relaying. Put another way, we can define the function of LGN or the ventral posterior nucleus as relaying retinal or medial lemniscal information, respectively. It is this latter aspect of thalamic functioning that chiefly concerns us in this section.

Layer 5 Corticothalamic Inputs as Drivers

Since, as defined above, the driver input is what is relayed by thalamus, we can define the function of thalamic relays by identifying the source and nature of their drivers. This may seem obvious and trivial for well-studied relays like the LGN, but there are many other less well understood relays with unknown functions because, until recently, their driver inputs remained undefined. Examples are the pulvinar and medial dorsal nucleus. We now know that a major source of driver input to thalamic relays like the pulvinar and medial dorsal nucleus is layer 5 of cortex. This is illustrated in Figure 6.

Figure 6(a) illustrates several key points of this arrangement. All thalamic relays receive a feedback corticothalamic projection from layer 6, and they also have inputs from the TRN; not shown for simplicity are inputs to relay cells from interneurons and the parabrachial region (see Figure 4). However, while some thalamic nuclei relay subcortical driver inputs to cortex (Figure 6(a)), others instead relay driver input that arises from cortical layer 5, and this appears to be feed-forward (Figure 6(b)). Because of this arrangement, we refer to the type of thalamic relay of Figure 6(a) as first order, because this is the first relay of a particular type of information to cortex, and that of Figure 6(b) as higher order, because this represents a relay of information already in cortex but from one cortical area to another. Examples of first-order relays are the LGN for vision, the ventral posterior nucleus for somesthesis, and the ventral (or lemniscal) portion of the medial geniculate

Figure 6 Schematic diagrams showing organizational features of first- and higher-order thalamic nuclei. (a, b) Distinction between first-order and higher-order thalamic nuclei. A first-order nucleus (a) represents the first relay of a particular type of subcortical information to a first-order or primary cortical area. A higher-order nucleus (b) relays information from layer 5 of one cortical area to another cortical area. This relay can be between first- and higher-order cortical areas as shown or between two higher-order cortical areas. The important difference between them is the driver input, which is subcortical (a) for a first-order thalamic nucleus and from layer 5 of cortex (b) for a higher-order one. Note that all thalamic nuclei receive an input from layer 6 of cortex, which is mostly feedback, but higher-order nuclei in addition receive a layer 5 input from cortex, which is feed-forward. (c) Role of higher-order thalamic nuclei in corticocortical communication. This involves a projection from layer 5 of cortex to a higher-order thalamic relay to another cortical area. As indicated, the role of the direct corticocortical projections, driver or modulator, is unclear. Note that in all drawings the driver inputs, both subcortical and from layer 5, are typically from branching axons, the significance of which is elaborated in the text. FO, first order; HO, higher order; LGN, lateral geniculate nucleus; TRN, thalamic reticular nucleus. Reprinted from Sherman SM (2005) Thalamic relays and cortical functioning. *Progress in Brain Research* 149: 107–126.

nucleus for sounds; examples of higher-order relays for these same sensory modalities, respectively, are most of the pulvinar, most of the posterior medial nucleus, and most of the medial and dorsal (or nonlemniscal) portion of the medial geniculate nucleus. We say 'most' here, because as defined by cytoarchitectonic boundaries, a minor part of these higher-order nuclei may relay subcortical driver inputs. Thus, there are small retinorecipient and tectorecipient zones of the pulvinar, a spinothalamic zone of the posterior medial nucleus, and an inferior collicular input to the nonlemniscal part of the medial geniculate nucleus that may be first-order relays. This has to be clarified, and it will not be considered

further here, but it does point up a potential shortcoming of classically defined, cytoarchitectonic boundaries for functional thalamic relays. The key to this division of thalamic relays into first and higher order is the observation that the layer 5 inputs to relay cells have the same properties as do the subcortical drivers (e.g., retinal input to the LGN and medial lemniscal input to the ventral posterior nucleus). Support for this can be found in Table 1: note from the first two columns of Table 1 that the layer 5 input to higher-order relays matches retinogeniculate input on all criteria; in contrast, the second and third columns show that the corticothalamic inputs from layers 5 and 6 differ on all criteria.

Branching of Driver Afferents to Thalamus

Another feature shown in Figures 6(a) and 6(b) is that the driver inputs to both first- and higher-order relays are borne mostly or wholly via axons that branch, with one branch innervating thalamic relay cells and the other innervating extrathalamic targets in the brain stem and spinal cord. For instance, most or all retinogeniculate axons branch to innervate the pretectum and/or superior colliculus, and, similarly, most or all layer 5 corticothalamic axons branch to innervate targets in the pons, midbrain, medulla, and sometimes even spinal cord. Limited data are consistent with a similar arrangement for relays of somatosensory and auditory information. RW Guillery has described this feature of driver afferents and suggested what its functional significance might be; this is briefly outlined below. This branching of afferent drivers to thalamus appears to be a general feature of thalamic relays and is not limited to the LGN and pulvinar.

The main extrathalamic targets of these branches seem to what can generally be described as motor centers. Thus, retinogeniculate axons branch to innervate pretectal and superior collicular targets implicated in eye movements, pupillary control, etc. Similarly, the layer 5 corticothalamic axons branch to innervate targets in brain stem and sometimes spinal cord that also appear to have motor functions. One interpretation of this pattern is that the information actually relayed by thalamus relates to motor commands, starting with first-order relays as perhaps quite crude commands that are constantly upgraded with further cortical processing and effected via higher-order layer 5 outputs from cortex. This notion implies that even first-order sensory processing, for instance, via the LGN, involves processing of motor commands, a notion that stands conventional views of early visual processing on its head. That is, conventionally, primary visual cortex (V1) is generally viewed as a purely sensory structure, and this view seems at odds with the idea that V1 is processing motor information. Furthermore, as already noted, V1 (and, indeed all cortical areas so far studied) has a layer 5 projection that branches to innervate pulvinar and extrathalamic motor targets, so that even the corticofugal outputs of V1 have a motor tag according to this perspective. Indeed, the whole notion that V1 or any other visual, auditory, or somatosensory area is purely 'sensory' is challenged by the observation that all of these areas have a motor output.

Role of Higher-Order Thalamic Relays in Corticocortical Processing

Figure 6(c) illustrates the suggested role played by higher-order thalamic relays. Information first reaches cortex via first-order relays, such as the LGN. Further processing of information as it is passed on to higher extrastriate visual cortical areas is relayed through higher-order thalamic nuclei. This can involve a number of hierarchical levels of both cortical and thalamic processing. The obvious question raised here is: if the cortico-thalamo-cortical pathways involving higher-order thalamic nuclei represent a significant information route, what of the direct corticocortical projections? The answer, simply, is not yet available, but to help to clarify the issue here, it is helpful to consider the three obvious hypotheses that follow.

Hypothesis 1: All information is relayed via higher-order thalamic nuclei One possibility is that all of the direct corticocortical pathways are modulators, in which case all information between cortical areas is relayed via the thalamus. One conclusion that could be drawn here is that all new information that reaches cortex, whether originating from a subcortical source such as the retina or from another cortical area, benefits from a thalamic relay. That is, for the same reason that retinal information is relayed by the LGN and does not project to visual cortex directly, information from one cortical area to another is relayed through thalamus. Benefits could include gating properties of the thalamus, the burst/tonic transition, etc.

A key challenge to this concept is whether or not higher-order relays such as the pulvinar have enough neurons to relay all of the requisite information needed for cortical processing. The pulvinar is indeed the largest thalamic nucleus and dwarfs the LGN. However, pulvinar neurons are orders of magnitude fewer than those in any cortical area, which poses a severe bottleneck on information transfer. Nonetheless, a very small percentage of visual cortical neurons are represented by the layer 5 efferents that could provide the afferent link in the cortico-thalamo-cortical pathway, and these numbers do not seem to pose a limitation on the role of the pulvinar as a central relay structure between cortical areas. We can thus ask

whether the limited number of layer 5 efferents to pulvinar is sufficient to project all of the information processed by a cortical area, such as V1. Unfortunately, we as yet have no answer to this question, because we simply do not know the nature of neural coding of this information that is passed on, and our ignorance here is such that we cannot rule out the possibility that the small number of layer 5 efferent cells is sufficient for this task. It is also possible that the full extent of information processed in a cortical area requires an additional, corticocortical route, the case to which we now turn.

Hypothesis 2: All information is relayed via direct corticocortical pathways The idea that the cortico-thalamo-cortical pathways involving higher-order thalamic nuclei serve as an information conduit implies that the relevant corticothalamic and thalamocortical projections are drivers. There is some evidence that the layer 5 inputs to higher-order thalamic relay cells act as drivers, but there is no direct evidence that the companion thalamocortical projections are drivers. Evidence from thalamocortical projections from first-order relays indicate that they behave essentially like drivers, so it seems plausible that this would extend to thalamocortical projections more generally. However, one idea for pulvinar projections to cortex is that these serve to regulate attentional responses, which, in turn implies that these projections could act as modulators. We need empirical evidence on the nature of thalamocortical projections from higher-order thalamic nuclei. If such evidence indicates that these higher-order thalamocortical inputs are drivers, then at least much information passed between cortical areas involves higher-order thalamic relays in a cortico-thalamo-cortical route. If, instead, the evidence is that these inputs are modulators, then we would conclude that virtually all corticocortical processing is based on direct corticocortical projections.

Hypothesis 3: Information is relayed in parallel by both pathways Perhaps the most likely notion is that the higher-order cortico-thalamo-cortical and direct corticocortical pathways represent two parallel, largely independent, and complementary routes of information flow. One example of this would be that the very large corticocortical projection handles all of the details of information that must be analyzed about the environment, and the cortico-thalamo-cortical projections inform the target cortical area about motor commands initiated by the source area. This is a more limited form of information but is essential, because higher-order cortical areas must maintain a real-time appreciation of how motor commands affect sensory processing. For example, higher visual cortical areas need to be able to factor in eye movements that cause the visual world to move on the retina and not view these as movement in the environment. This example of the limited sort of information carried by the cortico-thalamo-cortical pathways is consistent with the motor branches of the layer 5 axons described above.

Two further points need to be emphasized here. First, even if both pathways are involved in information flow, there is an important distinction to be made. Whatever information is carried by direct corticocortical connections, this remains in cortex and is thus different in kind from information carried by the layer 5 outputs to higher-order thalamic nuclei, because, as just noted, these layer 5 axons branch to carry the same information to various extrathalamic, subcortical targets. Second, this assumes the possibility that the driver/modulator distinction makes sense for intracortical pathways, but even if some corticocortical projections carry information, the massive potential problem remains to determine which pathways are modulators and which are drivers. Identifying the subset of drivers among these, and the subset may well be small, along with a full appreciation of the cortico-thalamo-cortical pathways, would allow the creation of a more complete and accurate hierarchical scheme for cortical processing.

Overview Figure 7 summarizes some of the key differences between the conventional view of corticocortical processing and the alternative view offered here. In the conventional view, information is relayed by thalamus to sensory cortex and passes within cortex to sensorimotor and then motor cortex before an output is generated to motor centers (Figure 7(a)). One problem with this is that it provides no specific role for most of thalamus, which we have defined as higher order, although there are suggestions that some of these thalamic nuclei could play a modulatory role in cortex related to attention. The alternative view (Figure 7(b)) differs from the beginning, since initial information to be relayed via a first-order thalamic nucleus reflects information sent to motor structures, perhaps reflecting an early motor command. From primary cortex, information can be relayed to other cortical areas via higher-order thalamic nuclei, and this can continue through several hierarchical stages. Also, each of these further thalamo-cortico-thalamic projections involves a layer 5 corticothalamic axon that branches to innervate extrathalamic motor structures as well as thalamus. The role of direct corticocortical pathways remains unclear in this view, but it is plausible that there are two information routes operating independently and in parallel, one the direct corticocortical route and the other, the cortico-thalamo-cortical route.

Figure 7 Comparison of conventional view (a) with the alternative view proposed here (b). The role of the direct corticocortical connections in (b) (dashed lines) is questioned (see text for details). FO, first order; HO, higher order. Reproduced from Sherman SM (2005) Thalamic relays and cortical functioning. *Progress in Brain Research* 149: 107–126.

It seems most likely that higher-order thalamic nuclei play an important and hitherto unappreciated role in corticocortical communication. Thus, thalamus is not there just to get information to cortex in the first place but rather continues to play a role in further cortical processing of that information. What is less clear is the role of direct corticocortical pathways and their relationship to the cortico-thalamo-cortical pathways. If the driver/modulator distinction has relevance for these pathways, and that is a major proviso, then it will be essential to identify which of these pathways, if any, are drivers. Only then can we have a clearer understanding of processing among the related cortical areas.

Conclusions

We have come a long way from the bad old days when the thalamus was seen as a dull, machinelike relay, acting up in an interesting fashion only during epilepsy or slow-wave sleep. To a large extent, this misconception grew out of the success of the receptive field approach to the study of sensory systems, particularly vision. Studies of the retina showed that receptive fields become increasingly complicated as one ascends synaptic hierarchies, leading ultimately to the classic center/surround receptive field of ganglion cells projecting to the LGN. This process continues across synaptic hierarchies in cortex, providing receptive fields there with exquisite sensitivity to orientation, direction of movement, spatial frequency, stereoscopic depth, etc. We believe that this receptive field elaboration in retina and cortex is ultimately used to encode all features of the sensory environment. The one synapse in the visual system across which no significant receptive field elaboration occurs is the retinogeniculate synapse, since the same basic center/surround organization is seen in retinal afferents and their target geniculate

relay cells. Because of the prevalent receptive field chauvinism dictating how one determined functional organization, this led to the notion that the LGN specifically and thalamus more generally represented an uninteresting, simple relay.

We can now turn that view on its head. Indeed, while the rest of the visual and other sensory systems are engaged in receptive field elaboration, the thalamus has a completely unique role to play in information processing. Recent appreciation of the complex cell and circuit properties of thalamus make it clear that it is anything but simple and uninteresting in its functioning. These properties serve to regulate the flow of information to cortex through mechanisms such as gain control of the retinogeniculate synapse (or equivalent for other nuclei), the burst/tonic transition, etc., and here we are probably just seeing the tip of the iceberg, given the preponderance of modulatory pathways and voltage-gated conductances in addition to the T channels than can be manipulated. There is also the point that thalamus is not there just to get information to cortex but continues to play a significant role in corticocortical communication.

The challenge for students of the visual system is at least twofold. One is to gain a better appreciation of how and under what conditions information is affected before being relayed by the LGN or pulvinar to cortex. The other is to address questions about the pulvinar. One of the great problems here is that we have no complete map of pulvinar that includes a full demarcation of what regions of pulvinar innervate which regions of cortex and which are innervated by each cortical area, with a separate mapping of layer 5 and layer 6 inputs. Given these variables and the presence of more than 30 visual cortical areas with which the pulvinar is involved in rhesus monkeys and humans, it may be that more than a hundred separate pulvinar regions remain to be discovered. This is a daunting task and should be seen as one of the major challenges for future studies of the visual system.

Thalamus and Oculomotor Control

J Schlag, University of California at Los Angeles, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Is There an Oculomotor Thalamus . . . and If So, What Defines It?

The thalamus is an ensemble of nuclei located in the diencephalon. The output neurons of these nuclei project to the telencephalon (i.e., cerebral cortex and basal ganglia in mammals). Descending projections practically do not exist (or have not been found) except from the reticular nucleus, a thin cellular shell which envelops practically the whole thalamus. Some thalamic nuclei, such as the lateral and medial geniculate nuclei, are easy to characterize in terms of a single function (respectively, visual and auditory). Their anatomy is straightforward: each geniculate nucleus receives an input of its proper sensory modality and projects to a limited, specific cortical area called a primary sensory area. Geniculate nuclei are called relay nuclei, a term which is almost derogatory because it seems to imply that thalamic synapses have no processing function; in return, geniculate nuclei receive a massive feedback from their own cortical areas. Thus are formed separate thalamocortical loops operating as specialized functional units. They are the earliest stages in seeing and hearing in the examples presented herein. Other thalamic nuclei are parts of other similar units, but not all can be as simply characterized.

What could be an oculomotor thalamus? An oculomotor apparatus would rely on a variety of signals of different sensory modalities, such as visual, auditory, and vestibular, and on a variety of internal signals, such as those that guide a search of the environment on the basis of past experience. It would induce appropriate ocular movements, such as saccades and pursuit; and it would also cooperate with other nonocular movements, such as movements of the head (to extend the span of visual exploration) and movements of the hand (to point, reach, and grasp). That is probably how an oculomotor thalamus would look like if we were searching for it.

The region of the thalamus that best fits this description is centered on the internal medullary lamina (IML) in mammals. The IML is a sheet of fibers that encapsulates the mediodorsal (MD) nucleus. Sagittally on both sides, the IML runs between the MD nucleus medially and the bulk of the other thalamic nuclei laterally, among which the most important, in our point of view, are, from back to front, the pulvinar (Pul), lateral posterior (LP), ventral lateral (VL), and ventral anterior (VA) nuclei (see Figures 1 and 2 for orientation). Caudally, the IML splits to form an envelope (capsule) around the centre médian (CM), a motor nucleus that is highly developed in primates. Within the IML are clusters of neuronal cell bodies, called intralaminar nuclei. The largest intralaminar nuclei are the paracentral (Pcn) and the central lateral (Cl) with its dorsal extension, the central superior lateral (Csl), all of which certainly are parts of the oculomotor thalamus.

The IML seems to be a good landmark to indicate the location of neurons with oculomotor properties. Indeed, based on microelectrode recordings, such neurons are situated within the lamina and, mostly, on both sides of it, in the so-called paralaminar (paralamellar) region and the multiformis sector of the MD, medially, and the paralaminar region of VL and VA, laterally. Here attention should be called to an ambiguity persisting in the literature about the labels used to designate these thalamic sectors: namely, the cells that some authors regard as intralaminar neurons are regarded by other authors as paralaminar MD. The reason for this ambiguity is that the borders of the lamina are not clear, certainly being less obvious than are the boundaries traced in atlases and used by neurophysiologists to locate their microelectrode tracks (this problem has been discussed in detail by EG Jones). This whole territory, intralaminar and paralaminar, is sometimes referred to as the central thalamus, and this terminology is adopted here.

Comparing the spatial relations of the thalamic nuclei considered here with the spatial relations of cortical frontal areas reveals a systematic organization that is well demonstrated by simultaneously injecting tracers of different colors in selected areas of the frontal lobe. After retrograde transport, the cell bodies of thalamic neurons which project to each of the injected cortical areas are discriminately marked. These neuronal populations are independent but adjacent. Figures 1 and 2 show frontal sections of the monkey thalamus and schematics of the frontal lobe. In Figure 1, the injected areas are the supplementary eye field (SEF; black), the motor cortex (area 4; red), and the prefrontal cortex (blue). In Figure 2, the injected cortical areas are the saccadic sector of frontal eye field (FEFsac; red), the SEF (black), and the dorsal premotor cortex (PMd; blue).

With respect to the lamina, the more medial thalamic populations (i.e., lateral part of MD) are reciprocally interconnected with the prefrontal cortex

Figure 1 (a) Retrogradely labeled cell bodies of thalamic neurons projecting to the three frontal lobe areas (left lateral view of the brain and cross-sections): prefrontal cortex along sulcus principalis in blue, rostral sector of supplementary motor cortex corresponding to supplementary eye field in black, and motor area in red. (b–f) Coronal sections through the thalamus, from most rostral (b) to most caudal (f). Note, particularly in panels (b–d), the distribution of marked thalamic neurons: those projecting to prefrontal cortex (in blue) are most medial and those projecting to motor cortex (in red) are most lateral. Nuclei mentioned in the text (see **Figure 2** for more abbreviations): Cl, centralis lateralis; CM, centre médian; LP, lateralis posterior; MD, medialis lateralis; Pcn, paracentralis; Pul, pulvinar; VL, ventralis lateralis; X, area X of VL. In this list, the intralaminar nuclei (inside the internal medullary lamina) are Cl, centralis superior lateralis, and Pcn. Adapted from Goldman-Rakic P and Porrino LJ (1985) The primate mediodorsal (MD) nucleus and its projection to the frontal lobe. *Journal of Comparative Neurology* 242: 535–560, with permission.

Figure 2 Retrogradely labeled cell bodies of thalamic neurons projecting to the three frontal lobe areas (two of them are different from those illustrated in Figure 1): saccadic portion of frontal eye field in front of arcuate sulcus (FEFsac, in red), supplementary eye field (SEF, in black), and hand sector of premotor cortex (PMd, in blue). The most rostral thalamic cross-section is 1111; the most caudal is 1041. Note the distribution of marked thalamic neurons: those projecting to the FEF are most medial; those projecting to the premotor cortex are most lateral. AD, anterior dorsalis; AV, anterior ventralis; Cdc, centralis densocellularis; Cl, central lateral nucleus; Cn Md, centrum medianum; Csl, centralis superior lateralis; LD, lateralis dorsalis; MDmc, medialis dorsalis, pars magnocellularis; MDpc, medialis dorsalis, pars parvocellularis; mf, medialis dorsalis, pars multiformis; Pcn, paracentral nucleus; R, reticular nucleus; Re, nucleus of reuniens; Sm, stria medullaris thalami; VAmc, ventralis anterior, pars magnocellularis; VApc, ventralis anterior, pars parvocellularis; VLcc, caudal portion of ventralis lateralis, pars caudalis; VLcr, rostral portion of ventralis lateralis, pars caudalis; VLm, ventralis lateralis, pars medialis; VLo, ventralis lateralis, pars oralis; VPI, ventralis posterior inferior; VPLc, ventralis posterior lateralis, pars caudalis; VPLo, ventralis posterior lateralis, pars oralis; VPM, ventralis posterior medialis; X, area X in the ventral lateral complex. Adapted from Tian J-R and Lynch JC (1997) Subcortical input to the smooth and saccadic eye movement subregions of the frontal eye field in Cebus monkey. *Journal of Neuroscience* 199: 9233–9247. Copyright 1997 by the Society for Neuroscience.

(see Figure 1), a cortical region implicated in 'executive' functions as studied in cognitive tasks that often – but not always involve directing gaze in monkeys. In fact, the same types of neuronal behavior are found at both the thalamic and cortical stages of this system. On the other side, the more lateral thalamic populations (i.e., in VL and VA) are more clearly motor. This is the part of the thalamus that receives inputs from the cerebellum (via deep cerebellar nuclei) and from the basal ganglia, and is interconnected with the motor and premotor cortices, which are the caudal parts of the frontal lobe. Here in these interconnections, the accent is on 'motor' function, of which the oculomotor function is an integral part. From an oculomotor point of view, unit studies that have focused on this thalamic region have stressed, in particular, the role of neurons in timing eye movements (see later). Between these medial and lateral thalamic sectors is the thalamic region interconnected with the frontal eye field and supplementary eye field (see Figures 1 and 2). In this thalamic region many neurons fire or pause with saccades or with fixation. In summary, the schematic views presented here relate the rostral part of the frontal cortex with the more medial structures of the central thalamus and the caudal part of the frontal cortex with the more

lateral structures. In addition, areas of the parietal lobe dealing with visuospatial functions (including visual motion and visual pursuit) are interconnected with thalamic populations lateral to the IML caudally (i.e., Pul and LP).

It should also be mentioned that there are cells in other thalamic nuclei, such as the lateral geniculate nucleus and the pulvinar, that change their firing rate when eye movements occur. Some cells in the pregeniculate nucleus discharge with saccades. But these are not really parts of an oculomotor apparatus – rather, they modify visual processing when eye movements occur.

Activity Patterns of Cells in the Oculomotor Thalamus

Single-unit recording work has been done by different groups of investigators with somewhat different primary interests. For one group, the main concern was studying oculomotor mechanisms at the level of the forebrain, whereas for another group, the accent was on using eye movements as a tool to explore visuospatial or cognitive functions. In this last case, saccades proved to be a very convenient way to provide evidence of an individual's choice in a behavioral task. Microelectrode experiments were performed, first in cats, but mostly in monkeys. Practically all types of neuronal patterns of activity described in other oculomotor structures (FEF, SEF, and superior colliculus (SC)) were found in the oculomotor thalamus during the performance of a large variety of tasks. Figure 3 presents some of these patterns and some of the criteria by which they are recognized. We should distinguish the following criteria:

- *Visual responses*. Phasic or tonic (or both in succession). The cell in Figure 3(b) is phasic. With a fixed latency, it is active after a stimulus onset whether

Figure 3 Some of the main patterns of firing observed in the monkey's central thalamus, with a few of the experimental conditions used for diagnostics. Schematic representations based on actual data. In each case, the upper trace is the single-unit record; the bottom traces are the horizontal records of stimulus and eye positions (vertical positions not shown for simplicity). Triangles indicate stimulus onsets and offsets (VTEM, visually triggered eye movement). Three units (a–c) produce similar bursts but are distinguished from each other by the conditions (1–3) in which such bursts occur: stimulus presentation with no targeting saccade in condition 1, stimulus presentation and targeting saccade in 2, and spontaneous saccade of exploration in 3. Another useful discriminating paradigm (not shown) to distinguish visual from saccadic activity is the memory-saccade task. Other information is discussed in the text. Adapted from Schlag J and Schlag-Rey M (1986) Role of central thalamus and supplementary eye field in voluntary control of gaze in space. *Bulletin of Tokyo Metropolitan Institute for Neurosciences* (1986 supplement): 17–31.

the eyes capture the stimulus or not, but it is not active with a saccade of the same amplitude and direction if there is no visual stimulus. Central thalamus neurons have large receptive fields (>10° in diameter), generally contralateral. The responses of the simplest of visual neurons do not depend on stimulus characteristics (such as color or shape), but, as shown, notably, by Stanford's group, more complex neurons may selectively respond to one of these characteristics if the monkey has learned that it is a cue requiring fixation of that stimulus to obtain a reward. Such cells are commonly encountered in frontal and parietal cortices. Some of these neurons continue firing even if the visual target is temporarily blanked.

- *Fixation neurons*. These are different from visual tonic neurons with a foveal receptive field because they still fire if the stimulus vanishes but the eyes continue to fixate. Figure 3(f) shows the activity of a fixation cell in the presence of the fixated stimulus. These neurons deserve to be listed apart from other visual neurons for two reasons. First, about half of these units are activated, with the other half being inhibited (silenced) during fixation. Second, the role of these units may not be visual but intentionally motor, blocking the gaze and maintaining it on a site of interest. Note that, if such a site of interest were a smoothly moving stimulus, some of these cells could fall in the category of pursuit neurons (see later).
- *Delay activity*. This is the tonic firing which, in many neurons, fills the period between an initial phasic visual response and the saccadic activity. It does not depend on the persistence of the visual stimulus. Delay activity is often considered as evidence that some spatial information (such as a goal location) has been entered and retained in memory. A recent comparison of delay activity between MD, SC, and FEF neurons indicates that, in MD at least, there is less sustained delay activity than in the SC and FEF.
- *Gap activity*. This appears during the brief gap (100–200 ms) that the investigator may insert between the extinction of the fixation point (which is the 'go' signal for a saccade) and the onset of the visual target. This activity is interpreted as a sign of disengagement of attention.
- *Saccadic activity*. This is usually directional (but not always). Directional activity is produced only when saccades terminate within a given area of the visual field (called 'movement field' by analogy to the sensory notion of receptive field). This is the case for the cell shown in Figure 3(a): it discharges prior to a saccade in the preferred direction whether or not there is a stimulus to be acquired. It is not activated (Figure 3(a,1)) by a stimulus if there is no saccade. Movement fields are usually contralateral. Some of these activities are presaccadic, starting as early as 300 ms before saccade onset. The discharge rate increases progressively, culminating in a burst, which often terminates after the saccade. Some neurons fire after saccade onset. Presaccadic neurons appear to be more numerous medially to the lamina while mid- or postsaccadic neurons are found mainly on the lateral side. Some neurons, such as the one illustrated in Figure 3(c) (to be contrasted with presaccadic and visual phasic) are activated only by visually guided (not spontaneous) saccades – that is, visually triggered eye movement (VTEM). Many neurons are visuomotor, giving first a visual response (as described previously) to a visual target and then being reactivated at the time of the saccade. Usually for these visuomotor neurons, there is a good correspondence between the location and size of their receptive field and movement field.
- *Pause neurons*. These stop firing during saccades, usually irrespective of their direction (see Figure 3(d)). Thus, they resemble the omnipause neurons of the pontine raphé, but they display a wider variability in the thalamus: some are better synchronized with saccade onset, others with saccade offset, and some show a strong rebound of activity after the pause, others do not. What seems striking in these neurons is the precise timing of their activity shifts. Pause cells have a particularity that may be important: they exist in the brain stem and thalamus, but apparently it seems that nobody has noticed their presence at the cortical level.
- *Eye position activity*. This is related to eye orientation in orbit along a given axis. It differs from visual tonic, fixation, and pursuit activity, as it does not require that a stimulus be or have been present (Figure 3(e)). In total darkness, the eyes wander and sometimes rest somewhere. To differentiate this from a real fixation, Fischer has appropriately called it 'eye parking.' Eye position neurons are best demonstrated in total darkness. In the audiomonitor, they sound like the output of a voltage-to-frequency converter. Usually, their frequency of firing is linearly related to ocular eccentricity in a given direction (most often contralateral) across the whole field or starting around the middle. Like presaccadic burst neurons, about half of the thalamic eye position neurons start changing their firing rate before saccades, which suggests that their activity is related to the production of movement rather than to its effect. There are preliminary indications that some thalamic eye position cells are also affected by head position.

- *Pursuit activity.* This occurs before and during initiation of smooth pursuit. The firing rate is proportional to the speed of target motion in a preferred direction. Such neurons continue firing even though the tracking stimulus is briefly extinguished, indicating that the signal they carry is motor or movement related, but not visual.

Finally, there are classes of activity that have been observed but not yet systematically studied, such as continuous activation (or silence) that starts when a monkey explores a display containing one target and several distractors, and lasts (several seconds) until the target is finally discovered.

Where Is the Central Thalamus in the Oculomotor Circuitry?

It is difficult to identify the origin of all of the aforementioned signals, as the central thalamus simultaneously is the obligatory gate for all incoming information to reach the cerebral cortex and is a recipient of feedback from this same cortex. The best known sources of inputs to this part of the thalamus, relevant to oculomotricity, are (1) SC, (2) substantia nigra, which receives oculomotor signals from the caudate nucleus and projects also to the superior colliculus, and (3) dentate nucleus of the cerebellum.

By the technique of retrograde transneuronal transport of herpes simplex virus type 1 (HSV-1) in cebus monkeys, Lynch and collaborators have clearly demonstrated the relations of these three input structures to the FEF via the thalamus. The virus injected into the FEF invades not only the thalamic cells projecting directly to the FEF but also, transsynaptically, the neurons projecting to these thalamic cells. The neurons are then immunohistochemically marked and the following organization emerges: the FEF is ultimately reached by neurons from the stratum opticum and stratum griseum intermedium of the SC via the paralaminar part of MD, by neurons from the pars reticularis of the substantia nigra via the magnocellular portion of VA, and by neurons from the posterior dentate nucleus via the area X of VL. Of these three pathways, the one originating in the superior colliculus has been further studied in detail by Sommer and Wurtz using physiological stimulation and recording in behaving monkeys. The aim was to identify the particular SC, MD, and FEF cells that happen to form a three-neuron pathway in order to compare their responsiveness during a task of visual targeting. To meet the criterion of connectivity, three conditions must be simultaneously satisfied: SC neurons must be antidromically activated from MD, MD neurons must be orthodromically activated from SC and antidromically activated from FEF, and FEF neurons must be orthodromically activated from SC. The main observations derived from such an experiment are as follows: the SC signals sent through this thalamocortical pathway are a fair sample of those generally found at the site of origin in the intermediate layers of the SC; the topography of visual and saccadic signals is conserved in terms of the location and size of receptive and movement fields. Visual signals from SC arrive in FEF too late to account entirely for the visual responses in FEF; the latter have a shorter latency and, thus, must be triggered from another source (maybe other visual areas). In contrast, presaccadic activity (as defined earlier) is transmitted fast (within around 2 ms) and is practically unchanged from what it is in SC, but the cells on which this activity impinges in FEF are not the movement-only neurons. Therefore, it does not seem that the immediate source of FEF presaccadic activity is the SC input.

What, then, is the significance of this presaccadic activity in an ascending pathway, a pathway which is, in fact, in the reverse direction from that expected of a motor signal? It can be a corollary discharge, a signal of the kind used by the brain, for instance, to take into account a shift in orientation of its receptor organs (the eyes in this case) when trying to locate visual features in the environment. The typical test in this situation is the double-step task. It consists in presenting two brief targets that the individuals will have to acquire in succession. As the targets have been extinguished before the first saccade, the individual has to rely on its memory of their positions. This is not a problem for reaching the first target but, for reaching the next one, the individual will have to calculate the trajectory of the second saccade taking into account the detour to reach the first target. Information on that detour is what a hypothetical corollary discharge is assumed to convey. If one of the roles of the SC–MD–FEF pathway is to provide this corollary discharge, blocking this pathway should impair the performance of the double-step task. More precisely, it should impair the second saccade in that task if the first saccade is contraversive, because what would be missing after a lesion is the corollary discharge of a vector if it is contraversive. Yet the first saccade would not be affected. That is what an injection of muscimol (a γ-aminobutyric acid agonist and inhibitor of transmission) has shown.

It would be quite interesting to study the possible effect of the same muscimol injection on the visual properties of neurons in the lateral intraparietal cortex (LIP). The receptive field responses of these neurons are modulated by eye position (gain fields). As the eye position signal very likely is provided by the brain stem

via the central thalamus, one could expect that LIP neurons will lose their eye position dependency.

Let us continue our listing of other important structures, in addition to (1) SC, (2) substantia nigra, and (3) dentate nucleus of the cerebellum, relevant to oculomotricity, which project to the central thalamus: (4) nucleus prepositus hypoglossi (5) vestibular nuclei, and (6) brain stem reticular formation. The nucleus prepositus hypoglossi, situated in the medulla, caudally to the abducens nucleus, contains eye position neurons which could be at the origin of the eye position signal recorded in the central thalamus. Vestibular nuclei projections seem to be divided into two streams: one to the central thalamus, the other to the somatosensory part of the thalamus (ventrolateral posterior nucleus), which is understandable, since information on balance concerns quite a number of other things than moving the eyes. Brain stem reticular formation is the most extensive and polyvalent part of the brain stem. Included are regions of the reticular formation clearly involved in saccade generation and in ocular pursuit. However, at the present time, it is very difficult to determine the contribution of particular reticular neurons to the massive ascending flow toward the central thalamus.

Finally, it is appropriate to mention again cortical feedback as an important input. It comes from the cortical areas with which the neural populations forming the central thalamus are related. Whereas in cases involving the lateral geniculate nucleus, the input from this cortical feedback is larger than the peripheral (visual) input; whether this is also true for the central thalamus is not known. A remarkable feature, however, has been signaled by Leichnetz: some descending projections from the FEF travel through the thalamus, via the IML, on their way down to the SC and midbrain tegmentum. When the existence of this transthalamic pathway was first reported, it was taken as an exception to the classic rule that all descending cortical projections to the brain stem and spinal cord pass through the internal capsule (i.e., around the thalamus, not through it).

Descending projections of the saccadic region of FEF terminate in the IML somewhat rostrally to – but with considerable overlap with – the projections from the pursuit region of the FEF. It is not yet clear whether the input to IML neurons is from collaterals of axons continuing toward the brain stem, or from a separate set of axons exclusively aimed at the thalamus. It will be interesting to clarify this issue because, if the input were from collaterals, one could assume that the thalamus receives from the cortex the same information that the cortex sends to the brain stem (perhaps including copies of motor commands).

Unfortunately, we still know very little about interneuronal processing within the thalamus, even in the case of the relay nuclei. This, of course, is the major obstacle to formulate hypotheses regarding thalamic function.

What Is Learned by Turning the Central Thalamus On (Stimulation) or Off (Lesion)?

Electrical stimulation within the central thalamus triggers saccades which are usually contraversive. When the head is immobilized, depending on the exact site of stimulation, evoked saccades are of either the fixed-vector type (constant amplitude and direction wherever the saccade trajectory starts in space) or goal-directed type (converging to a given orbital position). In cats, when the head is freed, head rotation also can be produced by the same stimulation. This seems to be the case for stimulation of most, if not all, oculomotor structures in the brain. The fact that saccades can be triggered from the thalamus is not surprising but it is not very informative, given that a bunch of '*fibres de passage*' (the IML) cross the central thalamus. Thus, theoretically, evoking an eye movement could be due to stimulating the thalamocortical afferents to a cortical eye field, which then retransmit this signal down to the brain stem (the descending transthalamic pathway from FEF) and/or the SEF to the brain stem, the SC afferent input to the central thalamus, which would be antidromically invaded first, followed by orthodromic invasion of collaterals within the brain stem, or any combination of these.

In cats, stimulation in a region of the central thalamus preliminarily treated with ibotenic acid, a toxin known to kill cell bodies but to spare fibers as they pass the cells, still can elicit saccades. Thus, of the three routes that we are considering here, the first one (activating the thalamocortical pathway), although not excluded, does not seem to be the only solution. For the same reason as for stimulation experiments, the effects of thalamic lesions by coagulation or pathological processes need to be interpreted with caution because, whenever the internal medullary lamina is encroached upon, fibers which may have originated far away from the site of the lesion are destroyed . The first reports concerning unilateral thalamic lesions in cats, monkeys, and humans describe the effect as a contralateral, probably motor, neglect. This neglect is transitory and similar to the one observed with some frontal lobe lesions.

Recently, two studies were made with chemical, reversible, lesions of the central thalamus in monkeys. The results are interesting particularly because they show a differentiation depending on the exact site of

the blockage, medial versus lateral to the IML. In the first study (Sommer and Wurtz, reported earlier), muscimol injected in MD affects the performance of the double-step task. As mentioned, this effect is interpreted as due to the suppression or weakening of a corollary discharge. In the other study (by Tanaka), muscimol was injected on the other side of the IML – that is, in the paralaminar VL, the region where dentate (i.e., cerebellar) projections impinge. Here, the deficit is in the timing of contraversive saccades, as revealed when the monkey's task requires that such saccades be self-triggered. Indeed, at the time of the first unit recordings in the central thalamus, it was already noted that one of the striking characteristics of these neurons (particularly the pause cells) is their capacity to mark the timing of all saccadic events as if this were some sort of controller clocking these events for the benefit of cortical areas.

Final Words

We began by asking the question: is there an oculomotor thalamus? The answer is, in a sense, yes. We saw that the central thalamus is certainly not homogeneous. On the other hand, its different parts are not dispersed all over the thalamus. They are gathered together very likely because they collect and make use of the same information. One may view the central thalamus as the director of the saccadic chorus. It would not produce any 'sound' itself, but it is in an ideal position to coordinate all of the voices of the centers variously suspected to initiate eye movements: SC, FEF, SEF, and basal ganglia. As unit recordings indicate, when a saccade is produced, all of these structures always agree on the direction of the movement, even when conflict is likely. Indeed, all cells whose field contains the goal of that movement always fire in unison. This makes it difficult for the investigator to detect where the decision to move has been made in the brain. Patricia Goldman-Rakic has promoted the idea that there is a "distributed neural network subserving spatially guided behavior." With her collaborators, she has demonstrated the existence of multiple direct interconnections between frontal and parietal cortical areas controlling spatial behavior. At the same time, she pointed out that the thalamic regions communicating with these cortical areas were contiguous or overlapping. In fact, in the past, the central thalamus, not yet suspected of any oculomotor role, was known as the site from where the most widespread, synchronized electrocortical potentials, the so-called recruiting waves, were produced by 10 Hz stimulation. These waves progressively invade most of the frontal and parietal lobes. They may have been the first sign, not well understood then, that the central thalamus operates as a hub. Today, further support for this view is found in the fact that electrical stimulation of the IML in the central thalamus is used for rescuing brain-injured patients from a minimally responsive state.

Introduction

The diencephalon comprises the hypothalamus, epithalamus, and thalamus, the latter consisting of the ventral thalamus, or subthalamus, and the dorsal thalamus. Both the ventral thalamus and the dorsal thalamus vary greatly across vertebrates in their degree of development and, to some extent, even in their component parts.

In mammals, nuclei of the ventral thalamus generally can be divided into motor system-related nuclei, which influence the degree of inhibition of motor system-related nuclei within the dorsal thalamus, and visual system-related nuclei, which influence eye movement control. Mammalian ventral thalamic nuclei do not directly project to the telencephalon, in contrast to dorsal thalamic nuclei that relay ascending sensory and related information to the telencephalon. How all of these nuclei evolved has been difficult to fathom due to the many differences in their anatomical organization and degree of elaboration in comparison to other amniotes and, to a much greater degree, across anamniotes.

Evolution of the Ventral Thalamus

Ventral Thalamic Organization in Anamniotes

The ventral thalamus comprises at least three nuclei in most anamniotes, all of which are most prominently related to the visual system. In cartilaginous fishes (sharks, skates, and rays) and ray-finned fishes (generally referred to as bony fishes), these three nuclei are called nuclei intermedius, ventromedius, and ventrolateralis (Figure 1). They all receive direct visual input from the retina. Generally similar nuclei are present in amphibians, although whether their homology to the ventral nuclei of fishes is discretely one-to-one remains to be clarified. Within their ventral thalamus, amphibians have a nucleus ventromedialis and two divisions of a nucleus ventrolateralis. They also have a heavily retinorecipient nucleus of Bellonci in a more lateral position, which extends caudally as the neuropil of Bellonci. While most connections of the ventral thalamic nuclei of anamniotes are unknown, for the most part (the exception being a somatosensory pathway in a ray-finned fish), they do not appear to relay sensory information to any part of the telencephalon, in marked contrast to dorsal thalamic nuclei, particularly in amniotes.

An important recent finding is that the dorsal thalamic nuclei of amphibians that do project to the telencephalon may not receive direct sensory input, at least from the retina or the somatosensory nuclei of the medulla. Rather, they may receive inhibitory input from the ventral thalamic nuclei, the latter serving as the only diencephalic sites for direct receipt of these inputs. This aspect of dorsal thalamic organization and its implications for evolution of the two main divisions of the dorsal thalamus across all vertebrates will be considered later.

Ventral Thalamic Organization in Amniotes

Visual ventral thalamus In reptiles (Figure 2) and birds, the ventral thalamus contains ventromedial and ventrolateral nuclei, about which little is known, and a major visual system nucleus, the pars ventralis of the lateral geniculate nucleus (LGNv). The latter nucleus consists of a lateral neuropil region that borders a more medially lying cell plate. It receives a variety of visual inputs, including from the optic tectum (the homolog of the mammalian superior colliculus) and the retina. In reptiles, a related nucleus lies immediately dorsal to the LGNv, the intergeniculate leaflet, homologous to the nucleus of the same name in mammals, and an additional, visual system-related nucleus, nucleus ovalis, is present at a more rostral level. In birds, the intergeniculate leaflet is referred to as the nucleus of the marginal optic tract. Mammals likewise have an LGNv, which in primates is known as the pregeniculate nucleus.

None of these visual components of the ventral thalamus in amniotes projects to the telencephalon but all contribute to brain stem systems involved in the regulation of eye movements. In mammals, this influence is known to occur via connections with the pretectum and superior colliculus and is likely similar in reptiles and birds. Whether the ventral thalamus is involved in eye movement regulation in fishes has not been established, but the receipt of visual inputs combined with outputs to brain stem rather than telencephalic sites is a ventral thalamic hallmark that clearly was established early in its evolutionary history and has been elaborated particularly within the amniote radiation.

Motor ventral thalamus Motor system-related nuclei within the ventral thalamus have not been identified in anamniotes. In mammals, the main motor system-related component of the ventral thalamus is the

subthalamic nucleus, which uniquely (1) receives GABAergic input from the external segment of the globus pallidus (GPe), (2) contains glutamatergic neurons, and (3) projects to the internal segment of the globus pallidus (GPi). This nucleus is a key component of the so-called indirect loop formed by projections from the ventral anterior (VA) and ventral lateral (VL) nuclei of the dorsal thalamus to neocortex, thence to the caudate-putamen, thence to GPe, thence to the subthalamic nucleus, thence to GPi, and thence and back to VA and VL. The effect of subthalamic nuclear input to GPi is an increase in the firing of the GPi neurons, which themselves are inhibitory to the neurons within VA and VL, thus decreasing the excitatory thalamic input to cortex and thus producing an inhibitory effect on the initiation of movements.

A nucleus that contains glutamatergic neurons and has the same connections with the globus pallidus and the dorsal thalamus has been identified in both reptiles and birds and was thus evolutionarily established at the origin of amniotes if not earlier. In birds, this nucleus was previously called the anterior nucleus of the ansa lenticularis, but a recent update in avian neuroanatomical nomenclature by The Avian Brain Nomenclature Forum recommended using the name of subthalamic nucleus for this nucleus in birds, since its homology with the subthalamic nucleus of mammals is well established. In reptiles, the same glutamatergic cell group is called the anterior entopeduncular nucleus.

Thalamic reticular nucleus In amniotes, an additional component of the ventral thalamus, the thalamic reticular nucleus, is present. In mammals and birds, this nucleus is composed fully or predominantly of GABAergic neurons. In mammals, it is well established that these neurons receive inputs from various specific dorsal thalamic nuclei and from the various neocortical areas to which these dorsal thalamic nuclei project. In turn, the thalamic reticular nucleus projects back to the dorsal thalamic nuclei, thus serving as a brake and perhaps a firing pattern-coordinating mechanism on an otherwise purely positive feedback loop of glutamatergic projections from the dorsal thalamus to neocortex and reciprocally back to dorsal thalamus. The thalamic reticular nucleus of mammals has been proposed to be a crucial component of the thalamocortical neural circuitry involved in the generation of consciousness.

In crocodiles, a thalamic reticular nucleus is present but seems to be differently constituted than in birds and mammals. While lying in a similar location and having similar projections to the dorsal thalamus, the thalamic reticular nucleus in crocodiles contains several subpopulations of neurons, only one of which is GABAergic. Thus, this nucleus may have undergone a process of parallel evolution in the lines leading to extant birds and mammals, independently gaining a high percentage of GABAergic neurons in both lineages.

The possible role of the thalamic reticular nucleus in the production of consciousness in mammals and birds makes its evolutionary history of particular interest. GABAergic neuronal populations have been

described within various dorsal and ventral thalamic locations in a variety of anamniotes, including lampreys, some ray-finned fishes, and amphibians. Ventral thalamic neurons in amphibians are the most likely source of inhibitory inputs identified to the dorsal thalamic nuclei, and it is thus highly likely that these neurons are GABAergic and possibly homologous to the thalamic reticular nucleus of amniotes. Thus, such a nucleus, either as a discrete cytoarchitectonic entity or as scattered population(s) of neurons, may likewise be present in fishes and an evolutionary ancient attribute of the thalamus of vertebrates. The presence of such a nucleus in amphibians and possibly other anamniotes would indicate that the relative paucity of GABAergic neurons within the thalamic reticular nucleus of crocodiles might represent a secondary specialization within this taxon rather than being representative of the basal amniote condition.

Evolution of the Dorsal Thalamus

The dorsal thalamus varies greatly across vertebrates in the degree of its development and its importance in the relay of ascending sensory information to the telencephalon. Also, the sites within the telencephalon, to which its various nuclei project, vary markedly. Since in mammals the dorsal thalamic nuclei constitute an exclusive gateway for the relay of sensory information to most parts of the dorsal pallium in the telencephalon, which in mammals mainly comprises neocortex, dorsal thalamic evolution is crucially related to neocortical evolution. The dorsal thalamus in mammals is the most elaborate in terms of number of nuclei and their connections across all vertebrates, which one might well expect given the complexity of the mammalian telencephalon but which also made deciphering its evolutionary history a highly challenging problem. In order to explicate dorsal thalamic evolution across vertebrates, its organization in extant anamniotes and amniotes is considered first. Then the two basic divisions of the dorsal thalamus that are present in anamniotes – the lemnothalamus and the collothalamus – are defined, followed by an examination of whether these two divisions can also be recognized across amniotes. Finally, the differential evolution of these two divisions across tetrapods is discussed.

Dorsal Thalamic Organization in Anamniotes

Among anamniotes, the connections and histochemistry of the dorsal thalamic nuclei in the jawless fishes – lampreys and hagfishes – have not been studied in enough detail to allow meaningful comparisons with those of jawed vertebrates. In jawed fishes, the dorsal thalamus generally comprises three nuclei (Figure 1) – nucleus anterior, which lies in the most rostral part of the dorsal thalamus, and nuclei dorsalis posterior and centralis posterior, which occupy the caudal part of the dorsal thalamus. In cartilaginous fishes, as studied in a species of shark, nucleus anterior receives direct retinal input and projects to a part of the pallium in the telencephalon called the central nucleus. The dorsal posterior nucleus received visual input relayed to it via the optic tectum and also projects to the telencephalon, to site(s) in the subpallium and/or pallium. Also, in another shark species, auditory evoked potentials have been recorded from another part of the pallium, possibly relayed there through the central posterior nucleus. In a skate, nucleus anterior has been reported to project to the medial pallium, a proposed homolog of the hippocampal formation of amniotes. While most thalamotelencephalic projections are ipsilateral, the latter projection is notable for being bilateral.

In contrast to the situation in mammals, the dorsal thalamus in ray-finned fishes is not the only set of nuclei by which ascending sensory information is relayed to the telencephalon. A collection of nuclei not present in other vertebrate groups, the preglomerular nuclear complex (Figure 1), which is a part of a more caudal diencephalic component called the posterior tuberculum, serves as the main relay for a number of the major ascending pathways, particularly for the lateral line and gustatory systems. Parts of the hypothalamus and, at least in one species, ventral thalamic nuclei also participate in the ascending relay of some sensory information to the telencephalon. The dorsal thalamic nuclei relay some information to the telencephalon as well, especially for the visual and auditory systems. As is apparently also the case for cartilaginous fishes, the dorsal posterior and central posterior nuclei receive these visual and auditory inputs, respectively, from the midbrain roof. A number of the ascending projections, whether relayed via the preglomerular nuclear complex, the dorsal posterior and central posterior nuclei of the dorsal thalamus, or other sites, terminate in the medial zone of the pallium, which in ray-finned fishes is called area dorsalis. Due to differences in the embryological development of the pallium in ray-finned fishes, this medially lying pallial region actually corresponds topologically to the lateral region of the pallium in the other major vertebrate groups and is a good candidate for a homolog of the mammalian amygdala, particularly its basolateral, thalamorecipient part. Visual projections relayed directly from the retina through nucleus anterior to a more lateral part

of the pallium in ray-finned fishes have been reported in goldfish. The possible homology of this part of the pallium remains unresolved, but it corresponds topologically to part of the dorsal pallium of amniotes.

In amphibians, the rostral part of the dorsal thalamus, nucleus anterior, projects robustly to the medial pallium, and this projection, like that reported in skates, is bilateral. In contrast to the situation in fishes, retinal as well as somatosensory inputs to nucleus anterior are relayed to it from neighboring ventral thalamic nuclei, and the input of the latter appears to be inhibitory. The more caudal part of the dorsal thalamus in amphibians is composed of several nuclei, and, like the situation in fishes, receives its predominant inputs from the midbrain roof. This part of the dorsal thalamus projects predominantly to the striatum in the ventrolateral wall of the telencephalon, with only a slight projection reaching the most ventral part of the lateral pallium.

Two Divisions of the Dorsal Thalamus in Anamniotes

Based on the preceding survey, several points about dorsal thalamic organization in anamniotes can be made for the general case: (1) the dorsal thalamus is divided into two parts, a more rostral part usually termed nucleus anterior and a more caudal part that comprises the dorsal posterior and central posterior nuclei in most fishes and several comparable nuclei in amphibians; (2) nucleus anterior receives direct retinal (and other sensory system) projections, at least in fishes, and (3) projects to part(s) of the dorsal and/or medial (hippocampal) pallium; (4) telencephalic projections from nucleus anterior are frequently bilateral; (5) the more caudal part of the dorsal thalamus receives its predominant inputs from the midbrain roof, and (6) may project to the striatum as well as to the lateral part pallium, in amphibians the projection being almost all to the striatum; and (7) all known telencephalic projections from the caudal part of the dorsal thalamus are ipsilateral only.

Based on the preceding listed differences between the more rostral part of the dorsal thalamus (the nucleus anterior of anamniotes) and its more caudal part, two fundamental divisions can be recognized – a rostrally lying lemnothalamus and a more caudally lying collothalamus (Figure 1). The term 'lemnothalamus' is in accord with the previously established usage of the word lemniscus – the prefix 'lemno' meaning a ribbon and the term 'lemniscus' applied to fiber tracts that originate from a secondary sensory cell group (such as the dorsal column nuclei or the retinal ganglion cells) and ascend directly to the thalamus, that is, without first synapsing in any part of the midbrain roof. Thus, the lemnothalamus comprises the nucleus or nuclei within the rostral part of the dorsal thalamus that receive their sensory (or other) inputs directly, that is, without relay through the midbrain roof. The term 'collothalamus' refers to the source of its predominant inputs being the midbrain roof, which in mammals is referred to as the colliculi.

Dorsal Thalamic Organization in Amniotes

Collothalamus in amniotes From the studies of Harvey Karten and his co-workers and colleagues in the 1960s and 1970s, homologies between some dorsal thalamic nuclei in sauropsids (birds and reptiles) and mammals were strongly indicated based on similarities of their predominant afferent inputs from the midbrain roof. At that time, they were not yet recognized to constitute the collothalamus, since the basic organization of the dorsal thalamus into two divisions had not yet been realized. Nonetheless, a nucleus in receipt of visual projections from the superficial part of the rostral midbrain roof, called nucleus rotundus in both birds and reptiles (Figure 3), was identified as a homolog of the tectorecipient part of the nucleus lateralis posterior/pulvinar (LP/pul) complex of mammals. A nucleus in receipt of somatosensory projections from the deep part of the rostral midbrain roof, called the caudal part of nucleus dorsolateralis posterior (cDLP) in birds and various terms in reptiles, including nucleus medialis posterior (Figure 3), was identified as a homolog of part of the tectorecipient posterior nuclear group (PO) of mammals. A nucleus in receipt of auditory projections from the caudal part of the midbrain roof, called nucleus ovoidalis in birds and various terms in reptiles, including nucleus medialis (Figure 3), was identified as a homolog of the mammalian medial geniculate nucleus (MGN), particularly its ventral division.

The telencephalic projections of these nuclei in sauropsids and mammals are of crucial significance to their postulated relationships of homology, and in the past decade a considerable degree of debate has arisen concerning this matter. In mammals, LP/pul, PO, and MGN project to various areas of the lateral part of neocortex, its occipitotemporal/insular regions, but they also generally project to the basolateral part of the amygdala and, in addition to these pallial targets, generally to the striatum. For those that project strongly to neocortex, their projection to the amygdala, where present, is minor and vice versa. In sauropsids, nuclei rotundus, ovoidalis, and cDLP generally also project to the striatum, but they additionally project to only one pallial target, a specific locus for each within a large structure called

Figure 3 Transverse hemisections with mirror image drawings through four levels of the dorsal thalamus of an adult mammal, the raccoon *Procyon lotor*, with a most rostral, showing most of the lemnothalamic (in blue) and collothalamic (in yellow) nuclei. The intralaminar nuclei are divided into rostral, lemnothalamic and caudolateral, collothalamic groups, as indicated by their blue or yellow shading, respectively, with the former including the central medial, rhomboid, and center median nuclei and the latter the parafascicular, paracentral, and central lateral nuclei. the dorsal ventricular ridge (DVR) in reptiles and to specific loci within a part of the same structure that is referred to as the nidopallium in birds. The question is therefore whether the latter part of the pallium in sauropsids is homologous to the lateral part of mammalian neocortex, to the basolateral amygdala, to both, or, as also proposed, to neither. The nidopallium/reptilian thalamorecipient DVR have long been regarded as homologs of specific thalamorecipient and related cell populations (specifically those of layer IV and of V–VI) within neocortex. Recent embryological evidence of gene expression patterns supports a reinterpretation such that the nidopallium/reptilian thalamorecipient DVR are actually homologous to the basolateral amygdala of mammals. However, the latter interpretation does not offer a cogent hypothesis for the evolutionary origin of the laterally lying neocortical areas that also receive these ascending collothalamic inputs. An alternative explanation is that the nidopallium/reptilian thalamorecipient DVR are homologous as a field to both the basolateral amygdala and the lateral neocortex.

Since the homologous relationships of the dorsal thalamic nuclei that project to these various targets are linked to the homologous relationships of their pallial target(s), resolution of this major issue will require further experimental evidence to illuminate the evolutionary history with full clarity. While nucleus ovoidalis (and its reptilian homologs) is generally accepted as the homolog of MGN, whether it is comparable to the ventral division of MGN or to one or more of its other components, such as its medial, magnocellular component, is debated. More vigorously contested is whether the nucleus rotundus of sauropsids is homologous to the LP/pul complex of mammals or, along with cDLP, to one or more components of the posterior nuclear group.

That these various nuclei in sauropsids and mammals (Figures 3 and 4) constitute a division of the dorsal thalamus – the collothalamus – is, however, quite well established, whatever the outcome of the homology issues among the individual nuclei. They share several crucial features with the caudal part of the dorsal thalamus of anamniotes, including receipt of their predominant inputs via relays through the

Figure 4 Transverse hemisections with mirror image drawings through four levels of the dorsal thalamus of an iguana *Iguana iguana*, with A most rostral, showing most of the lemnothalamic (in blue) and collothalamic (in yellow) nuclei. midbrain roof and projections to the telencephalon that are generally to both the striatum and to the pallium. Also, all projections of these nuclei to the telencephalon are ipsilateral only. Recent gene expression also has supported the recognition of the collothalamus in embryonic mice; in contrast to the more rostrally situated lemnothalamus, it is positive for calretinin and negative for the gene *Math4a*.

Lemnothalamus in amniotes Due to the complexity and marked elaboration of the lemnothalamus in amniotes, the key to recognizing that it is a unitary entity and consistent across all jawed vertebrates lay in realizing that its various attributes overlap in their distribution across different nuclei and different groups of nuclei (Figures 3 and 4). First, one can recognize that the nuclei that do not receive their predominant input from the midbrain roof form a diverse set in both sauropsids and mammals. Then, the question becomes whether enough commonalities exist across them and in what pattern to allow for recognition of them as constituents of a fundamental dorsal thalamic division.

Aside from the collothalamic components of the mammalian dorsal thalamus already discussed, this part of the brain also contains a diverse array of nuclei and nuclear groups, which can only be briefly summarized here. Most rostrally in position in adult mammal brains is the anterior nuclear group, which is mostly interconnected with limbic areas (hippocampal and related cortices) but does receive a direct if sparse retinal input on its lateral aspect. Caudally adjacent to the anterior nuclear group is the medial nuclear group, the most prominent nucleus of which is the dorsomedial nucleus. This nucleus receives a major input from the olfactory cortex and also from the ventral pallidum, and it projects to prefrontal cortex. Like the dorsomedial nucleus, a relatively small nuclear group, the midline nuclei, also receive ventral striatopallidal inputs related to the limbic system. In contrast to the specific sensory relay nuclei of the dorsal thalamus, the intralaminar nuclei give rise to widespread projections to neocortex, albeit that these projections are individually restricted in their points of origin but nevertheless blanket the cortex in their range of projection coverage. Among a diverse set of afferents to the intralaminar nuclei is the rostral part of the reticular formation, essential for the maintenance of conscious wakefulness. In a more lateral position is the ventral nuclear group, which contains a number of nuclei involved in the somatosensory and motor feedback systems. The VA and VL both receive inhibitory motor-related inputs from the GPi and also inputs from the substantia

nigra pars reticulata and deep cerebellar nuclei, respectively. These nuclei project to motor cortical areas. The more caudally lying ventroposterior lateral (VPL) nucleus is the main somatosensory relay nucleus for the body with input from the dorsal column nuclei, and a nucleus medial to it, the ventroposterior medial nucleus (VPM), serves the same function for the trigeminal system from the head. These nuclei project to the primary somatosensory cortex. Finally, the dorsal lateral geniculate nucleus (DLGN) receives a massive visual input directly from the retina and projects to striate cortex.

One component of the puzzle solution for dorsal thalamic organization derives from embryological evidence published in Jerzy Rose in 1942 on the development of the dorsal thalamus in rabbits. Rose identified five cell groups in the developing dorsal thalamus that he called pronuclei and that ultimately give rise to all of its component, individual nuclei. All collothalamic nuclei are derived from two pronuclei – the dorsal and medial geniculate pronuclei – with the latter giving rise to the MGN and the former to both PO and LP/pul. The origin of the latter two nuclei from just one pronucleus is consistent with the enigmatic and seemingly entwined evolutionary origin of these nuclei and, correspondingly, of the lateral part of neocortex and the basolateral amygdala, as discussed above. The other three pronuclei identified by Rose are the medial and central pronuclei and the lateral geniculate pronucleus. The latter gives rise to the DLGN, while the medial pronucleus gives rise to the medial nuclear group and the central pronucleus to the anterior, intralaminar, and ventral nuclear groups. (Some of the caudally lying intralaminar nuclei are now assigned to the collothalamus, based on their predominant midbrain roof afferent input, but, consistent with Rose's embryological analysis, the rostral intralaminar nuclei are clearly lemnothalamic components.) The facts that (1) one pronucleus, the central, gives rise to both the anterior and ventral nuclear groups, (2) the lateral geniculate pronucleus lies rostrally early in development (rather than caudally as in the adult condition) and (3) shares a direct retinal input, albeit sparse, with part of the anterior group, and the sharing of other commonalities of both afferent and efferent connections, including (4) at least some bilateral projections to the telencephalon and (5) a conspicuous lack of any projections to the striatum, indicate that the derivatives of the central, medial, and lateral geniculate pronuclei of mammals indeed forms a set of rostral thalamic nuclei that comprise an embryologically coherent division of the dorsal thalamus.

Similarly in sauropsids, the set of dorsal thalamic nuclei that are not part of the collothalamus also have overlapping and shared features that correspond to those in mammals and allow their identification as a coherent dorsal thalamic division. Recent findings indicate a number of rather precise, if not completely one-to-one, comparisons between the various rostrally lying, noncollothalamic nuclei in sauropsids and mammals. Components of the formerly called nucleus opticus principalis thalami (OPT) in birds and a homologous cell group in reptiles are clearly homologous in a one-to-one manner to the DLGN of mammals. Two other nuclei in reptiles, nucleus dorsolateralis anterior (DLA) and nucleus dorsomedialis (DM), are homologous as a field to multiple nuclei in birds. The latter avian nuclei include two similarly named nuclei and other nearby nuclei that, as a group, are called the dorsal thalamic zone (DTZ) as well as nucleus dorsalis intermedius ventralis anterior (DIVA) and the ventrointermediate area (VIA). The connections and location of the medial components of the DTZ nuclei resemble those of the mammalian rostral intralaminar, midline, and mediodorsal nuclei. DIVA receives ascending somatosensory input from the dorsal column nuclei and thus resembles the mammalian VPL. VIA receives motor system-related inputs from GPi, the substantia nigra pars reticulata, and deep cerebellar nuclei and thus closely resembles both VA and VL of mammals. Thus, there is now substantial evidence that this set of nuclei in birds is homologous as a field to the DLA-DM nuclei of reptiles and also homologous as a field to the full set of lemnothalamic nuclei (i.e., all besides the DLGN) identified above in mammals. Finally, as noted above for the collothalamus, recent developmental data supports the concept of the lemnothalamus as an embryological entity. The developing lemnothalamus in mice is distinguished from the collothalamus in its negativity for calretinin and in being positive for expression of the gene *Math4a*.

Differential Evolution of the Collothalamus and Lemnothalamus in Tetrapods

Dramatic changes occurred for both the collothalamus and the lemnothalamus at the origin of amniotes, and whether the condition in extant amphibians reflects the ancestral tetrapod condition or, at least in some respects, a secondarily modified condition remains to be resolved. In extant amphibians, the collothalamus receives its predominant input from the midbrain roof, as is the case in all other vertebrate groups and thus clearly the basal ancestral condition. However, in amphibians it projects massively to the striatum and only very sparsely to the most ventral part of the lateral pallium. If the latter condition also is ancestral for tetrapods, then a dramatic shift of most of these projections to pallial targets would

have occurred at the origin of amniotes. This shift would have occurred in conjunction with elaboration of both the lateral parts of neocortex and the basolateral amygdala in mammals and of the DVR/nidopallium in sauropsids.

The amphibian lemnothalamus also is somewhat unique among vertebrates. It lacks direct receipt of retinal and dorsal column sensory inputs, in contrast to the situation in fishes and amniotes. In fact, in its connections the amphibian lemnothalamus more closely resembles a portion of the DLA-DM nuclei of reptiles and the corresponding lemnothalamic components in birds and mammals than it does the DLGN-VPL nuclei of mammals and the DLGN-DIVA nuclei of birds. Nonetheless, the amphibian nucleus anterior is clearly the lemnothalamus, and it projects robustly and bilaterally to the medial pallium. Thus, if this telencephalic projection pattern represents the ancestral tetrapod condition, then a second dramatic shift in connections occurred with the origin of amniotes, from predominantly medial pallium to predominantly dorsal pallium – the dorsal, or general, cortex in reptiles, the visual and somatosensory-motor Wulst and related pallial areas in birds, and the primary visual, somatosensory, motor, and prefrontal cortices of mammals. The bilaterality of the lemnothalamic projections has been maintained to some extent in sauropsids and decreased markedly in mammals. Nevertheless in mammals, some bilateral lemnothalamic projections persist and represent a marked contrast to the dedicatedly ipsilateral collothalalmic projections.

The evolutionary split between mammals and sauropsids was correlated with differential evolution of the lemnothalamus and collothalamus. Extant reptiles are characterized by a markedly elaborated collothalamus but with a modest lemnothalamus. However, while ancestral birds retained the elaborated collothalamus, they also elaborated the lemnothalamus, gaining specific nuclei such as DIVA and VIA that respectively mimic the specific lemnothalamic nuclei VPL and VA/VL of mammals. In contrast, early mammals favored elaboration of the lemnothalamus, as is retained in extant monotremes (platypus and echidna). Subsequently, beginning in marsupials and in many of the orders of placental mammals, the collothalamus was elaborated in correlation with the elaboration of the many supernumerary association visual cortices and several association somatosensory, insular association cortical areas. Thus, while the sauropsid line initially favored the collothalamus and its corresponding pallial areas, and the mammalian line initially favored the lemnothalamus and its corresponding pallial areas, within both lineages the other part of the thalamopallial system became elaborated subsequently – in birds within sauropsids and in many mammalian orders.

The AIM Model of Dreaming, Sleeping, and Waking Consciousness

J A Hobson, Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

When we go to sleep at night and dream, our conscious state changes radically. When we first become drowsy, fleeting dream images may occur. We then become oblivious and hard to rouse from deep sleep. Later in the night, when sleep lightens, we may experience vivid, bizarre dreams from which spontaneous or easily induced awakenings may occur. By studying the changes in the brain which are associated with these changes in our state of consciousness, we may learn more about the physiological mechanisms underlying our states of mind.

During waking we can attend to events in the outside world, form perceptions of events, and/or direct our thoughts to those percepts or to other matters, such as the review of our behavior, our plans, or our feelings. When we go to sleep, we become unaware of the outside world and lose the ability to construct thoughts. These perceptual and cognitive defects persist even when we dream: perceptions are then almost entirely internally generated and we have difficulty reasoning about them; we almost always believe that we are awake instead of dreaming.

From the vantage point of the cognitive neuroscience of consciousness, we can tentatively explain these phenomena as a function of three factors:

1. Factor A: the level of electrical activation in the brain.
2. Factor I: the status of gating information flow to and from the brain.
3. Factor M: the nature of the mode of information processing within the brain.

The level of consciousness is thus low or high, depending upon the level of activation (A). The focus or direction of consciousness is either strongly external or strongly internal, depending on whether the input–output gates of the brain are open or closed to the flow of information (I). The mode (M) of information processing within the brain is set by the ratio of aminergic to cholinergic modulation. Since these three factors can be quantified using experimental data, it is possible to construct a three-dimensional state space model (Figure 1). The state of consciousness, a point with values A, I, and M, varies over time, the fourth dimension of the model. Normal sleep cycles appear as elliptical trajectories in the resulting state space.

Definition of Consciousness

For the purpose of the conscious state paradigm, consciousness can be simply defined as awareness of the outside world, our bodies, and ourselves. Consciousness can be further distinguished in two ways. The first distinction is between primary consciousness (which does not depend upon language and may well be shared with many other mammals) and secondary consciousness (which does depend upon language and may be a uniquely human capability). The second distinction is between the components of consciousness, which are shown in Table 1. These components of consciousness vary significantly in strength over the normal wake–sleep–dream cycle.

The functions listed in Table 1 are the aspects of consciousness which are commonly studied by cognitive neuroscientists. Here we investigate the common mechanisms by which all of these aspects are changed as a function of the changes in conscious state experienced by us as waking, sleeping, and dreaming.

Characteristics of Consciousness

Consciousness is graded and its components vary in strength as the brain changes state over the course of each day of each life and over a lifetime. In other words, consciousness is more or less intense and its components change in relative strength as a function of the sleep–wake cycle. For example, in waking, perception can be exteroceptive, thought can be logical, and memory can be good. By contrast, in dreaming, all three of those cognitive functions are altered; internal perception is enhanced, emotion is intensified and confabulation runs wild, and logical thought and memory are greatly impaired. Table 2 lists some of the state-dependent consciousness components.

Changes in the Brain and in the Body during Sleep; Changes in Consciousness

As shown in Figure 2, sleep onset is associated with thalamocortical deactivation. This deactivation is signaled, first, by electroencephalogram (EEG) slowing (stage I) and next by definitive blockage of thalamic transmission with the appearance of EEG spindles (stage II). After that there is a further slowing in frequency and an increase in amplitude of cortical slow waves (stages III and IV). Muscle tone decreases passively, postural shifts stop, and eye movements are greatly reduced as this pattern evolves. During the evolution of these stages of so-called nonrapid eye movement (NREM) sleep, individuals may have

Model factor	Psychological	Neurobiological
A-Activation: energy level of processing capacity	• Word count • Cognitive complexity, e.g., perceptual vividness, emotional intensity, narrative	• EEG activation • Firing level and synchrony of reticular, thalamic and cortical neurons
I-Information: source internal or external	• Real world space, time and person referents and their stability • Real vs. imagined action	• Level of presynaptic and postsynaptic inhibition • Excitability of sensorimotor pattern generators
M-Mode: organization of data	• Internal consistency? • Physical possibility? • Linear logic?	• Activity level of aminergic neurons

Figure 1 The activation/input source/neuromodulation (activation/information/mode; AIM) model. Illustration of three-dimensional state space and the psychological neurobiological correlates of each dimension.

Table 1 Components of consciousness

Component	*Definition*
Attention	Selection of input data
Perception	Representation of input data
Memory	Retrieval of stored representations
Orientation	Representation of time, place, and person
Thought	Reflection upon representations
Narrative	Linguistic symbolization of representations
Emotion	Feelings about representations
Instinct	Innate propensities to act
Intention	Representations of goals
Volition	Decisions to act

fleeting dreams as their brains are disconnected from sensory input, but they soon become oblivious with little or no memorable mental activity. Measures of this deactivation process yield low values of factor A in the AIM model. At the same time that factor A decreases, factors I and M are also decreasing as the sensory gates close and aminergic modulation decreases.

After 70–80 min, often signaled by a posture shift, the EEG is reactivated and reverses its downward path, moving rapidly up through stages III and II to enter stage I. At the same time the electromyogram (EMG) is actively inhibited and the electooculogram (EOG) shows the increasingly clustered and intense eye movements that give REM sleep its name. The values of factor A activation increase to waking levels (and beyond), but sleep persists. But both factors I and M go to their lowest values in REM as the activated brain is actively put offline and further demodulated. The alternation of NREM and REM sleep continues throughout the night at 90- to 100-min intervals. As the night progresses the NREM periods become shorter and less deep while the REM periods become longer and more active. In the last two cycles the alternation is usually between stage II and stage I REM. This increasing brain activation is associated with an increase in dreaming. Although dreaming is always more intense in REM, it also occurs in NREM sleep, especially in the second half of the night.

Formal Analysis of Dream Content

In order to compare with waking the nature of conscious experience in REM and light NREM sleep, it has

Table 2 State-dependent consciousness components

Function	*Nature of difference*	*Causal hypothesis*
Sensory input	Blocked	Presynaptic inhibition
Perception (external)	Diminished	Blockade of sensory input
Perception (internal)	Enhanced	Disinhibition of networks storing sensory representations
Attention	Lost	Decreased aminergic modulation causes a (decrease in) signal-to-noise ratio
Memory (recent)	Diminished	Because of aminergic demodulation, activated representations are not restored in memory
Memory (remote)	Enhanced	Disinhibition of networks storing mnemonic representations increases access to consciousness
Orientation	Unstable	Internally inconsistent orienting signals are generated by cholinergic system
Thought	Reasoning *ad hoc*; logical rigor weak; processing hyperassociative	Loss of attention, memory, and volition leads to failure of sequencing and rule inconstancy; analogy replaces analysis
Insight	Self-reflection lost (failure to recognize state as dreaming)	Failure of attention, logic, and memory weakens second- and third-order representations
Language (internal)	Confabulatory	Aminergic demodulation frees narrative synthesis from logical restraints
Emotion	Episodically strong	Cholinergic hyperstimulation of amygdala and related temporal lobe structures triggers emotional storms, which are unmodulated by aminergic restraint
Instinct	Episodically strong	Cholinergic hyperstimulation of hypothalamus and limbic forebrain triggers fixed-action motor programs, which are experienced fictively but not enacted
Volition	Weak	Top-down motor control and frontal executive power cannot compete with disinhibited subcortical network activation
Output	Blocked	Postsynaptic inhibition

Figure 2 Behavioral states of humans. States of waking, nonrapid eye movement (NREM) sleep, and REM sleep have behavioral, polygraphic, and psychological manifestations. The sequence of these stages is represented in the polygraph channel. Sample tracings of three variables used to distinguish state are also shown: the electromyogram (EMG) is at its highest in waking, intermediate in NREM sleep, and lowest in REM sleep; the electroencephalogram (EEG) and electooculogram (EOG), which are both activated in waking and REM sleep and inactivated in NREM sleep. PGO, pontogeniculooccipital; 5-HT, 5-hydroxytryptamine (serotonin); NE, norepinephrine.

proved propitious to quantify such aspects of consciousness as (1) the sense modalities that are represented and the intensity of the internally generated percepts, (2) the occurrence and strength of self-reflective awareness and executive thought, (3) the dreamer's orientation in time and space, and dream personnel, (4) the dreamer's emotion profile (presence and strength of emotions such as elation, anxiety/fear, anger, shame, guilt, sadness, and eroticism), and (5) the identification by the dreamer of the possible memory sources of the dream content. This approach has led to the characterization of dream consciousness as having (1) strong sensorimotor perceptions (with a preponderance of vivid visual imagery as the dreamer moves through a fictive reality); (2) impoverishment of executive ego function (with the delusional belief that one is awake and a failure to develop or sustain logical thinking); (3) discontinuity and incongruity of plot features as the basis of bizarre cognition; (4) potentiation of anxiety, anger, and elation together with a weakening of shame, guilt, and sadness; and (5) inability to specify the memory source of the confabulated dream content in about 80% of the cases.

Dreaming is thus characterized by visual hallucinations, by disorientation, by lack of insight and judgment, and by memory loss (with compensatory confabulation). These formal similarities are so strong as to lead to the hypothesis that dreaming, although normal, is a state akin to delirium. Since delirium is caused by diseases and by drugs which interfere with normal neuromodulation, it is natural to wonder if, in normal sleep, there are changes in neuromodulation during the wake–sleep cycle.

Cellular and Molecule Mechanisms of Mammalian Sleep

All mammals share with humans the regular periods of NREM and REM sleep. This is so whether the animals are aquatic, terrestrial, or arboreal, and whether they are large surface-dwelling carnivores (e.g., lions) or small nest-dwelling herbivores (e.g., mice or rabbits). As an experimental model, the domestic cat has appealed to neurobiologists because it is so docile and so prodigious a sleeper. As experimental animals, cats are more expensive and more ethically problematic than are rats, but they are large enough to carry the microelectrode, microinjection, and microdialysis array, the equipment necessary to perform physiological and pharmacological experiments. They are well studied neuroanatomically so that stereotaxis is facilitated.

Using cats, neuroscientists have shown that the two brain-activated states, waking and REM sleep (with high values of A), are at opposite poles with respect to both input–output gating (high I in waking, low in REM) and neuromodulation (high M in waking, low M in REM). On all these dimensions, NREM sleep is quite different (low A and intermediate I and M). In addition to demonstrating that aminergic levels decline in NREM sleep and reach their nadir in REM, it has been shown that the cholinergic level declines as animals go from waking to NREM, but rises again and reaches its highest level, in REM sleep, especially in the brain stem. This gives factor M (defined as the ratio of aminergic to cholinergic modulation) a highly differentiating power for distinguishing the three states: M is highest in waking, intermediate in NREM sleep, and lowest in REM sleep. This finding is potentially relevant to our understanding of the brain basis of the many phenomenologic distinctions between waking, sleeping, and dreaming. The mode of information processing has changed dramatically.

The importance to REM of the pontine brain stem is demonstrated by the presence of the cell bodies of both cholinergic and aminergic neurons there. Furthermore, it has now been conclusively demonstrated that the microinjection into the pontine tegmentum of both cholinergic agonists and cholinesterase antagonists produces dramatic increases in REM sleep. All of these effects are blocked by pretreatment of the injection sites by atropine. There is no longer any doubt that compared to waking and NREM sleep, REM sleep is hypoaminergic and hypercholinergic. This robust physiological difference correlates with – and hypothetically causes – the psychological differences.

Based upon new studies in rats, a flip-flop switch for REM sleep triggering has recently been proposed. Each side of the switch contains γ-aminobutyric acid (GABA)ergic neurons, and this resulting mutual inhibition guarantees that when one side is on, the other is off. The REM-on population contains two populations of glutaminergic neurons: one population projects to the basal forebrain and produces the forebrain activation while the other projects to the medulla and spinal cord, producing atonia. The cholinergic system is activated as part of the REM-on switch and can, in turn, activate that side of the switch. The REM-off population includes the dorsal raphe nuclei. At a still deeper level, the activation of protein kinase in the pontine tegmentum has been shown to accompany REM sleep, suggesting that pedunculopontine intracellular protein kinase A (PKA) activation is involved in REM sleep generation.

Input–Output Gating

Michel Jouvet called REM sleep 'paradoxical' because sleep persists despite the EEG evidence for strong brain activation. A partial explanation of the paradox is

the simultaneous blockade of sensory input and motor output, the neurophysiological mechanisms of which are now well understood. Ottavio Pompeiano used classical Sherrington reflexology techniques to show that motor output is blocked in REM by descending inhibition from the pontomedullary brain stem to the anterior bone cells of the spinal cord. That this inhibition is induced by powerful and active postsynaptic inhibition of the final common path motor neurons was shown by Michael Chase. Chase also demonstrated that the spinal inhibition of REM is mediated by glycine.

As for the inhibition of sensory input, it was also Pompeiano who demonstrated that presynaptic inhibition is associated with the clusters of eye movement during REM sleep. An associated occlusion of sensory input excitation also accompanied the REMs. This co-option of input-processing channels (including the all-important thalamocortical system) is effected by the internally generated pontogeniculooccipital (PGO) waves, first described by Jouvet. These cortical activation waves were later shown to be of entirely internal origin and were enhanced by cholinergic microstimulation. PGO wave generation is inhibited by noradrenaline and serotonin.

The emerging picture of REM sleep is a high level of activation in a brain which is not only off-line by virtue of sensory input and motor output blockade, but is also stimulated by phasic activation signals of its own devising. The coactivated mind is therefore fooled by its own parasitic excitation; the brain-mind then develops the illusion or fictive experience of perceiving and moving through dream space.

Efferent Copy Generation

The PGO waves of REM sleep not only constitute internally generated phasic activation signals for the dreaming brain-mind, but they also convey to the thalamus and cortex feed-forward information about the direction of the upcoming eye movements. As such, they are classical efferent copy stimuli from the oculomotor circuits to the visual forebrain. Such eye movement activity can also be recorded in waking when it forms an integral part of the startle response. In waking, the PGO waves rapidly habituate as the startle response diminishes. The second and third stimuli of a train evoke a much weaker or no response because they are no longer novel. The mechanism of this attenuation is thought to be aminergic inhibition of the cholinergic-modulated PGO generator neurons of the lateral pons.

The relative continuity of waking consciousness is, in part, a function of PGO wave damping, whereas the bizarre discontinuity of dream consciousness is a function of PGO wave disinhibition. Dream consciousness reflects this dishabituation by the increase in the emotions of surprise and anxiety. These dream features could be mediated by excitation of the amygdala, a major target of the PGO waves. In REM sleep, the efferent copy information about the direction of eye movement that is conveyed by the PGO system is not integrated with changes in visual input, as occurs in waking, because in sleep there is no visual input. It is tempting to speculate that the efferent copy information that is generated in REM sleep is not only a physiological cause of dream surprise, but is also used in perceptual aspects of dream plot construction.

The oculomotor system of the pons is only one of many motor program generators that are activated in REM sleep. Locomotion is commanded but, because the anterior horn cells are hyperpolarized, real motor behavior is not generated and REM sleep dreams reflect this by the intensity of fictive motoric action in dreams. There is hardly a sentence in the REM sleep dream report that does not contain an action verb. We are always walking, running, flying, or swimming in our dreams. Even if we lead sedentary waking lives, stationary activity is not represented in our dreams.

The finding of motor pattern generator activation in REM sleep and its correlation with the fictive motility of dreaming is a good example of how the close study of neurophysiology can provide dream theory with a new paradigm and new hypotheses regarding the origin of dream plots. Of course, the approach does not allow us to propose why a given dreamer has a given dream or what that dream might mean. But it does provide encouragement for an alternative way of approaching even interpretive questions. For example, our dreams are full of movement because brain motor pattern generators are activated in REM sleep. Further evidence that this theory may be correct is given by experimental and clinical discoveries, both of which reveal unexpected and unwanted enactment of REM sleep motor commands. The experiments of Michel Jouvet and of Adrian Morrison showed that cats with lesions in the vicinity of the locus coeruleus in the pons evinced REM sleep without atonia. In other words, the cats showed sleep with EEG activation REMs but suddenly stood up and evinced a wide variety of attack and defense behaviors. They were then in a dissociated state of REM sleep in which they expressed automatic behaviors that are normally suppressed by the motor inhibition of REM. On the basis of these observations, Jouvet boldly proposed that the cats were acting out their dreams.

That idea gained credence when it was reported by Carlos Schenk and Mark Mahowald that humans

did precisely the same thing when they became afflicted by what they called the REM 'sleep behavior disorder.' Schenk's and Mahowald's patients, mostly >50-year-old males, performed motor acts in sleep that corresponded to their dream reports. One patient, dreaming that he was playing football, got up out of bed and tried to tackle a chest of drawers. Another, dreaming that he was diving, stood up on the side of the bed and propelled himself into the baseboard of his bedroom, which he imagined to be a swimming pool. Presumably, these experimental and natural pathological conditions of REM sleep without atonia are due to damage of that subpopulation of glutaminergic REM-on neurons that convey inhibitory commands from the flip-flop switch to the spinal cord.

These examples would seem to make more plausible the suggestion that dream consciousness is a function of brain activation in sleep and that the important differences between the dreaming and waking states of consciousness are determined by specifiable differences between the mechanisms of brain activation in the two states. In particular, it is the presence or absence in input–output gating that determines the relationship between the outside world and internal perceptions, beliefs, and actions.

Differences in Regional Brain Activation

EEG evidence had long suggested that the brain was similarly activated in waking and REM sleep dreaming. The recent advent of PET imaging technology revealed that this was an oversimplified conclusion. Most brain regions are less active in NREM sleep than in either the wake or REM sleep state. But when REM is compared to the wake state, differences emerge which are of great relevance to studies of conscious state determination.

Certain brain regions are more active in REM than in waking. They include the pontine tegmentum (which animal studies have shown to be the probable site of the REM sleep and PGO wave generator), the amygdala (which animal studies have shown to be involved in mediating emotion, especially the anxiety which is so common in dreaming), the parietal operculum (which is thought to mediate visuomotor integration of cardinal perceptual feature of dreaming), and the parahippocampal and deep frontal cortices (which may process emotional data and integrate it with cognitive information).

One brain region is notably less active in REM than in waking. The dorsolateral prefrontal cortex (DLPFC) remains at the same low level seen in NREM sleep. Other human studies have implicated the DLPFC in the executive ego functions that are so conspicuously deficient in dreaming: short-term memory, self-reflective awareness, intentional decision making, and volitional action. The brain lesion studies done by Mark Solms have revealed that two of the structures selectively activated in REM sleep are, when damaged, associated with a complete cessation of dream recall. They are the parietal operculum (damage to which causes problems with sensorimotor integration) and the deep frontal white matter (damage to which causes emotional apathy). Patients often complain of cessation of dreaming following lobotomy, which consists of severance of the deep frontal white matter.

Field Studies of Waking, Sleeping, and Dreaming Consciousness

The invention of the 'Nightcap', a two-channel event recorder, has made possible the field study of conscious experience in humans as they lead their otherwise normal waking and sleeping lives. In addition to wearing the Nightcap for recording their head and eye movements while asleep, participants carried radio beepers so that they could be contacted throughout the day and night to collect reports of conscious experience (see Figure 3(a)). This combination of techniques allowed us, for the first time, to collect reports of consciousness experience in the same persons, from several brain states, around the clock. Over 3000 reports from ten people ages 20–40 years were elicited from active and quiet waking states, from five intervals during sleep onset and from both NREM and REM sleep. The reports were transcribed and scored for dimensions such as word count (REM reports were 6 times as long as NREM reports), internally generated percepts (REM sleep highest, active waking lowest). These data, shown in Figure 3(b), suggest a general psychophysiological law: thinking is incompatible with hallucination and vice versa. The implications of these findings for conscious state control and for psychiatry are loud and clear. One striking finding was a reciprocal increase in internally generated perception and a decrease in thinking across the five states.

Convergence of Physiology, Psychology, and Philosophy

The integration of the fields of psychology and physiology, envisaged by William James and the young Freud over 100 years ago, is now beginning, with sleep and dream science leading the way. The Finnish philosopher of science Antti Revonsuo has recently championed the theory, first put forth by Michael Jouvet, that REM sleep dreaming allows the sleeping brain to run adaptive behavioral programs of fight and flight. According to this view, REM sleep dreaming has a Darwinian function even if dream behavior

Figure 3 (a) Central arousal accompanying the activated states of rapid eye movement (REM) sleep and waking can be measured using the 'Nightcap,' a simple ambulatory monitor. The Nightcap is a two-channel recording device that distinguishes waking, REM and NREM sleep. One channel of the Nightcap monitors eye movement and the other monitors body movements. The Nightcap eyelid-movement readout is thought to reflect activity in portions of the brain stem oculomotor nucleus that innervate the eyelid and are adjacent to portions of the medial brain stem ascending reticular system, the activity of which, in turn, generates forebrain activation. (b) Decline in directed thought and reciprocal increase in hallucinations during progression from active waking through sleep onset and NREM to REM sleep.

is fictive. For the German philosopher Thomas Metzinger, the occurrence of lucid dreaming, out-of-body experience and dreaming itself, supports his phenomenal self-model of consciousness. The phenomenal self is a constantly renewed functional state of the brain whose vicissitudes can, for the first time in human history, begin to be explained.

AIM: An Integrated Model of the Human Brain Mind

Using physiological measures, it is now possible to create a three-dimensional model of brain-mind state space (see Figures 1 and 4). Activation, assessed from EEG and/or thalamocortical cellular activity, gives values and axis A, running from left (low) to right (high) across the front wall of the state space. Input–output gating is measured as EMG activity, values of H-reflex, and PGO waves. It runs from the front to the back of the state space. The vertical axis, M, measures the ratio of the strength of aminergic to cholinergic neuron modulation. Unfortunately, factor

Figure 4 The three-dimensional activation/information/mode (AIM) state space model showing normal transitions within the AIM state space, from wake, to non-rapid eye movement (NREM), and then to REM sleep. REM occupies the lower right-hand front corner, in which activation is high, input is entirely internal, and the forebrain is cholinergically activated and aminergically demodulated. ACh, acetylcholine; NE, norepinephrine; 5-HT, 5-hydroxytryptamine.

M cannot yet be measured in humans, but pharmacological studies indicate that inferences from neurobiological studies in animals are valid.

In the model, time is the fourth dimension and the solution of AIM is constantly changing, even in the waking domain (at the far right, upper, rear corner of the state space) as we change the focus of attention, day dream, or enter altered states such as hypnosis. We may become drowsy, doze, or fall frankly asleep, in which case AIM moves down, forward, and to the left and then occupies the NREM sleep domain in the center of the state space. Finally, AIM moves to the REM sleep domain in the right front lower corner of the state space.

During a normal night of sleep, AIM function follows an elliptical trajectory that repeats itself 4 or 5 times per night. The ellipse shifts sequentially to the right and to deeper parts of the state space in successive cycles. These elliptical orbits in AIM state space conform to the mathematical description of the reciprocal interaction model, giving an internally consistent picture of sleep physiology.

Consciousness is most intense in the right portion of the state space and lowest on the left. It is interoceptive toward the front of the state space and exteroceptive toward the back. The kind of consciousness is given by the mode dimension. It is highest at the top of the state space and lowest at the bottom. Abnormal states of consciousness such as narcolepsy, the REM sleep behavior disorder, delirium, and other psychoses can also be modeled in the normally forbidden zones of AIM state space.

Thermoregulation during Sleep and Sleep Deprivation

R Szymusiak, University of California, Los Angeles, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The regulation of sleep and the regulation of body temperature are tightly coupled. Sleep onset in mammals is accompanied by reductions in metabolic rate, accelerated heat loss, and an integrated fall in body temperature. Homeostatic responses of the thermoregulatory system to heat or cold challenge are suppressed during sleep, and in some species thermoregulatory adjustments are almost completely absent during rapid eye movement (REM) sleep. Long-term sleep deprivation in animals can be associated with chronically elevated metabolism and food intake, accompanied by significant decreases in core body temperature.

In addition to changes in thermoregulation during sleep, manipulation of environmental temperature or body temperature can alter sleep. In all mammals studied, sleep is suppressed in moderately warm or cold environments. This suppression of sleep by thermal stress can be viewed as adaptive from a homeostatic standpoint because thermoregulatory responses are diminished during sleep. In some circumstances, manipulation of body temperature can promote sleep. For example, in humans, whole-body warming by hot bath immersion a few hours prior to habitual bedtime can reduce sleep latency and increase stage 3/4 sleep amounts.

Neuronal systems that regulate sleep and body temperature are localized in the preoptic and anterior hypothalamus (POAH). Many thermo-sensing neurons in the rostral hypothalamus also exhibit changes in activity across the sleep–wake cycle. Of particular importance may be groups of hypothalamic warm-sensing neurons that are spontaneously activated during sleep onset and sleep. Thus, functional interactions between sleep-regulatory and thermoregulatory neurons in the rostral hypothalamus can explain the close coupling between body temperature and arousal states.

Understanding sleep and thermoregulatory interactions may provide insight into clinical problems. Recent evidence has demonstrated the importance of thermoregulatory adjustments occurring around the time of sleep onset in determining sleep latency, sleep composition, and sleep quality in humans. Therapies that target the thermoregulatory control of arousal states may provide novel approaches to treating disorders of initiating and maintaining sleep.

Thermoregulation during Sleep

Changes in Body Temperature and Metabolism during Sleep

In mammals, the onset of sleep is associated with a fall in core body temperature and a readjustment of thermoregulatory control. The magnitude of the drop in body temperature during sleep varies across species and can be influenced by variables such as ambient temperature and phase of the circadian rhythm. The sleep-related fall in body temperature during sleep is actively regulated and is not simply a passive consequence of behavioral inactivity. Sleep onset in mammals is accompanied by coordinated decreases in metabolic heat production and increases in heat loss through increased peripheral vasodilation and/or sweating.

The decrease in body temperature during sleep can be understood as a resetting of the body's thermostat to a lower level. In other words, sleep appears to be accompanied by a lowering of the thermal set point, the level of body temperature that the thermoregulatory system will defend and maintain. At the transition from waking to sleep, the thermoregulatory system responds as if the set point has been adjusted to a lower level. The transition is accompanied by an integrated series of thermoregulatory responses, including a reduction in metabolic rate and enhanced heat loss to the environment through peripheral vasodilation and sweating. Body temperature falls to a new regulated level which is maintained during sleep.

This lowering of the set point and consequent energy savings can be taken as evidence for a potential energy conservation function of sleep. Energy savings are achieved in two ways: (1) by lowering metabolic heat production and (2) by lowering body temperature. The lowering of body temperature reduces the core temperature-to-ambient temperature gradient, which serves to minimizes heat loss to the environment. This latter factor can be important in small mammals with a high surface-to-volume ratio, which have inherently higher rates of environmental heat exchange. Behavioral aspects of sleep onset such as seeking a thermally comfortable nest and adoption of curled heat-conserving postures can also contribute to energy savings by minimizing heat exchange with the environment.

Thermoregulatory Responses to Thermal Challenge Are Influenced by Sleep

The decline in the thermal set point during sleep onset and non-REM sleep is also accompanied by

reduced thermoregulatory responses to thermal challenges. Thermoregulation is not suspended during sleep, but the responsiveness of the thermoregulatory system appears to be diminished; that is, the magnitude of the regulatory response to a given thermal challenge is reduced during sleep compared to waking.

Compared to non-REM, thermoregulatory responses during REM sleep are reduced even further. This is particularly true for responses to cold stress because the inhibition of motor neurons that is characteristic of REM sleep is incompatible with increasing heat production via shivering or elevated muscle tone. As a result of these thermoregulatory changes, animals may be particularly vulnerable to thermal stress during REM sleep. Infants and small mammals with a large surface-to-volume ratio are most vulnerable.

Exposure to hot or cold environments frequently cause sleep disruption and sleep loss. This response may be adaptive in minimizing exposure to thermal stress during sleep when homeostatic compensation is weak. Thermal factors have undoubtedly played a role in the evolution of behavioral strategies for species-specific selection of sleeping environments (e.g., nests, sheltered locations, and adoption of heat conserving postures). Diminished thermoregulatory adjustments to heat and cold stress during sleep dictate that thermal homeostasis can be best achieved over the course of a several-hour sleep episode by the selection of a sleeping environment that poses minimal thermal challenge and ultimately maximizes heat conservation. This is a strategy that has been adopted by several species.

Effects of Environmental and Body Temperature on Sleep

Exposure to moderate hot or cold environments suppresses sleep and/or causes sleep fragmentation in mammals. The most sensitive species are those with large surface-to-volume ratios that experience more rapid environmental heat exchange. In rodents, in which thermoregulatory responses during REM sleep are absent or weak, REM sleep suppression can occur under conditions of minimal thermal stress and in the absence of any significant change in non-REM sleep amounts. From a thermoregulatory perspective, the REM-sleep-suppressing effects of heat and cold exposure in these species can be viewed as adaptive. Increased time spent awake or in non-REM sleep means that lower threshold and stronger thermoregulatory responses are evoked to maintain thermal homeostasis.

Mild increases in ambient temperature or mild warming of the body can promote sleep. An animal's thermoneutral zone is defined as the range of environmental temperatures at which resting metabolic rate is minimal and constant. Within the thermoneutral zone, minimal effort is required to maintain thermal homeostasis because the heat produced by the resting metabolic rate is largely balanced by heat loss to the environment. Within the thermoneutral zone, thermal homeostasis can usually be maintained through peripheral vasomotor adjustments that regulate rates of heat loss from the skin, with vasoconstriction occurring at the low end of the zone and vasodilation at the high end. Exposing rats to an environmental temperature that is at or just above the high end of the thermoneutral zone, at which peripheral blood flow and skin temperatures are high, increases time spent in non-REM sleep and enhances electroencephalogram (EEG) slow-wave activity during sleep.

Whole-body warming, achieved by immersion in a hot bath a few hours prior to normal bedtime, promotes sleep in humans. Hot baths prior to bedtime can reduce sleep latency and increase amounts of stage 3/4 sleep in the first half of the night. Similarly, exercise late in the day reduces sleep latency and increases stage 3/4 sleep. The sleep-enhancing effects of exercise are dependent on an accompanying increase in body temperature. If exercising subjects are prevented from raising their body temperature by being cooled with a fan during exercise, the sleep-promoting effects of exercise are prevented.

Collectively, these findings are consistent with the idea that the mild activation of thermoregulatory heat defense mechanisms is conducive to sleep, particularly sleep onset and slow-wave sleep. The critical feature is that the warming must be mild such that it evokes mild compensatory thermoregulatory responses (e.g., increased peripheral vasodilation). More severe heat challenges that evoke stronger regulatory responses such as intense sweating or panting cause sleep disruption, not sleep promotion.

Brain Circuits That Regulate Sleep and Body Temperature Are Functionally Interrelated

Temperature-Sensing Neurons in the Hypothalamus Control Body Temperature

Neurons in the POAH are critically involved in thermoregulation. Experimental damage to the POAH in animals causes persistent deficits in thermoregulatory defense against heat and cold exposure. Direct infusion of various neurotransmitters or neuromodulators into the POAH can alter body temperature and thermoregulatory function.

Specialized temperature-sensing neurons localized in the POAH play an important role in body temperature control. Warm-sensing neurons are excited by local increases in temperature and inhibited by cooling. Cold-sensing neurons are excited by local decreases in temperature and inhibited by local warming. The functional importance of these temperature-sensing neurons for thermoregulatory control is evidenced by experimental findings that localized warming or cooling of the POAH can evoke fully integrated heat defense or cold defense responses that are qualitatively identical to those evoked by exposing the whole animal to hot or cold environments.

Hypothalamic Temperature-Sensing Neurons Are Involved in Sleep Regulation

The neural control of sleep and thermoregulation intersect in the POAH and adjacent brain structures. Experimental POAH damage that disrupts thermoregulation also causes persistent insomnia, suggesting that thermo- and sleep-regulatory neuronal systems are anatomically related. They appear to be functionally related as well. As previously summarized, local warming or cooling of the POAH can evoke robust whole-body heat and cold defense responses. Milder increases in POAH temperature, in addition to suppressing metabolic rate and augmenting peripheral vasodilation, reduce sleep latency, promote non-REM sleep and increase EEG slow-wave activity during non-REM sleep. Local POAH cooling has the opposite effects, causing sleep suppression and suppression of EEG slow-wave activity during sleep.

Potential mechanisms underlying many of the effects of environmental and body temperature on sleep are revealed by the study of the spontaneous discharge patterns of POAH thermo-sensing neurons during waking and sleep. As documented by single-neuronal recordings in cats and rats, the majority of POAH warm-sensing neurons exhibit an elevation of spontaneous discharge rate during sleep onset and non-REM sleep compared to waking. The majority of cold-sensing neurons are maximally activated during waking and exhibit declining discharge during sleep onset and non-REM sleep. Thus, the changes in POAH thermo-sensing neuronal activity at sleep onset mimic the pattern expected to accompany a lowering of the thermal set point, with the activation of warm sensors and inhibition of cold sensors. This pattern of thermoreceptor activity is consistent with the thermoregulatory responses that normally accompany sleep onset (i.e., reduced metabolic rate and increased heat loss at the periphery). The ability of local POAH warming to evoke non-REM sleep and EEG synchrony indicates that the activation of POAH warm-sensing neurons is sufficient for sleep promotion.

Control of Body Temperature during Sleep Deprivation

Acute Sleep Deprivation: Interactions with Circadian Control of Body Temperature

In healthy individuals, entrained to a light–dark cycle and adhering to a regular sleep–wake schedule, habitual sleep onset reliably occurs a few hours after the 24 h body temperature maxima, on the falling phase of the 24 h body temperature rhythm. Sleep onset is associated with an acceleration in the rate of the decline in body temperature as the activation of heat-loss processes during sleep are expressed. Morning awakenings occur on the rising phase of the temperature rhythm, shortly after the 24 h temperature minimum. Thus, when individuals maintain a regular sleep schedule, sleep–wake rhythms and body temperature rhythms are closely coupled with a characteristic phase relationship.

The fall in body temperature that normally occurs during the sleep period is not a passive consequence of changes in muscle activity and heat production associated with waking versus sleep. The body temperature rhythm persists during sleep deprivation or during constant routine protocols in humans, in whom levels of activity, food intake, light exposure, and so on are maintained at constant levels throughout a 24 h period. Nevertheless, behavioral changes associated with waking and sleep do exert positive and negative masking effects on the circadian temperature rhythms, such that the magnitude of the 24 h peak-to-trough difference in body temperature is reduced during sleep deprivation or constant routine, compared to normal entrained conditions.

An important feature of arousal state regulation is that short-term sleep deprivation or sleep restriction leads to compensatory rebound increases in sleep amount and sleep depth once the opportunity for sleep is provided. Homeostatic increases in sleep following sleep deprivation/restriction involve complex changes in neurophysiological and neurochemical mechanisms that are not yet completely understood. One effect of short-term sleep loss is to change the normal phase relationship between the occurrence of sleep/wakefulness and the 24 h body temperature rhythm. Thus, extending wakefulness through the night and attempting to sleep the next morning results in sleep onset occurring on the rising phase of the body temperature rhythm.

The phase relationship between sleep and body temperature rhythms at sleep onset is an important determinant of subsequent sleep amount and composition. This has been most convincingly demonstrated in human subjects undergoing internal or forced desynchronization in environments without time cues. During internal desynchronization, sleep and body temperature rhythms free run with different periods, and eventually the two rhythms temporally dissociate. In forced desynchrony protocols, subjects adhere to a sleep–wake schedule significantly longer than 24 h (e.g., 28 h), and when this is done in the absence of time cues, body temperature and sleep rhythms dissociate as in internal desynchronization. With both methods, over the course of several days the onset of the major sleep period occurs at all phases of the body temperature rhythm. Sleep episodes that are initiated on the falling phase of the temperature rhythm are associated with shorter sleep latencies, few episodes of waking during the sleep period and maximal amounts of deeper sleep stages. In contrast, sleep episodes initiated on the rising phase of the temperature rhythm are associated with longer sleep latencies, short sleep episode durations, more REM sleep but less stage 3/4 sleep. Thus, depending on the timing of sleep loss and recovery sleep, the adverse effects of short-term sleep deprivation include impaired alertness during sustained waking and impaired depth and quality of recovery sleep. The effects of partial sleep loss are cumulative, and the level of sleepiness will increase over several days of sleep restriction, due, in part, to the inadequate restorative effects of suboptimal recovery sleep.

Chronic Sleep Deprivation Causes Dysregulation of Body Temperature in Rats

The effects of long-term total sleep deprivation on thermoregulation have been studied in rats by Rechtschaffen and colleagues. Total sleep deprivation applied over many days in the rat results in a syndrome that includes increased food intake; increased energy expenditure; weight loss; an initial mild elevation in body temperature, followed by profound decreases in temperature as the duration of deprivation increases; and death within 11–32 days (average ~17 days). Several findings indicate that sleep deprivation in rats causes a profound dysregulation in the homeostatic systems that control metabolism and body temperature. The increased food intake occurring during sleep deprivation is more than offset by increased energy expenditure, such that rats actually lose weight in spite of a near doubling of food intake. The increase in energy expenditure appears, at least in part, to be an attempt to compensate for increased heat loss. Ultimately, rates of heat loss are so high that the core body temperature falls to well below normal levels, and rats become profoundly hypothermic during the last few days of survival. This fall in body temperature is not regulated; that is, there is no apparent lowering of the set point for body temperature during sleep deprivation. When sleep-deprived rats are given the opportunity to control the temperature of their environment, they select higher temperatures from the beginning of deprivation and select extremely high temperatures later in the deprivation period when they are hypothermic. Thus, they behaviorally try to raise body temperature to combat the hypothermia evoked by unregulated elevations of heat loss. The mechanisms responsible for the changes in metabolism and thermoregulation evoked by sleep deprivation are not understood, but findings do suggest that sleep is necessary for the proper functioning of these regulatory systems.

Thermoregulatory Control of Human Sleep

Thermoregulatory Changes Influence Sleep Onset and Sleep Maintenance

Neurobiological studies in experimental animals have revealed close anatomical and functional interrelationships between sleep and body temperature-control mechanisms in the brain, and they indicate that the activation of hypothalamic neuronal circuits that promote heat loss normally occurs during sleep onset and non-REM sleep. In humans, the magnitude of the heat-loss response around the time of sleep onset is an important determinant of sleep latency, sleep amount, and sleep quality. The magnitude of heat-loss response in humans can be reliably assessed by quantifying the temperature gradient from distal skin sites (the hands and feet) to proximal skin sites (e.g., the forehead, stomach, thigh, or some weighted average of several proximal skin sites). A high distal-to-proximal skin temperature gradient occurs when the temperature of the feet and hands are warm with respect to proximal sites, indicative of elevated blood flow to distal skin and elevated heat exchange at these sites. A low distal-to-proximal gradient reflects peripheral vasoconstriction and diminished peripheral heat loss. A high distal-to-proximal skin temperature gradient is associated with reduced sleep latency, increased stage 3/4 sleep, and reduced number of arousals from sleep. The distal-to-proximal gradient is also positively correlated with subjective sleepiness after morning awakenings and after awakenings from daytime naps.

It can be hypothesized that thermoregulatory responses that normally accompany sleep onset in humans play a role in reinforcing and consolidating circadian and homeostatic aspects of sleep regulation. In an entrained individual, habitual sleep-onset times occur on the descending phase of the body temperature rhythm. Homeostatic sleep drive is also high at this time because of sustained prior waking. As body temperature falls following the nadir of the 24 h rhythm, the activation of heat-loss mechanisms result in elevated skin temperatures. This leads to the activation of peripheral warm sensors and excitation of hypothalamic warm-sensing neurons via peripheral-to-central thermosensory pathways. The activation of central warm-sensors increases sleep propensity via suppression of arousal systems and hasten sleep onset, resulting in further increases in peripheral skin temperature and heat loss. Thus, thermoregulatory changes have the potential to exert feed forward excitatory effects on brain mechanisms that control sleep onset and sleep maintenance, leading to more rapid and seamless transitions from waking to consolidated sleep.

Thermoregulation and Disordered Human Sleep

Insomnia is the most common sleep complaint, and sleep disturbance is a prominent symptom in several psychiatric and neurological disorders. In many instances, insomnia complaints are accompanied by abnormalities in circadian rhythms, including abnormalities in the body temperature rhythm. Sleep-onset insomniacs may exhibit a phase delay in the body temperature rhythm of >2 h, indicating a disturbance of circadian timing or entrainment. This phase delay means that attempts to fall asleep often occur in closer than normal proximity to the body temperature peak and that thermoregulatory adjustments that promote sleep might not be as readily evoked. In the elderly, phase delays in the body temperature rhythm may also be a contributing factor to the increased incidence of insomnia. In affective disorders, the amplitude of the 24 h body temperature rhythm is reduced. The diminished nocturnal peak in the temperature rhythm results in a lower body temperatures at bedtime and a weaker heat-loss response at the time of sleep onset, resulting in more prolonged and disrupted wake-to-sleep transitions.

Although body-temperature abnormalities in disorders associated with insomnia may be secondary to other underlying pathologies, the manipulation of thermoregulatory control, either pharmacologically or behaviorally (e.g., by hot bath immersion), in ways that promote heat loss at sleep onset may help to improve sleep amount and sleep quality.

Thermoregulation: Autonomic, Age-Related Changes

R B McDonald, University of California, Davis, CA, USA

© 2009 Elsevier Ltd. All rights reserved.

Introduction

The inability to appropriately thermoregulate during exposure to heat and cold has been generally accepted as an age-related change in humans. Epidemiological observations of increased mortality during severe cold and hot weather also emphasize a possible age-related attenuation in thermoregulation. It remains unclear, however, the extent to which biological factors impact clinical hyper- and hypothermia in senescent humans. A majority of case studies have found that diminished thermoregulatory capacity in the senescent human reflects more closely socioeconomic factors such as insufficient living area heating or cooling, malnutrition, and lack of adequate health care. Nonetheless, experimental evidence in humans and laboratory rodents has reported senescent-related alteration in autonomic mechanisms that regulate body temperature. In this article, we will briefly explore possible affects of biological aging on the autonomic control of thermoregulation.

'Problems' of Interpretation of Aging Research

Definition of Aging

Research into the mechanisms underlying the aging process, including altered autonomic regulation of body temperature, poses experimental design concerns that do not often occur in other disciplines. Lack of a generally accepted definition of aging should be viewed as primary among these concerns. The difficulty in defining aging arises from an inability to determine when aging begins. Biological aging should include all events occurring to a particular system throughout the life span. Evolutionary, genetic, and developmental data have clearly established a link between development and the rate of aging. Although some investigations have begun to approach aging from this broad perspective, such experimental designs are difficult to construct and restrict the investigator to observational studies. Narrowing the definition of biological aging to a postreproductive period in which biological deterioration can be clearly identified increases mechanistic observations. However, since narrow definitions of aging do not include early life events, the true cause and effect relationship may be missed. Nonetheless, Dr. Edward Masoro's definition of biological aging has provided a good guide for most aging research:

> Aging can be defined as deteriorative changes with time during post-maturational life that underlie and increase vulnerability to challenges, thereby decreasing the ability of the organism to survive. (Masoro EJ, 1995: 3–21)

Designs in Research on Thermoregulation and Aging

Appropriately interpreting results from investigations evaluating the biology of senescence can be difficult for the nonspecialist. The difficulty in interpretation arises from the fact that extrinsic and behavioral factors such as physical activity level, acclimation, and disease have significant biological aging effects that, in turn, can affect thermoregulation. Cross-sectional designs, investigations that compare different age cohorts at one point in time, are the most common but least powerful design used in senescence research. The length of the human life span precludes, for the most part, longitudinal design except by large multiinstitutional programs (e.g., the Baltimore Longitudinal Study), and these investigations are limited to observational evaluation.

Cross-sectional designs can be problematic because selecting the appropriate older age group that represents accurately the 'normal' senescence process cannot be easily achieved; we return to the question, 'when does aging begin?' This problem reflects that the beginning of senescence in humans is highly variable, may not affect all physiological systems equally, and does not correlate with chronological age. For example, all 70-year-old humans will have some functional loss in at least one physiological system, but not all 70-year-old people will experience decrements in the same physiological system. Investigations using cross-sectional designs will control for individualized senescence by including an older age group with a wide range of ages (e.g., 65–80 years). Such a wide age range will often result in significant error about the mean as compared to the variation seen in younger groups.

Rats and mice have been the overwhelming animals used to model humans in senescence-related research evaluating possible alterations of thermoregulation. Their short life span (2–4 years) provides the investigator an opportunity for mechanistic study using powerful longitudinal designs. However, application of results to humans may be limited due the differences in effector organs responsible for heat dissipation and

Table 1 Tissues and organs of heat dissipation and production in humans, rats, and mice

Species	*Insulation*	*Heat dissipation (hot environment)*	*Heat production (cold environment)*
Human	Subcutaneous fat	Convection resulting from the transfer of heat from blood to skin throughout body Evaporation resulting from increased sweat gland function	Shivering via increased skeletal muscle metabolism
Rats and mice	Fur and air gap between skin and muscle	Convection resulting from the transfer of heat from blood to skin limited to tail	Nonshivering thermogenesis in brown adipose tissue Shivering via increased skeletal muscle metabolism

production (Table 1). It remains unclear as to how or if neural feedback, from the different sensor systems and effector organs of heat production and dissipation in rodents versus humans, may impact thermoregulation during senescence.

Disease and Its Effect on Thermoregulation during Senescence

The separation between disease and the biological process of aging presents yet another issue that must be considered when investigating senescent-related effects on thermoregulation. Clearly, older individuals are more likely to have disease than are younger individuals. It can be difficult to determine if the finding of altered thermoregulation reflects biological aging *per se* or reflects the outcome of a disease: the discussion herein relies on data from investigations in which a clear attempt has been made to control for disease.

Acclimation and the Sedentary Life Style

The ability to thermoregulate appropriately in hot and cold environments depends, in part, on one's acclimation to the ambient conditions. Well-acclimatized individuals will tolerate deviations from thermoneutrality better than will the nonacclimated. Moreover, a sedentary lifestyle in which individuals live at ambient temperatures close to thermoneutrality will reduce sweat gland density, capillary density of skin, and muscle mass, all outcomes that are independent of age and all of which impact thermoregulatory capacity.

Physiology of Thermoregulation

Hypothalamic Regulation of Body Temperature

Humans and rodents maintain a constant body temperature by balancing heat production with heat loss. The equilibrium point of heat production and loss, thermoneutrality, occurs at an ambient temperature of approximately 21 °C in the human and 23–25 °C in rats and mice, and does not appear to change with age. Exposure to environmental temperatures above or below thermoneutrality will result in various physiological responses that work to keep a stable core body temperature (38 °C humans, 38–39 °C mice and rats). Communication between neural centers within the hypothalamus and peripheral sensors and effector organs regulate, almost exclusively, the processes that maintain stable body temperature in homeotherms (Figure 1). The preoptic area of the hypothalamus contains heat- and cold-sensitive neurons that respond to changes in blood temperature, although heat-sensitive neurons far outnumber cold-sensitive sensors. Thus, detection of increased body temperature occurs, for the most part, within the hypothalamus. Detection of a cold environment occurs via temperature sensors within the skin; these sensors send afferent signals to the posterior hypothalamus at or near the level of the mammillary bodies (cold sensors in the skin outnumber heat sensors 10 to 1). The posterior hypothalamus also serves to coordinate the temperature-sensing 'data' from both the preoptic area and the periphery and, in turn, takes appropriate action through efferent signals.

Neural Regulation of Skin Blood Flow and Sweat Glands

Changes in skin blood flow, comprising the initial physiological response to increased or decreased ambient temperatures, are regulated by sympathetic vasodilation and vasoconstriction mechanisms. An increase in core temperature causes the release of vasoconstrictor tone, resulting in increased blood flow. If convective heat losses resulting from relaxation of the vasoconstrictor tone continue to be insufficient to cool the core, cholinergic active vasodilation causes further increase in skin blood flow that, in turn, increases convective heat loss. Sweat glands are innervated by cholinergic fibers that secrete

Figure 1 Neural pathways of thermal regulation. Sympathetic pathways are the sole neural tracks that influence thermoregulation; the parasympathetic system does not exert a significant effect on thermoregulation. Vasoconstriction and initiation of nonshivering thermogenesis occur in response to the release of norepinephrine attaching to α-adrenergic receptors in blood vessels and to α- and β-adrenergic receptors in brown adipose tissue. Vasodilation in the human is caused by epinephrine exciting the β-adrenergic receptor; acetylcholine causes vasodilation in rats (muscarinic receptors). Sweat glands are innervated by cholinergic nerve fibers that secrete acetylcholine, but the glands are also responsive to epinephrine secreted by the adrenal gland.

acetylcholine and are stimulated simultaneously with active vasodilation. Decreased skin and core temperatures result in activation of norepinephrine-mediated vasoconstriction beyond the normal vasoconstriction tone. Various other peptides, such as neuropeptide Y, can be co-released with norepinephrine and may also have a significant effect on vasoconstriction.

Effect of Senescence on the Response to Heat and Cold Exposure in Humans

Changes to Core Temperature

Mean core temperatures of humans exposed to cold or heat decrease (cold) or increase (hot) slightly more in senescent versus adult individuals. The differences in

core temperature are modest (no more than 0.1–0.2 °C difference) and are not generally considered physiologically important. Physical activity and acclimation to the ambient temperature improve the core temperature of older individuals, suggesting that behavior rather than aging *per se* may be of greater importance as the cause of senescent-related alterations in core temperature. The experimental evidence does not support the suggestion that the older population (defined here as those over 65 years of age) has a higher risk of developing clinical hypo- or hyperthermia, as compared to younger populations. However, recent investigations have found that senescent-related alterations in core temperature leading to thermal sickness are progressive in the aged cohort. That is, the most significant alteration in the loss or gain in body heat, as measured by core temperature, appears to be limited to the oldest old (i.e., individuals in their ninth and tenth decades of life).

Autonomic Response

The onset of vasoconstriction and vasodilation during thermal stress While changes in core temperature in response to heat and cold stress do not appear to be a general hallmark of senescence, there is agreement that the autonomic response may be altered. For example, the time to onset of sweating during passive heat exposure occurs significantly later in older versus younger individuals and is independent of the anatomical location (Figure 2). Once sweating has begun, however, the rate and amount appear to be similar in both young and old individuals. Moreover, there does not appear to be a significant difference in sweat glad density or skin temperature threshold that initiates sweating between healthy senescent and younger individuals. Together, lack of differences in sweat rate, sweat glad density, and thresholds suggests that the delay in sweating during passive heat stress reflects some alteration at the interface between efferent neural signaling and the effector organ.

Figure 2 Time to onset of sweating in younger (ages 20–24 years; $n = 7$) and older (64–76 years; $n = 7$) men exposed to heat (35 °C) and a relative humidity of 45%. The lower leg of each person was also placed in a water bath (42 °C) during the passive heat exposure. From Inoue Y, Shibasaki M, Ueda H, et al. (1999) Mechanisms underlying the age-related decrement in the human sweating response. *European Journal of Applied Physiology* 79(2): 121–126, with permission.

Differences observed in the onset of vasoconstriction during cold exposure are consistent with senescent-related attenuation in the autonomic response within the efferent pathways during a thermal challenge. That is, the cold-induced decrease in skin blood flow occurs much later in the senescent individual as compared to a younger adult. However, an older individual's capacity to sense a drop in ambient temperature, as determined by subjective rating scales, does not differ from that of younger persons. The ability of the elderly to accurately sense a decrease in ambient temperature corresponds to the decrease in skin temperature. If the afferent signal to the hypothalamus was disrupted, these two measures – the sensing of cold and drop in skin temperature – should be discontinuous. Therefore, altered skin blood flow concomitant with appropriate thermal senescing suggests that the neural mechanisms that inform the thermoregulatory center of a change in ambient temperature – the afferent pathways – function normally. The delay in cold-induced vasoconstriction during senescence implies that the disruption in the autonomic response more likely reflects changes to efferent pathways. It remains unclear, however, if the senescent-related alteration in autonomic response to heat and cold stress occurs at the level of the hypothalamus or the peripheral effector organs.

Senescence and central-mediated autonomic response to thermal stress Evaluating the central-mediated (hypothalamic) autonomic response to thermal stress in humans is difficult, and most conclusions on a central-mediated role are based on circumstantial rather than direct experimental evidence. For example, the circadian rhythm of body temperature has been used as an indicator of hypothalamic function, as the suprachiasmatic nucleus regulates exclusively this 'biological clock.' Several investigations have found a senescent-related decrease in the amplitude of the circadian rhythm of body temperature and sleep, a finding consistent with alterations in hypothalamic regulation. However, senescent-related changes in the circadian rhythm of body temperature and sleep are almost always associated with an underlying disease, a sedentary life style, and/or psychological conditions that disrupt normal patterns of daily life. Investigations controlling for these confounding

variables have found that alterations in the circadian rhythm of body temperature and sleep are limited, for the most part, to the oldest individuals in the senescent group, a conclusion similar to that suggested for alterations in core temperature.

Senescence, skin blood flow, and vasodilation response to heat Several investigations have demonstrated that skin blood flow of elderly persons at rest and during heat stress does not increase to the same degree as that observed in younger individuals. Initially, senescent-related changes to the skin architecture, including diminished arteriole and capillary density, were suggested to be the primary cause of altered skin blood flow. Investigations comparing different anatomical sites for a senescent-related attenuation of skin blood flow have shown that the largest alterations occur at sites normally exposed to the environment. For example, heat-induced increase in forearm-skin blood flow occurs significantly later and is less robust than that observed from sites on the chest and back. These data imply that senescent-related alterations to skin blood flow caused by changes in the skin structure reflect more closely photoaging than they do the biological process of senescence.

Nonetheless, attenuated heat-induced skin blood flow of older individuals has also been reported at anatomical sites typically not exposed to the sun (i.e., chest and thigh). The question, then, becomes 'does the blunted heat-induced skin blood flow observed in the elderly reflect a decrease in vasodilation or the failure to release vasoconstriction tone?' Evaluation of decreased vasodilation versus sustained vasoconstriction tone can be achieved by comparing skin treated with bretylium tosylate, an agent that blocks vasoconstriction, to nontreated skin. These investigations have consistently shown no effect on skin blood flow by the blocking agents. That is, reduced heat-stress blood flow in the senescent individual appears to reflect altered active vasodilation.

The mechanisms underlying the altered vasodilation of the elderly during heat exposure remains to be elucidated. There is agreement that aged vessels are less responsive to neural transmitters, have fewer receptors, and less ligand binding to the receptor, but these effects have not been tested directly during heat exposure and also appear to be influenced significantly by underlying disease. Findings of a diminished level of neural density in senescent skin have been inconsistent. Increases, decreases, and no difference in neural density of aging skin have been reported. This inconsistency most likely arises from different anatomical sites sampled and the disease states of the individuals.

Figure 3 Mean cutaneous vasoconstriction (CVC) responses to sequential norepinephrine (NE) infusions in young ($n = 11$) and older ($n = 11$) individuals. Reproduced from Thompson CS, Holowatz LA, and Kenney WL (2005) Cutaneous vasoconstrictor responses to norepinephrine are attenuated in older humans. *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 288(5): R1108–R1113, used with permission from the American Physiological Society.

Senescence, skin blood flow, and the vasoconstriction response to cold The decrease in skin blood flow during local and systemic cooling of healthy senescent individuals appears to be blunted compared to younger persons. Altered senescent-related skin blood flow during cold exposure reflects diminished vasoconstriction and appears to be related to both a decreased effect by norepinephrine (Figure 3) and a loss of contribution to vasoconstriction from co-released transmitters. Cold-induced vasoconstriction has been shown to be enhanced by neurotransmitters co-released with norepinephrine. When yohimbine and propranolol are used to antagonize norepinephrine's effects during local cold exposure, vasoconstriction decreases, but remains robust in the younger individuals, indicating contribution by co-released neurotransmitters. However, yohimbine and propranolol completely block vasoconstriction in the elderly. That is, co-released peptides, such as neural peptide Y (NPY), must be compensating for the diminished effect of norepinephrine in the younger vessel, yet there is no compensation in the older vessel. While some evidence suggests that the co-released neural peptide may be NPY, the precise identity of the agent remains to be elucidated.

Summary of the Effects of Senescence on the Response to Heat and Cold Exposure in Humans

Senescent-related alterations to core temperature during thermal stress are minimal. Reports of a greater risk of hypo- and hyperthermia in the elderly have now been judged to reflect more closely factors such as disease, physical activity level, psychological

impairment, and socioeconomic level, rather than biological aging *per se*. Sympathetic regulation of vasoconstriction and vasodilation appears to decline with age and reflects a general desensitivity to neural transmitters. Vasoconstriction and vasodilation can be improved by acclimation to the ambient temperature and increased physical activity, suggesting that behavior may also a have a significant role in the maintenance of sympathetic regulation. Recent investigations have suggested that if diminished thermoregulatory capacity occurs as the result of biological aging, the effects are progressive within the senescent cohort. That is, altered thermoregulation is most pronounced in people nearing the end of their natural life span (i.e., the ninth and tenth decades of life).

Effect of Senescence on the Response to Cold Exposure in Laboratory Rodents

The use of laboratory rodents, particularly rats and mice, to evaluate the affect of senescence on thermal stress has been, for the most part, limited to investigations describing changes to cold exposure. Young and old rodents do not tolerate heat exposure greater that 2–3 °C above normal body temperature (38–39 °C) and mortality rates increase significantly after 2 h. Thus, the discussion presented here is limited to the autonomic response observed in cold exposure of senescent mice and rats.

Response of Core Temperature to Cold Exposure

Observations of the effect of advanced age on cold-exposed core temperature in rats and mice have not been consistent. The differences in mean values for cold-exposed core temperature, when present, are modest, and the variations about the mean are considerably greater than those seen in younger animals. If an age-related decrease in cold-exposed temperature exists in animals, the decline appears to be more pronounced in males than in females (Figure 4). An inability to maintain core temperature during senescence does not correlate to a decline in the mean cold exposure oxygen consumption, a finding that indicates appropriate shivering response. Small and nonsignificant declines in muscle mass among 27-month-old versus 12- and 5-month-old rats are consistent with adequate shivering during senescence. Therefore, if senescence does cause altered cold-exposed core temperature in rodents, then the changes must be due to increased heat loss – that is, altered vasoconstriction, or alterations to brown adipose tissue (BAT) nonshivering thermogenesis (NST).

Figure 4 The change in core temperature in male and female Fischer 344 rats after 4h of exposure to 6 °C. Resting core temperature did not differ between 6-, 12-, and 26-month-old groups. Data adapted from Gabaldón AM, Gavel DA, Hamilton JS, et al. (2003) Norepinephrine release in brown adipose tissue remains robust in cold-exposed senescent Fischer 344 rats. *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 285(1): R91–R98, with permission.

Autonomic Response to Cold Exposure

Nonshivering thermogenesis: A mechanism of heat production in rodents Brown adipose tissue is the principal anatomic location of NST. The contribution of NST to overall heat production during cold exposure in the rat has been estimated to be as high as 30–40% of the total body oxygen consumption. Nonshivering thermogenesis in BAT is initiated by release of norepinephrine from terminal endings of sympathetic neurons (Figure 5). Norepinephrine binds primarily to β_3-adrenergic receptor, and the transduction of this signal is mediated through a second-messenger pathway involving adenylyl cyclase. The oxidation of fatty acids, the primary fuel substrate for BAT, is uncoupled from the electron transfer system by a novel protein, uncoupling protein 1 (UCP1), so that heat, rather than ATP, is the metabolic end product.

Senescence and nonshivering thermogenesis BAT mass declines significantly with age. However, the decrease in BAT mass with chronological age most likely reflects long-term disuse of this tissue, because animals are typically housed at thermoneutral temperatures. This suggestion is consistent with the observation that cold exposure of old rats at 10 °C for five consecutive days significantly increases brown fat mass and BAT cell size.

Brown fat thermogenesis potential as measured by UCP1 concentration does not change with age. Therefore, any senescence-related attenuation of

Figure 5 Schematic description of the influence of norepinephrine (NE) on the uncoupling of oxidative phosphorylation from electron transport that leads to nonshivering thermogenesis. β_3, β_3-adrenergic receptor; HSL, hormone-sensitive lipase; GDP, guanosine diphosphate; UCP, uncoupling protein.

NST more likely reflects alteration in sympathetic activity. This suggestion seems unlikely, however, as senescence has been associated with an increase rather than a decrease in sympathetic activity. Elevated plasma norepinephrine levels have been observed in several studies, and neural recordings of sympathetic signaling to brown fat are greater in 30- versus 5-month-old mice exposed to several hours of cold. Finally, brown fat tissue norepinephrine release measured during cold exposure remains robust in old rats (Figure 6). The preponderance of evidence indicates that neural signaling to aging brown fat is intact in the senescent animals.

Vascular response to cold exposure in rats Rodents rely on sympathetic-mediated changes in vessel diameter to regulate blood flow during exposure to cold. However, vasoconstriction is limited to the exposed skin of the tail. Vasodilation occurs in organs (such as skeletal muscle and BAT) that rely on an increase in local blood flow to enhance tissue oxygen demands of cold-exposed energy production. Indirect measurement of blood flow using radiolabeled microspheres has demonstrated that older rats are capable of increased vasodilation during cold exposure to the same degree as younger animals (Table 2). Vasoconstriction, as measured by heat loss index of the tail, also declines to the same degree in young and old rats. Vasoconstriction and vasodilation during cold exposure appear to respond appropriately in aged animals.

Summary of Autonomic Reponses to Cold in Rodents

The decline in mean core temperature in old versus young rats is modest, is greater in males than in females, and supports the results observed in humans. Vasoconstriction and vasodilation respond appropriately during cold exposure, and brown fat thermogenesis does not appear to be altered. These results

Table 2 Tissue masses and resting (23 °C) and cold-exposed (6 °C) regional blood flow of brown adipose tissue and soleus muscles in rats

Rat tissue/age	*Mass (g)*	*Blood flow (ml min^{-1} g^{-2})*

suggest that autonomic control of thermoregulation in aged rats remains intact. It must be kept in mind that conclusions suggesting little or no change in thermoregulation of the aged rodent are based on the group means. Significant declines in core temperature and alteration in autonomic control of cold-induced thermoregulation can be identified in individual animals.

Response to Thermostress and the Rate of Aging

The evidence from studies in humans and rats suggests that senescence-related alterations in autonomic control of thermoregulation may be limited to individuals nearing the end of their natural life span. Moreover, investigations evaluating possible senescent-related alterations to heat and cold exposure in both humans and rodents have shown considerable inconsistency of results and high levels of variation about the mean for the outcome variable in old versus young groups. Investigations in both humans and animals report that core temperatures for some individuals do not change, whereas core temperatures for other individuals of identical age decrease (cold) or increase (hot) significantly. Together, these finding would suggest that distinct cohorts exhibiting different senescent-related outcomes may exist within the population of individuals considered old.

Cold-Exposed Core Temperature and Weight Loss

Our laboratory began investigating the possibility of multiple cohorts within the aged population when, by serendipity, we noticed that the old animals exhibiting decreasing core temperature during cold exposure were also the animals with the lowest body weights. Retrospective analysis in our longitudinal studies revealed that a drop in core temperature

Figure 7 Relationship between body weight and intraperitoneal temperatures during cold exposure in two aged-matched male Fischer 344 rats. Line A is a weight-stable animal that lived to an age of 911 days. The rat represented by line B died at 870 days. Values above lines are the 4 h intraperitoneal temperatures (°C) of rats exposed to 6 °C. Data adapted from McDonald RB, Florez-Duquet M, Murtagh-Mark CA, et al. (1996) Relationship between cold-induced thermoregulation and spontaneous rapid body weight loss of aging F344 rats. *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 271(5): R1115–R1122, with permission.

corresponded to weight loss and that the rats with altered core temperature died within days or a few weeks after the onset of weight loss. This suggested that alterations in autonomic regulation of body temperature decline only near the end of the life span.

We formally tested this hypothesis by measuring body weight daily and performing cold-exposure trials (6 °C for 4 h) on an every-other-week basis starting at 20 months of age (mean life span of Fischer 344 rats is 24–25 months). We found that cold-exposed core temperature in all old animals declined only after the onset of body weight loss and declining food intake (Figure 7). No decline in core temperature

in senescent versus presenescent rats occurred during the weight-stable phase. The decline in core temperature during the weight-loss phase was rapid, and the several animals became hypothermic, with body temperature below 33 °C, within 2 h of cold exposure. Most important, however, was our finding that the start of the terminal phase and decline of core temperature occurred in all animals tested and at various ages between 22 and 32 months. That is, loss in thermoregulatory capacity was not related to chronological age.

Hypothalamic function, thermoregulation, and the terminal phase The rapid and spontaneous loss in weight and food intake decline, combined with the dramatic alterations in cold-exposed thermoregulation, suggested a disruption in a central-mediated mechanism. Experiments were initiated to test the functionality and responsiveness of the hypothalamus, the primary center of thermoregulation. As a first step in evaluating hypothalamic function during the terminal phase, endogenous circadian rhythm of body temperature was followed longitudinally starting at 20 months of age. Continuous measurement of core temperature under constant darkness was performed by radiotransmitters implanted in the visceral cavity. Disruption of endogenous phase, rhythm amplitude, and period coincided with the start of body weight and food intake decline and occurred in all animals (Figure 8). Moreover, 24 h mean body temperature, a highly stable variable throughout the majority of the life span, abruptly declined at the start of weight loss and continued until death. These results indicated strongly that neural centers within the hypothalamus were disrupted during the terminal phase and that it was only during the rapid and spontaneous loss in weight that differences in autonomic function in thermoregulation were noted.

The rapid decline in core temperature leading to hypothermia in the senescent rats precludes experiments using the cold-exposure paradigm. We confirmed, however, that loss in mean body temperature coincided precisely with diminished food intake, a physiological system also highly regulated by the hypothalamus. Thus, we are able to use the decline in food intake as a surrogate model for temperature regulation and track possible alteration in hypothalamic function. To this end, several experiments have been completed evaluating the role of NPY, a potent stimulator of food intake, in hypothalamic regulation.

Figure 8 Seven days of core temperature data from three representative old male F344 rats (a–c) during analysis periods of presenescence (left) and senescence (right). Note that the temperature scale in the senescence period for rat a is different from that for rats b and c. Reproduced from McDonald RB, Hoban-Higgins TM, Ruhe RC, et al. (1999) Alterations in endogenous circadian rhythm of core temperature in senescent Fischer 344 rats. *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 276(3): R824–R830, used with permission from the American Physiological Society.

The infusion of NPY directly into the paraventricular nucleus of the hypothalamus does not stimulate food intake in the senescent rat to the same degree as that observed during the weight-stable period. The lack of an effect of NPY on stimulating food intake in the senescent rat does not reflect declining receptor number, fewer NPY-sensitive neural cells, or alterations to pathways of peptides that are co-released with NPY – for example, γ-aminobutyric acid (GABA).

We have recently completed preliminary work describing gene expression within the hypothalamus between weight-stable and non-weight-stable old rats using microarrays. We find that differences in DNA expression are limited to only a few genes (3% of those tested, a finding constant with other microarray analyses in aging research) and that the genes with the greatest difference in expression were limited to specific types of cell functions. The majority of expression difference occurred in genes coding for ion channel proteins. A potassium channel had the highest degree of difference. The other genes were involved in signal transduction and nerve growth and maintenance factors. We did not find significant difference in any genes that coded for specific neural transmitters involved in thermoregulation or food intake. Our results indicate that the loss in function in the hypothalamus that may impact thermoregulation occurs at the level of cell processes common to all physiological systems and is not limited to any particular system.

Conclusion

The data from both humans and laboratory animals are consistent in that autonomic control of thermoregulation is well maintained through out most of the life span, including during a significant portion of old age. While there appear to be some alterations to autonomic mechanisms that can be directly related to biological aging, these changes tend to be modest and do not significantly affect core temperature. The current data suggest that many of the changes occurring to sympathetic-mediated vasoconstriction, vasodilation, and NST during old age can be prevented or reversed through acclimation and changes in life style.

Nonetheless, there does appear to be a period near the end of the life span in which alterations to autonomic regulation of body temperature declines. Evaluations of the vasoconstriction and vasodilation mechanisms in humans have found that heat conservation and convective heat loss do result in changes to core temperature in the oldest old. These observations in humans have been confirmed in rodents, in which losses in several autonomic mechanisms of thermoregulation coincide with a terminal phase of life characterized by declining body weight, food intake, and mean body temperature.

Thirst

E M Stricker, University of Pittsburgh, Pittsburgh, PA, USA

© 2009 Elsevier Ltd. All rights reserved.

This article focuses on the seven signals that influence thirst in rats. Four signals are excitatory: increased plasma osmolality detected by cerebral osmoreceptors, decreased blood volume detected by cardiac stretch receptors, increased circulating levels of angiotensin II (Ang II) detected by Ang II receptors in the subfornical organ, and hypertonic fluid emptied from the stomach into the small intestine detected by putative osmo- or sodium receptors in the abdominal viscera. In addition, three signals inhibit thirst: decreased plasma osmolality detected by cerebral osmoreceptors, increased arterial blood pressure detected by arterial baroreceptors, and hypotonic fluid emptied into the small intestine detected by visceral osmo- or sodium receptors.

Drinking behavior stimulated by the sensation of thirst together with the complementary secretion of the antidiuretic hormone vasopressin (VP) from the posterior lobe of the pituitary gland comprise the major response components in the regulation of body fluid balance. The homeostasis of body fluid, in turn, is traditionally viewed as involving the regulation of its osmolality and of blood volume. However, the control of thirst is more complex than can be described by a two-factor model, and consideration of plasma sodium (Na^+) concentration (pNa) and of arterial blood pressure also must be included in an informed discussion. Each of these four variables (i.e., blood osmolality, volume, pressure, and Na^+ concentration) can be increased or decreased from normal levels, potentially providing eight distinct signals that may affect thirst. This article is organized around these four variables and focuses on the signals that actually do appear to influence water intake.

Fluid Osmolality and Na^+ Concentration

It has long been recognized that thirst is stimulated by increases in the extracellular concentration of nonpermeable osmolytes, such as Na^+, that cause osmotic movement of water from body cells. Thus, hyperosmotic solutions of glucose and urea do not increase water intake, but hypertonic solutions of NaCl or sorbitol do. This increase in effective plasma osmolality (pOsm) stimulates cerebral osmoreceptors located in the vascular organ of the lamina terminalis (OVLT), a structure in the basal forebrain that lacks a blood–brain barrier and therefore can respond readily to alterations in pOsm. In fact, increases in pOsm of only 1–2% stimulate thirst in animals, and further increases elicit proportional increases in water intake. Thirst is stimulated when projections from the OVLT activate neurons in the median preoptic area in the lamina terminalis ventral to the anterior commissure, although the subsequent neural circuitry that mediates thirst and drinking behavior has not been determined. Other projections from the OVLT to the paraventricular and supraoptic nuclei of the hypothalamus stimulate VP secretion. Surgical destruction of the OVLT eliminates both water drinking and neurohypophyseal VP secretion in response to increased pOsm.

Given this arrangement, osmoregulation was initially envisioned as a single-loop negative-feedback system in which dehydration increases pOsm and thereby provides a stimulus for thirst, whereas water intake serves to decrease pOsm back to normal and thereby causes satiation by removing the excitatory signal for thirst. However, the control system for osmoregulatory thirst cannot be that simple in organization because a substantial delay occurs between the time when water is ingested and the time when it appears in the circulation (from which it can affect pOsm and the cerebral osmoreceptors). Specifically, in both dogs and humans, it takes 10–20 min for ingested water to produce significant decreases in pOsm, whereas thirst and water intake are terminated much more rapidly (as is secretion of VP). Thus, an early stimulus must occur that signals the brain in anticipation of subsequent rehydration. Such an effect resembles feed-forward reflexes found in the control of numerous autonomic functions (e.g., insulin secretion in response to the taste of food before its digestion and assimilation).

This anticipatory element in the control of water intake was clarified by a series of elegant investigations reported by Ramsay and colleagues. Their research used dogs as experimental subjects, although later work extended their findings to human and nonhuman primates. Briefly, dehydrated dogs were observed to drink water rapidly but to stop after only a few minutes, well before dilution of blood plasma became evident. This early inhibition of thirst (and of VP secretion) occurred even when dogs were fitted with a gastric fistula, which drained ingested water from their stomachs and thereby prevented the possibility of rehydration. The same rapid effects occurred when dogs drank hypertonic NaCl solution (although, ultimately, when the saline was absorbed and pOsm was elevated, the dogs became even thirstier and secreted more VP than before, as might be expected). These observations highlight the importance of an early inhibitory signal in the control of water intake and

suggest its basis: a neural input to the brain from the oropharynx, associated with rapid swallowing during the act of drinking, which allowed dogs to meter their intake. This signal had a rapid but temporary inhibitory effect on thirst and VP secretion. When ingested water was subsequently absorbed and pOsm was diluted back to normal levels, a more sustained termination of thirst and VP secretion was produced due to rehydration. This hypothetical arrangement is consistent with the finding that a rapid inhibition of thirst and VP secretion was not observed in dehydrated dogs when a volume of water comparable to that consumed was intubated into their stomachs, bypassing their oropharynx.

Rats also utilize early feedback signals from drinking, although via a different mechanism. When rats were infused intravenously with hypertonic NaCl solution to stimulate VP secretion, 5 min of water intake caused a rapid decrease in plasma levels of VP without noticeable changes in pOsm. These effects were not associated with the act of drinking because intake of the same volume of isotonic saline had no effect on plasma VP levels. Thus, the animals appeared to be responding to the composition of the ingested fluid and not to its volume. In addition, previous findings had indicated that thirsty rats drank increased amounts of water when the pyloric sphincter was ligated (thereby preventing gastric emptying) and that gastric water loads in rats produced rapid decreases in plasma VP levels before a substantial reduction of pOsm occurred. These observations collectively suggest the existence of a visceral osmo- or Na^+ receptor that detects ingested water after the fluid leaves the stomach and before it enters the general circulation.

Fibers of the vagus nerve project from the abdominal viscera to the area postrema and adjacent nucleus of the solitary tract (AP/NTS) in the brain stem. Consistent with the possibility that these fibers serve to mediate the early effects of ingested water, considerable overdrinking occurred in thirsty rats when these sensory nerve fibers were destroyed by systemic injection of the neurotoxin capsaicin. Overdrinking was also observed when the projection sites were eliminated by lesions of the AP/NTS. In both cases, the animals acted as if they no longer received an early message that water had been consumed; that is, they kept drinking. It was only later, when the ingested water had been absorbed and diluted circulating plasma, that OVLT osmoreceptors were affected and thirst was reduced. Visceral osmo- or Na^+ receptors also have been implied by findings that thirst can be stimulated by gastric loads of hypertonic NaCl solution, before systemic increases in pOsm are detected. Similarly, thirst resulting from overnight water deprivation is considerably enhanced by a gastric load of hypertonic saline.

Rats with lesions of the AP/NTS have other features of disrupted osmoregulation. Besides drinking excessive amounts of water when thirsty, they also have a blunted secretion of VP in response to hypertonic saline infused intravenously and impaired urinary excretion of an administered NaCl load. Moreover, they drink hypertonic NaCl solution in unusually large bouts, as if they were not receiving early signals of the dehydrating solution from visceral Na^+ receptors. These results suggest an important role of the AP/NTS in osmoregulation in rats. Because the AP lacks a blood–brain barrier, it is possible that it directly detects some pertinent feature of body fluid composition in addition to receiving input from the viscera. Observations that rats with AP/NTS lesions secrete VP normally in response to hypertonic mannitol solution but not in response to equi-osmolar saline solution provide further information that this brain stem area plays a role in Na^+ regulation rather than in osmoregulation.

To summarize, it is well established that cerebral osmoreceptors mediate thirst and secretion of VP in response to increases in pOsm. However, other factors are also important because drinking and neurohypophyseal secretion can be influenced even when no changes in circulating pOsm are evident. For example, an 'anticipatory signal' from visceral osmo- or Na^+ receptors contributes importantly to these regulatory responses in rats. These receptors project to the AP/NTS, implicating a role for these brain stem structures in Na^+ regulation that is consistent with other findings in which the AP/NTS was surgically destroyed. The organization of the relevant neural circuits that control water intake and neurohypophyseal VP secretion remains to be clarified, as does the difference in their operation in response to NaCl loads and osmotic loads not containing Na^+, and their separate contributions to the control of NaCl appetite, thirst, and VP secretion.

Blood Volume

It has long been known that a sudden reduction in blood volume induced by hemorrhage can stimulate water intake and VP secretion in the absence of any changes in pOsm. However, hemorrhage is not an ideal treatment in laboratory studies of behavior in part because of the debilitation that could result from anemia or severe arterial hypotension. Instead, extravascular administration of colloidal solutions has proven to be an easy and effective treatment in rats to reduce plasma volume without affecting pOsm or

arterial blood pressure. Such solutions leach isosmotic plasma from the circulation into an extravascular depot by raising oncotic pressure in the local interstitial space and thereby disrupting the Starling equilibrium across the capillary membranes. Injection of colloidal solutions in rats produces a dose-related increase in water intake and VP secretion that is proportional to the induced plasma volume deficit.

These effects of hypovolemia occur in the absence of changes in arterial blood pressure. Stretch receptors located in the walls of the great veins that return blood to the heart and in the right atrium have been identified and presumed to mediate the increase in thirst and VP secretion after blood loss, and drinking in response to hypovolemia has been abolished by destroying the cardiac receptors. Moreover, water intake has been blunted in hypovolemic rats by inflating a small balloon in the venous–atrial junction to prevent detection of the loss in blood volume. However, neither thirst nor VP secretion was eliminated during hypovolemia by destruction of the NTS in rats, although the procedure did eliminate autonomic reflexes evoked by cardiac baroreceptors. These findings suggest that cardiac receptors are not essential for eliciting drinking in response to hypovolemia. The enzyme renin is secreted from the kidneys in response to hypovolemia, and it in turn causes the formation of angiotensin II (Ang II) in the blood. Because Ang II can stimulate drinking and VP secretion, it seems plausible that the renin–angiotensin system might be involved in signaling hypovolemia in rats with NTS lesions.

The role of the renin–angiotensin system in thirst during hypovolemia has been illuminated by other studies. Colloid treatment stimulates thirst in rats lacking kidneys. Similarly, elimination of Ang II-induced drinking by destroying the subfornical organ (SFO), the site of action of circulating Ang II, does not affect drinking in response to substantial plasma volume deficits. Thus, circulating Ang II clearly is not necessary for the drinking response to hypovolemia. However, when plasma volume deficits are relatively small, it is important to note that rats with SFO lesions do not drink as much water in response to hypovolemia as do control rats. Assuming that the main effect of SFO lesions in these experiments was to eliminate the stimulus of thirst provided by Ang II (without affecting any other signal of thirst), these findings suggest that even small amounts of circulating Ang II may contribute importantly to thirst in hypovolemic rats by lowering the threshold amount of depletion required for eliciting a drinking response. The fact that Ang II does not enhance water intake during substantial hypovolemia may be attributed to the potent inhibitory effect of osmotic dilution that results from the renal retention of ingested water. For example, a 2–3% dilution of pOsm will abolish water intake and VP secretion in rats with 35% plasma volume deficits.

Hypovolemic rats need both water and NaCl to replace their plasma volume deficits. Thus, when they drink only water, they still need NaCl to reexpand plasma volume. Therefore, it is appropriate that hypovolemia stimulates salt appetite in rats in addition to thirst. It is not a goal of this article to discuss the biological bases of salt appetite, but it is worth noting that osmotic dilution, which inhibits thirst during hypovolemia, also serves to disinhibit salt appetite. The NaCl intake that can then occur removes osmotic dilution and its inhibition of thirst, which is reestablished when rats drink water again. By alternating intake of water and NaCl solution, hypovolemic rats can effectively repair their plasma volume deficits while also regulating their pOsm.

Numerous investigations have examined the effects of concurrently presenting osmo- and volume regulatory signals that influence water intake. Increases in pOsm combined with decreases in plasma volume produced additive effects on water intake (and VP secretion) in rats. As mentioned previously, osmotic dilution completely inhibited water intake and VP secretion, even when hypovolemia was pronounced. In contrast, plasma volume expansion did not inhibit drinking in response to osmoregulatory thirst. Additional studies are needed to determine whether hypervolemia similarly has little effect on thirst induced by Ang II.

To summarize, there is no doubt that signals of thirst and VP secretion exist independent of osmoregulatory and Na^+ regulatory needs. One such signal is related to a decrease in blood volume and is presumed to be detected in part by cardiac baroreceptors. Vagal fibers project from the heart to the NTS, and from there they appear to be involved in a neural circuit that includes the median preoptic area in mediating thirst and the hypothalamic supraoptic and paraventricular nuclei in mediating VP secretion. However, the signal of hypovolemia is complex in that it also involves a blood-borne hormone, Ang II, and perhaps additional receptors that monitor blood volume and provide a separate signal that influences thirst and VP secretion. The potent effects of osmotic dilution in rats despite hypovolemia indicate that inhibitory signals participate in the control of thirst and VP secretion, not just variable degrees of excitation. These and other observations also reveal the hierarchies of homeostasis: The osmoregulatory controls of thirst and VP secretion appear to be much more potent than the volume regulatory controls.

Arterial Blood Pressure

Observations that vasodilating drugs can stimulate substantial water intake and VP secretion in rats in the absence of changes in pOsm or blood volume indicate that additional signals may provide excitatory stimuli for these responses. Arterial baroreceptors, located in the carotid sinus and aortic arch, are known to provide neural information to the brain stem that is the basis of numerous autonomic reflexes, and such afferent neural stimulation also may evoke thirst and VP secretion. Activation of the sympathoadrenal system by input from these arterial baroreceptors stimulates renin secretion from the kidneys, and blood-borne Ang II may provide the relevant signal to the brain instead of, or in addition to, a neural signal from arterial baroreceptors. In addition, a decrease in arterial blood pressure reduces renal blood flow and thereby provides a direct stimulation of renin secretion that is independent of the sympathoadrenal system.

The possibility that Ang II mediates thirst in rats during arterial hypotension was strongly supported by early observations that bilateral nephrectomy, which eliminated plasma renin, also abolished the drinking responses to hypotensive agents. However, two complications arose in interpreting those findings. First, nephrectomy removed circulating Ang II and its potent pressor effects in addition to its dipsogenic effects, and animals became so hypotensive that they could not readily behave; in other words, their failure to drink may reflect debilitation rather than an absence of thirst. However, later studies revealed that drinking induced by vasodilating agents could be eliminated by nephrectomy or by pharmacological blockade of the renin–angiotensin system, even when arterial blood pressure was modulated and the induced hypotension was not so severe as to preclude drinking behavior. These findings offer little support for the hypothesis that neural signals from arterial baroreceptors directly stimulate thirst during hypotension, independent of the renin–angiotensin system.

A second complication arose when plasma levels of Ang II, which were significantly elevated in rats during arterial hypotension, were found to be not nearly as high as those required to produce the same amount of drinking when Ang II was administered intravenously. One possible explanation was that Ang II was a dipsogen only in pathophysiologic or pharmacologic circumstances. An alternative view seems more likely to be correct: Ang II, when infused, actually provides a mixed stimulus of thirst. That is, Ang II possesses both an excitatory component that results when Ang II binds to receptors in the SFO and an inhibitory component that is associated with the induced elevation in arterial blood pressure. This inhibitory component would not be present during arterial hypotension when renin is secreted normally, hence the lower amounts of Ang II required to elicit thirst in that circumstance.

Consistent with the critical role of Ang II in thirst during arterial hypotension are observations that drinking was enhanced considerably when the hypertensive effects of Ang II were blunted by simultaneous administration of vasodilating agents. Additional support came from findings that water drinking in response to intravenous Ang II was greatly augmented in rats with NTS lesions, which could not receive the neural signal of hypertension from arterial baroreceptors. Sinoaortic denervation produced the same increase in the drinking response to intravenous Ang II, demonstrating that the arterial baroreceptors are involved in mediating this inhibitory stimulus.

These experiments indicate that changes in arterial blood pressure provide two signals that are relevant to the control of thirst. During arterial hypotension, increased activity in the renin–angiotensin system provides a blood-borne, excitatory stimulus of thirst. The second signal arises during arterial hypertension, and it inhibits thirst. The inhibitory effect of increased arterial blood pressure has been seen not only when rats are infused intravenously with Ang II but also when pressor agents are given to rats made thirsty by infusion of hypertonic saline. This inhibitory effect was linear when blood pressure increased from approximately 120 to approximately 160 mmHg, above which no further inhibition was seen. It is of interest that the same limits in detection of hypertension are seen in the familiar baroreceptor reflex control of heart rate. That inhibitory effect is known to be mediated by arterial baroreceptors and, apparently, so is the inhibition of thirst because it did not occur in rats after sinoaortic denervation.

Summary

Two systemic osmoregulatory signals (one excitatory and one inhibitory), two presystemic osmo- or Na^+ regulatory signals (one excitatory and one inhibitory), one excitatory volume regulatory signal, and two signals associated with changes in arterial blood pressure (one excitatory and one inhibitory) sum to a total of seven stimuli that have been identified in the control of thirst. Figure 1 summarizes these acute signals. The most well-established stimulus, increases in systemic pOsm, as produced experimentally by intravenous injection of hypertonic saline, provides an excitatory stimulus for thirst. This signal is generated by osmoreceptors in the OVLT, which apparently stimulates thirst by activating the median preoptic area. Gastric NaCl loads, whether administered by

Figure 1 Schema showing the four excitatory signals (solid arrows) and the three inhibitory signals (dashed arrows) in the control of thirst in rats. ABP, arterial blood pressure; pAngII, plasma angiotensin II; pVol, plasma volume.

the investigator or consumed by the experimental subject, also increase pOsm and have the more rapid effect of stimulating thirst presumably via visceral osmo- or Na^+ receptors. Hypovolemia, as produced experimentally by subcutaneous injection of colloid in rats, lowers plasma volume and provides another mixed signal for thirst, in part neural (presumably from cardiac baroreceptors through the NTS) and in part humoral (Ang II acting on receptors in the SFO). Decreases in arterial blood pressure, as produced by vasodilating agents, stimulate renin secretion (via baroreceptors in both the carotid sinus–aortic arch and the kidneys), which stimulates thirst when Ang II acts on receptors in the SFO. There is no compelling evidence to indicate that arterial baroreceptors act directly to stimulate thirst when the renin–angiotensin system is blocked.

Acute increases in arterial blood pressure such as might arise from intravenous administration of the α-adrenergic receptor agonist phenylephrine inhibit water intake regardless of whether thirst is stimulated by hyperosmolality, hypovolemia, or Ang II. This inhibitory effect appears to be mediated by arterial baroreceptors. Increases in plasma levels of Ang II that result not from endogenous renin secretion but from intravenous administration of renin or Ang II provide a stimulus of thirst that has both excitatory and inhibitory components. Excitation results from activation of Ang II receptors in the SFO, whereas inhibition appears to be mediated by arterial baroreceptors. In consequence of this mixed input, the levels of plasma Ang II that are required to stimulate thirst are much higher than those required to stimulate thirst when rats are hypovolemic or hypotensive.

Decreases in pOsm induced by gastric water loads provide another inhibitory stimulus of thirst, and they do so in two ways. First, the water depresses the activity of putative visceral osmo- or Na^+ receptors even before water has diluted circulating pOsm (in rats; in dogs, a similar early signal is generated by the act of drinking). Second, the subsequent absorption of water into the general circulation dilutes systemic pOsm, which presumably decreases the activity of cerebral osmoreceptors.

For purposes of simplicity, Figure 1 and this article generally did not include consideration of the close link between thirst and salt appetite, the close link between the controls of salt appetite and food intake, or the close link between the controls of VP secretion and thirst. Nor has there been consideration of the important contribution of neurohypophyseal oxytocin secretion to osmoregulation (by stimulating natriuresis) and to the maintenance of arterial blood pressure (by stimulating renin secretion). Nor was it mentioned that most instances of water intake by free-feeding humans occur in the absence of body fluid deficits, and that we generally rely on our kidneys to eliminate excesses in body fluids such as occur when water is ingested with meals or in caffeinated or alcoholic beverages. Nonetheless, it should be apparent that research focused on the biological bases of thirst and satiety for water has enabled great advances in our understanding and this remains a lively field of investigation today.

Thyroid Hormone and Transcriptional Regulation in the CNS

D Forrest and J Nunez, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Introduction

Two major iodothyronines, thyroxine (3,5,3′,5′-tetraiodothyronine or T4) and 3,5,3′-triiodothyronine (T3) are synthesized in the thyroid gland (Figure 1). T3, the primary active form of thyroid hormone (TH), is also produced by local conversion of T4 to T3 by deiodination in some peripheral organs. The major actions of T3 are mediated by a nuclear TH receptor (TR) that acts as ligand-regulated transcription factor to control the expression of target genes. TH has cell type-specific effects in almost all tissues.

In human development, TH deficiency, during critical periods of neuronal differentiation, produces permanent and severe mental retardation (cretinism) if hormone replacement therapy is not performed as soon as possible after birth. Iodine is required for TH synthesis, and low iodine intake (endemic hypothyroidism) remains the major cause of cretinism in several developing countries. In addition, sporadic congenital hypothyroidism may arise in about 1:3500 newborns and is usually caused by defects in the developmental formation of the thyroid gland or in TH biosynthesis. Previously, this was the major cause of cretinism in developed countries, but screening is now performed on all newborn infants, followed by hormone replacement therapy as necessary. Timely hormone replacement reduces the occurrence of severe mental deficiencies. Neurological defects are also associated with mutations in one of the receptors, TRβ, in the syndrome of TH resistance, and in a TH transporter, MCT8, in a form of X-linked mental retardation.

Abnormalities in TH levels in adults are associated with different consequences than those arising during development. In adulthood, hypothyroidism is associated with depression and is recognized as a secondary cause of dementia, whereas hyperthyroidism may be associated with mania and anxiety disorders.

Some of the underlying actions of TH in the CNS were first suggested by Eayrs and Legrand between the 1950s and 1970s in pioneering studies on model species. These studies, mainly on the rat, indicated that several steps in brain maturation including cell migration, outgrowth of neuronal processes, acquisition of neuronal polarity, synaptogenesis, and myelin formation were delayed under hypothyroid conditions, whereas glial cell proliferation (gliosis) and neuronal cell death were increased. As a result, synaptic activity is reduced. In contrast, excessive TH can accelerate development prematurely with deleterious consequences on the CNS. In addition to general functions in neuronal and glial differentiation, TH has specific actions in different brain regions and sensory systems.

TH Receptors

The major actions of TH ultimately concern the regulation of target genes (Figure 2). The mechanism of action involves: (1) uptake from the blood of both T_4 and T_3 by target tissues; (2) conversion of T_4, either to T_3, the active hormone, or to reverse T_3 (3,3′,5′-triiodothyronine or rT_3), an inactive derivative, by deiodinases; (3) binding of T_3 to the TR; and (4) activation or inhibition of transcription of specific genes.

In 1986, the groups of Evans and Vennström reported independently the cloning of cellular homologs (c-erbA) of the viral erbA oncogene and showed that they encoded high-affinity nuclear T3 receptors (Figure 3). A small family of TRα and TRβ receptors is encoded by the *THRA* and *THRB* genes, respectively (human nomenclature). In mice and model species, the genes are named *Thra* and *Thrb*, respectively (or, as members of the wider superfamily of nuclear receptor genes, *Nr1a1* and *Nr1a2*). Related *Thra* and *Thrb* genes exist in mammalian, avian, amphibian, and fish species, suggesting that both genes are fundamental to T3 signaling. *Thrb* generates two major receptor isoforms, TRβ1 and TRβ2, by alternative promoter usage. *Thra* encodes a single T3 receptor, TRα1. In some species, additional variant TR products are produced. Mammalian but not nonmammalian species express a TRα2 splice variant that does not bind T3 and which may act as a weak antagonist of normal TR function. A TRβ3 isoform with a variant N-terminus occurs in rat. The major TRα1, TRβ1, and TRβ2 isoforms contain a DNA-binding domain, a C-terminal ligand-binding domain, and a variable N-terminal domain.

Several properties of TRs are of importance:

1. TRs bind to TH-responsive elements (T3RE) in responsive target genes. A typical T3RE contains two half sites that bind two TR molecules. Each half site has a consensus sequence, AGGTCA, that may be arranged as a direct repeat, inverted palindrome, or palindrome with variations in the

Figure 1 Iodothyronines produced by the thyroid gland and by metabolic deiodination in peripheral tissues. Type 2 deiodinase converts T4 into the major active ligand, T3. Type 3 deiodinase mediates inner-ring deiodination of T4 or T3 to form the largely inactive metabolites rT3 and 3,3′-T2, respectively.

Figure 2 Steps in the nuclear action of TH. T4 and T3 produced by the thyroid gland are transported by the blood to target tissues. Following cellular uptake in the CNS, T4 is converted to T3 or to rT3 by type 2 or type 3 deiodinases, respectively. T3 binds its receptor (TR), triggering transcriptional regulation of target genes and the production of specific mRNAs and proteins. TR activity is regulated by T3 ligand and by transcriptional corepressors (CoR's) or coactivators (CoA's). In a target tissue, T3 levels may be amplified by type 2 deiodinase in the target cell itself or, in more distant cells, through a paracrine-like mechanism of control. Transporters for uptake and release of hormone may be important in local hormonal communication between cells.

number, spacing, and orientation depending on the gene. Negative and positive response T3REs have been identified.

2. TRs can bind to the T3RE as monomers or more stably as homodimers (TR/TR) or as heterodimers with retinoid X receptors (TR/RXR).
3. TRs are bound to chromatin both in the absence or presence of TH. Some T_3-responsive genes can be repressed by the hormone-free TR.

In the absence of T3, the TR may bind a target gene together with corepressors to form a multi-subunit repressor complex. The binding of ligand displaces corepressors and allows coactivators to bind the complex. These events are associated with histone-modifying activities that promote transcription induction. A number of cofactors for TR have been identified and some such as hairless and alien may have specific roles in brain.

Receptor Functions in the CNS

In vitro, the major TRα1, TRβ1, and TRβ2 isoforms have similar transactivation potential on most reporter genes, suggestive of a high degree of functional overlap. However, each gene displays a physiological specificity *in vivo* which is determined to a large

Figure 3 TRs in mammals. TRα1, TRβ1, and TRβ2 are T3 receptors found widely in mammalian and nonmammalian vertebrate species. TRα2 only occurs in mammals and because of a C-terminal splice variation, it does not bind T3, nor transactivate; its physiological role is unclear.

extent by its particular expression pattern. *In vivo*, the different isoforms may have interchangeable, additive, or cell type- and gene-specific functions.

TRα1 is near-ubiquitously present in the brain from early stages of embryogenesis. TRα1 is also the major TR isoform in embryonic stem cells and it can mediate a neuronal-like differentiation of these cells in response to T3. In contrast, TRβ1 is induced in the later embryonic and neonatal period in many brain regions. TRβ2 is the most restricted isoform, being expressed in retinal photoreceptors, the anterior pituitary gland, and paraventricular nucleus of the hypothalamus which releases TRH (thyrotropin-releasing hormone (TRH)). Both TRβ1 and TRβ2 are also expressed in the cochlea.

Mutations in human *THRB* cause an autosomal dominant syndrome of resistance to TH with a variety of symptoms that in many cases include mental retardation, other neurological deficits, or a degree of hearing loss. The *THRA* gene has so far not been associated with inherited disease.

Targeted mutations in mouse *Thrb* result in seizure susceptibility, behavioral abnormalities, and sensory deficits in hearing and color vision. Mutations in mouse *Thra* cause anxiety, behavioral abnormalities, defective oligodendrocyte and neuronal differentiation, and impaired glucose uptake in brain regions (Table 1).

Table 1 Neurological phenotypes associated with mutations in the TH receptor genes *Thra* and *Thrb* in mice

TH Availability in the Brain

The amount of T3 available to the brain depends on the iodine present in the diet, the activity of the thyroid gland, the uptake of T4 and T3 by target tissues, and the activation or inactivation of hormone by deiodinases. Each of these events may vary during development. *In utero*, some TH is transferred from the mother to the fetus.

TH synthesis and the iodine supply. The iodine supply determines the ratio of T3 and T4 synthesis in the thyroid gland and the amount of hormone generated during each developmental stage. Both T4 and T3 are produced in a two-step process catalyzed by thyroid peroxidase. Several tyrosine residues of a large glycoprotein, thyroglobulin, are iodinated yielding mono-(MIT) and diiodotyrosine (DIT) residues. Some of these residues are coupled to form either T4 or T3 residues. The relative amount of T4 and T3 depends on the DIT/MIT ratio that increases with the level of thyroglobulin iodination. Thus, depending on the iodine supply, varying amounts of

T4 and T3 bound to thyroglobulin are stored in the thyroid follicle (colloid). T3 is present at only 10–25% of the level of T4 within thyroglobulin in a euthyroid status but when the iodide intake is low, the thyroid gland produces more T3 than T4.

Thyroid-stimulating hormone and feedback control of TH secretion. The amount of TH present in the fetal blood varies during development. TH transferred from the mother to the fetus before the onset of the fetal thyroid function is probably important during early stages of brain development. In the human fetus, the thyroid gland is functional at mid-gestation when it begins to produce small amounts of T4 and T3. T4 and T3 levels markedly increase in the blood at birth. The fetus may be protected against TH excess by type 3 deiodinase, a TH-inactivating enzyme (see Figure 1) expressed in the placenta. The release into the blood of T3 and T4 is controlled by a cascade of stimulatory mechanisms. The hypothalamus produces the TRH that stimulates the pituitary to release thyrotropin (thyroid-stimulating hormone, TSH); TSH then stimulates the activity of the thyroid gland. The secretion of both TRH and TSH is inhibited by a classical negative feedback loop. TRH and TSH are suppressed mainly via TRβ, when the level of TH in the blood is high. Both in the hypothalamus and pituitary, the negative feedback also depends, at least partly, on the local conversion of T4 to T3 by type 2 deiodinase.

In adulthood, the rat thyroid gland produces maximally ~3.0 mole of T4 and ~0.3 mole of T3 per mole of thyroglobulin when iodine is not limiting. Yet, the concentration of T3 in the serum is ~50 times lower than that of T4 and depends probably not only on its rate of secretion from the thyroid gland but also on its clearance rate and its uptake by the target cells. The half-life of T3 is shorter than that of T4 (7–9 days for T4 and 8–9 h for T3, depending on age).

T4 to T3 conversion by deiodination. T3, the active ligand, is produced locally in some target tissues by outer-ring deiodination of T4 by type 2 deiodinase (Figures 1 and 2). In contrast, type 3 deiodinase inactivates the hormone by inner-ring deiodination of T4 or T3 to produce rT3 and 3,3′-diiodothyronine (3,3′-T2), respectively. A third enzyme, type 1 deiodinase, may be more important in homeostatic control of hormone levels through metabolism in liver and kidney than in the CNS. Type 2 and 3 deiodinases are differentially expressed in the nervous system and are thought to regulate ligand availability in local environments. For example, seasonal reproduction in Japanese quail is controlled by changing day length, which alters the periodic expression of type 2 deiodinase in the mediobasal hypothalamus. In mice, the deletion of type 2 deiodinase produces deafness, suggesting the importance of local production of T3 in the inner ear. Otherwise, these mice have a relatively mild phenotype compared to that caused by TH deprivation, suggesting that the T3 produced by the thyroid gland may be adequate for TH action in other tissues.

Hormonal uptake and communication between cells. The importance of regulated uptake of TH by CNS target tissues is indicated by reports of mutations in the monocarboxylate transporter *MCT8*, a TH transporter *in vitro*, in cases of human X-linked mental retardation. *MCT8* and other transporter genes may regulate uptake of T4 and T3 from serum and also hormonal transfer between cells. The generation of T3 by type 2 deiodinase can occur not only in the target cell but also in some cases in nearby cells, implying that transporters are necessary for ligand transfer between cells in a local environment. Such a paracrine-like mechanism has been proposed in brain regions and in the cochlea.

Actions in the Nervous System

Glucose Utilization and Synaptic Activity

Glucose is the sole nutrient used by the brain to produce the energy required for synaptic activity. Because a close correlation exists between local neural activity and glucose metabolism, the severe reduction in glucose utilization seen in the hypothyroid brain might explain the decrease in synaptic activity. Studies in mutant mice showed that the regulation of brain glucose utilization depends primarily upon TRα1 rather than TRβ (Figure 4). Experiments performed by stimulating the whisker-to-barrel pathway in TRα mutant mice show that glucose utilization is decreased by ~50% in all four stations of this pathway, suggesting that synaptic activity is reduced to the same extent. These changes in glucose utilization might provide an explanation at the molecular level of the well-known increase in oxygen consumption and basal metabolic rate induced by TH in many tissues including the developing brain.

Genes regulated by TH include those encoding proteins modulating metabolic, synaptic, or cell division activities such as srg-1, RC3/neurogranin, calmodulin-dependent protein kinase, glutamine synthase, protein kinase C, prostaglandin D2 synthase, calbindin, and cyclin-dependent kinase. Other types of target genes include hormones (growth hormone, TRH, TSH) and transcription factors. Some responsive genes may be regulated directly at the transcription level, while others may be regulated indirectly or at a post-transcriptional level. There have also been proposals

Figure 4 Glucose utilization in the brain of mice carrying TRα or TRβ mutations. Quantitative color-coded autoradiographs of brain sections from wild-type or TRα- and TRβ-mutant mice. Local rates of glucose utilization established by the deoxyglucose method are encoded in the calibrated color scale at the bottom of the figure. Redrawn from Itoh Y, Esaki T, Kaneshique M, et al. (2001) Brain glucose utilization in mice with a targeted mutation in the thyroid hormone alpha or beta receptor gene. *Proceedings of the National Academy of Sciences of the United States of America* 98: 9913–9918.

of nongenomic actions of TH, although the relevance to the brain and the mechanisms are currently unclear.

Oligodendrocyte Differentiation and Myelin Synthesis

TRs are expressed in oligodendrocytes, the glial cell type responsible for formation of the myelin sheet. Oligodendrocyte differentiation as well as the expression of several myelin proteins (proteolipid, myelin basic protein, MAG) are under TH control. These findings might explain the actions of TH on myelination, which would probably contribute to the changes in electrical activity seen in the hypothyroid brain.

TH and Axonal and Dendritic Outgrowth during Morphological Neuronal Differentiation

TH actions on the formation of axons and dendrites is important for neuronal connectivity. Synaptic activity is severely impaired in neonatal hypothyroidism. In the rat cerebellum, for instance, the output of the granule cells from the proliferative zone, the external granular layer, is slowed, and the length of the parallel fiber, the axons of the granule cells, is shorter. Simultaneously, the growth and arborization of the dendritic tree of the Purkinje cells is reduced. Similar effects are noted in other brain regions but at different developmental stages, for instance, 2 weeks after birth in the cerebellum and hippocampus but sooner after birth in the cortex.

TH also stimulates neurite outgrowth in primary neuronal cell cultures. Both axonal and dendrite outgrowth require microtubule assembly and stabilization. Microtubules and associated motor proteins are also required for the transport of vesicles containing neurotransmitters from the cell body, where they

Figure 5 Comparative rates of microtubule assembly during postnatal brain development in normal (circles) and hypothyroid (triangles) rats. Rates of assembly were measured in brain supernatants containing an equivalent tubulin concentration of 1 mg ml^{-1}. The column shows that injection of TH at birth restores near-normal assembly rates 14 days later. Results are expressed as percentages of maximal values measured in euthyroid rat brain supernatants. Redrawn from Fellous A, Lennon AM, Francon J, and Nunez J (1979) Thyroid harmones and neurotubule assembly *in vitro* during brain development. *European Journal of Biochemistry* 101: 365–375.

are synthesized, to the presynaptic nerve terminals. The rate of microtubule assembly is decreased by TH deprivation during development and restored by TH administration (Figure 5). In contrast, hypothyroidism, when established in adulthood, has no effect on the rate of microtubule assembly. TH also regulates the expression of brain-specific tubulins and of various microtubule-associated proteins (MAPs) that stimulate microtubule assembly. Two major MAPs, tau and MAP2, are axon and dendrite specific, respectively. Juvenile tau and MAP2 splice variants are

produced at early developmental stages and have a much lower assembly-stimulating activity than the adult species. The replacement of immature tau variants by mature forms is regulated by TH at the level of alternative splicing. The expression of MAP2 is also regulated by TH.

TH also regulates axonal outgrowth indirectly by stimulating the expression of neurotrophic factors, such as nerve growth factor (NGF), and their receptors. In turn, NGF stimulates neurite outgrowth and also, as shown in PC12 cell cultures, the expression of tau proteins.

The Auditory System

Hearing is one of the most sensitive functions controlled by TH. Hypothyroidism, in early human development *in utero* or in the neonatal period, presents a risk for deafness. Hearing loss may also arise in 20% of cases of resistance to TH. Evidence in rodent models indicates that T3 acts at several levels in the auditory system from the cochlea and auditory nerve to the auditory centers in the brain stem and cortex. Studies of hypothyroid rodent models indicate that the hormone is required during the first two postnatal weeks, a period that encompasses terminal differentiation in the cochlea and the onset and maturation of auditory function. This period corresponds to a somewhat earlier prenatal/neonatal window in humans and points to the role of TH as a stimulus for the correct onset of auditory function.

TRs are essential for cochlear development with TRβ having the primary role and TRα1 a lesser contribution. TRβ is expressed in the hair cells and supporting cells of the sensory epithelium, the cells that secrete the tectorial membrane, the stria vascularis, spiral ganglion, and other areas. In hypothyroid or TR-deficient mice, the differentiation or function of many of these areas is retarded. There is delayed onset of a potassium current that is thought to allow inner hair cells to mediate high-frequency transduction, and the endocochlear potential is reduced.

The synchronization of these complex events required for the onset of cochlear function is unlikely to be mediated directly by circulating T4 and T3 but rather by type 2 deiodinase which is induced in the cochlea in the postnatal period prior to the onset of hearing in mice. Type 2 deiodinase can convert serum T4 into T3, thereby amplifying local levels of active T3 ligand that trigger TR activity in the cochlea at the appropriate time. The partition of the cochlea into compartments suggests that transporters are important in the uptake of T4 and release of T3 to the responsive cells within the cochlea.

The Color Visual System

The differentiation of cone photoreceptors, the sensory cells that mediate color vision, has only recently been recognized as being dependent upon a TR, based on studies in mice. There had been relatively little previous study of the role of TH in the retina, and the possibility of color blindness has been largely overlooked in human congenital thyroid disorders where the major concern understandably has been with mental retardation. In the mouse retina, TRβ2 is expressed in newly generated cones where it controls the expression of the opsin photopigments that mediate color perception. This is a highly cell-specific role for a TR isoform.

Color vision in most mammals is based upon two opsin pigments that allow the discriminatory detection of short (S, blue) or medium-long (M, green) wavelengths of light. The differential distribution of M and S opsins in cones across the retina is thought to be a prerequisite for color perception. TRβ2-deficient mice have defective medium-long wave responses due to a lack of M opsin (**Figure 6**). All cones instead express S opsin. TRβ2 therefore is necessary for M opsin activation and for restricting the spatial distribution of S opsin in cones across the retina. These studies suggest that a TR is unexpectedly critical for programming the diversification of the cone subtypes that mediate color vision.

The type 3 deiodinase is involved in retinal development. This hormone-inactivating enzyme regulates cell division in the dorsal–ventral axis of the retina in *Xenopus* to control asymmetric development of the retina. The role of deiodinases in cone opsin expression has not yet been reported. However, T3 administration can suppress S opsin expression in cones in the neonatal mouse.

TRβ2 is the most conserved TRβ isoform, and it is found in the retina in a range of vertebrate species, including birds, amphibians, and humans, suggestive of a conserved role in cone photoreceptors. Color visual defects have been noted in rare cases of human resistance to TH. However, the incidence of any color visual deficiencies in this resistance syndrome or other human congenital thyroid disorders has not been investigated systematically and is currently unknown.

Conclusions

Studies in model species suggest that at least three periods exist during CNS development, each characterized by the type of TR that is expressed and by the amount of TH available. At early fetal stages, only TRα1 is expressed, the fetal thyroid gland is inactive,

Figure 6 TRβ2 and cone photoreceptor development in mice. In most mammals, cone photoreceptors differentially express two opsins for sensitivity to short (S, 'blue') or medium-longer (M, 'green') wavelengths of light. Immunostaining detects M and S opsins in the cone outer segments of adult wild-type mice. TRβ2 is expressed in the newly generated cone photoreceptors where it programs the correct pattern of opsin expression. TRβ2-deficient mice lack M opsin and instead all cones express S opsin. With special thanks to Dr. Lily Ng for provision of this picture.

and small amounts of TH are transferred from the mother to the fetus. After the onset of TH production by the fetal thyroid gland at mid-gestation, the production of T3 is low and TRα1 is still the main TR present. Around the time of birth, there is a burst of TH production and an induction of TRβ. It is possible that different genes are controlled by TH during each developmental period.

The timetable of TH action varies between brain regions. Thus, neuronal proliferation is terminated soon after birth in the rodent cortex or cochlea, whereas it ceases later in the cerebellum and hippocampus. During these periods, TH exerts multiple effects via TRα1, TRβ, or both on the expression of genes that allow the formation of the neuronal network, that is, genes involved in establishing the connectivity between neurons and the production of energy for synaptic activity. Finally, terminal differentiation in tissues such as the hypothalamus, pituitary, cochlea, or photoreceptors requires the expression of specific genes regulated by TRβ. In some situations, much of the requisite T3 is produced locally by type 2 deiodinase. Type 3 deiodinase is probably important to protect cells from inappropriate T3 stimulation at certain stages.

The genes regulated by TH are often responsive only for a limited time within each developmental period, perhaps explaining why the multiple defects produced by congenital hypothyroidism are permanent if replacement therapy is not performed as soon as possible after birth. Such changes may also explain why the effects of TH during development and in adulthood are so different. The expression of some genes is not abolished but rather delayed by neonatal hypothyroidism. The temporal sensitivity of TH actions emphasizes the role of TH in the timing and synchronization of development during the construction of the neuronal network and in the process of achieving normal connectivity and behavior.

Tinnitus

P J Jastreboff, Emory University School of Medicine, Atlanta, GA, USA

© 2009 Published by Elsevier Ltd.

Introduction and Definitions

Tinnitus is defined as a perception of a sound that is not related to an acoustic source or electrical stimulation of the auditory pathways. As such it is a phantom auditory perception, that is, a perception of a sound without any corresponding vibratory activity within the inner ear. In this respect it is similar to the phenomena of phantom limb and phantom pain. Perception of phantom sound must last for at least 5 min to be classified as tinnitus since more than 90% of the population occasionally experiences a short perception of a phantom sound that disappears within seconds.

Somatosounds (sounds produced by a body) are sometimes classified as 'objective tinnitus,' in contrast to 'subjective tinnitus,' perceived without corresponding sound. Use of this classification has been criticized because detection of somatosound depends heavily on the equipment used. In this article, the term tinnitus is used to denote a phantom auditory perception.

Tinnitus is not a disease but a symptom triggered by variety of factors. It seems that in the majority of cases, it is linked to a dysfunction of the periphery of the auditory system, and only in approximately 1% of cases it can be associated with some medical problem. Indirect results, however, suggest that the inner ear (the cochlea) does not directly generate the tinnitus signal. For example, cutting the auditory nerve is not an effective method of alleviating tinnitus, and sometimes the perception of tinnitus does not even change. Moreover, in spite of many years of intensive study, there is no compelling evidence of any specific neuronal activity recorded from the auditory nerve of animals which can be clearly linked to tinnitus. This discrepancy could be explained by discordant dysfunction theory, discussed in the section titled 'Models of tinnitus.'

It is important to differentiate two subpopulations of people who have tinnitus. For only a small proportion of people with tinnitus is it bothersome and affects their lives, evoking anxiety, annoyance, panic, problems with concentration, sleep, and so forth. Consequently, it is labeled clinically significant tinnitus as these people need professional help. The effects of tinnitus may reach a profound level, to the point of totally controlling patients' lives and contributing to suicidal tendencies. On the other hand, the majority of people with tinnitus just experience it without any negative consequences.

General Description of Tinnitus Perception

Tinnitus can be perceived as a wide variety of sounds. The most typical descriptions are ringing, hissing, cycads, escaping steam, and roaring. Tinnitus can be intermittent or continuous and may fluctuate in volume or change pitch. It can be perceived in one ear, in both ears, or in the head. The perceived loudness may vary significantly over a period of days.

Examples of tinnitus and somatosounds are presented here. The sounds of tinnitus have been recreated by Dr. Jonathan Hazell, who used a musical synthetizer and interacted with patients until patients stated that the synthesized sound is very close to their tinnitus. In addition, a somatosound recorded in the ear canal of a patient and probably caused by jugular venous flow in the middle ear cavity is included, along with a somatosound from a patient diagnosed with palatal myoclonus.

Epidemiology

Continuous tinnitus is perceived by 10–20% of the general population, with bothersome tinnitus affecting 3–8%. It is estimated that highly debilitating tinnitus exists in about 0.5% of the general population.

Tinnitus occurs in all age groups. Recent data show that prevalence of tinnitus in children is similar to that observed in adults and that when children are bothered by tinnitus, it affects them to the same extent as it does adults. The prevalence of tinnitus perception increases significantly with aging; however, prevalence of the bothersome tinnitus declines for people 65 and older. As prevalence of hearing loss increases systematically with aging and prevalence of bothersome tinnitus decreases for older age groups, this observation argues against a simplistic link between bothersome tinnitus and hearing loss.

Medical Conditions Related to Tinnitus and Somatosounds

Traumatic noise exposure, hearing loss, and head trauma are typically associated with tinnitus. The majority of cases of vestibular schwannoma exhibit tinnitus, and for Ménière's disease, low-pitch roaring, (tinnitus) is an obligatory symptom for diagnosis.

Tinnitus accompany hyperacusis (defined as abnormally strong reactions to sound occurring within the auditory pathways) is present in more than 85% of cases, and hyperacusis is present in 25–30% of tinnitus cases.

It appears that hormonal changes such as those that occur during pregnancy, menopause, or thyroid dysfunction promote tinnitus. Permanent damage of the inner ear typically produces permanent tinnitus, while transient impairment of inner ear function (e.g., resulting from moderate noise overexposure) may yield temporary tinnitus (called 'disco tinnitus'). A long list of medications presumably inducing tinnitus is widely propagated; however, a critical review of the literature reveals that only aminoglycosides and quinine in high doses, some anticancer drugs, and withdrawal from benzodiazepines evoke tinnitus. Tinnitus could be a first indication of ototoxicity and emerges before hearing loss when patients are treated with ototoxic drugs. Salicylates (e.g., aspirin) reliably induce tinnitus in humans, and salicylates are used in animal models to produce tinnitus. As very high doses are needed to induce tinnitus, aspirin is not a significant factor clinically.

Contrary to common belief, there are no clear data proving that any dietary manipulation evokes or relieves tinnitus. Smoking has been associated with increased prevalence of tinnitus, and alcohol in moderation offers some protective effect.

Disorders of the somatosensory system (e.g., temporomandibular joint disorder) have been linked with tinnitus. Indeed, many patients can modulate their tinnitus by performing manipulations of the head and neck areas. Moreover, it is possible to evoke short temporal tinnitus by such manipulations in a significant proportion of people without tinnitus. Recent systematic neurophysiological studies have revealed strong somatosensory input to low levels of the auditory pathways such as the ventral and dorsal cochlear nuclei. It is possible to envision chronic tinnitus resulting predominantly from somatosensory input, but the data supporting such a possibility are limited. Currently, somatosensory modulation is used for research purposes (e.g., in imaging studies) as it offers a possibility of time-locked modulation of tinnitus.

Somatosounds have a variety of sources. Frequently they are related to the cardiovascular system, typically abnormalities of blood flow in the head area that are pulsatile in synchrony with the heartbeat. Nonpulsatile somatosounds could be related to palatal or middle ear myoclonus or a constantly open eustachian tube, resulting in the perception of air flow over its opening. Another interesting case is the rare perception of spontaneous otoacoustic emissions generated in the inner ear.

Measurements

Separate methods are needed for evaluation of tinnitus severity and for delineation of its perception. For tinnitus severity, a variety of questionnaires are used. Psychoacoustic properties of tinnitus are described by pitch match, loudness match, maskability (i.e., minimal level of white noise required to suppress its perception), and postmasking effects (disappearance of tinnitus for a certain time or increase in its loudness). Perceived pitch covers the full range of hearing, and in the majority of cases, tinnitus is perceived in the higher frequency ranges (above 4 kHz). The loudness match determined by psychoacoustic methods is stable for a given patient, disregarding subjective loudness perception. For the majority of patients, tinnitus loudness match is within 15 dB of their hearing threshold for the frequency corresponding to tinnitus pitch. Notably, there is no relation between psychoacoustic characterization of tinnitus and its severity.

A number of physiologic measurements have been tried for objective detection of tinnitus. Evaluation of the specifics of cochlear sound transduction, function of the olivocochlear efferent system, spontaneous activity of the auditory nerve, auditory brain stem responses, and late cortical potentials have failed to provide clear correlates with the presence of tinnitus. Substantial progress has been achieved, however, with positron emission tomography, functional magnetic resonance imaging, voxel-based morphometry, and magnetoencephalography. Strongest results were obtained with magnetoencephalography, which demonstrated changes in tonotopic organization of the auditory cortex in frequency areas corresponding to tinnitus pitch match. Furthermore, the extent of tonotopic map modification correlates with subjectively perceived strength of tinnitus.

Results of imaging studies regarding activation of various parts of the auditory system have frequently been inconsistent with one other. The majority of these studies, however, have shown significant activation of nonauditory structures, particularly the limbic system. Specifically, the auditory thalamus, various parts of the limbic system, the nucleus accumbens, the reticular formation, and the cerebellum have been shown to have changed activity in relation to tinnitus.

Differentiation between Experiencing Tinnitus and Being Bothered by Tinnitus

As tinnitus is a perception of a sound, the auditory system has to be involved. At the same time, there is a lack of correlation between psychoacoustic characterization of tinnitus and its severity or treatment outcome. These observations suggest a need to identify

two different classes of mechanisms: The first is those mechanisms related to generation to tinnitus-related neuronal activity (referred to, for brevity, in this article as the tinnitus signal) and tinnitus perception, which would be common to all people perceiving tinnitus regardless of whether they have a problem with it. The second class of mechanisms, specific to bothersome tinnitus, addresses the issue of how the tinnitus signal evokes negative reactions in the brain and body, resulting in tinnitus' being a problem.

Potential Generators of Tinnitus-Related Neuronal Activity

There is a consensus that in the majority of cases, the peripheral auditory system is involved in tinnitus generation. There is a small percentage of purely central tinnitus, such as occurs after cutting of the auditory nerve or in cases of auditory imagery or musical hallucinations. On the other hand, there is no consensus regarding other aspects of tinnitus-related neuronal activity. A dominant view is that tinnitus perception results from detection of an increase of the spontaneous activity within the auditory pathways. There are data, however, strongly pointing out that actually modification in temporal patterns of discharges, specifically bursting activity, is related to tinnitus and that the increase of spontaneous activity is rather linked to hearing loss, which typically accompanies tinnitus. The synchronization of the activity between neurons has been proposed as well, and although absent at the lower level of the auditory system, it might play some role in the auditory cortex.

The list of main proposed mechanisms of generation of tinnitus-related neuronal activity covers a wide variety of structures and dysfunctions, including hypoxia and ischemia in the cochlea; abnormal neurotransmitter release from the inner hair cells; abnormalities in transduction processes within the cochlea; damage of the auditory nerve; decreased activity of the cochlear efferent system; somatosensory–auditory interaction; neuronal plasticity, cortical reorganization of tonotopic maps, and hypersynchrony of neuronal discharges; enhanced sensitivity of the auditory pathways after decrease of the auditory input; and discordant damage or dysfunction of outer and inner hair cells.

It is expected that for various types of tinnitus, different mechanisms are responsible for tinnitus emergence. Until now none has been proven. While other postulates might be correct, there is growing evidence supporting the last two hypotheses.

Until the late 1980s there was no accepted animal model of tinnitus, and it was difficult to validate proposed hypotheses because of inherent limitations of research on humans. A number of animal models are available now, allowing study of the physiological aspects of tinnitus perception.

Enhanced Sensitivity of the Auditory Pathways and Emergence of Tinnitus after Decreased Auditory Input

It is possible to induce temporary tinnitus in a majority of people just by placing them in a very quiet environment. Moreover, tinnitus gets louder under such conditions. One of the mechanisms potentially involved in both these observations is enhanced sensitivity and increased amplification within the auditory pathways after decreased auditory input. Behavioral data argue that the auditory system (as other sensory systems) works as an automatic gain control system, that is, when input signal is low, then amplification increases, and when input signal is higher, then gain of the system is lowered. In an anechoic chamber, participants hear weak, normally unnoticeable sound, such as heartbeat or the movement of clothes caused by breathing, with all these sounds perceived as being quite loud. Recordings of single-unit activity from various centers of the auditory pathways have shown that the sensitivity of the neurons does indeed increase under conditions of low auditory input or when the inner ear is damaged. Opposite behavioral effects are observed when participants are in noisy environments. Enhanced amplification within the auditory pathways may happen as a result of various reasons and evoke or enhance tinnitus or induce hyperacusis.

Models of Tinnitus

A challenge to modeling tinnitus is the lack of abundant neurophysiological data and the fact that there are likely to be several types of tinnitus, each generated by a different underlying mechanism. A starting point for models is the apparent paradox of a lack of tinnitus-related activity in the cochlea coupled with the presence of sound perception, pointing to a central origin for the generation of tinnitus. The observation that tinnitus often accompanies hearing loss focuses attention on the central auditory pathway. One simple model would propose that a normal balance of excitatory and inhibitory input to some center in the pathway is disrupted by hearing loss. If the disruption is to the inhibitory input, the resulting excitatory input is unbalanced and could lead to tinnitus. This discordant dysfunction theory has been applied to the dorsal cochlear nucleus, a cochlear nucleus subdivision that has abundant interneurons, many of which are inhibitory. Indeed, experimental evidence in animals shows abnormally high 'spontaneous' activity in this center accompanying hearing loss. The particular neural pathways involved remain obscure. The auditory nerve

does provide two types of input to the dorsal cochlear nucleus: type I fiber inputs from the inner hair cells and type II fiber inputs from the outer hair cells. Inner hair cells are contacted by 95% of afferent fibers of the auditory nerve (which are type I, thick, fast, and myelinated), and these cells act as a transducer, converting the vibration of the basilar membrane of the cochlea into electrical impulses within the auditory nerve. Total deafness occurs if all these cells are damaged, even with untouched outer hair cells. Outer hair cells function as a mechanical amplifier, enhancing vibration for the lower half of the range of perceived sound levels by about 60 dB. It is possible to have normal hearing even if 30% of outer hair cells are damaged. Rapid decrease of their function has been associated with an emergence of tinnitus in humans. They are contacted by about 5% of auditory nerve fibers (type II, thin, slow, and unmyelinated). Outer hair cells are preferentially damaged by intense sound exposure. However, both type I and type II inputs are likely to excite their targets in the brain, and thus further inhibitory interneurons, perhaps to one of these pathways within the dorsal cochlear nucleus, would need to be involved to generate unbalanced excitation.

Specifically, the discordant dysfunction theory proposes that when an imbalance of functional properties of outer and inner hair cells occurs, it yields the disinhibition of spontaneous neuronal activity in the dorsal cochlear nucleus, causing a general increase of the spontaneous activity and emergence of bursting, epileptic-like activity, which after further processing within the auditory pathways is perceived as tinnitus. Therefore, while there is no vibratory activity related to tinnitus in the cochlea, the cochlea still may serve as a source of the tinnitus neuronal signal.

The Neurophysiological Model of Tinnitus

Disregarding specifics of mechanisms yielding the presence of the tinnitus signal in the auditory pathways, there is consensus that once it is detected, it is perceived as a sound. Little attention has been given to mechanisms involved in converting tinnitus from benign perception of a sound to a significant problem affecting people's lives. In the past, the dominant approach was through psychology, with no attempt to identify specific neurophysiological structures and mechanisms involved. The neurophysiological model of tinnitus, which attempts to approach tinnitus from the point of view of neuroscience, points out the inherent involvement of the central nervous system (CNS) in tinnitus, and attempts to indicate systems, structures, and the role of specific mechanisms of the brain function in clinically significant tinnitus.

The observation that tinnitus pitch, maskability, and loudness are not correlated at all with tinnitus severity for the population of patients strongly supports the postulate that the auditory system is secondary in clinically significant tinnitus. The neurophysiological model of tinnitus postulates that in the case of bothersome tinnitus, systems other than the auditory system of the brain have to be involved. The limbic and autonomic nervous systems play the major role, and other systems, such as prefrontal cortex and cerebellum, may be involved as well. Furthermore, the model stresses strongly the importance of subconscious processing of the information and the importance of the principles of conditioned reflexes in governing the connections between auditory and other brain systems.

Briefly, tinnitus-related neuronal activity which originates in the auditory system starts to activate other brain systems because of both cognitive assessment of tinnitus and subconscious connections created as the result of one of the principles of conditioning. Temporal association of signal (tinnitus) and reinforcement (annoyance, strong emotional upheaval due to any reason) are sufficient to produce this conditioned reflex. Indeed, a study performed to identify factors most frequently linked to the emergence of clinically significant tinnitus revealed that in a majority of cases, it develops as the result of factors totally irrelevant to hearing, such as retirement, losing a job, divorce, and so forth.

The diagram of the main systems and connections involved in clinically significant tinnitus is presented in Figure 1(a). In cases when people experience tinnitus but are not bothered by it, only the auditory system is activated. Once tinnitus-related neuronal activity spreads to the limbic and the sympathetic part of the autonomic nervous systems, the new functional connections are created, enhanced, and governed to a large extent by the principles of conditioned reflexes. The autonomic nervous system consists of two reciprocally antagonistic parts, the sympathetic and the parasympathetic systems. Activation of the sympathetic system prepares people for physical or mental action, and activation of the parasympathetic system sets the stage for rest and relaxation. Overactivation of the sympathetic system yields stress, anxiety, panic attacks, and the fight-or-flight reaction. All behavioral reactions exhibited by tinnitus patients, such as anxiety, annoyance, panic, decreased ability to enjoy life activities, problems with attention, and problems with sleep, are consistent with activation of the sympathetic system. When the term 'autonomic nervous system' is used in this discussion, it denotes the sympathetic system unless otherwise specified. According to the neurophysiological model of tinnitus, problems

Figure 1 The neurophysiological model of tinnitus. (a) The block diagram outlining structures and connections involved in clinically significant tinnitus. The tinnitus signal, typically generated at the periphery of the auditory system, is detected and processed in subconscious pathways of the auditory system and finally perceived at the auditory cortex. If tinnitus is classified as an important negative stimulus, self-enhancing loops, governed by principles of conditioned reflexes, develop. Note existence of two loops: high, involving consciousness, and low, the subconscious loop. (b) Specific functional connections at which habituation of tinnitus occurs. H_{ER}, habituation of emotional reactions; H_{AR}, habituation of reactions evoked by the autonomic nervous system; H_P, habituation of tinnitus perception. The primary goal of tinnitus retraining therapy is to achieve habituation of reactions; habituation of perception will follow automatically.

arise from proper reaction of the brain to an inappropriate stimulus, that is, the reactions would be appropriate to a life-threatening stimulation, but tinnitus perception results from compensatory action of the auditory system to a situation which does not indicate danger.

The activation of the limbic and autonomic nervous systems by tinnitus signal occurs via two pathways: conscious and subconscious, or high and low loops, respectively (Figure 1(a)). The conscious loop involves high cortical areas, perception, cognition, and verbalization. During the process of development of clinically significant tinnitus, this path is created first. Tinnitus attracts attention, thoughts, concerns, and fears, which activate the limbic and autonomic nervous systems. If these initial thoughts are properly addressed by demystification of tinnitus and its categorization as a neutral stimulus, initial activation of the limbic and autonomic nervous systems is extinguished, and tinnitus does not become a problem. If, however, these thoughts are not addressed properly or, even worse, are enhanced by negative counseling, these connections become stronger, and problems caused by tinnitus are enhanced. The presence of reciprocal connections – signals from the auditory subcortical and cortical areas activating the limbic system and evoking

(negative) emotions – in turn changes reactivity of the auditory centers, causes enhancement of initial connections, and finally results in establishment of strong reactions of the limbic and autonomic nervous systems. These reactions act as negative reinforcement for a conditioned reflexes arc which links the tinnitus-related neuronal activity within the auditory system (conditioned stimulus) with reactions. They enhance cognitive concerns as well as further worsening the problem. Note that the outlined processes by definition involve neuronal plasticity.

At a subconscious level, the tinnitus signal is going through strong functional connections between the medial geniculate body and the lateral nucleus of the amygdala, which is one of the crucial components of the limbic system. This low loop develops after the high loop, it is governed by principles of conditioned reflexes, and it might become dominant in chronic tinnitus. Therefore, because of the presence of the low loop, the activation of the limbic and autonomic nervous systems might occur even without conscious perception of tinnitus. Notably, a signal conveyed via this route cannot be directly modified by conscious thinking, and a method appropriate for retraining of conditioned reflexes would be more appropriate.

Treatments

Treatment of tinnitus is a challenging problem at both the theoretical and the clinical level. Observations of what works and what does not provide some insight into mechanisms of tinnitus. Thousands of years of attempts at treatment (tinnitus was first described in Babylonian clay tablets) have not brought consistently positive results. Only selected treatment methods are outlined.

Suppression or Weakening the Tinnitus Signal

The first class of approaches is aimed at suppressing tinnitus perception temporarily (masking) or partially decreasing it. In neurophysiological terms, total suppression of tinnitus perception would mean that detection of tinnitus-related neuronal activity is prevented by providing the auditory system with another stimulation which would make detection of the tinnitus signal impossible. Attempts to apply this method have revealed that clinically relevant suppression of tinnitus perception in practice can be achieved in only a small percentage of cases. Direct stimulation of the auditory nerve via a cochlear implant increases the effectiveness by about 50%, but this method can be used only by the very small proportion of tinnitus patient who are profoundly deaf. Electrical stimulation applied outside the cochlea has failed to be substantially effective. Direct electrical stimulation of the auditory cortex is under investigation but has failed so far to show superior results.

A weakening of tinnitus-related neuronal activity can be achieved via a variety of methods. The simplest, and the most popular, is by enriching auditory background stimulation, and it is implemented in a wide variety of sound therapy. Two neurophysiological mechanisms are bases for decreasing the strength of the tinnitus signal (i.e., tinnitus-related neuronal activity). First, the strength of any signal depends on its difference with background rather than on its absolute physical value. Second, the sensitivity to sensory signals depends on longer-term average input. Consequently, by an increase of the auditory background, the tinnitus signal is decreased due to the combined action of both mechanisms. The type of sound is in this respect secondary; however, it plays a role because of other factors (e.g., ease of habituation, inherent preference for certain sound levels, emotional and cognitive connotations).

Another class of treatments attempts to modify the tinnitus signal at the central level rather than by stimulation of the periphery. In addition to direct electrical stimulation of the auditory cortex, transcranial magnetic stimulation has been tried recently. Strong pulses of the magnetic field are applied to the skull outside the cortical area to be stimulated. Magnetic field crosses the skull easily and evokes a strong electrical field in the cortex, which in turn stimulates cortical fibers. The effects on the brain function depend on the frequency of stimulation. High frequency evokes direct inhibitory action on the cortical activity, while low-frequency stimulation appears to induce plastic changes in organization of cortical networks and potentially their interaction with subcortical centers. While it is not clear what specific reorganizations occur, this approach has been shown to attenuate tinnitus. The effects are mild, however, and it is not clear whether they are long lasting. Nevertheless, observation that transcranial magnetic stimulation has some impact on tinnitus supports the importance of the modification of the CNS in tinnitus treatment.

Psychological Approaches

Psychological treatments cover a variety of approaches, from simple attempts to distract attention from tinnitus to improved coping and up to behavioral cognitive therapy. Behavioral cognitive therapy seems to be most effective in the class of psychological treatment and is based on the assumption that because thoughts evoke emotions, it is possible by changing thoughts to

modify emotions evoked by tinnitus. There are well-established, effective methods to achieve this goal, and this method is effective in a significant proportion of patients. According to the neurophysiological model of tinnitus, behavioral cognitive therapy nullifies the high loop and therefore decreases stimulation of the limbic and autonomic nervous systems.

Medications

Pharmacological approaches have been tried for a long time and, in spite of their lack of success, are still among the most popular. Some medications aim at the periphery of the auditory system, others at the limbic and autonomic nervous systems to decrease anxiety and annoyance and improve coping. Trials of new pharmacological candidates are ongoing, but so far research has failed to show any drug to be consistently effective for tinnitus.

Tinnitus Retraining Therapy

All treatment methods presented so far aim at modification of tinnitus perception or signal or alleviation of tinnitus-evoked reactions. Tinnitus retraining therapy (TRT) differs in this respect as it aims to retrain the brain to extinguish specific, tinnitus-related functional connections between the auditory and the limbic and autonomic nervous systems and through this mechanism to decrease or remove tinnitus-evoked reactions (Figure 1(b)). TRT attempts to modify neither the source of the tinnitus signal nor the brain centers involved in reacting to it. As a consequence, TRT is independent of the source of the tinnitus signal (tinnitus etiology) and can be used to treat any type of tinnitus.

Briefly, TRT consists of counseling and sound therapy, both strictly based on the neurophysiological model of tinnitus. The goal is to achieve habituation of the tinnitus-evoked reactions, which will be followed automatically by habituation of tinnitus perception (Figure 1(b)). Habituation of reactions is basically identical to the passive extinction of conditioned reactions. TRT uses a modified version of passive extinction of conditioned reflexes in which both the reactions and the stimulus are decreased simultaneously. Habituation of tinnitus can be achieved by a variety of methods. TRT's approach is easily implemented and works on both the tinnitus and the decreased sound tolerance (hyperacusis and misophonia) that frequently coexists with tinnitus.

The role of counseling is to reclassify the tinnitus signal into the category of neutral stimuli, as habituation of any stimulus is difficult when the stimulus has negative connotations and impossible when these associations are very strong. It effectively disrupts the higher loop and decreases stimulation of the limbic and autonomic nervous systems by cognitive processes. In this respect it is similar to behavioral cognitive therapy but uses a different counseling approach.

Sound therapy is the second part of TRT. It aims to decrease the strength of the tinnitus signal through application of a number of guides provided by the neurophysiological model of tinnitus (e.g., use of sound during the night and avoiding annoyance and suppression of tinnitus perception).

Future Goals

It has been argued that tinnitus is a phantom auditory perception and should be analyzed from the point of view of neuroscience rather than by ear-oriented (e.g., otolaryngological or audiological) or mind-oriented (e.g., psychological) approaches. Significant progress in understanding mechanisms of tinnitus and its treatment has been achieved in large part because of the shift from earcentric or black-box approaches to neuroscience. A number of important neurophysiological questions remain, however.

Significant efforts focus on delineating structures in the brain which are involved in the phenomenon of tinnitus. Imaging studies are consistent in indicating involvement of the limbic system and parts of the brain involved in anxiety, but data from the auditory system are much more variable and unclear.

Researchers still debate what tinnitus-related neuronal activity looks like. The dominant belief, that it takes the form of increased spontaneous activity, has been challenged, and it has been proposed that changes in temporal patterns of neuronal dischargers, involving high-frequency, bursting, epileptic-type activity, is in reality a neuronal correlate of tinnitus.

There is even less clarity on the neurotransmitters and receptors involved. Gamma-aminobutyric acid, glutamate, serotonin, and other systems, as well as *N*-methyl-D-aspartate receptors, have been implicated. There are, however, no data proving clear involvement of any of these systems, and drug trials for tinnitus so far argue against a dominant involvement of any of these systems in tinnitus.

Due to obvious limits on research on humans, animal models of tinnitus are extremely important. Since the mid-1980s, when the first valid animal model of tinnitus was introduced, a variety of models have emerged, including most recently a model based on prepulse inhibition of the startle reaction. By acknowledging the crucial involvement of the CNS in tinnitus and combining animal and human research, it should be possible to achieve better understanding of this elusive phenomenon and to find more effective methods for its alleviation.

Published by Elsevier Ltd.

Introduction

Tuberoinfundibular peptide of 39 residues (TIP39) is a neuropeptide discovered in 1999. It is part of an extended family of polypeptide hormones that includes parathyroid hormone (PTH), parathyroid hormone-related protein (PTHrP), secretin, vasoactive intestinal polypeptide (VIP), pituitary adenylate cyclase-activating polypeptide (PACAP), glucagon, glucagon-like polypeptide 1 and 2 (GLP1 and GLP2), glucose-dependent insulinotropic polypeptide (GIP), growth hormone-releasing hormone (GHRH), and corticotropin-releasing hormone (CRH). These peptides act on members of the Family B group of guanine nucleotide binding protein-coupled receptors (GPCRs). Family B receptors share a predicted architecture with other GPCRs, including an extracellular N-terminus, seven membrane-spanning domains that anchor them to the plasma membrane, and a cytoplasmic C-terminus. Family B receptors have few amino acid sequences in common with the largest group of GPCRs, the Family A or rhodopsin-like receptors, or with Family C, which includes the metabotropic glutamate receptors. Family B receptors share a clear but graduated amount of amino acid sequence similarity, a relatively large N-terminus, and a number of highly conserved extracellular cysteine residues. Ligand activation of Family B receptors leads to the stimulation of cyclic adenosine monophosphate (cAMP) synthesis and, in many cases, a tissue-dependent increase in cytoplasmic calcium concentration. TIP39 activates the parathyroid hormone 2 (PTH2) receptor. Quite a bit is known about the structures and neuroanatomical distributions of TIP39 and the PTH2 receptor, but current data provide only hints about their potential physiological functions.

Discovery of TIP39

The discovery of TIP39 stemmed from the identification of the PTH2 receptor. Sequence analysis of receptors for secretin, VIP, and PTH, which were each cloned in 1991, suggested that they formed a distinct receptor family. Sequence identities between the initially described Family B GPCRs were exploited to screen for additional related receptors. In the approach that led to the identification of the PTH2 receptor, a cDNA clone with homology to known Family B receptors was isolated and then introduced into tissue culture cells, which were subsequently screened for stimulation of second-messenger production by a panel of plausible ligands. The PTH2 receptor was so named because it was potently activated by PTH, and not by any of the other potential ligands tested, and because another receptor activated by PTH had been previously described. The first described PTH receptor was isolated from a kidney cell line. It is expressed at relatively high levels in skeletal tissues and kidney, and it clearly mediates the major effects of PTH on mineral homeostasis. It appears not to discriminate between PTH and the distinct protein, PTHrP. Thus, it was originally designated the PTH/PTHrP receptor. It is now also referred to as the PTH1 receptor. The PTH2 receptor was identified in brain-derived cDNA libraries. It is relatively highly expressed in a number of central nervous system areas and at extremely low levels in bone and the kidney.

In contrast to the PTH2 receptor, there have been only a few reports, based on PCR, of PTH mRNA in the rodent brain. Our group failed to detect it using several sensitive techniques. This led to the hypothesis that the brain might contain a different PTH2 receptor ligand. An activity consistent with this possibility was found in an acid extract prepared from bovine hypothalamus. This extract stimulated cAMP production much more potently in tissue culture cells expressing the PTH2 receptor than in their parent cell line or cells expressing the PTH1 receptor. From an antibody-absorption experiment, the activity also appeared to be immunologically distinct from PTH. The ligand specificity of the PTH2 receptor was initially determined using a human cDNA clone. Subsequently, it was observed that PTH was much less potent at the rat PTH2 receptor than at the human PTH2 receptor and that activity present in the hypothalamic extract caused a significantly greater maximal production of cAMP via the rat PTH2 receptor than did PTH. This collection of evidence suggested the existence of an endogenous PTH2 receptor ligand distinct from PTH.

TIP39 was isolated using a classic peptide hormone purification strategy. A crude peptide extract prepared from large (50-kg) batches of bovine hypothalamus was fractionated by a series of chromatography steps. At each stage, fractions containing the activity of interest were identified by their ability to much more potently stimulate cAMP formation in

PTH2 receptor-expressing cells than in similar cells expressing the PTH1 receptor. Once a fraction containing a single major species was obtained, its amino acid sequence was determined using a combination of microscale Edman degradation and mass spectrometry. The sequence was a 39-residue polypeptide without any posttranslational modification. To prove that the sequenced peptide was in fact responsible for the activation of the PTH2 receptor, it was chemically synthesized. Chemically synthesized TIP39 has exactly the properties predicted from the initial crude acid extract. It potently stimulates cAMP production via both human and rat PTH2 receptors, it has little or no effect at PTH1 receptors, it is approximately equipotent with PTH at the human PTH2 receptor, and its intrinsic efficacy is significantly greater than that of PTH at the rat PTH2 receptor (Figure 1).

TIP39, Parathyroid Hormone, and Parathyroid Hormone-Related Protein Form a Discrete Peptide Family

Only bovine TIP39 protein has been purified, but TIP39's sequence has been deduced for human, rat, mouse, zebra fish, fugu, and tilapia using reverse transcription polymerase chain reaction (RT-PCR) and genome sequence analysis. Human and mouse predicted TIP39 transcripts encode a polypeptide of 98 residues composed of a hydrophobic leader sequence followed by a predicted signal sequence cleavage site and then approximately 30-amino-acid residues before two arginine residues (a common endopeptidase cleavage site) that precede the 39-amino-acid peptide that was purified. Mature PTH and PTHrP are polypeptides of approximately 84 and 170 residues, depending on the species and tissue. A 34- or 36-residue N-terminal fragment is sufficient for high-affinity binding to, and activation of, the PTH1 receptor. Using human sequences for reference, 11 of the first 34 residues are identical between PTH and PTHrP. Human TIP39 contains four of the residues shared by PTH and PTHrP and an additional four residues of PTH (Figure 2). Interaction of the C-terminal half of PTH, PTHrP, and TIP39 with their receptors is largely responsible for their high-affinity binding, whereas N-terminal peptide sequences are critical for receptor activation. Most of the residues that TIP39 shares with PTH and PTHrP are within the C-terminal receptor-binding part of the peptide. Although the number of amino acid identities between TIP39 and PTH is small, the peptides are predicted to form nearly superimposible α helices. In addition, although TIP39 completely fails to activate PTH1 receptors and has very low binding affinity, progressively removing

Figure 2 Amino acid sequence alignment of human TIP39 (hTIP), with N-terminal portions of human parathyroid hormone (hPTH) and human parathyroid hormone-related protein (hPTHrP). Standard single-letter amino acid symbols are color coded by functionality. Acidic residues have a red background, basic blue, hydrophobic green, and hydrophilic purple. Residues identical in the three polypeptides are indicated with yellow bars, and additional identities between TIP39 and PTH with orange. In addition to a limited number of amino acid identities between TIP39 and PTH and PTHrP, there is an overall pattern of similar residues. TIP39, tuberoinfundibular peptide of 39 residues.

N-terminal residues increase its affinity for the PTH1 receptor to the point that an analog of TIP39 with its first six residues deleted is a potent competitive antagonist at the PTH1 receptor (6 nM affinity). Thus, TIP39, PTH, and PTHrP form a peptide family with partially overlapping selectivity for the PTH1 and PTH2 receptors.

Two Discrete Groups of TIP39 Neurons Have Widespread Projections

There are two major groups of neurons that synthesize TIP39 (Figure 3). One is at the thalamic-midbrain junction. The distribution of these cells does not fit well within described anatomical borders. They are concentrated near the midline around the subparafascicular nucleus and spread caudo-laterally through the parvicellular subparafascicular nucleus (Figure 3(a)). At the midline, they are intercalated with the A11 group of dopaminergic cells. The TIP39 neurons that extend laterally partially overlap a strip of calcitonin gene-related peptide (CGRP)-containing neurons, but are generally somewhat medial to these cells. There is only a small amount of co-localization of CGRP and TIP39. The second significant group of TIP39 neurons is in the lateral part of the rostral pons, in the medial paralemniscal nucleus (Figure 3(b)). None of the TIP39 neurons contains markers for the classical neurotransmitters glutamate, γ-aminobutyric acid (GABA), acetylcholine, or catecholamines, and their location does not correspond to serotonin-, histamine-, or acetylcholine-synthesizing neurons.

Both groups of TIP39 neurons have widespread and distinct projections (Figure 4). The subparafascicular TIP39 neurons have more anterior projections, including to specific parts of the cerebral cortex, deep forebrain structures, amygdala, thalamus, and hypothalamus. Neurons in most of these areas also send projections to the areas of TIP39 neuron concentration. In general, these areas can be categorized as part of the limbic system or involved in autonomic or endocrine regulation. The TIP39 neurons in the medial paralemniscal nucleus have more caudal projections, including several midbrain, pontine, and brain stem regions, as well as some that descend into the spinal cord. Many of the areas that receive projections from paralemniscal TIP39 neurons are involved in processing auditory information.

There is an excellent correlation between the distributions of TIP39- and PTH2 receptor-containing fibers (Figure 5). Antibodies to both TIP39 and the PTH2 receptor label neuronal fibers and terminals much more strongly than cell bodies. Stronger labeling of processes suggests that most of these proteins are transported out of the their cell bodies and function in axonal terminals or dendrites. Many areas of TIP39 concentration are far removed from TIP39-synthesizing cell bodies. TIP39 disappears from fibers and terminals following lesions that damage the areas of cell body concentration, and microinjections of neuronal tract-tracing agents prove the actual axonal projections of TIP39 neurons. Neurons that synthesize PTH2 receptors are spread much more widely than TIP39-synthesizing neurons. Many areas contain both PTH2 receptor-synthesizing cell bodies, identified by *in situ* hybridization detection of mRNA, and PTH2 receptor-containing fibers, identified by antibody labeling. Thus, it is less clear whether the PTH2 receptor functions in dendrites, nerve terminals, or both because the PTH2 receptor-containing fibers near PTH2 receptor-synthesizing cell bodies could be dendrites, local axonal arborizations, or projections of distant neurons. Immunohistochemical double-labeling shows a co-localization of PTH2 receptors and a vesicular glutamate transporter (VGLUT2). Because VGLUT2 functions to package glutamate into secretory vesicles, this suggests a presynaptic, nerve terminal, localization of PTH2 receptors.

TIP39 Expression Decreases and Becomes Sexually Dimorphic during Postnatal Development

In rat, TIP39 expression can be detected within a few days of birth, and at this time it has a distribution essentially like that seen in older animals. The level of expression increases until around postnatal day 14, and it rapidly decreases after this (Figure 6). The expression of TIP39 in males and females is not obviously different until it starts to decline. The

Figure 3 Rat brain distribution of TIP39 neurons: (a) sagittal slice, subparafascicular area (inset scale bar = 1 mm); (b) sagittal slice, medial paralemniscal nucleus (inset scale bar = 1 mm); (c) coronal slice, subparafascicular area (scale bar = 1 mm); (d) drawing in the coronal plane, medial paralemniscal nucleus; (e) photomicrograph, corresponding to the framed area in (d), with fluorescent immunolabeling (scale bar = 500 μm); (f) horizontal section with fluorescent immunolabeling, posterior intralaminar complex of the thalamus (scale bar = 500 μm). In (a–b), immunolabeling for TIP39 is shown in sagittal rat brain sections. The framed areas are magnified in the insets to more clearly show labeled cell bodies. In the medial part of the subparafascicular area (a), the TIP39 cell group has a sigmoid shape in sagittal sections. TIP39 neurons are distributed around the magnocellular subparafascicular nucleus between the midline and the fasciculus retroflexus in the periventricular gray of the thalamus, an area that has no obvious histological distinction from the more caudal periaqueductal gray. In (e), paralemniscal TIP39 neurons are located above the rubrospinal tract immediately medial to the lateral lemniscus in the rostral pons. In (f), the laterally located TIP39 neurons are continuous with the medial subparafascicular area near the middle of its sigmoid shape. TIP39 neurons are located in the parvicellular subparafascicular nucleus below the fasciclus retroflexus. A long line of TIP39 neurons that reaches the medial part of the medial geniculate body is situated further caudo-laterally in the posterior intralaminar complex of the thalamus. 3V, third ventricle; 5n, trigeminal nerve; DpMe, Deep mesencephalic nucleus; fr, fasciculus retroflexus; IC, inferior colliculus; ll, lateral lemniscus; MB, mamillary body; MGB, medial geniculate body; ml, medial lemniscus; PAG, periaqueductal gray; pc, posterior commissure; PIL, posterior intralamniar nucleus of the thalamus; PL, medial paralemniscal nucleus; py, pyramidal tract; rs, rubrospinal tract; scp, superior cerebellar peduncle; SPF, subparafascicular area; SPFp, parvicellullar subparafascicular nucleus; TIP39, tuberoinfundibular peptide of 39 residues; VPM, ventral posteromedial thalamic nucleus; ZI, zona incerta. (a, b) Modified from Usdin TB, Dobolyi A, Ueda H, and Palkovits M (2003) Emerging functions for tuberoinfundibular peptide of 39 residues. *Trends in Endocrinology and Metabolism* 14: 14–19. (c–f) Modified from Dobolyi A, Palkovits M, and Usdin TB (2003) Expression and distribution of tuberoinfundibular peptide of 39 residues in the rat central nervous system. *Journal of Comparative Neurology* 455: 547–566.

decrease is greater in males than in females, so adult females have significantly greater expression of TIP39 than adult males. After rats are approximately 3 months old, it becomes difficult to detect TIP39 in males, and female levels are dramatically lower than in younger animals. The developmental pattern is similar in the subparafascicular and paralemniscal TIP39 neurons. Postpubertal gonadectomy has no

Figure 4 Projection of TIP39 neurons. The major target areas of the subparafascicular TIP39 neurons (SPF) are the medial prefrontal (MPF), insular cortex (Ins), and ectorhinal cortex (Ect), lateral septum (LS), the amygdala (Amy; in particular the central amygdaloid nucleus, amygdalo-striatal transitional zone, posterodorsal medial amygdaloid nucleus, and amygdalo-hippocampal transitional zone), bed nucleus of the stria terminalis (BST), hypothalamus (Hyp; in particular the preoptic area, paraventricular and dorsomedial hypothalamic nuclei, lateral and posterior hypothalamic areas, and arcuate and ventral premamillary nuclei), and paraventricular thalamic nucleus (PVT). The periaqueductal gray (PAG; particularly its lateral part) and the medial geniculate body (MGB; mostly its medial nucleus as well as the adjacent suprageniculate, posterior intralaminar thalamic, and peripeduncular nuclei) receive significant projections from both the subparafascicular area and the medial paralemniscal nucleus (PL). The medial paralemniscal nucleus also projects to the superior colliculus (SC; mostly its deep layers), inferior colliculus (IC; mostly its external cortex), parabrachial nuclei (PB), periolivary area (POA), and subcoeruleus area (SCA). TIP39, tuberoinfundibular peptide of 39 residues.

effect on TIP39 expression. Gonadectomy at postnatal day 26 (which is before puberty) decreases the postpubertal decline, but does not eliminate it or remove the sexual dimorphism. There is not yet any experimental data addressing the significance of the developmental decline in TIP39 expression, but the timing and gender difference suggest that TIP39 may be involved in functions related to reproduction.

Initial Investigations of TIP39 Function

The anatomical distributions of TIP39 and the PTH2 receptor provide some hints about their possible functions. Some of these possibilities have been investigated by the administration of synthetic TIP39 *in vivo* or its addition to primary cell cultures. It should be emphasized that the number of these studies is small and that the concentration, spatial distribution, and timing of TIP39 delivery in these experiments is nonphysiological. These experiments do provide some intriguing suggestions for possible functions of endogenous TIP39 that can be followed up with other types of experiment.

Effects of TIP39 in Pain Assays

There is intense labeling in the outer layers of the dorsal horn of the spinal cord and the spinal trigeminal tract by an antibody to the PTH2 receptor (Figure 7). Most primary afferent (dorsal root ganglion) neurons concerned with pain perception project to this area. *In situ* hybridization detection of PTH2 receptor mRNA suggests that the PTH2 receptors in this zone are contributed by both a local population of intrinsic spinal cord neurons and a population of dorsal root ganglion neurons. Microinfusion of TIP39 into a mouse paw causes a withdrawal response, consistent with the activation of nociceptive sensory neurons. Although not yet demonstrated, this suggests that PTH2 receptors are present in the peripheral terminals of some sensory neurons. Consistent with this, TIP39 stimulates cAMP accumulation in a dorsal root ganglion-derived hybrid cell line (F11) and causes an increase in cytoplasmic Ca^{2+} concentration in some of the cells in dorsal root ganglion primary cultures. Intrathecal injection of TIP39 causes a scratching, biting, and licking response that is characteristic of pronociceptive peptides such as substance P and CGRP. Intrathecal administration of TIP39 also potentiated the responses in several spinally mediated pain assays, including the tail-flick test, and paw withdrawal from pressure. It did not change the response in the hot plate test. These results suggest that the activation of the PTH2 receptor facilitates some aspects of pain perception. In striking congruence with this, intrathecal administration of an antibody to TIP39 increased the response threshold in the same tests as those in which the sensitivity was increased by TIP39. A simple interpretation of this observation is that TIP39 release is provoked by the stimuli used in these pain assays, that it contributes to the normal response, and that antibody sequestration of TIP39 removes this pro-nociceptive influence. However, only a small number of

Figure 5 Labeling with antibodies at the level of the tuberal region of the rat hypothalamus in coronal sections: (a) PTH2 receptor distribution; (b) TIP39 distribution. Scale bar = 500 μm. A similar distribution of immunolabeling can be observed in most areas. As shown in (a), PTH2 receptor immunolabeling is more intense in the ventromedial hypothalamic nucleus, arcuate nucleus, and median eminence. The micrograph in (a) is saturated in the arcuate nucleus and the median eminence to demonstrate the labeling in other regions. 3V, third ventricle; AHp, anterior hypothalamic nucleus, posterior part; Arc, arcuate nucleus; CA, central amygdaloid nucleus; Ect, ectorhinal cortex; f, fornix; ic, internal capsule; LA, lateral amygdaloid nucleu; LH, lateral hypothalamic area; MA, medial amygdaloid nucleus; me, median eminence; mt, mamillothalamic tract; ot, optic tract; parathyroid hormone (PTH); sd, paraventricular thalamic nucleus; TIP39, tuberoinfundibular peptide of 39 residues; Re, reuniens nucleus; VMH, ventromedial hypothalamic nucleus; ZI, zona incerta. TIP39-containing nerve fibers have been observed in the spinal cord. Further investigation is required to determine whether TIP39 released from these fibers has a significant physiological role.

PTH2 receptors are also found in several brain areas involved in pain perception, particularly in several midline thalamic nuclei that are thought to be involved in processing the emotional aspects of pain perception. The Place Escape Avoidance Paradigm (PEAP) is a test designed to evaluate an affective (emotional) aspect of nociception. Rats are placed in a chamber with light and dark halves. When they are in the dark half, which they normally prefer, an inflamed hindpaw is stimulated with a blunt probe and when they are in the normally less-preferred light half of the chamber, the noninflamed hindpaw is stimulated. When a drug is administered, its effect on the proportion of time an animal spends in the two halves of the chamber is used as a measure of the drug's effect on the aversive quality of the stimulus. Intracerebroventricular administration of TIP39 decreased the apparent aversiveness of stimulation of an inflamed paw. This effect is opposite in direction to the pro-nociceptive effects of TIP39 observed in spinal-based tests following intrathecal administration of TIP39. Although there is not yet a physiological or mechanistic explanation for these observations, it may be relevant that TIP39-containing fibers in the spinal cord arise from the medial paralemniscal nucleus, whereas subparafascicular TIP39 neurons project to midline thalamic and other brain areas that may be involved in affective aspects of nociception. TIP39 arising from these two areas may have different biological functions.

Figure 6 TIP39 expression is age- and gender-dependent: (a) postnatal day (PND) 14, male; (b) PND 57, male; (c) PND 125, male; (d) PND 14, female; (e) PND 57, female; (f) PND 125, female. Scale bar = 200 μm. Dark-field photomicrographs of TIP39 *in situ* hybridization signals in the subparafascicular area demonstrate that TIP39 mRNA levels decrease during postnatal development and are higher in adult females than males. The changes in *in situ* hybridization signal are consistent with data obtained with TIP39 immunolabeling and quantitative reverse transcription polymerase chain reaction (RT-PCR). In addition, similar changes take place in the medial paralemniscal nucleus. 3V, third ventricle; fr, fasciculus retroflexus; TIP39, tuberoinfundibular peptide of 39 residues. Modified from the Dobolyi A, Wang J, Irwin S, and Usdin TB (2006) Postnatal development and gender-dependent expression of TIP39 in the rat brain. *Journal of Comparative Neurology* 498(3): 375–389.

TIP39 Modulation of Hypothalamic Function

PTH2 receptors are present in several medial hypothalamic areas, including the periventricular, paraventricular, arcuate, dorsomedial, and ventromedial nuclei, as well as the median eminence. Several experiments have investigated effects of TIP39 on the secretion of hypothalamic-releasing factors. The results are not entirely consistent, but each of the experiments suggests a role for TIP39 in hypothalamic function. In one experiment, intracerebroventricular administration of TIP39 decreased the episodic increases in serum growth hormone that occur in male rats. The anatomy suggests that this may have occurred via increased somatostatin action on pituitary growth hormone cells following activation of PTH2 receptors that are highly expressed on periventricular somatostatin cells. In an experiment performed by a different group of investigators, the addition of TIP39 to acute hypothalamic slice cultures stimulated release of several hypothalamic hormones (CRH, VIP, gonadotropin-releasing hormone, and GHRH) but not thyrotropin-releasing hormone or somatostatin. The release of CRH was particularly striking in this experiment because the effect of TIP39 was as large as that evoked by depolarization with potassium. Intracerebroventricular administration of TIP39 was reported to increase plasma adrenocorticotropic hormone and leutenizing hormone but to have no effect on growth hormone, prolactin, or thyroid-stimulating hormone. A third group of investigators has provided evidence that brain delivery of TIP39 inhibits vasopressin secretion and that it has a particularly strong effect on dehydration-induced vasopressin release. The differences in the reported effects of TIP39 may result from differences in experimental procedures, such as periodic sampling from individual animals versus single pooled determinations, different dosages, and effects in acute slices versus intact animals.

TIP39 Has Effects in Animal Models of Anxiety and Depression

Areas of PTH2 receptor and TIP39 concentration such as the prefrontal cortex, septum, bed nucleus

Figure 7 PTH2 receptor expression in the lower brain stem and spinal cord: (a) antibody labeling of the PTH2 receptor in the spinal trigeminal tract; (b) section of the spinal cord with an attached dorsal root ganglion. In (a), sensory fibers of the trigeminal nerve that convey information related to pain from the face have their first synapses in the spinal trigeminal tract where gold-colored labeling indicates the presence of PTH2 receptors in nerve fibers. This region is equivalent to the dorsal horn of the spinal cord. In (b), clusters of silver grains from *in situ* hybridization detection of PTH2 receptor mRNA indicate the cells both in the outer part of the dorsal horn of the spinal cord and in the dorsal root ganglia, as well as a few deeper spinal cord cells that synthesize PTH2 receptors. Parathyroid hormone (PTH).

of the stria terminalis, and several amygdaloid nuclei may be relevant to affect and anxiety. Intracerebroventricular delivery of TIP39 had no obvious effect on locomotor activity. It does increase the number of open-arm entries in the elevated plus-maze test, the type of response produced by anxiolytic drugs. It also decreased the amount of time that rats were immobile and increased the amount they spent attempting to escape in the forced swim test, the type of effect that antidepressant drugs produce.

Summary

TIP39 is a neuropeptide synthesized by two highly localized groups of neurons, in the subparafascicular area and the medial paralemniscal nucleus. These cells project to distinct areas distributed throughout the central nervous system. There is strong evidence suggesting that TIP39 is a natural ligand for the PTH2 receptor. The PTH2 receptor is a member of the B Family of GPCRs. Like other members of this family, its activation leads to an increase in intracellular cAMP and sometimes also intracellular Ca^{2+} concentration. The PTH2 receptor is primarily localized on presynaptic nerve terminals of glutamatergic neurons. Thus, the physiological function of TIP39 may be to facilitate glutamate release in the areas to which it projects. Preliminary data hint at roles for TIP39 and the PTH2 receptor in the modulation of some aspects of pain sensation, auditory perception, control of pituitary hormone secretion, mood, anxiety, and reproductive behavior. Major questions remain regarding the stimuli that activate TIP39 neurons and the biological significance of TIP39 action.

Topographic Maps: Molecular Mechanisms

A C Lin and C E Holt, University of Cambridge, Cambridge, UK

Topographic maps are a widespread organizing feature of the central nervous system, especially in early sensory processing, whereby spatial relations between cells are preserved between the projecting set of neurons and the receiving set. That is, neighbors in the projecting set connect to neighbors in the receiving set. The effect is that neurons in higher circuits are arranged in a 'map' representing spatial or frequency information about the external world. As information moves toward higher processing centers, it remains organized topographically, so that, for example, neighboring columns of the visual cortex process information from neighboring areas of the visual world, and neighboring columns of the auditory cortex process sounds of similar frequencies.

Ongoing work has revealed two major themes in topographic map development. First, axon guidance cues and their receptors are expressed in gradients in the projecting and receiving layers, which guide projecting axons into a crude topographic map. Second, this crude map is then refined by activity-dependent remodeling of axonal projections, in which neural activity in the projecting layer leads to the elimination of axonal projections not well correlated with their neighbors. This article focuses mainly on the retinotectal projection because it is by far the best characterized of the topographic maps, but reference is also made to other systems, where the same general principles apply.

The Purpose of Topographic Maps

At first glance, it might be unclear why sensory processing is organized topographically. There is no homunculus 'viewing' a projection of the outside world inside the brain, and it would seem that it is the pattern of connections that matters for information processing, not whether neurons processing neighboring stimuli in the external world are neighbors themselves. However, the topographic organization of sensory processing does have important functional benefits. Much of sensory processing relies on comparing neighboring stimuli, most notably in center-surround receptive fields that allow the visual system to analyze edges and motion. The spatial proximity of neurons that respond to neighboring stimuli makes this kind of processing more efficient, since the transmission of action potentials is costly in both energy and time. In addition, some diffusible cues, like nitric oxide, rely on near-neighbor relations. Some circuits rely directly on axon length for processing; for example, the auditory system calculates interaural time difference using coincidence detectors with the delays inherent in action potential transmission to determine how long the sound from one ear must be delayed to match the timing of the sound from the other ear. In this case, the spatial arrangement of cell bodies relates directly to circuit function.

Perhaps more importantly, topographic mapping is efficient developmentally. An arbitrary spatial arrangement of neurons and their synapses, though theoretically possible, would require every connection to be specified individually, a daunting prospect in an organism with billions of neurons and trillions of synapses but only a few tens of thousands of genes. In contrast, topographic mapping allows axonal targets to be determined with only a few broad gradients and activity-dependent refinement of projections (see below). That is, the mechanism of topographic map formation may itself be the functional rationale behind topographic maps.

Historical Perspective

The topographic organization of sensory processing has been recognized since the nineteenth century, but the mechanism by which maps are established was debated until Roger Sperry's classic experiments in the 1940s and 1950s led to his proposal of the 'chemoaffinity hypothesis.' Using the regenerative capacity of amphibian nervous systems, Sperry severed frog optic nerves and allowed the retinal axons to reinnervate their target, the optic tectum (OT). Even if the optic nerve was artificially scrambled or if the eye was rotated 180°, axons always regrew to the correct targets according to the original topographic map. Strikingly, if the eye was rotated 180°, the frog behaved as if its visual world was upside down, as if the formerly 'top' part of the eye, now on the bottom, reconnected to the 'top' part of the retinotopic map in the tectum. These classical experiments argued for the 'chemoaffinity hypothesis,' that axonal connections are specified by complementary molecular identification tags on the axon and its target. To overcome the problem that there could not be enough molecules to mark each cell individually, Sperry proposed overlapping and orthogonal gradients to mark each cell with its 'latitude and longitude.' This combinatorial code would provide each cell with a unique molecular identity defined by expression levels of each tag. This model has been broadly validated with some

modifications (see below) in the last decade with the identification of these molecular tags, especially the Ephs and ephrins.

Axon Guidance Cues in Topographic Mapping

Ephs and Ephrins

The axon guidance cues most involved in topographic mapping are the ephrins and the Eph receptor tyrosine kinases. The Eph receptors (discovered in an erythropoietin-producing hepatocellular cell line) form the largest subfamily of receptor tyrosine kinases and are divided into two classes, EphA and EphB. Their ligands, the ephrins (Eph-receptor interacting proteins), are similarly divided into two classes, ephrinA and ephrinB; generally, EphAs bind ephrinAs while EphBs bind ephrinBs. EphrinAs are glycosylphosphatidylinositol (GPI)-linked to the membrane, while ephrinBs are transmembrane proteins. In addition to 'forward signaling' from ligand to receptor, ephrins are also capable of 'reverse signaling' from receptor to ligand, most clearly with ephrinBs through their intracellular domain, but potentially also with ephrinAs through an unknown mechanism. Ephrins and Ephs can be both attractive and repulsive guidance cues, but function only when membrane bound, suggesting that they guide axons through contact attraction or repulsion rather than long-range guidance.

Nasal–Temporal Mapping in the Retinotectal Projection

Retinal ganglion cell (RGC) axons project onto the OT in nonmammalian vertebrates (the 'retinotectal' projection), and onto the superior colliculus (SC) in mammals (the 'retinocollicular' projection). In both cases, the projection is topographic, such that nasal axons project posteriorly, and temporal axons project anteriorly (Figure 1). (For simplicity, this article refers to the retinotectal projection, with the understanding that similar principles apply in the retinocollicular projection.) Retinotectal topography can be observed by recording receptive fields of tectal neurons to see which part of the retina they respond to, and by anterograde and retrograde tracing, where a lipophilic dye is injected into the retina or tectum, to see which part of the other layer is connected by RGC axons.

Classic experiments by Bonhoeffer and colleagues in the 1980s using the 'stripe assay' showed that temporal axons were selectively repelled by membranes from the posterior tectum. Retinal axons were allowed to grow on alternating stripes of membranes from anterior and posterior tectum. Temporal axons grew only on anterior stripes, while nasal axons grew indiscriminately (Figure 2). The directed growth of temporal axons was due to repulsion from posterior stripes rather than attraction to anterior stripes, because heat inactivation of posterior membranes alone abolished the striped outgrowth pattern, while heat inactivation of anterior membranes had no effect. These findings confirmed the central principle of the chemoaffinity hypothesis, but with a surprising twist – instead of the prevailing idea of attraction between matching tags on axons and their targets, these findings suggested repulsion between axons and inappropriate targets.

Eventually, ephrinA2 and ephrinA5 were identified as the critical ligands in the tectum, and EphA5 and EphA6 (EphA3 in chick) as the receptors in RGCs. EphA receptors are expressed in a low nasal to high temporal gradient in RGCs, while EphrinAs are expressed in a low anterior to high posterior gradient in the tectum (Figure 1(d)). The same principle holds in another retinal target in mammals, the dorsal lateral geniculate nucleus (dLGN) in the thalamus, where ephrinA2 and ephrinA5 are expressed in a high ventral–lateral–anterior to low dorsal–medial–posterior gradient (see Figure 4(b)). Knocking out or mis-expressing ephrinA2/A5 disrupts retinotectal topography, though some retinotopy remains intact, suggesting that other molecules are involved (see below).

In the tectum, ephrinA expression is thought to be patterned by the transcription factor Engrailed-2, which, like the ephrinAs, is expressed in a low anterior to high posterior gradient. In the retina, the nasal–temporal axis is patterned by the transcription factors BF1 (expressed nasally) and BF2 (expressed temporally), and SOHo1 and GH6 (expressed nasally). SOHo1 and GH6 repress EphA3 expression in chick, suggesting a mechanism by which a low nasal to high temporal gradient of EphA expression is created.

RGCs also express ephrinAs themselves, in a high nasal to low temporal gradient (Figure 1(d)). EphrinA5 has been shown to silence EphA3 responsiveness through *cis*-interactions when the two are co-expressed (i.e., interactions on the same cell, as opposed to *trans*-interactions between ephrinA and EphA on different cells), suggesting that ephrinA expressed on nasal axons could silence what little EphA receptor they do have. Thus, the counter-gradient of ephrinA may enhance the gradient of EphA signaling in RGCs. Also, it has been suggested that ephrinA expressed by early-arriving retinal axons might sharpen the tectal ephrinA gradient, because nasal axonal arbors in the posterior tectum would express high ephrinA on top of tectal ephrinA, while temporal axonal arbors in the anterior tectum would express low ephrinA.

Figure 1 (a) Schematic of nasal–temporal and ventral–dorsal retinal axes. (b) The retinocollicular projection: ventral view of the human brain, showing the retina, lateral geniculate nucleus (LGN), and superior colliculus (SC). (c) The retinotectal projection: lateral view of a *Xenopus* embryo, showing the retina and tectum. (d) Schematic of retinotectal/retinocollicular topography and gradients of guidance cues and their receptors. Dorsal tectum in *Xenopus* corresponds to medial tectum in chick and medial SC in mouse; ventral tectum in *Xenopus* corresponds to lateral tectum/SC in chick and mouse.

Initially, tectal ephrinAs were thought to be purely repulsive. In this model, temporal axons expressing high levels of EphA receptor are repelled by the high levels of ephrinA in the posterior OT/SC and therefore remain in the anterior tectum, while nasal axons expressing low levels of EphA receptor are unaffected by ephrinA and continue to grow into the posterior OT/SC. Axon–axon competition and a hypothetical opposing gradient would explain why all axons did not simply crowd into the anterior tectum. (For a review of computational models of molecular gradients in retinotopic mapping, see 'Further reading.')

However, recent findings suggest that ephrinAs have concentration-dependent biphasic effects. EphrinA2 promotes *in vitro* retinal axon outgrowth at low concentrations and inhibits it at high concentrations, with the tipping point between positive and negative effects for a particular axon varying depending on its nasal–temporal position. Nasal axon growth is promoted by ephrinA2 up to a higher concentration than temporal

Figure 2 The stripe assay. Membranes from anterior (white) and posterior (green) tectum are laid down in alternating stripes, and retinal pieces are explanted on them so that axons will grow over the stripes. Temporal axons avoid posterior membrane stripes, whereas nasal axons grow indiscriminately. Temporal selectivity is abolished by heat inactivation of posterior membranes, but not anterior membranes.

axons. Each axon therefore terminates around the tipping point between a positive and negative response to ephrinAs. Another molecule mediating biphasic guidance is Engrailed-2. In addition to its role in transcriptional regulation of tectal ephrinA levels, Engrailed-2 attracts nasal axons but repels temporal axons. Unlike ephrins, Engrailed-2 passes directly into growth cones *in vitro* and may function by binding to intracellular signaling molecules rather than receptors; presumably, nasal and temporal growth cones differ in these intracellular molecules.

In frogs and fish, ephrin gradients act by controlling how far posterior the growing RGC axons extend: RGC axons grow 'up' an ephrinA gradient, and depending on how much EphA receptor they express, they stop at a certain zone, which becomes the target. In contrast, in birds and mammals, axons substantially overshoot the target (though still biased toward the target), and the critical step for topographic mapping is selective interstitial branching near the target zone (Figure 3). This difference may be due to species differences in size and developmental timing: frog and fish RGC axons innervate the tectum early, when it is still very small (150–200 μm), and both the retina and tectum continue to grow as the retinotopic map is refined. In contrast, the OT in chick and SC in mouse are relatively large (10 000 μm in chick, 2000 μm in mouse) when RGC axons arrive and do not grow substantially during map refinement. In addition to mediating retinal axon extension, EphAs and ephrinAs are thought to mediate selective interstitial

Figure 3 In frogs and fish, axons stop growing near the eventual target zone (gray circle) and arborize there. In contrast, in birds and mammals, axons considerably overshoot the target zone and selectively grow interstitial branches at the target zone. This difference may be due to the vastly different sizes of the tectum/SC between the two cases (bars).

branching by blocking branching posterior to the target zone. As with axon extension, branching anterior to the target may be blocked by axon–axon competition or by ephrinA biphasic action, in which branches need a certain threshold of ephrinA (attractive at low concentrations) to grow.

A straightforward nasal–temporal mapping only applies to organisms with mostly monocular vision, where each retina projects mainly to the contralateral OT. In organisms with binocular vision, such as humans, each retina projects to both sides of the brain. In the right retina, for example, the nasal half projects to the left side of the brain while the temporal half projects to the right side. Each retina therefore needs two topographic maps, and, indeed, the human embryonic retina displays a bidirectional high central to low nasal/temporal gradient of EphA receptors, while the dLGN displays a complementary gradient of ephrinAs (Figure 4). Remarkably, this finding was predicted by Sperry almost half a century ago.

Dorsal–Ventral Mapping in the Retinotectal Projection

Retinal axons also map topographically in the dorsal–ventral dimension. Dorsal RGCs map to the ventral tectum (lateral tectum in chick, SC in mouse), whereas ventral RGCs map to the dorsal tectum (medial tectum/SC). Until recently, dorsal–ventral mapping was poorly understood compared to anterior–posterior mapping, but in the last few years it has been shown that dorsal–ventral mapping is established by ephrinBs and EphBs, as well as Wnt-3 and its receptors Ryk and Frizzled.

EphrinBs are expressed in a high dorsal to low ventral gradient in both the retina and the tectum, while EphBs are expressed in high ventral to low dorsal gradients (Figure 1(d)). Like EphAs, retinal gradients of ephrinBs and EphBs are set up by transcription factors – Vax2 (expressed ventrally) and Tbx5 (expressed dorsally). Ventral Vax2 represses ephrinB expression, to create the high dorsal to low ventral ephrinB gradient, while dorsal Tbx5 represses EphB expression, to create the high ventral to low dorsal EphB gradient.

In frogs, reverse signaling by EphBs in the tectum onto ephrinBs in RGCs mediates dorsal–ventral mapping: ephrinB-expressing dorsal axons are attracted to EphB-expressing cells in the ventral tectum. Ectopic expression of ephrinB in ventral RGCs shifts their tectal projections ventrally, while expression of dominant-negative ephrinB in dorsal RGCs shifts their projections dorsally. Chick and mouse dorsal–ventral mapping appears to be achieved by forward signaling from tectal ephrinBs to RGC EphBs: interstitial branches of EphB-expressing ventral axons are attracted to ephrinB-expressing cells in the medial tectum/SC. Knocking out EphB2 and EphB3 in mice causes axonal branches to project too far laterally.

In chick and mouse, the counteracting force that pulls axons toward the lateral tectum/SC is created by a Wnt-3 gradient as well as biphasic action by

Figure 4 Schematic of retinotopic mapping in organisms with binocular vision. (a) Nasal axons cross at the optic chiasm to the contralateral side of the brain, while temporal axons project to the ipsilateral side, so that each side of the brain processes the contralateral half of the visual field. (b) Topographic mapping between the retina and the dLGN is achieved by a bidirectional high central to low nasal/temporal gradient of EphAs in the retina and a high ventral to low dorsal gradient of EphrinAs in the dLGN.

ephrinB. Wnt-3 is expressed in a high medial to low lateral gradient in the tectum. The receptor Ryk, which mediates repulsive responses to Wnt-3, is expressed in a high ventral to low dorsal gradient in the retina, while the receptor Frizzled, which mediates attractive responses to Wnt-3, is expressed evenly in the retina (Figure 1(d)). The Ryk-mediated repulsive response and Frizzled-mediated attractive responses both drive interstitial branches laterally: high-Ryk-expressing ventral axons are repelled by Wnt-3 while low-Ryk-expressing dorsal axons are attracted to low Wnt-3 levels (such as those in the lateral tectum), though still repelled by high Wnt-3 levels. This lateral-driving effect of Wnt3 counteracts the effect of ephrinB, which attracts axons medially. EphrinB itself may also have biphasic effects; in chick, high levels of ephrinB can be repulsive, indicating that axons from a given DV retinal position have an 'optimum' level of ephrinB that their interstitial branches grow toward.

Guidance Cue Gradients in Other Topographic Maps

Although the role of guidance cue gradients in topographic mapping has been most thoroughly studied in the retinotectal projection, similar principles apply in other sensory projections, including a role for ephrins and Ephs. In the thalamocortical projection, ephrinAs and EphAs play double roles (Figure 5). In early development, EphA receptors are expressed in a high anterior to low posterior gradient in the thalamus, and ephrinAs are expressed in a high posterior to low anterior gradient in the ventral telencephalon. Thalamic axons pass through the ventral telencephalon en route to the cortex, so this initial mapping step sorts them into cortical areas. For example, axons from the anterior thalamus end up in the anterior cortex, in the motor cortex, while axons from more posterior regions of the thalamus end up more posteriorly in the cortex, for example, in somatosensory or visual cortex. EphrinAs and EphAs are then reused later in development; both are expressed in high medial to low lateral gradients, with EphAs in the ventrobasal thalamus and ephrinAs in somatosensory cortex (S1). These complementary gradients arrange a somatotopic map in an analogous way to the retinotectal map: EphA-expressing medial thalamic axons are repelled away from the ephrinA-expressing medial S1 into the lateral S1. Thus, ephrinAs and EphAs are used twice in thalamocortical mapping: first at an intermediate target to mediate 'inter'-areal mapping and then within cortical areas to mediate 'intra'-areal mapping.

EphrinAs and EphAs also play a role in topographic mapping between the hippocampus and septum, and between motor axons and muscles. In both cases, the mechanism is similar to that described for AP retinotectal mapping: high-EphA-expressing axons are repelled from high-ephrinA areas of the target. In the auditory system, functional studies of topography have not yet been done, but there are gradients of EphA4 and ephrinB2 that could form the basis of a tonotopic map in the avian nucleus laminaris, the target of axons from the nucleus magnocellularis, which is in turn the target of cochlear ganglion cells. Interestingly, ephrins have a conserved role in topographic mapping beyond vertebrates: in *Drosophila*, the single Eph and ephrin homologs are required for topographic mapping in the visual system. The reuse of Ephs and ephrins across different projections suggests an evolutionarily efficient modular approach to topographic mapping that would

Figure 5 Topography in the thalamocortical projection uses EphA and ephrinA gradients twice. In early development, thalamic axons are sorted toward the correct cortical areas by an ephrinA gradient at an intermediate target, the ventral telencephalon. Later on, thalamic axons are sorted within each cortical area by a second ephrinA gradient.

allow newly evolved projections to be patterned by co-opting a standard package of Eph and ephrin gradients.

Activity-Dependent Refinement of Topographic Maps

Correlated RGC Firing Is Required for Topographic Map Refinement

Molecular gradients are insufficient to establish a refined topographic map, most likely because they act over too long a range to ensure precise mapping at the cellular level. Moreover, in frogs and fish, retinotectal topography shifts throughout life, as the retina grows radially at the periphery while the tectum grows linearly at the posterior edge. Retinotopic map refinement occurs through correlated activity in RGCs, where cells that are close together fire around the same time, while cells that are far apart do not. Correlated retinal firing occurs naturally in vision; neighboring RGCs have neighboring receptive fields, so they are likely to receive, and transmit, similar input. In amphibians and fish, where embryos develop externally, the retina becomes responsive to visual input around the time when axons arrive in the tectum, so normal visual input may suffice to provide the correlated firing patterns needed to refine retinotectal projections. However, in mammals, where embryonic retinas develop in the dark, correlated firing is provided by spontaneous 'retinal waves' of depolarization that move across the retina. These waves have been observed by multielectrode arrays as well as calcium imaging of depolarization. Because they occur every few minutes and the depolarization only lasts for a few seconds, cells that fire together temporally are very likely to be located together spatially.

Figure 6 Activity-dependent mechanisms are required to refine initially broad axonal arbors to create precise retinotopy. Refinement can be blocked by interfering with correlated neuronal activity in RGCs, for example, with TTX, NMDAR antagonists, knockout of the $\beta 2$ subunit of the nicotinic ACh receptor, and rearing under stroboscopic conditions.

Eliminating correlated retinal firing blocks the refinement of retinotectal mapping, as measured by the size of axonal arbors or receptive fields (Figure 6). Blockade of neuronal activity in the retina causes abnormally broad axonal arbors and receptive fields

in the tectum, even though the basic shape of the topographic map remains intact, suggesting that molecular gradients suffice for a crude topographic map, but refinement requires activity. This finding holds whether neuronal activity is abolished pharmacologically, by intraocular injection of tetrodotoxin (TTX), or by genetic knockout, for example of voltage-dependent sodium channels. Importantly, it is not electrical activity in RGCs *per se* that matters, but correlated firing patterns. The $\beta 2$ subunit of the nicotinic acetylcholine receptor (nAChR) is required for spontaneous waves of activity in the developing retina, but not for neuronal activity *per se*. Mice lacking $\beta 2$ nAChR exhibit random spontaneous retinal activity instead of retinal waves, and indeed develop abnormally large axonal arbors, just like those of TTX-injected animals. Correlated retinal firing can be inhibited in fish, which lack retinal waves, by rearing them under stroboscopic illumination, which artificially increases correlation of firing between RGCs that are far apart; this treatment, like the $\beta 2$ nAChR knockout, decreases retinotopic refinement.

Additional support for this model comes from artificial ocular dominance bands induced by transplanting extra eyes onto frog embryos, where normally only one eye innervates each tectum. Ectopic and native RGCs innervate the same tectum, and presumably express and encounter the same set of molecular gradients, yet the two projections gradually segregate into exclusive ocular dominance bands reminiscent of those discovered by Hubel and Wiesel in the cat visual cortex. Ectopic RGC innervation is presumably an extreme case of uncorrelated firing, as RGCs from two different eyes would be even more uncorrelated than RGCs far apart in the same eye. Ocular dominance bands are thus an extreme example of activity-dependent refinement of topography, as two sets of axons uncorrelated with each other segregate within a region defined by the coarse topography set up by molecular gradients.

Postsynaptic NMDA Receptors Induce Map Refinement by Eliminating Inappropriate Connections

N-methyl-D-aspartate receptors (NMDARs) are ionotropic glutamate receptors that are blocked by a magnesium ion unless the dendrite is already depolarized, meaning that NMDARs act as 'coincidence detectors' that only activate when more than one synapse fires nearly simultaneously onto the dendrite. In long-term potentiation, Ca^{2+} influx through NMDARs activated by coincident stimulation leads to signaling that strengthens the synapse, and it is thought that a similar mechanism operates in the stabilization of synapses that are 'in sync' with their neighbors and the withdrawal of axonal branches from synapses that are 'out of sync.' Indeed, blocking NMDARs in postsynaptic tectal cells prevents retinotopic refinement of the presynaptic retinal axons. In addition, calcium/calmodulin-dependent kinase II (CaMKII), which is activated by NMDARs, is required in postsynaptic tectal dendrites for pruning presynaptic RGC axonal arbors. Time-lapse imaging in dually innervated frog tecta shows that axonal branch elimination rates, but not addition rates, are higher in areas dominated by axons from the other eye. This bias is NMDAR dependent, suggesting that correlated firing acts through NMDARs to eliminate axonal branches not well correlated with their neighbors.

The nature of the retrograde signal activated by postsynaptic NMDARs to axonal branches, telling them whether to stabilize or retract, remains unclear, although a few candidate mechanisms exist. Nitric oxide (NO) has been suggested as a retrograde messenger since NO synthetase is expressed in tectal cells and NO collapses growth cones *in vitro*. However, blocking NO synthetase appears to slow down, but not ultimately prevent, retinotopic refinement in mouse and chick, while it has no effect on refinement in frogs and fish. Brain-derived neurotrophic factor (BDNF) is produced by tectal neurons where it is released by neuronal activity, and it promotes axonal branching and synapse formation, making it a good candidate for an activity-dependent retrograde messenger. However, the effects on axonal branch dynamics of blocking neuronal activity do not match those of blocking BDNF, suggesting that BDNF may not directly mediate the effects of correlated neuronal activity, but rather modulates them in a complex way that is not fully understood. Work in fish suggests a role for arachidonic acid, a cleavage product of diacylglycerol; both applying arachidonic acid globally and inhibiting its release by postsynaptic cells block retinotopic refinement. Cell adhesion molecules may also serve as activity-dependent retrograde messengers. Applying antibodies against neural cell adhesion molecule (NCAM) or glycoproteins to the tectum inhibits retinotopic map refinement. NCAM, N-cadherin, and glycoprotein L1 are inserted into the membrane in an activity-dependent fashion in other systems, suggesting that they may similarly be inserted by NMDAR activation to aid in axonal branch or synapse stabilization. These candidate mechanisms all seem to converge on interrelated presynaptic signaling pathways involving Ca^{2+}, phospholipase C (PLC), growth-associated protein 43 (GAP-43), Rho GTPases, and others, ultimately influencing the actin cytoskeleton to cause stabilization or retraction of axonal branches.

Conclusions

Our understanding of the molecular mechanisms behind topographic mapping has increased greatly in the last decade. An emerging principle is that topographic mapping efficiently uses a relatively small number of genes to pattern connections among billions of neurons. Matching gradients of axon guidance cues in the target layer and their receptors in the projecting layer set up a coarse topographic map, while activity-dependent mechanisms refine this map to make it more precise by eliminating inappropriate connections. The conservation of the molecular principles of topographic mapping across phyla and across different neural projections suggests that these principles may be a basic method of nervous system organization that evolution has repeatedly turned to. Future work will surely shed further light onto the development of topographic maps.

Torsion Dystonia

X O Breakefield, Harvard Medical School, Boston, MA, USA

© 2009 Elsevier Ltd. All rights reserved.

Dystonia Is a Movement Disorder Caused by Abnormal Neural Circuitry in the Brain

Dystonia is the third most common movement disorder in humans, with essential tremor being the most common and Parkinson's disease the second most common. Dystonia is a syndrome characterized by sustained contractions of skeletal muscles, including simultaneous contractions of agonist and antagonist muscles leading to twisting movements and abnormal postures. These contractions can affect isolated (focal) areas of the body, such as writer's cramp (affecting the hand), blepharospasm (rapid eye blinking), torticollis (turning of the neck), and spastic dysphoria (abnormal speech resulting from laryngeal dystonia). Dystonia may also affect larger regions, involving a segment of the body, such as an arm or leg, or may be generalized involving multiple body regions including the face, head, arms, trunk, and legs. These abnormal movements may be sustained or episodic, but they generally only occur during the waking state and not during sleep. Dystonia can begin at any time during life, although onset in childhood usually is associated with involvement of more body parts and a more severe course. Dystonia beginning in adulthood usually manifests as a focal dystonia, and may be task specific, as in writer's cramp and musician's dystonia. Some hereditary forms of dystonia (dystonia-plus syndromes) include other movement abnormalities, such as myoclonus and parkinsonism.

Dystonias can be caused by a variety of environmental and/or genetic factors including lesions, trauma, drugs, toxins, and metabolic disorders. Most genetic forms of dystonia are inherited as autosomal dominant conditions with reduced penetrance with no apparent neurodegeneration. However, imaging studies reveal abnormal patterns of excitability and architecture in the brains of some mutant gene carriers, as well as in apparently sporadic cases. Cases of injury-induced dystonia implicate the basal ganglia and/or cerebellum as target brain regions, but physiologic abnormalities are apparent at multiple levels in the central nervous system (CNS) in pathways involving sensory input and motor output.

Primary and Secondary Forms and Contribution of Genetic Factors

Dystonia can be secondary to a number of diseases, including Wilson's disease, Huntington's chorea, and Parkinson disease, as well as exposure to toxins such as carbon monoxide, drugs (particularly neuroleptics blocking the D2 receptor), viral infection, head injury, or stroke (especially in the basal ganglia). Primary dystonia is distinguished by a lack of other neurologic symptoms or neuropathology and a high hereditary component. The prevalence of primary dystonia in North America is estimated at 3/10 000, but this is likely to be an underestimate as many cases are misdiagnosed or do not come to medical attention. There is a tenfold higher frequency of dystonia in the Ashkenazic Jewish population due to a founder mutation which causes early onset generalized torsion dystonia. Primary dystonias differ in age of onset, site of symptoms, and presence of other movement abnormalities. The majority of patients with primary dystonia have adult onset, focal dystonias with no definable etiologic cause, although there is assumed to be a genetic susceptibility component. Fifteen genes underlying dystonia have been classified based on familial patterns of inheritance and distinctive age and site of onset, distribution of symptoms, and progression of disease with six considered to be pure dystonia (with no other symptoms with the exception of tremor) and the rest as dystonia-plus syndromes (with other movement abnormalities).

The prototypical pure dystonia is early onset generalized torsion dystonia (DYT1). This disorder appears early in life (1–28 years of age, mean 13 years with 30–40% penetrance) and often progresses to involve multiple body regions. In younger individuals, symptoms usually start in a lower limb and progress over a 5-year period to involve many parts of the body, often leading to severe disability. Later onset of DYT1 dystonia is more likely to be limited to upper body parts with little to no cranial involvement. There is a window of susceptibility for manifestations, with individuals who have not onset by 28 years usually being dystonia free for life. DYT1 dystonia has a relatively high incidence in the Ashkenazic Jewish population, and both affected and nonaffected carriers have increased frequency of depression and deficits in motor sequence learning tasks.

DYT6 dystonia is another form of primary genetic dystonia that typically becomes apparent in adolescence, has prominent cranial and cervical involvement, and has an increased incidence among Mennonites. Other pure primary dystonias include

whispering dysphonia (DYT4), adult onset focal dystonia (DYT7), and multifocal/segmental dystonia (DYT13). Dystonia-plus syndromes include dopa-responsive dystonia (DRD, previously classified as DYT5), which is an early onset generalized dystonia distinguished by diurnal fluctuations in symptoms, and dramatic response to L-3,4-dihydroxyphenylalanine (L-dopa) therapy. Myoclonus-dystonia (DYT11) includes rapid brief muscle contractures (jerks) in addition to the dystonia with onset in childhood or adolescence usually affecting the arms and upper body parts. Myoclonus-dystonia is frequently accompanied by psychiatric manifestations and in some cases responds favorably to alcohol, with an increased tendency to alcoholism. Rapid onset dystonia (DYT12) typically has sudden onset (within hours to weeks) in adolescence or young adulthood in response to physical or mental stress. Movement abnormalities include spasms affecting the upper limbs, face, and voice, as well as, in some cases, a slowness typical of parkinsonism. Once the symptoms of rapid onset dystonia appear, they are permanent. Paroxysmal dystonia-dyskinesia (DYT8) is an episodic syndrome induced by a number of agents/conditions, such as alcohol, caffeine, hunger, and fatigue. Symptoms begin in childhood or adolescence and include dystonic and choreic movements. One of the few dystonias in which neuronal degeneration is apparent is X-linked dystonia-parkinsonism (DYT3, lubag) which has a high frequency in the Philippines. Onset is usually focal starting anywhere from 12 to 50 years of age, with generalization to other body parts and parkinsonian features in many of the patients over time. Symptoms are associated with progressive degeneration of the basal ganglia.

Genes/Proteins Identified as Causing Dystonia

Six of the DYT genes have been identified and most encode known proteins with apparently unrelated functions or unknown functions. One of the most informative of the genetic forms of dystonia is dopa-responsive dystonia, sometimes termed 'Segawa's syndrome.' These patients typically have a childhood age of onset with generalization and persistence throughout life, but with dramatic improvement of symptoms in response to L-dopa. This disorder was previously classified as 'DYT5,' but with the recognition that several different genetic defects can produce the same syndrome this nomeclature has been superseded by more specific designations. The most common cause of DRD is heterozygosity for an inactivating mutation in the gene for GTP cyclohydrolase (*GCHI*). GTP cyclohydrolase catalyzes the first step in the biosynthesis of tetrahydrobiopterin – the cofactor for tyrosine hydroxylase (the rate limiting enzyme for dopamine syntheses), as well as tryptophan hydroxylase, nitric oxide synthase, and phenylalanine hydroxylase. Rarely, DRD may be caused by homozygous compromising mutations in the gene for tyrosine hydroxylase (*TH*). Both of these defects lead to deficient dopamine synthesis, and in both cases administration of the precursor L-dopa bypasses the defect and produces striking clinical improvement, pointing to the importance of dopaminergic transmission in the pathogenesis of dystonic movements.

A clinically similar syndrome, early onset generalized torsion dystonia (DYT1), is not responsive to L-dopa, but may also involve dopaminergic transmission. Highest levels of the message for the responsible protein, torsinA, are found in the dopaminergic neurons in the substantia nigra, albeit high levels are found in some other neuronal populations as well. TorsinA is expressed in most cells in the body, with highest levels during the early postnatal period. Most cases of DYT1 dystonia are caused by the same mutation, deletion of three base pairs (delGAG) in exon 5 in the gene for torsinA (*DYT1 or TOR1A*) present in the heterozygous state. This deletion results in loss of a glutamic acid residue in the C-terminal region of the protein. TorsinA, and its three homologs, torsinB, torp2, and torp3, are members of a family of chaperone proteins referred to as 'ATPases associated with a variety of cellular activities' (AAA), which usually form six-membered rings and mediate configurational alterations in proteins as part of folding, denaturation, or movement within cells. The mutant form of torsinA is thought to function as a dominant-negative, resulting in reduction of wild-type torsinA activity to critically low levels in some cells. Although the function of torsinA is not known, it is primarily located in lumen of the endoplasmic reticulum and nuclear envelope where it appears to be involved in processing of proteins through the secretory pathway and/or linking the endoplasmic reticulum or nuclear envelope to the cytoskeleton.

Less is known about the proteins implicated in other forms of dystonia. The gene responsible for the DYT11 form of myoclonus dystonia (*SGCE*) encodes epsilon sarcoglycan, a transmembrane glycoprotein in the family of sarcoglycan proteins that function in the dystrophin complex linking the cytoskeleton to the cell membrane and extracellular matrix. DYT11 is inherited in an autosomal dominant fashion and may be caused by a number of different disruptive mutations. Affected individuals are heterozygous for the mutation, inheriting the mutant gene from their father with inactivation of the normal

allele caused by maternal imprinting. Thus, this syndrome is due to a loss of function state, despite the autosomal dominant pattern of inheritance. Most proteins in the sarcoglycan family are expressed predominantly in skeletal muscle and autosomal recessive mutations in other members of this family cause limb-girdle muscular dystrophies. Epsilon sarcoglycan is unique in this family in that it is expressed at high levels in the brain during development around the time of birth, suggesting it may affect the architecture of neuronal circuitry. Recently, the gene for rapid onset dystonia-parkinsonism (DYT12) has been identified as the alpha 3 subunit of the sodium pump responsible for ion transport across the plasma membrane. A number of different missense mutations have been found to act in a dominant manner to deregulate activity of this oligomeric pump. Mutations in another subunit of this pump, the alpha 2 subunit, have been associated with migraines and infantile convulsions. The gene for paroxysmal dystonia-dyskinesia (DYT8), termed the myofibrillogenesis regulator (MR-1), encodes a protein homologous to a detoxifying enzyme and is expressed throughout many regions of the brain. Reduced levels of this enzyme may increase toxicity of the compounds which induce dystonia attacks.

Animal models of dystonia can be divided into genotypic and phenotypic types, which are as heterogeneous as are the human dystonias. The genetic models attempt to replicate the underlying molecular defects which give rise to human disease, while the phenotypic models are the result of spontaneous mutations or neurotoxin administration, and mimic the motor abnormalities seen in humans. Collectively, the animal models of dystonia implicate altered neurotransmission in the basal ganglia and cerebellum, as well as more widespread involvement in sensory/motor circuit pathways in dystonia. It is important to note that no existing model has succeeded in combining both aspects, that is, none of the existing genetic models have a clear dystonic motor phenotype, and none of the phenotypic models result from mechanisms known to cause human dystonia.

A number of genetic models are available for dystonia. The endogenous mouse torsinA gene (*Tor1a*) has been engineered to create a knockout of the gene function and a knock-in of the delGAG mutation. Knockin mice bearing the delGAG in the heterozygous state (a genetic analog of the human disease state) manifest hyperactivity and difficulty in beam walking, but no apparent dystonic posturing, and have abnormal levels of dopamine metabolites in the brain. In cases where the human delGAG gene is overexpressed in transgenic mice, hyperactivity and defects in motor learning are seen, as well as some changes in dopamine metabolites in the striatum. Transgenic mice with high levels of mutant torsinA expression show ubiquitin-positive aggregates in some brain regions suggesting limited neuronal atrophy. In contrast, mice bearing homozygosity for knock-in of delGAG in *Tor1a* or knock-out of *Tor1a* die at birth. The brains of these animals have normal gross morphology, but postmigratory neurons show abnormalities of the nuclear envelope with vesicles in the nucleoplasmic space.

There are several examples of rodent models which have a clear dystonic motor phenotype. *dt/dt* mice manifest an autosomal recessive condition resembling generalized dystonia in humans. This is due to disruptive mutations in the *Bpag1* gene encoding a member of the cytolinker plakin family which bridges actin filaments and microtubules in the cytoskeleton. This syndrome is associated with degenerative changes, primarily in sensory neurons, involving axonal swelling and interference with retrograde and anterograde transport, and progresses to loss of peripheral nerve endings and eventual death of sensory neurons. Another model resembling generalized dystonia is the *dt/dt* rat in which homozygotes for the mutant allele develop generalized dystonia shortly after birth. Although there are no obvious neuropathologic changes, the cerebellum has a small size, reduced rate of complex spiking, and elevated levels of GABA in Purkinje cells. Surgical resection of the cerebellum relieves the clinical symptoms in these animals, suggesting that it is a nexus of abnormal circuitry. Collectively, the observations implicate defective climbing fiber innervation of Purkinje cells. Recently, the rat *dt* gene has been identified as encoding caytaxin, a lipophilic molecule binding protein which is also defective in a hereditary human ataxia syndrome.

Several rodent models are available for episodic dystonia. The *dt* sz hamster carries an autosomal recessive mutation which produces a syndrome similar to generalized paroxysmal, stress-induced dystonia in humans. Dystonia in these animals apparently results from abnormal GABAergic transmission in interneurons in the basal ganglia with attacks involving dopamine overflow and resulting in inhibition of the endopeduncular nucleus (equivalent to the globus pallidus pars interna in humans, a basal ganglia output nucleus). Both deficits in GABA and dystonic episodes resolve with age. The *dt* sz gene has not yet been identified. Mutations in the Cav2.1 calcium channel, which regulates neurotransmitter release, also produce dystonic features in the autosomal recessive mouse mutants, *tottering* and *leaner*. Totterer mice show a background ataxic state with dystonic symptoms being episodic and precipitated by stress,

caffeine, and alcohol with progression to a generalized state. There is no apparent neuronal degeneration in *totterer* animals. In *leaner* mice, dystonia is chronic and generalized with evidence of widespread cerebellar atrophy. In humans, mutations in the *CACNA1A* gene encoding this channel underlie two forms of ataxia as well as hemiplegic migraine.

Dystonic symptoms can also be produced by delivery of toxins to rodents and nonhuman primates. The active component of moldy sugarcane, 3-nitropropionic acid, can cause lesions in the basal ganglia resulting in dystonia in young humans. This agent inhibits mitochondrial respiration and leads to neuronal death, with the striatal neurons being especially sensitive. Rodents and nonhuman primates exposed to peripheral administration of this agent also develop dystonic symptoms proportional to the extent of damage in the striatum. Low dose microinjection of the glutamate receptor agonist kainate into normal mouse cerebellum, but not into Purkinje cell-deficient cerebellum or into the basal ganglia of mice, produces a progressive but temporary generalized dystonic phenotype. Interestingly, dystonia can also be seen in Parkinson patients, 1-methyl-4-phenyl-1,2,3, 6-tetrahydropyridine (MPTP)-exposed humans, and healthy or MPTP-treated nonhuman primates as a consequence of dopamine deficiency, and may occur in these same patients and animal models as a form of dyskinesia resulting from L-dopa administration leading to elevation of dopamine levels in the striatum. This bimodal response to dopamine depletion and replacement emphasizes the point that the dynamics of dopamine release, and not simply the amount present, influence the appearance of dystonia.

Pathophysiology and Imaging

In most types of dystonia, there is no apparent neuropathology, albeit only a few brains have been evaluated to date. Most types of primary dystonia are considered to be a neurofunctional disease resulting from abnormalities in the microcircuitry of the brain and leading to disorganized sensorimotor integration at the level of the spinal cord, brainstem, basal ganglia, cerebellum, and somatosensory motor cortex. Some insight into the affected circuitry has been gained from analysis of transmitter status, electroencephalographic (EEG) and magnetoencephalographic (MEG) studies, as well as functional magnetic resonance imaging (MRI) and positron emission tomography (PET) analyses. Neurophysiologic abnormalities are detected at multiple levels in the CNS in affected individuals and can also be detected in unaffected mutant gene carriers for DYT1 and DYT6 dystonia. Individuals who carry genes for dystonia but lack overt symptoms seem to have intrinsic subtle differences in their brain connectivity (endophenotype), which may have a developmental component, as well as increased plasticity of some neuronal synapses, which continues throughout life. These abnormalities appear to affect primarily the communication between the sensory input and motor output, but these network based studies cannot determine the primary source of disruption within the interconnected circuitry. A network approach may still, however, be useful for therapy, as evidenced by the ability of deep brain electrical stimulation at a single node point in the globus pallidum to normalize abnormalities throughout the network and relieve dystonic movements in many patients even after years of suffering from severe dystonia.

Several different neurotransmitters have been implicated in the abnormal signaling in dystonic brains. A strong case can be made for dopaminergic involvement given that dystonia can be induced by D2 receptor antagonists (tardive dyskinesia and tardive dystonia), PET imaging shows a decrease in D2 binding sites, and a reduction in dopamine levels and ratio to its metabolite 3,4-dihydroxy-phenylacetic acid (DOPAC) have been found in brains of mutant DYT1 carriers. Further, DRD individuals with decreased dopamine synthetic capacity develop dystonia which can be virtually cured by administration of L-dopa, and the highest levels of torsinA in the human brain are found in dopaminergic neurons of the substantia nigra innervating the striatum. Cholinergic involvement through interneurons in the striatum is also implicated by the ability of anticholinergic medication acting on muscarinic receptors to relieve dystonic symptoms. Low GABA levels have been found in the sensorimotor system, involving the spinal cord, brainstem, and cortex, in individuals with hand dystonia which could also account for reduced inhibition of the surround mechanisms leading to overflow activation of neighboring muscles.

The 'mismatch' in dystonia between sensory input and motor output is revealed in a number of ways, for example, peripheral nerve injury can induce dystonia in the affected body part, while cutaneous stimulation can relieve dystonia in an affected body part; in individuals with hand dystonia, the representation of the affected hand in the somatosensory cortex is disorganized and enlarged as compared to normal individuals. When monkeys are overtrained to a specific hand task, they can develop dystonic posturing of the hand, which correlates with larger receptive fields in the corresponding motor cortex and overlapping representations of individual digits. This may be analogous to musician's dystonias where extensive overuse of a set of muscles leads to dystonic symptoms in that body part in a task-specific and stereotypic

manner. EEG and MEG in hand dystonias also shows less segregated representation of the individual digits in the somatosensory projection within the cortex, and transcranial magnetic stimulation (TSM) demonstrates that the area of cortex influencing movements in the affected body part is greatly enlarged.

Overall studies support both an altered basal ganglia circuitry in individuals predisposed to dystonia, as well as an ongoing hypersensitivity to synaptic plasticity. With regard to basal ganglia circuitry, PET and functional MRI show dystonia is associated with abnormal activity in multiple brain regions, including basal ganglia, motor cortex, supplementary motor areas, and cerebellum. In particular, the premotor cortex is more active during movement in dystonia gene carriers and there are abnormalities in basal ganglia and outflow pathways to the sensorimotor cortex and other regions involved in movement. Unaffected DYT1 carriers also show increased metabolic activity in posterior putamen/globus pallidus, cerebellum, and supplementary motor cortex. A similar pattern of abnormal metabolic activation is seen in affected and unaffected DYT1 and DYT6 carriers, which is distinct from the abnormal patterns seen in DRD carriers and in individuals with Parkinson's disease. Diffusion tensor imaging of the microstructure of white matter pathways reveals abnormalities in mutant DYT1 carriers that suggest altered connectivity patterns in the supplemental motor areas. Interestingly unaffected DYT1 carriers show a selective deficit in motor sequence learning, although motor execution is normal. Imaging studies suggest that unaffected carriers shift from normal striatal processing of sensory and motor coordination to a cerebellar processing.

One of the most intriguing aspects of dystonia is the apparent increase in synaptic plasticity, responsible for changing the strength of synapses in response to neuronal activity, processes which contribute to long-term potentiation (LTP) and long-term depression (LTD) involved in learning. This has been revealed by repetitive transcranial magnetic stimulation (rTMS), which can measure changes in excitability of evoked responses in the sensorimotor cortex. In hand dystonia, the premotor cortex and connected motor areas respond more strongly to rTMS conditioning than do the same regions in normal brains. This suggests that neural circuits in premotor cortex may be more readily modifiable by focal transcranial magnetic stimulation (fTMS) (presumably due to increased plasticity). In a paired associative stimulation model, focal hand dystonia patients also show evidence of enhanced plasticity of sensorimotor circuits, with greater facilitation and loss of spatial specificity. Thus certain connections within the brains of individuals predisposed to dystonia may have enhanced plasticity leading to aberrant reinforcement of synaptic connections, with the potential to become self-reinforcing feedback loops.

Therapy

Treatment for dystonia has been limited, but is improving. Patients have been treated with drugs/toxins, neurosurgery, deep brain stimulation, and behavioral modification. Drugs most commonly used include L-dopa, with patients with DRD as well as some patients with focal dystonia, parkinsonism, and spastic paraplegia showing marked improvement for life on this drug. High dose anticholinergics, such as trihexyphenidyl, are commonly used to treat primary and secondary dystonia with 30–50% of individuals demonstrating at least a modest response. This drug is an antimuscarinic agent and may act through modifying striatal cholinergic receptors. Treatment with anticholinergics is accompanied, however, by a range of peripheral side effects as well as CNS symptoms including memory loss and behavioral changes. Another drug commonly used to treat childhood dystonia is the GABA agonist, baclofen. Because of poor transfer across the blood–brain barrier, this drug is sometimes administered intrathecally in severe cases. Again, only a portion of patients respond, and there can be extensive peripheral and CNS side effects. A major improvement in the treatment of focal dystonia symptoms has been the injection of the light chain of botulium toxin (BTX) into affected muscles from where it is taken up by endocytosis into the terminals of innervating motor neurons. The BTX-A serotype cleaves SNAP-25 needed for fusion of synaptic vesicles to the presynaptic membrane and hence blocks acetylcholine release. The BTX-B serotype cleaves synaptobrevin or the vesicular-associated membrane protein, again blocking vesicular release. Recovery of function returns within 3–6 months, at which time the toxin can be reinjected. A small percentage of patients develop antibodies to the toxin which can be overcome by using a different serotype. BTX treatment can be quite effective in focal dystonia, but is of limited utility in segmental or generalized dystonia.

The earliest neurosurgical procedures for dystonia involved ablative thalamic surgery, which frequently had severe side effects, including loss of speech, and with dystonic movements resuming over time. Based on observations that generalized dystonia patients have a reduced rate and irregular electrical discharge from the globus pallidus as compared with normal individuals, newer interventions have included pallidotomy and deep brain stimulation (DBS) of the

globus pallidus. In particular, pallidal DBS has been shown to be especially effective in early onset generalized dystonia due to DYT1 mutations. With DBS, a gradual reduction in dystonic movement is observed which evolves over days to weeks. Improvements in this technology should be forthcoming. Other potential therapeutic strategies such as use of small interfering RNAs to block expression of dominantly acting proteins associated with dystonia and gene replacement for defective proteins using vectors are options for the future.

Tourette Syndrome as a Neurotransmitter Disorder

C Winter and A Heinz, Universitätsmedizin Berlin, Berlin, Germany

© 2009 Elsevier Ltd. All rights reserved.

Clinical Manifestation

Current estimates suggest prevalence rates of Gilles des la Tourette syndrome (GTS) in school-age children of approximately 1% with a 3:1 male-to-female ratio. According to the *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM-IV), GTS diagnosis is based on the occurrence of multiple motor and one or more phonic tics for a minimum of 1 year, with a potential tic-free period that is no longer than 3 months and an onset of the disease prior to the age of 18 years. In addition to the expressed tics, patients also often report a variety of sensory and mental states associated with and often preceding the occurrence of the motor tics. With the perception of these intruding mental precursors, motor phenomena are often experienced as an inescapable and counterproductive consequence that is suppressible only to a variable and limited extent. During the duration of the disease, the symptoms change in intensity, complexity, and their domain of expression. After the age of 20, expressed motor tics tend to decline; congruently, cases of complete cessation in early adulthood have been reported. In more than 50% of patients, GTS is associated with psychiatric conditions which may proceed and outlast the primary disease, for example, attention-deficit/hyperactivity disorder, obsessive–compulsive behavior, and learning disorders. These symptoms are not required for the diagnosis of GTS, but they may severely affect the patients' quality of life and cause patients' functional impairment.

The co-occurrence of tics and psychiatric conditions, predominantly obsessive–compulsive disorders, has stimulated the search for a common neuropathological correlate of both syndromes. In this view, genetic studies support the notion of a spectrum disorder that may include simple tics, pure obsessions and compulsions, or GTS. When first described in 1885, GTS was considered hereditary. Nevertheless, for a long time thereafter it was predominantly ascribed to psychogenic processes; in this respect, some psychotherapeutic views described the tics as stereotyped attempts to express sexual wishes and ideas or the result of excessive or suppressed masturbations. However, in the 1960s the beneficial effect of neuroleptic drugs on the symptoms of GTS rendered the biological interpretation of the disease popular again. As a result, research approaches into the neurobiological mechanisms of GTS increased in the second half of the twentieth century, assigning the neurotransmitter dopamine and distinct brain regions and functional circuits a pivotal role in its manifestation.

Etiology

To date, the full etiology of GTS remains largely unknown, although various partly complementary, partly contradictory neurobiological hypotheses for the manifestation of the disease are defined at several levels of neurological integration, depending on the investigatory neurobiological approach (i.e., neuroanatomy, physiology, or biochemistry). Among these, neuroanatomical proposals point to abnormalities within specific portions of the cortico-striato-thalamo-cortical pathway or specific regions within the striatum (e.g., striosomes), whereas partially compatible physiological proposals emphasize the role of disinhibited afferent thalamo-cortical signal processing or impaired inhibition at the cortical level. Biochemical investigations describe abnormalities at the level of the neurotransmitter systems.

The different hypotheses may be integrated within one pathophysiological story that takes into consideration the wide distribution of the classical neurotransmitters within the functional and neuroanatomical circuits which have been implicated in the pathogenesis of GTS. In this view, the orbitofrontal cortex, the basal ganglia system, and the thalamus make up a system that regulates the planning of intentional behavior and is involved in GTS pathogenesis. Altogether, observations point to a disinhibition of the orbitofrontal cortex, the caudate, and the thalamus. Activation of the orbitofrontal cortex has been associated with error detection and the emotional evaluation of unsuccessful behavior strategies, especially in situations in which task outcome is uncontrollable. It has been suggested that the associated stimulation of the head of the caudate, in turn, disinhibits repetitive and stereotypic behavior patterns and may allow further stimuli to enter the orbitofrontal-striato-thalamic circuit. Consequently, the coupled activation of the orbitofrontal cortex and caudate may generate a vicious circle in which orbitofrontal cortex activation is associated with anxiety and other mental states preceding the occurrence of motor tics and a negative evaluation of performance outcome, whereas caudate stimulation may be associated with repetitive behavior patterns and the repeated admittance of stimuli that activate the neural network. GTS may thus resemble complex

repetitive tics because of the disinhibition of stereotypes encoded in the head of the caudate; on the other hand, it may differ from complex pure motor tics due to additional activation of the orbitofrontal cortex, which triggers subjective feelings such as anxiety, obsessive sensations, and the urge to start another attempt at successful motor performance.

General Aspects of Neurotransmitter Systems

Notably, the neurotransmitters involved in the etiopathologically crucial cortico-striato-thalamo-cortical circuitries – dopamine, serotonin, glutamate, γ-aminobutyric acid (GABA), norepinephrine, acetylcholine, and the opioids – have all been ascribed to the neurobiological events underlying GTS. The predominant neurotransmitter and the primary location of the dysregulation, however, still need to be clarified. Because the neurotransmitter systems are not isolated and independently operating functional units, it has been suggested that there are absolute or relative imbalances within interconnected transmitter systems which represent the predominant pathological factors in the manifestation of GTS.

How do these functional imbalances evolve? Dysregulations at the level of neurotransmitters can be the result of: (1) an inadequate production or metabolism as a result of, for example, structural deficit or an enzyme dysfunction; (2) a qualitative or quantitative transporter alterations; or (3) receptor malfunction. Consequently, there is a demand for methods which measure/label all the steps of neurotransmitter production, release, binding, and metabolism (i.e., the neurotransmitters themselves or their precursors) to understand the complex systems which may underlie the pathogenesis of GTS as a neurotransmitter disorder. Therefore, compounds are required that are specific for the enzymes which produce or degrade the neurotransmitter and for certain receptors and transporters. To date, the following methods are available for investigating the neurotransmitter systems: (1) animal lesion and morphological studies correlating region-specific malfunctions with the symptom profile; (2) clinical trials evaluating the functional response to specific medications acting in the respective neurotransmitter system; (3) cerebrospinal fluid (CSF), blood, and urine studies, as well as neurochemical assays on brain tissues analyzing *in vivo* and postmortem the contents of the neurotransmitters, their precursors, their metabolites, and specific enzymes; (4) positron emission tomography (PET)/single photon emission computed tomography (SPECT) studies demonstrating functional states of receptors and transporters, such as binding levels; and (5) genetic studies linking the target genes of the neurotransmitter systems with the clinical diagnosis.

This article reviews current hypotheses about the involvement of neurotransmitters in the manifestation of GTS as part of a dysregulated cortico-striato-thalamo-cortical interaction, taking into account the various investigatory approaches.

Specific Aspects on Neurotransmitter Systems

Dopamine

The neurotransmitter dopamine is central to motivation, reward, emotional responses, and the production of movements, and it constitutes the predominant neurotransmitter in the mesocortical, mesolimbic, and nigrostriatal pathways. As with other extrapyramidal hyperkinetic disorders, nigrostriatal dopaminergic dysfunction has been implicated in the pathogenesis of GTS motor tics.

Functional considerations The striatum constitutes the major input structure of the basal ganglia system for projections from motor and prefrontal cortices. The basal ganglia circuitry is often divided into two major parts: the direct pathway, containing direct inhibitory striatal projections to the basal ganglia output structures (globus pallidus internus and substanti nigra pars reticulata) and the indirect pathway, encompassing two consecutive inhibitory projections to the subthalmic nucleus which, in turn, projects to the output structures. Basal ganglia output structures control the activity of thalamo-cortical afferents. Accordingly, cortical activation of the direct pathway leads to an inhibition of the basal ganglia output structures, which in turn remove their tonic inhibition from the thalamus, consequently disinhibiting the thalamo-cortical projections in a self-perpetuating manner. In contrast, cortical activation of the indirect pathway results in an inhibition of the thalamo-cortical projections. Nigrostriatal dopamine regulates basal ganglia activity via binding to specific dopamine receptors that are variably distributed in the striatum. Historically, two different classes of dopamine receptors (D1 and D2) have been defined on the basis of their coupling to adenylate cyclase. Later, a total of five distinct dopamine receptors were discovered, which have several similarities, allowing a reallocation to the two major subgroups: D1-like receptors (D1A–1D and D5) and D2-like receptors (D2, D3, and D4). These receptors have opposite effects at the molecular level, with the D1-like receptors being excitatory and the D2-like receptors being inhibitory. Still, they often act synergistically when more complex outputs are taken

into account. With respect to the striatal distribution, excitatory Dl dopamine receptors are expressed mainly on striatal neurons of the direct pathway and inhibitory D2 receptors are expressed mainly on striatal neurons of the indirect pathway. As a result, the presence of dopamine supports the movement-releasing direct pathway and a disinhibition of the motor circuitry, whereas the absence of dopamine mainly disinhibits the movement-controlling indirect pathway and promotes an inhibition of thalamo-cortical projections. Pathologically high dopamine levels consequently cause hyperexcitability and disinhibition of cortical motor areas and facilitate motor output.

Hypothesis of phasic-tonic dopamine control In line with these considerations, GTS has long been associated with an excess in nigrostriatal dopaminergic activity and an imbalance of the direct over the indirect basal ganglia circuitry. Indeed, dopamine antagonists have been shown to be beneficial in the treatment of tic disorders. Moreover, mechanisms increasing dopamine neurotransmission (i.e., the administration of the dopamine precursor levodopa (L-DOPA) or dopamine agonists as well the withdrawal of dopamine antagonists) have been shown to induce or exacerbate preexisting tics. Dopaminergic mechanisms involved in the pathways are, however, not unidirectional, and recent studies indicated that dopamine agonists not only induce but can also alleviate otherwise therapy-refractory tics. These discrepancies may convincingly be explained by a hypothesis based on the regulation of dopamine release into subcortical regions via two independent mechanisms: (1) a phasic dopamine release and (2) a sustained background tonic dopamine release regulated by upstream cortical regions. In this respect, tonic dopamine is supposed to exist extracellularly in low concentration and to determine the long-term or homeostatic mechanism. This basal level of dopamine is analyzed when researchers apply biochemical methods such as microdialysis or postmortem high-performance liquid chromatography. Tonic dopamine is further supposed to be under the regulatory control of dopamine D2 autoreceptors. In contrast, phasic dopamine is released extracellularly in response to acute modulations. It can be measured by the use of stimulant challenges. A chronic reduction in dopamine release may, in turn, induce a supersensitivity of the postsynaptic dopamine receptors. A sudden stress-induced increase in phasic dopamine release might thus affect upregulated dopamine receptors and cause stronger effects. Although originally suggested for mesolimbic and mesocortical dopamine release in schizophrenic patients, recent research has shown that early cortical dysfunction may induce phasic striatal dopamine release and affect *in vivo* radioligand binding to dopamine receptors. Motor tics may thus be caused by stress-induced dopaminergic stimulation of the caudate nucleus, resulting in the release of perseverative behavior patterns.

Contemporary data How do clinical, biochemical, and binding studies fit into theses hypotheses? Complementing the assumption of a pathophysiologically relevant reduction in tonic striatal dopamine, clinical and biochemical studies demonstrated reduced levels of the dopamine metabolite homovanillic acid (HVA) in the CSF of untreated GTS patients and the restoration to normal after the administration of very low doses of the neuroleptic haloperidol. Furthermore, some studies of dopamine receptor binding in postmortem tissue showed increased densities of D2 receptor proteins. A study on monozygotic twin pairs discordant for GTS severity showed a positive correlation between D2 dopamine receptor binding to the radioligand (^{123}I)-iodobenzamide in the head of the caudate nucleus and phenotypic severity. In fact, the increased availability of D2 receptors in brain imaging studies may be due to decreased competition with endogenous dopamine, resulting in higher binding of the radioligand to D2 receptors. In addition, in a PET study, increased levels of D2 receptor binding were observed in a subgroup of GTS patients and correlated positively with the severity of vocal tics. Reflecting phasic dopamine hyperactivity, a PET study demonstrated elevated dopamine release in the putamen of drug-free GTS patients compared to healthy controls following intravenous amphetamine administration. Also, a very early study found in five GTS patients that their CSF had an elevated probenecid-induced accumulation of HVA, which is declarative of increased synaptic dopamine release.

In a recent review article, it was suggested that an overactive dopamine transporter system constitutes an important pathophysiological mechanism underlying GTS. It was hypothesized that such a situation could create (1) reduced basal levels of extracellular dopamine, due to increased reuptake; (2) higher concentrations of dopamine in the axon terminal, as reflected by a PET study revealing increased fluorodopa accumulation in the caudate nuclei of GTS subjects; (3) D2 receptor hypersensitivity and upregulation as a result of decreased basal intrasynaptic dopamine; (4) increased phasic dopamine release as a consequence of amphetamine or environmental stimulation; and (5) increased sensitivity to low-dose neuroleptics because there is a reduced amount of tonic dopamine available for the neuroleptic to block.

However, research approaches trying to assign GTS symptoms to dysfunctions on the level of the

dopamine transporters have so far resulted in partly contradictory data. Some authors found increased mean striatal presynaptic-binding levels using SPECT and increased striatal DAT using postmortem histology; in contrast, other investigators using SPECT and PET analysis did not find any differences in striatal DAT binding between GTS patients, with or without antipsychotic therapy, and healthy controls. Equivalently, controversial findings have been reported from investigations of the vesicular monoamine transporter type 2. Explanations for these data include variations in brain imaging techniques (i.e., selection of the reference point) and preexposure to neuroleptics.

Conclusion After we assess all the studies which have been undertaken to investigate the involvement of dopamine in the manifestation of GTS, our hypotheses cannot be consistently confirmed. Some studies (1) showed no changes in or even increased levels of the dopamine metabolite HVA in postmortem tissue or CSF, (2) showed reduced receptor binding rates in GTS patients compared to controls, and (3) questioned the concept of a potential pathophysiologically relevant hypersensitivity of D2 receptors because they demonstrated an absence of tic exacerbation following acute L-DOPA exposure. Also, findings are contradictory on a genetic level. A recent study specifically demonstrated an association between the dopamine receptor D2 gene and GTS, although another study on polymorphic markers at or near the gene loci for all known dopamine receptors and selected enzymes in a large multiple affected pedigree excluded a major role of the candidate genes in the etiology of GTS.

Altogether, to date these data appear inconclusive. This, however, might result from small-focused study designs, inconsistent with respect to pretreatment, age, and disease severity. Thus, further studies are required to draw firm conclusions about the role of dopamine in the manifestation of GTS.

Serotonin

In a previous study of our group, a significant negative correlation between tic severity and serotonin transporter availability in both the midbrain and thalamus was found. A reduction in serotonin reuptake sites may be associated with increased serotonin concentrations in the synapse and has been associated *in vivo* with increased concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid in the CSF. Also, midbrain pathology has been implicated in some previous studies of GTS. In the midbrain, the raphe area is the origin of cortical and subcortical serotonergic projections. Increased serotonin release from the dorsal raphe area may inhibit tonic dopamine release in the striatum via serotonin 5-HT2 receptors while not affecting the stress-induced excitability of dopaminergic neurons. In the thalamus, serotonergic stimulation changes rhythmic burst activity to single-spike firing mode and increases the evoked impulse activity of sensorimotor cortical neurons. Both mechanisms may thus be involved in the pathogenesis of tics by increasing the sensitivity of fronto-striatal-thalamic motor circuits to phasic dopamine release. Interestingly, in this study all tics were not associated with reduced serotonin transporter availability in GTS patients – only vocal tics. Vocal tics in GTS often manifest as coprolalia, which is classified as a compulsive impulse in traditional psychiatric psychopathology. The most compulsion-like complex motor tics were thus associated with dysfunction of serotonin reuptake. This observation links compulsive impulses with a serotonergic dysfunction and agrees well with a wide range of observations linking central serotonergic dysfunction with obsessive–compulsive disorders. Several groups demonstrated that the inhibition of serotonin reuptake by clomipramine or selective serotonin reuptake inhibitors reduces obsessive–compulsive symptoms more effectively than norepinephrine reuptake blockade. Some studies found elevated CSF 5-hydroxyindoleacetic concentrations in patients with obsessive–compulsive disorders. This may seem counterintuitive because the acute application of serotonin reuptake inhibitors increases serotonin synthesis and release. However, several studies observed that chronic treatment with selective serotonin reuptake inhibitors reduces serotonin synthesis and CSF 5-hydroxyindoleacetic acid concentrations, whereas the acute stimulation of serotonin 5-HT2c receptors with *m*-chlorophenypiperazine exacerbated obsessive–compulsive symptoms. Notably, however, not all the investigations on serotonergic neurotransmission in GTS pointed into the same direction. Consequently, in biochemical studies, the level of the serotonin metabolite 5-hydroxyindoleacetic acid has not consistently been found to be reduced in the CSF of GTS patients. In addition, changes may be region-specific because levels of the same metabolite were found to be normal in the cerebral cortex, whereas in basal ganglia regions they were found to be decreased. Plasma tryptophan, whole-blood serotonin, and 24 h excretion of serotonin have also been reported to be reduced in some studies of GTS subjects.

Glutamate and γ-Aminobutyric Acid

To date, there are only limited data on glutamate in the pathogenesis of GTS. Postmortem studies revealed reduced glutamate levels in the globus pallidus and the substantia nigra pars reticulata, and magnetic resonance imaging (MRI) volumetric studies demonstrated

a globus pallidus reduced in size. These findings suggest that reduced glutamatergic output of the subthalamic nucleus is pathophysiologically relevant. In a classic basal ganglia circuitry, the subthalamic nucleus lies within the indirect pathway. Despite its relatively small size, it is often referred to as the driving force of the basal ganglia because its glutamatergic projections to the output structures provide the main excitatory drive within the basal ganglia. The neuronal structure of the subthalamic nucleus suggests that it might serve as an interface where various (parallel) basal ganglia-thalamo-cortical circuits meet. Reduced activation or inhibition of the subthalamic nucleus decreases the overall electrophysiological and metabolic activities within the basal ganglia output structures, globus pallidus internus, substantia nigra pars reticulata, and pedunculopontine nucleus and consequently leads to a disinhibition of thalamo-cortical efferents. In obsessive–compulsive disorders and GTS, thalamo-cortical projections are pathophysiologically overactive and consequently might be associated with decreased levels of GABA. As a result, GABAergic cortical inhibition of incoming signals from the disinhibited thalamus might be impaired. This hypothesis is supported by clinical findings that GABAergic drugs prove beneficial in the treatment of tics. However, glutamate decarboxylase activity was unaltered in postmortem cortex tissue, as were levels of GABA in various brain regions, whole blood, and CSF.

Others

It has been suggested that alterations in norepinephrine are relevant in the manifestation of GTS because some (but not all) studies showed a beneficial effect of the a2-adrenergic receptor agonist clonidine on motor tics. With respect to the opioid system, functional imaging studies revealed decreased binding in the anterior cingulate and increased binding in the cortical areas. Finally, a general underactivity of central cholinergic mechanisms has been implicated in the pathophysiology of GTS; this hypothesis is based on early pharmacological studies and findings that nicotine binding to the nicotine acetylcholine receptors can provide short-term relief from GTS symptoms.

Conclusion

Considerable progress has been made over the last decades with respect to the pathophysiological mechanisms underlying GTS. From a neurobiological point of view, data from different investigatory levels indicate that the basal ganglia-cortico-thalamo-cortical circuits may be involved in the manifestation of both motor tics and complex obsessive–compulsive disorder symptoms. The wide distribution of the major neurotransmitters within the pathophysiologically relevant anatomical and functional circuitries suggests complex interactions between the different neurotransmitter systems and their contribution to the manifestation of GTS. To date, most studies have focused on the dopaminergic system, suggesting that dysregulations of the phasic-tonic dopamine release are pivotal in the manifestation of GTS. Several lines of evidence further indicate that GTS is heterogeneous in nature and suggest the segregation into clinically distinct subgroups. Accordingly, pathophysiological events and therapeutic approaches may be different among the subgroups, a hypothesis that is supported by the differential clinical response to substances acting on the dopamine system; in a significant minority of patients, dopamine antagonists do not appear to have a positive effect on tics, whereas dopamine agonists have been shown to be beneficial in some otherwise therapy-refractory patients. Assuming that there are subgroups may help to interpret the partly contradictory results of the various clinical, biochemical, functional imaging, and genetic studies. Other reasons for the contradictory results may include methodological limitations of study designs, differences in the duration of the disease, and differences in neuroleptic pretreatment.

In conclusion, further studies will be necessary to elucidate the role of the different neurotransmitter systems in the manifestation of GTS and to benefit the search for the most adequate therapy. Multimodal imaging studies and the investigation of specific animal models may be fruitful in further elucidating the complex interaction of neurotransmitter states, functional alteration patterns, and therapeutic responses.

Tourette's Disorder

V Gabbay, G S Hirsch, and B J Coffey, New York University School of Medicine, New York, NY, USA

Introduction

Tourette's disorder (TD) is a childhood onset neuropsychiatric disorder characterized by multiple, waxing and waning motor and vocal tics. It is named after the French neurologist, George Gilles de la Tourette, who in 1885 reported on nine cases which presented with motor and vocal tics, fears, phobias, and 'arithmomania' (counting obsessions).

The disorder often co-occurs with other psychiatric disorders such as attention-deficit/ hyperactivity disorder (ADHD) and obsessive–compulsive disorder (OCD). It is estimated that up to 3% of school-age children meet criteria for TD. Recent studies suggest that while tics may often persist into adulthood, tic severity often declines significantly in adolescence.

The past two decades have been marked by significant progress in the understanding of the clinical phenomenology, epidemiology, and psychiatric comorbidity of TD. However, TD and tic disorders continue to pose many challenges, especially in the areas of pathophysiology, genetics, developmental neuroscience, psychopathology, and treatment.

This article discusses the clinical phenomenology, clinical course, proposed etiological factors that play a role in the development of the disease, and treatment.

Classification and Clinical Phenomenology

What Are Tics?

Tics are sudden, repetitive, stereotyped, involuntary, or semivoluntary motor movements or phonic productions. Tics typically involve one muscle or a group of muscles and may be characterized by their anatomical location, number, frequency, duration, and complexity. Tics can be classified as 'simple' when they involve one muscle or sound. They are considered 'complex' when movements are slower, and more purposeful involving multiple muscle groups or, in the case of complex vocal tics, multiple sounds, words, or phrases.

Examples of simple motor tics are eye blinking, facial grimacing, shoulder shrugging, nose twitching, mouth opening, shoulder rotation, abdominal tensing, and head turning. Examples of complex motor tics are touching objects, jumping, brushing hair, making rude gestures (copropraxia), grabbing one's genitalia, imitating others' gestures (echopraxia), touching objects and self, gyrating, and bending.

Simple phonic tics are usually meaningless sounds or noises such as throat clearing, coughing, sniffing, grunting, blowing, and squeaking. Complex phonic tics include meaningful word productions such as repetitive words or phrases including the repetition of other's words (echolalia) or of one's own words (palilalia). Coprolalia, or shouting of obscenities or other inappropriate words and statements, is actually quite rare.

Tics are experienced as irresistible, but can be suppressed for varying periods of time. Many patients with TD characterize their tics as a voluntary response to an uncomfortable feeling that precedes them. These feelings, or premonitory sensations, have been described by the majority of Tourette's patients, even in children; these sensations can be localized or general, and physical or mental in nature.

While stress and excitement can exacerbate tics, relaxation can also induce increased tics in some individuals.

Diagnosis

The diagnosis of TD is made based on the history and clinical presentation. No specific laboratory tests are confirmatory. There are several classification systems that differ in their diagnostic criteria. According to the Tourette Syndrome Classification Study Group (1993), both multiple motor tics and one or more phonic tics must be present at some time during the illness, although not necessarily concurrently; tics must occur nearly every day, or intermittently throughout a period of more than 1 year, and during this period there must never be a break in symptomatology lasting more than 3 consecutive months; the anatomical location, number, frequency, type, complexity, or severity of tics must change over time; the onset must occur prior to the age of 18 years; involuntary movements and noises cannot be explained by other medical conditions; and motor tics, phonic tics, or both must be witnessed directly by a reliable examiner at some point during the illness or be recorded by videotape or cinematography.

The American Psychiatric Association DSM-IIIR required in addition that tics must be associated with marked distress or significant impairment in social, occupational, or other areas of functioning. While still debated in the scientific arena, this criterion was removed in the latest version of the DSM-TR (2000) and is not included in other classification systems.

Clinical Course

The typical course of TD is characterized by the onset of simple motor tics such as facial, head, or neck tics at about age 6 or 7, followed by a rostral–caudal progression of motor tics over several years. Vocal tics, usually simple such as throat clearing, or sniffing, typically start at age 8 or 9. More complex tics often begin later, as do obsessive–compulsive symptoms, by about age 11 or 12. Tics progress in a fluctuating manner, often described as waxing and waning. Tics tend to stabilize over time, and some patients have lengthy periods during which most or all manifestations diminish or remit. Recent studies indicate a remitting course, in which the worst period of tic severity is between the ages of 7 and 15 years, followed by a significant improvement by mid adolescence.

Epidemiology

Prevalence estimates for TD vary from 1 to 10 per 1000 depending on setting; a common prevalence figure is 1 per 200 for the full spectrum of TD and chronic tic disorders. More recently, prevalence rates have been estimated to be as high as 4% in a community-based study when all tic disorders are included. Studies in both children and adults suggest that males are at least 3–4 times more likely than females to manifest TD.

Psychiatric Comorbidity

Gilles de la Tourette described symptoms of anxiety, obsessions, and phobias in his first nine TD patients. Obsessive–compulsive symptoms, hyperactivity, inattention, anxiety, and aggressive dyscontrol have all been frequently described in association with TD.

OCD is often associated with TD in clinical settings. OCD is a psychiatric disorder manifested by uncontrolled intrusive, repetitive, and distressing thoughts such as unfounded fears (obsessions) or worries, and repetitive behaviors (compulsions) such as checking, hand-washing, or mental acts such as praying, counting, and repeating words. There appears to be a bidirectional relationship between TD and OCD. Twenty to forty percent of TD patients have been reported to meet full criteria for OCD, and up to 90% have been reported to have subthreshold symptoms such as repetitive counting, touching, or symmetry needs. Family studies indicate that OCD is found at a higher rate in close relatives than in controls which further supports the possible link between OCD and TD.

ADHD is another psychiatric disorder that frequently co-occurs in clinical settings, characterized by motoric hyperactivity, distractibility, and impulsivity. As many as half of TD patients present with ADHD symptoms prior to the onset of tics, and 50–75% of TD patients are found to meet criteria for ADHD. This rate is 10–20 times higher than that observed in the general population. The nature of the scientific relationship between ADHD and TD is not firmly established.

Other comorbid psychiatric disorders that have been reported include mood and anxiety disorders, such as major depression, bipolar disorder, separation anxiety disorder, panic disorder, simple and social phobias, and intermittent explosive disorder.

Although the nature of the relationship between TD and the psychiatric comorbid disorders is still not clear, tic, behavioral, cognitive, and emotional dysfunction may represent manifestations of an underlying core disinhibition problem. Often, it is the psychiatric comorbid disorders that are the primary clinical problem when these youth are evaluated in clinical settings.

Disorder Heterogeneity

Another interesting aspect of the etiology is the increasing evidence that TD may not be a unitary disorder. Two individuals can have entirely different presentations, with no overlapping symptoms, and still fulfill diagnostic criteria for TD. Also, a factor analysis of tic symptoms, involving 85 TD probands and information on 29 tic symptoms, presents evidence of four distinct symptom factors or categories: (1) aggressive phenomena (e.g., kicking, temper fits, argumentativeness); (2) purely motor and phonic tic symptoms; (3) compulsive phenomena (e.g., touching of others or objects, repetitive speech, throat clearing); and (4) tapping and absence of grunting. These four categories accounted for 61% of the variance in TD symptom manifestation. Additionally, specific factors were associated with ages of onset and comorbidities and higher rates of ADHD and OCD in relatives. These factors implicate different structural or genetic causations.

Etiology

The pathophysiology and etiology of TD are still unknown. However, studies suggest genetic, developmental, infectious, and neurobiological etiologies involving abnormalities in neurotransmitter systems and neuroanatomical regions, particularly the basal ganglia. Although a specific animal model has not been identified, some parallels may exist with horses that display spontaneous motor tics accompanied by vocalizations such as crib biting, and dogs and cats with acral lick syndrome.

Neuroanatomical Involvement

Neuroimaging studies suggest that the pathogenesis of TD entails abnormalities in corticostriatothalamic pathways. Structural magnetic resonance imaging (MRI) studies have indicated volume or asymmetry abnormalities in the basal ganglia including the caudate, and the lenticular nuclei in subjects with TD compared to controls, as well as loss of the normal asymmetry of the basal ganglia. A longitudinal MRI study documented inverse correlation between tic severity and caudate volume. Additionally, in 10 pairs of monozygotic twins, the right caudate was smaller in the more severely afflicted individuals, supporting evidence for the role of environmental components in addition to genetics.

Neuroimaging studies employing cerebral blood flow and energy (glucose) metabolism parameters (e.g., positron emission tomography (PET) and single photon emission computed tomography (SPECT)) suggest altered activity (increased or decreased and at times unilaterally) in various areas of brain (e.g., frontal and orbital cortex, striatum, putamen) in TD patients compared to controls or across brain regions within TD patients.

In a recent magnetic resonance spectroscopy study which allows the measurement of specific brain metabolites, reduced *N*-acetylaspartate and choline in the left putamen, along with reduced levels of creatine bilaterally in the putamen, were found in patients with TD. In the frontal cortex, TD patients had decreased *N*-acetylaspartate bilaterally, lower creatine and concentration on the right side, and reduced *myo*-inositol on the left side. The authors suggested that neuronal and glial activity in specific brain region may be impaired in TD.

Neurotransmitters

Several neurotransmitters and neuromodulators have been implicated in TD.

The role of dopamine in TD has been widely investigated. Medications such as neuroleptics, which block D2 dopaminergic receptors, are effective in suppressing tics. This is further supported by postmortem studies and neuroimaging studies, which suggested abnormal regulation of presynaptic dopamine release and postsynaptic uptake. A study in monozygotic twins concordant for TD, but discordant for severity, demonstrated abnormalities in dopamine 2 receptors in the caudate area in the more severely afflicted twin, further linking between dopamine in TD clinical presentation.

Another neurotransmitter that is considered to play a role in the etiology of TD is serotonin or 5-hydroxytryptamine-2 (5-HT2). Postmortem studies in patients with TD have identified low levels of serotonin in the brainstem, low levels of glutamate in the globus pallidus, and low levels of cyclic AMP in the cortex. The role of serotonin in TD is further substantiated by the efficacy of medications with serotonergic properties.

Genetics

The familial nature of TD has long been cited in the literature. Twin studies reported 89–94% concordance rates for TD, supporting its basis as a genetically transmitted disorder. Other studies have shown that first-degree relatives of TD patients have a higher percentage of TD, chronic tics, and OCD than normal controls. Another genetic study involving 76 families with a total of 110 pairs of siblings suggests the involvement of 4q and 8p as TD-related genes. A recent study suggests the role of SLITRK1 in a subtype of patients with TD. Additionally, a rare variant of the serotonin transporter polymorphism was identified (Val425) and was linked to OCD recently, but no studies examined its link with TD.

Immunological Link: Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcus

Swedo and colleagues have described a putative subgroup of children with TD and OCD with hypothetical antecedent group A beta hemolytic streptococcus (GABHS) infection who have symptom onset and/or exacerbation precipitated by streptococcus infection (pediatric autoimmune disorders associated with streptococcus or PANDAS). They describe specific diagnostic criteria for PANDAS, including prepubertal onset of tics and/or OCD, sudden, explosive onset and/or exacerbations, and a temporal relationship with symptoms and GABHS. A double-blind, placebo crossover study of prophylactic oral penicillin to attempt to reduce recurrences of tic/OCD exacerbations failed to show any differences between drug and placebo. Another study by the same group of investigators reported that rates of infection and associated tic/OCD exacerbations with prophylactic azithromycin and penicillin over 1 year were reduced compared to the previous baseline year without antibiotics.

PANDAS as a subtype of TD or OCD has not been confirmed or validated by scientific evidence to date. A multisite, prospective case-control (PANDAS and control subjects) 24-month epidemiological study currently underway seeks to clarify the putative relationship between streptococcus bacteria and tic exacerbations in both groups.

Treatment

Overview

Treatment is a challenging task and typically involves a multimodal approach including both pharmacological and behavioral treatments and guidance, education, and support to both patients and their families. Self-esteem at all times should be supported, as most patients with tic disorders will have at least some sense of personal and emotional vulnerability. Early on in the diagnostic process, educating the patient, family members, and school staff as to phenomenology and natural history of TD is an essential component of treatment. Interventions should be tailored to the individual, based on the clinical presentation. As previously noted, psychiatric comorbid disorders such as ADHD and OCD require attention during the initial evaluation phase.

Patients with symptoms that significantly interfere with adaptation to family, school, or work life, peer relationships, or developmental progress should be treated. Patients who suffer significant emotional distress or inadvertently cause significant distress to key persons in their lives may also be candidates for treatment, even when symptoms are relatively mild. Most patients with very mild symptoms need only monitoring, education, guidance, and support. Referral to the national Tourette Syndrome Association (TSA) or to local chapters of the TSA is an excellent way to maintain continuing education and support.

Pharmacotherapy

Several pharmacological agents have demonstrated efficacy in tic reduction. However, these medications may have limited efficacy in some patients, and can be associated with adverse effects.

Alpha-adrenergic receptor agonists The alpha-adrenergic receptor agonists, such as clonidine and guanfacine, are commonly used. These agents are recommended as first-line treatment for most patients with mild–moderate TD. It is suggested that presynaptic noradrenergic effects mediate the observed clinical improvement in motor and vocal tics. In addition, clonidine may also reduce the disinhibition, impulsivity, and hyperactivity often present in young TD patients. Studies have shown inconsistent therapeutic response and delayed onset of action. Sedation is often experienced and impacts on compliance.

Dopamine antagonists: Typical neuroleptics Since the late 1960s, when haloperidol was first introduced as a treatment for TD patients, it has been the only FDA-labeled, formally approved agent for treatment of TD. These medications block D2 (dopamine) receptors in the basal ganglia, and thus reduce tics. These medications are generally effective in tic reduction; however, they are associated with significant side effects such as extrapyramidal symptoms including tardive dyskinesia.

Atypical antipsychotics The newer, atypical neuroleptics are recommended as first line for moderate to severe tics. These agents, such as risperidone, have both potent serotonin 5-HT2 and dopaminergic D2 receptor antagonist properties. Compared to the typical neuroleptics, they have the potential advantage of less extrapyramidal side effects. Several reports have demonstrated efficacy in treating TD without major side effects. Common side effects of neuroleptics include appetite, weight gain, sedation, muscle cramps, and stiffness.

Selective serotonin reuptake inhibitors The selective serotonin reuptake inhibitors (SSRIs), including fluvoxamine, sertraline, and fluoxetine, are agents that block the reuptake of serotonin into the presynaptic terminal. Several studies have reported efficacy of SSRIs in treating TD patients. Nonetheless, other reports suggest that SSRIs may make tics worse.

Since many TD patients have obsessions or compulsions, and neuroleptics and the alpha 2 agonists do not effectively alter these symptoms, the SSRIs may be beneficial. In addition, complex motor tics such as repetitive squatting and touching may be very similar to compulsive rituals. Fluoxetine has received the most investigation in TD, but efficacy likely is relatively comparable among agents. Choice typically rests with consideration of the side effect profiles of the agents. When obsessions or compulsions are of moderate to severe intensity or impair adaptive functioning, SSRIs are indicated.

Benzodiazepines Another class of medications that may hold some promise is the benzodiazepines (e.g., clonazepam). Some studies suggest a reduction in tics independent of anxiolytic effects. This effect may also reflect a reduction in anxiety that, in turn, could reduce tic frequency. In addition, benzodiazepines can be used to treat comorbid anxiety or panic attacks that can also occur in TD patients. Side effects of particular concern in the juvenile population are sedation, cognitive impairment, and disinhibition.

Stimulants There has been a controversy in the past decade about the role of stimulants in TD; however, recent studies have demonstrated that some TD patients with significant ADHD may be candidates

for methylphenidate when no other treatments have been effective. A recent randomized controlled study of clonidine and methylphenidate in ADHD and chronic tics reported that the combination, and each drug, was more effective than placebo in reducing both tics and ADHD symptoms. Increase in tics did not occur in the methylphenidate group to any extent more significantly than in the placebo group. Side effects include insomnia, appetite suppression, and weight loss.

Atomoxetine Atomoxetine (Strattera), a nonstimulant agent, is a selective norepinephrine inhibitor, which was recently approved for treatment of ADHD in children, adolescents, and adults. It has also been studied in youth with ADHD and chronic tics. A recent randomized controlled trial demonstrated that atomoxetine was more effective than placebo in treatment of ADHD, and tics did not worsen compared to placebo. In addition, by some measures, tics reduced on atomoxetine. Therapeutic response, unlike stimulants, takes a few weeks. Side effects include headache, nausea, fatigue, and stomachaches.

Psychotherapeutic Modalities

Behavioral therapies Behavioral paradigms are often indicated in tic-disorder patients. Simple behavioral approaches can be used with the majority of TD patients to 'destimulate' and contain the symptoms. Specific paradigms are indicated for obsessions, compulsions, and possibly some complex motor tics. Relaxation techniques, such as deep breathing, guided imagery, and use of relaxation tapes, can be useful for the anxious or stressed TD patient.

Scientific evidence is growing for the utility of habit reversal therapy (HRT), also known as behavioral intervention for tics. The patient is taught, through developing awareness of premonitory sensations that precede tics, a competing response to the tics. Children as young as 10 years may be candidates for this treatment; parent support is a component of this approach.

Supportive psychotherapy Individual, group, and family therapies are supportive adjuncts to pharmacotherapy. Individual supportive therapy is indicated for patients having difficulty adjusting to the disorder, to their peers or family, or with school or occupational functioning. It is particularly useful when there is evidence of moderate stress or anxiety or another comorbid psychiatric disorder responsive to this form of psychotherapy (e.g., mild depression). It can help to restore or maintain self-esteem and promote mastery and coping.

School and occupational interventions Useful special educational interventions include creating moderate, task-oriented structure in the classroom, preferential seating, one-to-one support, or individualized educational or work plans. Flexibility is a key element in educational and occupational intervention. To promote tic control, there may be a need for optional 'timeouts' from class or work settings. Time limits may have to be extended or eliminated for exams. Some patients also may benefit from writing aides, such as silent typewriters and computers. Silent typewriters allow patients with handwriting difficulties to take notes in class without disturbing others. Adaptive, as contrasted to regular, physical education can be particularly helpful for children with TD. This form of physical education can be arranged through special education departments in local schools. Programs can be tailored to each child's needs, strengths, and weaknesses.

Specific workplace interventions include structured tasks, organization of tasks into smaller units, flexible time limits, and ample physical space.

Surgical Treatment

Stereotaxic neurosurgical techniques have been used in a few cases of severely impaired adults. Deep-brain stimulation has been used in several adult cases with intractable symptoms. However, given the significant medical risks for these procedures, there is no indication for use of these techniques in youth at this time.

Summary

In his 1885 paper, Gilles de la Tourette stated: "Everything is extraordinary in this disease: . . . its symptoms peculiar, its character equivocal, its causes unknown, its treatment problematical." We now know a considerable amount about this disorder that bears his name; it is a complex, neuropsychiatric disorder with a heterogeneous phenotype characterized by core disinhibition mediated by the corticostriatothalamic tracts. TD is genetically determined in most cases. There is a growing appreciation and understanding of the role of psychiatric comorbidity in the diverse clinical presentation. Treatment strategies should be multimodal in nature, and include pharmacotherapy and, where indicated, behavior, individual, family intervention, and psychoeducation.

There is still much to be learned about TD. Further investigation is needed to better understand the phenomenology, developmental psychopathology, and treatment. The concept of TD as a unitary disorder is being questioned; as evidence accrues at a genetic and molecular biology level, this will have significant impact on understanding etiology, as well as

development of treatment options. Pharmacologic treatment has advanced, but most often patients require multiple medications and adverse effects limit its use. Scientific evidence for behavioral treatment and alternative treatments are beginning to emerge.

The complex symptoms of TD and the psychiatric comorbid disorders can impair the functioning of patients in multiple ways and need to be addressed and prioritized. TD continues to pose challenges to those who work with this disorder. Yet, the enormous level of activity on the part of basic science and clinical investigators has potential to reap fruitful rewards for patients and their caregivers alike in the future.

Trace Monoamines and Receptors in Mammalian CNS

M D Berry, Brandon University, Brandon, MB, Canada

Introduction

The trace amines are a class of endogenous neuroactive amines primarily comprising 2-phenylethylamine (PE), tryptamine, the tyramines (ortho-, meta-, and para-), the octopamines, and the synephrines, although other family members may also exist. As can be seen from Figure 1, these amines are structurally related to the classical monoamine neurotransmitters dopamine (DA), noradrenaline, and 5-hydroxytryptamine (5-HT), as well as amphetamine-related drugs of abuse.

Trace amines have been found in all species so far examined, ranging from lower invertebrates such as the starfish *Pycnopodia helianthoides*, up to higher mammals, including humans. Although synthetic and degradative strategies are the same in all species, trace amine functioning appears to be distinct, certainly between invertebrate and vertebrate species. Thus, while trace amines, in particular the tyramines and octopamines, have been established as neurotransmitters in a number of invertebrate species, such a neurotransmitter function has not been established in vertebrates. Indeed, in vertebrate species, trace amines have been suggested to regulate the efficacy of coexisting neurotransmitters, rather than serving as true neurotransmitters. The recent discovery and preliminary characterization of a family of putative G-protein-coupled trace amine receptors has lent some support to this hypothesis. Mammalian trace amine receptors comprise a phylogenetically distinct family only distantly related to their invertebrate counterparts.

This article describes the synthesis and degradation of trace amines and distribution of trace amines and their receptors in the mammalian central nervous system (CNS). The current state of understanding of trace amine physiology and pharmacology is presented in the context of the putative trace amine receptors, along with the possible relevance of trace amines to human neurologic and psychiatric disorders.

Trace Amine Synthesis

As would be expected of such closely related structures, the synthesis of trace amines occurs through the same enzymatic mechanisms as for the monoamine neurotransmitters (Figures 2 and 3). 2-Phenylethylamine, the tyramines, and tryptamine are formed by the decarboxylation of the precursor amino acids L-phenylalanine, L-tyrosine, and L-tryptophan, respectively. This reaction is catalyzed by the enzyme aromatic L-amino acid decarboxylase (EC 4.1.1.28; AADC). Tyramines can be converted into the corresponding octopamines by further hydroxylation via the enzyme dopamine-β-hydroxylase. Synephrines can then be formed following N-methylation of octopamines by the enzyme phenylethanolamine-*N*-methyltransferase. There are thus direct parallels between the synthesis of trace amines and the more abundant monoamine neurotransmitters DA, noradrenaline, adrenaline, and 5-HT.

As would be expected, this synthesis occurs primarily within monoaminergic axonal terminals in the CNS. Unlike neurotransmitters such as DA, however, AADC is of prime importance in trace amine synthesis. With respect to DA, noradrenaline, and 5-HT synthesis, AADC is present in a large excess, and is not rate limiting. This has caused considerable confusion, however, since AADC is regulated in response to dopaminergic and noradrenergic receptor activation in regions throughout the CNS. Such regulation does not, however, alter DA or noradrenaline levels. As can be seen from Figures 2 and 3, AADC is, by default, rate limiting with respect to the synthesis of trace amines. No other enzymatic process is present, at least with respect to 2-phenylethylamine and tyramine synthesis. Further, there is no evidence for regulation of either dopamine-β-hydroxylase or phenylethanolamine-*N*-methyltransferase activity.

In addition to synthesis in monoaminergic neurons, trace amines may also be synthesized in the so-called D cells of the CNS. D cells are neurons, which, while being immunopositive for AADC, are immunonegative for tyrosine hydroxylase, tryptophan hydroxylase, and 5-HT. As such, D cells, while not capable of synthesizing DA, noradrenaline, or 5-HT, can synthesize trace amines. The function of D cells in the mammalian CNS is poorly understood, and whether they function as dedicated trace aminergic neurons requires investigation.

With respect to the ortho-, meta-, and para- forms of the tyramines, octopamines, and synephrines, differential synthesis is present. The para-structural isomers of both tyramine and octopamine predominate, with somewhat lower levels of meta-isomers. In both instances, the ortho-isoform is rarely identified conclusively. Few studies have examined for differences in the structural isomers of synephrines. However, given that synephrines are derived directly from octopamines, which themselves are synthesized from tyramines, it seems likely that the para-isoform will again predominate.

Figure 1 Similarity of trace amines to neurotransmitter monoamines and amphetamine. Structures in black represent the base trace amine structures. Minor additions to these structures give neurotransmitters (red) or amphetamine (blue). Methamphetamine and 3,4-methylenedioxymethamphetamine (MDMA) are also shown for comparison.

A further difference between trace amines and the monoamine neurotransmitters is seen when their tissue levels are compared. While whole brain levels of DA, noradrenaline, and 5-HT approximate 300–600 ng g^{-1} tissue in a number of mammalian species, the levels of the trace amines are at least two orders of magnitude lower, in the region of 1–5 ng g^{-1} of tissue. Notwithstanding such low levels, the trace amines are heterogeneously distributed within the mammalian CNS (see later). Further, their rate of synthesis is equivalent to that of neurotransmitter monoamines. As such, trace amines have an exceedingly rapid turnover rate, in the region of 30 s. Such a turnover is consistent with the apparent lack of storage of trace amines. Finally, in comparison to monoamine neurotransmitters, trace amines show a markedly elevated lipophilicity. Indeed, the trace amines so far studied do not appear to undergo storage and active release via exocytosis. Rather, trace amines appear to be 'released' by simple diffusion across cell membranes. As such, their endogenous levels within the CNS are a reflection of the steady state existing between synthetic and degradative pathways.

Trace Amine Degradation

Trace amine metabolism, with the exception of interconversion, proceeds primarily via oxidative deamination. As with monoamine neurotransmitters, this is

Figure 2 Relationship between trace amine and neurotransmitter synthetic pathways. Precursor amino acids are shown in black, trace amines in red, and neurotransmitter amines in blue. Enzymes common to the synthetic pathways are shown in green.

mediated by monoamine oxidase (EC 1.4.3.4; MAO). In general, the trace amines are rather nonselective substrates for both MAO types A and B. The exception to this is 2-phenylethylamine, which is the prototypical MAO-B selective substrate. Additional metabolic routes, such as deamination through the cytochrome P450 system, and O-methylation via catechol-O-methyltransferase (COMT), are minor fates of trace amine metabolism.

Tissue Distribution

Although trace amines are present in low levels, and readily cross cell membranes, they are heterogeneously distributed throughout the mammalian CNS (Table 1). In the rat, 2-phenylethylamine is particularly enriched in the olfactory tubercles, globus pallidus, and nucleus accumbens, while lower levels are seen in various brain stem regions. The tyramines and tryptamine, in contrast, are also enriched within the caudate putamen, with the cerebellum and cortical regions in addition to the brain stem showing low levels. Octopamine, meanwhile, shows higher levels in the hypothalamus and cerebellum, in comparison to other trace amines.

Figure 3 Relationship between tryptamine and 5-HT biosynthesis. Precursor amino acids are shown in black, trace amines in red, and neurotransmitter amines in blue. Enzymes common to the synthetic pathways are shown in green.

Trace Amine Receptors

Although the existence and distribution of invertebrate trace amine receptors is well established, mammalian equivalents were only identified in 2001. Somewhat surprisingly, the mammalian trace amine receptors do not show a close phylogenetic relationship to their invertebrate counterparts, suggesting a possible divergence in the physiological function of trace amines between invertebrates and mammals. The mammalian trace amine receptors form a distinct family of receptor protein termed trace amine-associated receptors (TAARs). A remarkable variability is present between mammalian species with respect to the numbers of receptors present within the genome (Table 2). The human and chimpanzee genomes each contain nine family members, while the rat has 19 members and the mouse, 16. In each instance, this number includes one or more pseudogenes; three in humans, six in chimpanzee, two in rat, and a single pseudogene in mouse. Phylogenetic and ligand-binding pocket analyses have identified three subclasses of TAAR, with each species so far studied containing at least one representative of each subclass (Table 2). All TAAR receptors show seven putative transmembrane domains consistent with the functional receptors being G-protein coupled. Both TAAR1 and TAAR4 appear to couple to the G_s protein, resulting in a stimulation of

adenylate cyclase and resultant cellular increase in cAMP levels.

In each species, all TAARs cluster around a narrow chromosomal region. In humans, the nine TAAR genes are located at chromosome 6q23.1, chromosome 1p12 in the rat, and within chromosome 5 in the chimpanzee. All TAARs are coded by a single exon with the exception of TAAR2, where coding is split between two exons. Although TAAR orthologs show the expected high degree of homology, the marked divergence in the number of pseudogenes and receptor subtypes between species of close phylogenetic relationship (e.g., human vs. chimpanzee; rat vs. mouse) has led to suggestions that TAARs represent a rapidly evolving receptor family, involved in adaptation responses to evolutionary events. This raises the intriguing possibility of TAAR representing novel targets for pharmacotherapy of diseases that are uniquely human in nature.

The CNS distribution of the majority of TAARs is unknown, with only TAAR1 studied in any detail so far. The greatest CNS levels of TAAR1 mRNA in humans are found in the amygdala, with lower levels present in the cerebellum, hippocampus, hypothalamus, and medulla. This correlates well with both the distribution of endogenous trace amines, and preliminary reports of TAAR protein distribution. TAAR6 mRNA shows a similar distribution, with highest levels seen in the amygdala and hippocampus, while TAAR8 also appears to be particularly located to the amygdala. In mouse, high levels of TAAR1 mRNA are seen in a number of regions, including the olfactory bulb, piriform cortex, various trigeminal nuclei, and the cerebellum. The thalamus, hippocampus, and hypothalamic and raphe nuclei show lower mRNA levels, whereas the lowest levels are seen in the septum, basal ganglia, and amygdala. Of particular interest, TAAR1 mRNA is associated with the major monoamine neurotransmitter neuron groups within the raphe nucleus (5-HT), locus coeruleus (noradrenaline), and ventral tegmental area (DA).

The cellular localization of expressed TAAR1 and TAAR4 appears to be consistent with the lipophilicity of the potential endogenous ligand trace amines. As such, both receptor subtypes have been shown to be primarily intracellular, with little, if any, expressed protein appearing within the extracellular membrane. In this aspect, it is noteworthy that TAAR1 and -4 are the only TAAR members so far shown to be responsive to trace amines. The cognate endogenous ligand(s) for the additional TAAR members awaits identification.

Receptor Pharmacology

As indicated, the only TAAR members shown to be activated by trace amines are TAAR1 and TAAR4. TAAR1 from all species is activated by low to submicromolar concentrations of 2-phenylethylamine and *p*-tyramine. In addition, rat TAAR1 is similarly stimulated by octopamine and tryptamine. In contrast, mouse and human TAAR1 show a much lower affinity for both octopamine, and, in the case of human TAAR1, tryptamine. Of note, however, there appears to be a marked disparity with respect to affinity assessed by functional assay of cAMP production, and binding affinity (K_i) value obtained from competition experiments. For example, 2-phenylethylamine displacement of tyramine binding at human TAAR1 occurs at concentrations at least one order of magnitude below those required for receptor activation by 2-phenylethylamine. The basis for this disparity is unclear. Whether it represents additional, as yet unidentified, trace amine receptors/binding sites requires further investigation.

In contrast, classical neuroactive biogenic amines are either ineffective at activating TAAR1, or show at best, partial agonist properties. Histamine, noradrenaline, and 5-HT show limited efficacy to activate TAAR1 from a number of species, although 5-HT can act as a partial agonist at the rat TAAR1. Similarly, DA appears to be a partial agonist at TAAR1 from all species examined. Of note, however, the *O*-methyl metabolite of DA, 3-methoxytyramine, shows considerably greater agonistic properties at TAAR1 than does the parent amine. A similar trend is seen with normetanephrine and metanephrine, the *O*-methyl

metabolites of noradrenaline and adrenaline, respectively. The deaminated *O*-methyl metabolites such as homovanillic acid are not, however, ligands at TAAR1. The relevance of such activity of previously assumed inactive metabolites requires further investigation. Two immediate possibilities arise. First, these observations may suggest that TAARs (at least TAAR1) function physiologically to respond to the levels of monoamine neurotransmitter metabolites, and thereby regulate neurotransmission. Alternatively, however, these observations may merely represent the increased lipophilicity of *O*-methyl metabolites providing increased access to the intracellular receptor pool.

Beyond endogenous amines and their derivatives, the pharmacological profile of TAAR1 has generated considerable interest. In particular, a number of drugs of abuse, particularly amphetamine and its derivatives, show full agonist activity. This is of particular interest given the close structural relationship between 2-phenylethylamine and amphetamine (Figure 1). Both amphetamine and its *N*-methyl derivatives methamphetamine and 3,4-methylenedioxymethamphetamine (MDMA; 'ecstasy') show low to submicromolar potency at TAAR1. Somewhat surprisingly, however, very little stereoselectivity was seen with amphetamine and methamphetamine, both R- and S- isomers being approximately equipotent although this maybe species dependent. The most potent amphetamine derivative at TAAR1 was *p*-hydroxyamphetamine, the major metabolite of amphetamine. In addition, the hallucinogenic ergoline *d*-lysergic acid diethylamide (LSD) shows submicromolar affinity as does the endogenous hallucinogen *N*,*N*-dimethyltryptamine. At present, antagonists of TAAR1 have not been identified. Indeed a number of compounds that show antagonist activity at other monoamine receptors/transporters, were found to be agonists at TAAR1. In particular, phentolamine (α-adrenergic antagonist), cyproheptadine (5-HT receptor antagonist), and nomifensine (DA transporter blocker) were effective TAAR1 agonists.

The identification of cognate ligands for TAAR family members is ongoing. A number of possibilities have been raised, including *O*-methyl metabolites of monoamines, thyronamine derivatives of thyroid hormone, imidazolines, and β-carbolines. Of interest in this respect is the previous identification of imidazoline-binding sites, which appeared distinct from known neurotransmitter-related receptors and enzymes. Whether these sites are synonymous with one or more TAAR requires clarification. Imidazoline ligands have been shown to be agonists at invertebrate octopamine receptors, although as discussed above, such activity may not be readily transferable to mammalian TAAR.

Physiological Responses to Trace Amines

Consistent with the distant phylogenetic relationship between invertebrate and vertebrate trace amine receptors, evidence suggests that mammalian and invertebrate trace amines may serve different physiological functions. Invertebrate trace amines, in particular, tyramine and octopamine, are well-characterized neurotransmitter substances. In mammalian species, however, this does not appear to be the case. Iontophoretic application of trace amines to neurons does not directly elicit changes in the membrane potential of the neuron under study. Rather, the trace amines appear to alter neuronal responsivity to coexisting neurotransmitters (Table 3). Specificity exists within these responses. 2-Phenylethylamine has been shown to potentiate neuronal responses to dopaminergic and noradrenergic stimuli, while having no effect on neuronal responses to acetylcholine, 5-HT, and glutamate. Earlier studies suggested that there was also no effect on γ-aminobutyric acid (GABA)-mediated transmission, although more recent evidence suggests that 2-phenylethylamine decreases inhibitory responses mediated by GABA-B receptors. Similarly, tyramines potentiate neuronal responses to DA, noradrenaline, and possibly GABA (at GABA-B receptors), while

Table 3 Interaction of trace amines with neurotransmitters

	2-Phenylethylamine	*p-Tyramine*	*Tryptamine*	*p-Octopamine*

Glutamate	−	−		

[a]Inhibitory 5-HT responses are potentiated while excitatory responses remain unaffected or are converted to inhibitory responses in the presence of trace amine.
Blank cells indicate that interactions between the individual neurotransmitter and trace amine have not been investigated.
+ = neurotransmitter response potentiated by trace amine; − = no effect on neurotransmitter response of trace amine.

leaving 5-HT and glutamate responsivity unaffected. Octopamines also potentiate neuronal responses to noradrenaline; however, in this instance, no effect is observed on DA-mediated responses, nor on those of 5-HT. Finally, tryptamines have been shown to potentiate 5-HT responses, while leaving cholinergic responses unaffected. However, this effect of tryptamines appears to be somewhat more complex than that observed with other trace amines. Specifically, inhibitory 5-HT responses have been shown to be potentiated, while excitatory responses remain either unaffected or are reversed to inhibitory responses in the presence of tryptamine.

Although the above-described responses require the presence of coexisting neurotransmitter, endogenous stores of neurotransmitter are not required. This is important, since at higher concentrations, trace amines will act as false transmitters, displacing monoamine neurotransmitters from synaptic vesicles. Such false transmitter responses, however, require concentrations at least two orders of magnitude above basal trace amine concentrations. Further, the modulatory responses of trace amines appear to be mediated at the level of postsynaptic receptors, since responses to synthetic agonists are also potentiated. However, a direct binding of trace amines to neurotransmitter receptors does not occur. The role of TAAR in these modulatory responses of trace amines, while intuitively attractive, has yet to be investigated. Heterodimerization, following trace amine binding, of intracellular TAAR with membrane-inserted neurotransmitter receptors has been hypothesized, but as yet not investigated.

Since the function of trace amines appears to be to modulate the efficacy of coexisting neurotransmitter substances at postsynaptic receptors, and the synthesis of trace amines (AADC activity) is inversely related to stimulation of neurotransmitter receptors, it has been suggested that trace amines may function as a fine-tune mechanism, keeping basal neuronal tone within defined physiological limits. Such a proposal appears consistent with the suggestions that trace amine receptors are involved in adaptive responses, which may vary from species to species. Further, such a function is also consistent with the very high turnover rate of trace amines, allowing a regulation of neurotransmission on a second-by-second basis.

Relevance to Human Pathology

Historically, alterations in trace amine metabolism have been reported in a number of psychiatric disorders, in particular schizophrenia and depression. Although the reported changes in trace amine and/or metabolite levels in various body fluids are indicative of altered trace amine functioning, such studies are difficult to interpret further with respect to any underlying pathology. Although there is currently no definitive link between trace amines and any pathologic condition, evidence is accumulating that trace amines may play a role. The following paragraphs will briefly outline those CNS disorders in which alterations in trace amine functioning is most strongly linked.

Trace amines have often been suggested as a possible etiological factor in schizophrenia. Initially, this was largely based on the close structural relationship between 2-phenylethylamine and amphetamine (**Figure 1**), combined with the well-documented similarity between symptoms of paranoid schizophrenia and amphetamine overdose. Further, in very high, supraphysiological doses, 2-phenylethylamine shows a pharmacological profile similar to that of amphetamine. This link is seemingly strengthened by the observed pharmacological profile of TAAR1, numerous psychoactive/hallucinogenic agents having been shown to be agonists at this receptor. Differences have however been observed in the behavioral phenotypes induced by amphetamine and 2-phenylethylamine. Possibly of greater relevance is the observed chromosomal location of the trace amine receptors, at chromosome 6q23.1. This location coincides with one of the most robustly replicated susceptibility factors identified for schizophrenia, the SCZD5 locus. Specifically this locus appears to correlate with the TAAR6 gene. Conformation of a role of TAAR mutations as a susceptibility factor for schizophrenia will, however, be difficult. The heterogeneity of the disorder is a major complicating factor, since a single cause is unlikely to be the root cause of all schizophrenic disorders. A further genetic link is seen with the observation that a variant form of COMT shows an increased transmission in patients with schizophrenia. As discussed previously, *O*-methyl metabolites of central monoamines appear to be particularly good agonists at TAAR.

Of possible relevance with respect to schizophrenia is the observed similarity between some of the cognitive associated symptoms associated with phenylketonuria and schizophrenia. Phenylketonuria, a classical inborn error of metabolism, is due to a deficiency in the ability to convert L-phenylalanine to L-tyrosine. In addition to the marked changes in amino acid metabolism that such a deficit causes, it would also be expected to cause a pronounced elevation in 2-phenylethylamine levels.

Considerable circumstantial evidence also exists linking an alteration in trace amine metabolism to affective disorders. In particular, depression has been hypothesized to be associated with a decrease in 2-phenylethylamine functioning. Decreases in

2-phenylethylamine and its main metabolite phenylacetic acid have been reported in various body fluids. Similarly, decreases in other trace amines and their primary metabolites have been sporadically reported. In agreement with a proposed 2-phenylethylamine deficiency, the combined administration of (–)deprenyl with L-phenylalanine has been suggested to be an effective therapy in up to 60% of patients. Such a regimen would be expected to elevate endogenous 2-phenylethylamine (PE) levels; (–)deprenyl is a selective inhibitor of MAO-B, thereby inhibiting PE metabolism, while L-phenylalanine is the precursor amino acid of PE, and is expected to simultaneously elevate PE synthesis. Somewhat surprisingly, however, replication of this study does not appear to have been attempted. In further support of an antidepressant role for 2-phenylethylamine, MAO-B knockout mice show a behavioural phenotype consistent with that seen following administration of known antidepressant compounds. The only change in neuroactive amines seen in these animals is a pronounced elevation of endogenous PE levels. Finally, the mood-elevating effects of exercise may be due to an exercise-induced increase in PE levels, although the molecular basis of such an elevation is unclear.

At the receptor and gene level, there is also circumstantial evidence to support a role for PE in mood elevation. As detailed above, the available evidence suggests that TAARs are particularly associated with the amygdala, a brain region particularly implicated in the control of emotion and affect. Polymorphisms in the trace amine synthetic enzyme AADC have been suggested to be a susceptibility factor for both unipolar and bipolar disorder, although such associations require replication. Further, bipolar disorder has been linked to chromosome 6q. As seen above, this is the site of all TAAR genes. In this aspect, a similar confounding factor applies, as was detailed with schizophrenia. Affective disorders represent a spectrum of disorders, with a single causative agent unlikely to be present. A number of known antidepressants result in a downregulation of β-adrenergic receptors. Of interest in this regard is evidence that chronic elevation of endogenous PE results in a similar downregulation. Finally, the antidepressant agent phenelzine has been shown to be metabolized to PE.

The link between trace amines and disorders of higher cognitive functioning such as schizophrenia and affective disorders is appealing. As detailed, TAARs have been suggested to be involved in adaptive responses. Further, the observed physiological effects of trace amines acting to modulate the efficacy of neurotransmitter amines, possibly functioning to keep neuronal tone within physiological limits, are an attractive site for therapeutics for disorders of higher cognitive functioning involving multiple neurotransmitter systems. In this respect, trace amines have been implicated in other disorders associated with higher cognitive functioning, in particular attention-deficit/hyperactivity disorder, and also eating disorders and drug abuse/dependence.

Though not psychiatric in nature, one final disorder which warrants consideration with respect to the trace amines is migraine. This neurovascular disorder has often been linked to the trace amines largely on the basis of the elevated levels of trace amines found in foodstuffs known to precipitate migraine attacks in susceptible individuals. In particular, chocolate contains high levels of 2-phenylethylamine, while red wine and aged cheeses contain high levels of tyramine.

Thus, although many questions remain unanswered with respect to the endogenous ligand and physiological functioning of TAAR, they have attracted considerable interest with respect to being a viable target for development of novel therapeutic agents. Of note, many of the diseases in which trace amines are being actively investigated are of unknown etiology and likely involve multiple neurotransmitter systems. The apparent role of trace amines in modulating the responsivity of a variety of neurotransmitter systems makes them an attractive area of investigation in various neurological and psychiatric disorders.

Introduction and History

Transcranial magnetic stimulation (TMS) is a noninvasive neurophysiologic method to induce electrical currents within the brain. This technique can be used to transiently disrupt the function of a targeted brain area, functionally map cortical areas, assess cortical excitability, and even modulate its level of activity when delivered as a repetitive train of pulses. TMS is being widely used to investigate complex aspects of human brain function, such as learning and cognition, as well as sensory and motor function. Furthermore, its potential as a novel therapeutic treatment is being actively pursued in a variety of neurological and neuropsychiatric disorders.

The first reports documenting activation of human brain by an electromagnetic field appeared as early as 1896. Jaques-Arsène d'Arsonval and, later, Sylvanus P Thompson (1910) demonstrated that placing the head near an electrical coil generating a time-varying magnetic field induced the sensation of phosphenes (i.e., the subjective sensation of light) and vertigo. Subsequent efforts were pursued aimed at refining the technique so that peripheral nerves could be selectively stimulated or muscular contractions could be induced. However, all these magnetic stimulation devices were technically difficult to operate, prone to extreme overheating, and had no mechanisms to address the interference generated by the stimulating fields. In the late 1970s and early 1980s, Anthony Barker and collaborators at the University of Sheffield, UK, overcame many of these earlier technical problems and developed a device capable of generating peak magnetic fields as high as 2 T. This work served as a precursor to the development of a stable and reliable device and, ultimately, the first commercially available magnetic stimulator. During the past 20 years, the application of TMS in clinical neurology and neuroscience research has grown steadily due to improvements in technology (e.g., coil design and the development of stimulators capable of rapid discharge rates), its combined use with other neuroimaging modalities, and a greater understanding of the technique.

How Does TMS Work?

The physical basis of TMS rests on the principles of electromagnetic induction originally discovered by Michael Faraday in 1831. Simply stated, a brief electrical pulse of rapidly alternating current passed through a coil of wire generates a strong, transient magnetic field. By placing a stimulating coil near a subject's scalp, the induced magnetic field pulse penetrates the scalp and skull virtually unattenuated (decaying only with distance) reaching the underlying brain tissue. The rate of change of this magnetic field in turn induces a secondary electrical current within brain tissue (or with any nearby conducting medium) (Figure 1(a)). Unlike direct electrical cortical stimulation, TMS does not require exposing the underlying cortex and is relatively painless and safe. In essence, TMS represents a method of 'electrodeless' electrical stimulation, whereby the magnetic component is responsible for bridging the transition between current passed in the coil and current induced in the brain.

The design of magnetic stimulators is relatively simple. A typical TMS machine consists of a main unit and a stimulating coil (Figure 1(b)). The main unit comprises a charging system, one or more energy storage capacitors, a discharge switch, and circuits for pulse shaping, energy recovery, and control functions. Different charging systems are possible; the simplest design uses step-up trans-formers operating at frequencies of 50–60 Hz. Energy-storage capacitors can also be of different types. The essential factors in the effectiveness of a magnetic stimulator are the speed of the magnetic field rise time and the maximization of the peak coil energy. Therefore, large energy-storage capacitors and very efficient energy transfer from the capacitor to the coil are important. Typically, energy storage-capacity is approximately 2000 J, and 500 J is transferred from the capacitors into the stimulating coil in less than 100 μs via a thyristor, which is an electronic device that is capable of switching large currents in a few microseconds. Finally, in order to induce currents in the brain of sufficient magnitude to depolarize neural elements, the peak discharge current needs to be on the order of several thousand amperes (approximately 10 mA cm^{-2}).

The effects of this induced current on brain tissue are dependent on numerous stimulation parameters, such as stimulation frequency and intensity as well as coil configuration and orientation. The voltage of the primary current and the geometry of the stimulating coil determine the strength and shape of the magnetic field and thus the density and spatial resolution of the secondary current induced within brain tissue. There are two main coil designs: round (circular) coils and figure-of-eight shaped coils (Figure 2). Round coils generate large and more diffuse currents and are useful for stimulating relatively large cortical areas. Figure-of-eight coils are more focal due to a maximal

Figure 1 (a) Schematic description of the currents induced by a circular coil. The induced magnetic field couples the primary current passed in the coil with the secondary current induced within neuronal tissue. (b) Schematic diagram of a standard magnetic stimulator circuit (single pulse).

current being generated at the intersection of the two round coil wings, and they are used for stimulating within a more circumscribed area. Evidence suggests that the locus of TMS stimulation has a spatial resolution of 1 cm^2 with a penetration depth of approximately 2 cm using commercially available figure-of-eight stimulation coils. It is also important to note that these values largely represent mathematical approximations and, in fact, current modeling evidence suggests that very different parameters may apply when stimulating patients with cerebral damage such as stroke. Stimulating at greater depths is possible, although larger amounts of current are required, which in turn compromise spatial resolution. Alternatively, penetration depth can be enhanced by using innovative coil designs that modify the decay of the magnetic field with distance. Even with such coils, the stimulation of structures closest to the coil is maximal, and the focality of the stimulation also decays with distance. Therefore, selective, direct, and precise stimulation of deep cerebral structures (e.g., limbic structures, basal ganglia, or brain stem) is not feasible with current stimulators.

When a coil is placed tangentially to the surface of the scalp, current flows parallel to its surface plane preferentially activating neural elements oriented horizontally within the cortex. Given that interneurons are horizontally oriented, it is thought that TMS is more likely to activate pyramidal cells indirectly in a transsynaptic manner. Typically, a single pulse lasts 200 μs; however, stimulation can also be delivered as a train of repetitive pulses (referred to as repetitive TMS or rTMS). rTMS has the advantage of being able

Figure 2 Figure-of-eight and circular coil designs. The spatial resolution of the figure-of-eight coil is much greater than its circular counterpart, enabling a more precise target location.

to modulate cortical excitability with effects lasting well beyond the period of stimulation.

From a safety standpoint, the pervasive concern of using TMS is the risk of inducing a seizure in subjects with a known prior history of epilepsy or other predisposing risk factor, such as taking medication

known to lower the threshold for seizure induction. Single-pulse TMS is considered safe and free of significant side effects; however, the use of rTMS, given its ability to modify cortical excitability, represents a much greater safety risk. Extensive studies have been carried out in order to establish appropriate safety guidelines, classify predisposing risk factors, and identify signs and surrogates of seizure induction. Since the institution of safety guidelines defining stimulation parameters and the monitoring and screening of appropriate subjects, the risk of TMS-induced seizures has been greatly reduced.

TMS in Motor Function

One of the first applications of TMS was in clinical neurophysiology. For example, when a TMS pulse is applied to the hand representation in motor cortex, a twitch in the contralateral hand can be evoked and a motor evoked potential (MEP) can be recorded. The neuronal conduction time of motor signals (i.e., from motor cortex to spinal cord) can be calculated by subtracting the latency of the evoked potential of the target muscle from the latency of motor potentials induced by the stimulation of spinal cord nerve roots. Given that a slowing of conduction time is typically seen in neurodegenerative disorders, measuring variables such as MEP amplitude and latency is useful in the evaluation of patients with multiple sclerosis, amyotrophic lateral sclerosis, or spinal cord damage. Similarly, TMS has been used to probe recovery of function following brain damage (e.g., stroke) and may have potential in the development of neurorehabilitative strategies. Focal stimulation by TMS can also be used to map the extent of cortical motor representations and function. Maps can be obtained at different times, within the same subject, and evaluated under different conditions. This is particularly useful in studying functional changes in cortical activity associated with cerebral plasticity. For example, neuroplastic changes in sensorimotor cortical representation can be demonstrated when one learns a skill such as playing a novel musical piece on the piano. In one study, it has been shown that cortical representation expands in accordance to overall improvement of playing ability and returns to normal size once the skill is adequately learned. TMS can also be used in a variety of ways to measure cortical excitability. Given that excitability represents an interaction of neurotransmitter levels and cortical circuitry; the effect of medications and various pathological conditions can be assessed through numerous measures using TMS. These measures in turn can be used to develop a relationship between physiological effects and neuropharmacology and potentially assist in the development of highly individualized pharmacological treatment for conditions such as epilepsy, depression, and Parkinson's disease.

Measures of Motor Function

One important measure of motor function that can be assessed using TMS is the motor threshold (MT). MT is defined as the lowest TMS intensity necessary to evoke an MEP in a target muscle in at least 50% of successive stimulations (e.g., in 5 out of 10 trials) using single pulses applied to the representation of the targeted muscle in the motor cortex. The MT provides fundamental information about the excitability of the core representation of a given target muscle within motor cortex and it is believed to reflect excitability of corticospinal neurons as well as the excitability of motor neurons in the spinal cord, neuromuscular junctions, and muscle. MT change has been studied in various diseases and has been shown to increase in neurological conditions that affect the corticospinal tract, such as multiple sclerosis and stroke, as well as brain or spinal cord injury. Depending on their mechanism of action, various medications have also been shown to affect MT.

One method used to study and characterize cortical efferent output is to compare how an increase in an MEP amplitude relates to increasing TMS intensity. This is known as the recruitment curve, an input–output curve, or a stimulus–response curve. Compared to the simple determination of the MT, this measure provides insight into the function of neurons that are intrinsically less excitable or spatially farther from the center of activation by TMS. Therefore, recruitment curves are likely related to the strength of corticospinal projections.

Central motor conduction time (CMCT) is defined as the latency difference between the MEPs induced by stimulation from the motor cortex and those evoked by spinal (motor root) stimulation. It is calculated by subtracting the latency of the peripheral segment of the motor pathway (spinal motor root to muscle) from that of the entire motor pathway (motor cortex to muscle; Figure 3, top). When a TMS coil is placed over the back of the neck or spine, the magnetic pulse will stimulate spinal nerve roots but not the descending spinal tracts. Abnormalities of CMCT have been demonstrated in a variety of neurological disorders. Significant prolongation of CMCT suggests demyelination of central motor pathways, whereas low-amplitude MEPs with little delay or absence of responses are more suggestive of loss of neurons or axons. The CMCT has also been shown to correlate with the grade of motor deficits following stroke damage.

When a subject is instructed to maintain muscle contraction of a targeted muscle and a single TMS
